Medicine is an ever-changing science undergoing continual development. Research and clinical experience are continually expanding our knowledge, in particular our knowledge of proper treatment and drug therapy. The authors, editors, and publisher have made every effort to ensure that all information in this book is in accordance with the state of knowledge at the time of production of the book.

Nevertheless, this does not imply or express any guarantee or responsibility on the part of the authors, editors, or publisher with respect to any dosage instructions and forms of application stated in the book. Every reader should examine carefully the package inserts accompanying each drug and check with a physician or specialist whether the dosage schedules mentioned therein or the contraindications stated by the manufacturer differ from the statements made in this book. Such examination is particularly important with drugs that are rarely used or have newly been released on the market. Every dosage schedule or every form of application used is entirely at the reader's own risk and responsibility. The editors and publisher welcome any reader to report to the publisher any discrepancies or inaccuracies noticed.

Special discounts on bulk quantities of Demos Medical Publishing books are available to corporations, professional associations, pharmaceutical companies, health care organizations, and other qualifying groups. For details, please contact:

# Preface

As with the first and second editions, the goal of this third edition of *Pediatric Epilepsy: Diagnosis and Therapy* is to assist all professionals involved in the care of pediatric patients with seizures and epilepsy. Our goal continues to be the perfect result: no seizures, no side effects, and no stigma to limit these children from achieving their full potential.

The scope and depth of coverage of this book remains unique in its field. We have again tried to balance discussions of practical medical management with the scientific basis of epilepsy and its treatment in a clear and concise manner. The book focuses on the special issues of children with epilepsy and is intended as both a practical guide and a reference for clinicians and investigators. With many more options for the treatment of epilepsy—including new antiepileptic drugs (AEDs), vagus nerve stimulation, the reintroduction of the ketogenic diet, increased emphasis on quality of life, as well as improved presurgical evaluation and surgical intervention—hope for a more normal life for all children with epilepsy should continue to grow. To accomplish all the new goals set for this third edition, the previous editors asked Drs. Douglas R. Nordli and Raman Sankar to join them as associate editors.

Since the publication of the second edition, there has been a rapid expansion of basic knowledge, diagnostic techniques, and treatments affecting the management of epilepsy, including advances in basic neurosciences, genetics, definition of syndromes, as well as medical and surgical therapeutic approaches. Because of the increasing familiarity and refinement of knowledge related to the concept of epilepsy syndromes, a new separate section

has been added to this third edition. This section consists of an expanded and comprehensive coverage of the syndromes *by age of onset*, taking into account the difficulties that can be encountered in making a fixed diagnosis of a seizure type or epilepsy syndrome in young infants.

Although the precise diagnosis of epilepsy has become more challenging and complex, the enhanced specificity of the final diagnosis will continue to improve therapeutic and prognostic accuracy. The diagnostic process has been further improved by the growing knowledge of metabolic disturbances, disease processes, and genetics of various forms of epilepsy. This has led to an ever-expanding availability of new diagnostic tests, especially those related to DNA analysis. Although the greater choice of diagnostic testing does not always yield an etiology in every patient, those patients without established etiology still have more and better therapeutic options. There has been further growth in the knowledge about clinical pharmacology of AEDs. In particular, experience and comfort have grown with the AEDs that had just been released at the time of the second edition, with recognition of new indications for some of these drugs. Throughout the discussion of individual drugs, available knowledge is discussed regarding their specific use and pharmacokinetics in newborns, infants, older children, and adolescents. Adverse effects are also covered, to include newer aspects as well as age-related, gender-related, and pregnancy-related issues. Epilepsy surgery has become one of the widely applied standard therapeutic approaches to pediatric epilepsy, and it has now truly been incorporated into the treatment paradigms.

In this third edition, every chapter either has been markedly updated or is a newly written chapter that was not included in the second edition. In the initial section on basic mechanisms of epilepsy, a new chapter by Dr. Edward Cooper on the epileptic channelopathies has been added because of the rapid and clinically relevant expansion of knowledge in this area during the past few years. Coverage of epileptogenic cerebral cortical malformations has been enhanced by the contribution of Drs. Christopher Walsh, Ann Poduri, and Bernard Chang. A new section on age-related syndromes has been created. This section is divided into groups of syndromes by age of onset and provides a more comprehensive and detailed coverage by several international authorities in the field, such as Drs. Shunsuke Ohtahara, Richard Hrachovy, Kazuyoshi Watanabe, Pierre Genton, Shlomo Shinnar, Tracy Glauser, Gregory Holmes, Chrysostomos Panayiotopoulos, Prakash Kotagal, and Samuel Berkovic. All of the chapters in this section now follow a unified structure. The section on general principles of therapy now includes a discussion of the emerging evidence-based approach to AED selection by Dr. Tracy Glauser. The issues of fetal effects of epilepsy and fetal effects of AEDs are covered separately by Drs. Mark Yerby and Torbjörn Tomson.

Systematic coverage of individual drugs and other medical treatment modalities was already quite extensive in the second edition but has now been enhanced and expanded to cover the newer drugs not covered previously, as well as updated to include new information on the previously discussed drugs. A chapter on sulthiame by Dr. Dietz Rating has been added, because of the unique role of this drug in the treatment of the common syndrome of benign rolandic epilepsy. Other new chapters cover vitamins, dietary considerations, and alternative therapies

(Dr. Orrin Devinsky); immunotherapy (Dr. Raman Sankar); and AEDs in development (Dr. Jacqueline French). The section on surgical treatment contains updated coverage of neurophysiologic evaluation (including magnetoencephalography), advanced imaging, surgical procedures, and outcomes, in addition to an update on vagus nerve stimulation. The section on psychosocial aspects has been expanded and includes chapters on costs of pediatric epilepsy, quality of life, intelligence, co-morbidities, and educational placement, as well as cognitive side effects of AEDs.

We would be remiss in introducing this third edition without acknowledging the contribution of several of the previous authors who have now died. Drs. Kiffin Penry and Fritz Dreifuss, two of the founding fathers of pediatric epilepsy in the United States, have left us to carry on their work. Dr. Eric Lothman died quite prematurely, but his contribution to the understanding of the pathophysiology of seizures and epilepsy remains current even in this edition and will do so for years to come. In honoring these and others who have encouraged and guided our careers, we hope that this book meets the needs of those who care for children with epilepsy as well as the children and families who have to deal with seizures.

For some, epilepsy will be a transient and distant memory, while for others epilepsy is an ever-present burden. Evaluating and treating these children in the most appropriate and efficient fashion while avoiding adverse cognitive and psychosocial effects remains both challenging and rewarding, and it requires state-of-the-art knowledge. We hope that you will find such knowledge in this book, and we hope that this third edition of *Pediatric Epilepsy: Diagnosis and Therapy* will help you and your colleagues provide state-of-the-art care to your patients and their families.

# Pathophysiology of Seizures and Epilepsy in the Immature Brain: Cells, Synapses, and Circuits

*Libor Velíšek*  
*Solomon L. Moshé*

**E**pidemiological studies show that the propensity of the young brain to develop seizures is much greater than that of the adult brain. These comprehensive studies cover not only the U.S. population (1, 2) but also populations in France, Great Britain, and Scandinavia, and thus the results appear to be geographically independent (3).

There are many more provoked seizures in neonates and infants than in adults. Their causes may involve trauma, hypoxic-ischemic encephalopathy, hypertension, metabolic abnormalities (amino acid disturbances, hypocalcemia, hypoglycemia, and electrolyte imbalance), infections, drug withdrawal, pyridoxine dependency, and toxins (4). Similarly, a genetic predisposition to epilepsy may be expressed in infancy. Genetic factors may involve congenital cerebral malformations and familial seizures such as neurocutaneous syndromes, genetic syndromes, and benign familial epilepsy (4). Additionally, several intractable seizure syndromes occur in early infancy or childhood and not later on (5). In children, focal dysfunction may often produce multifocal seizures and status epilepticus, suggesting less effective barriers for seizure spread and generalization (6).

There are several questions that can be posed. What are the conditions that make a part of the population prone to develop seizures or epilepsy at certain stages

of development? Are these conditions acquired or inherited? Are there any seizure-provoking factors in epileptic patients? What are the factors that recruit interictal activity in an epileptic patient to a full seizure? Are these factors intrinsic features of the neurons, glial cells, or extracellular space in the patient's brain or are they extrinsic, environmental factors? How do the seizures propagate? How (why) do they stop? What are the consequences?

Table 1-1 summarizes some important factors that may play a role for these developmental windows of increased susceptibility to seizures and in the development of epilepsy in the immature brain. In this table, factors A1 through A5 are operant in the normal and abnormal brain while factors B1 through B3 may be more specific for abnormal brains. The contribution of these factors in the pathophysiology of childhood seizures can be studied in animal models of seizures and, if available, in models of epilepsy. To study the age-related changes in seizure susceptibility in experimental animals, the investigator has to correlate the brain development of the animal to human brain development. Such correlations are difficult and should be viewed cautiously. Not all parameters studied follow similar developmental curves in animals and humans. This issue is very carefully reviewed in a recent article (7). Nevertheless, based on comparative ontogenetic studies of the rate of brain growth, an 8–10-day-old rat (PN8–10) may be considered equivalent to a full-term

TABLE 1-1

*Factors That May Explain the Propensity of the Immature Brain to Develop Frequent Seizures Compared to the Adult Brain*

**A. IN ANIMALS WITH NORMAL BRAIN DEVELOPMENT**

1. Excitatory processes developing before inhibitory processes
2. Differences in ionic microenvironment
3. Delayed development of circuits that can modify the expression of seizures
4. Seizures begetting seizures as a consequence of frequent seizures early in life
5. High chance of exposure to potentially epileptogenic stimuli (fever, infection, hypoxia)

**B. IN ANIMALS WITH ALTERED BRAIN DEVELOPMENT**

1. Genetic predisposition
2. High incidence of structural brain anomalies
3. High probability of seizures begetting seizures as a consequence of frequent seizures early in life

human. In this case a rat less than 8–10 days old may be considered as equivalent to a human premature infant (7–10). On the other end, the male rat undergoes puberty from 35–36 to 55 days of age, whereas the female rat is in puberty between days 33 to 45 postnatally (11). Thus, the brain development in the rat at 2–3 weeks postnatally may be equivalent to a human infant/toddler, while at 4–5 weeks it may be considered as equivalent to an older, pre- or peripubescent child (7). Additionally, there may be different developmental dynamics. In a previous review (12), we attempted to calculate the aging rate in developing rat versus developing human. Although our calculations were purely mathematical and did not consider major developmental milestones, we can conclude that the rate of aging in the immature rat compared to that in the child is much higher.

There is ample evidence that seizure susceptibility changes with age in experimental animals as it does in humans. In vitro studies of immature rat cortical neurons (2–3 weeks old) indicate that these neurons are more prone to develop epileptiform discharges following a variety of stimuli, such as low extracellular calcium (13), repetitive stimulation (14), penicillin, bicuculline, picrotoxin (15–18), or high potassium administration (19). In vivo studies indicate that, in 2–3-week-old rats, the susceptibility to seizures is higher, and seizures spread more easily than in any other ages in many seizure models including pentylenetetrazol (Figure 1-1A), bicuculline, allylglycine, kainic acid, N-methyl-D-aspartate (NMDA) (Figure 1-1B), and kindling (Figure 1-2) (20–34). These young, 2–3-week-old rats are also more prone to develop

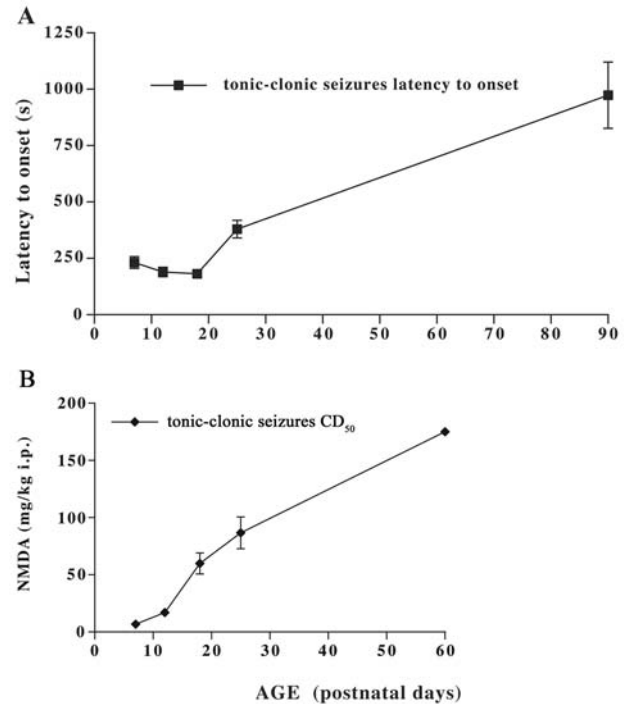

FIGURE 1-1

Increased susceptibility of immature rats to tonic-clonic seizures induced by pentylenetetrazol or NMDA. Increased susceptibility to seizures in immature rats is illustrated using two parameters. (A) Male rats at PN12, 18, 25, and adult rats were injected with 100 mg/kg of pentylenetetrazol subcutaneously. Latency to onset of tonic-clonic seizures, which occur throughout development (20), was determined. A shorter latency to onset of seizures indicates increased susceptibility to seizures. PN12 and PN18 rats have the shortest latencies. (B) Convulsant dose eliciting seizures in 50% of rats ( $CD_{50}$ ) was calculated from dose responses for NMDA-induced tonic-clonic seizures, which also occur throughout development (21). A lower  $CD_{50}$  indicates increased susceptibility to seizures. PN12 rats required lowest doses of NMDA for induction of tonic-clonic seizures. Modified from (21, 22).

status epilepticus than older rats. Indeed, in many seizure models 2–3-week-old rats are also more prone than younger, 1-week-old rats, to develop seizures, defining thus a specific developmental window for increased seizure susceptibility.

It should be noted that most of the experimentally induced seizures are models of *acute* seizures following the single administration of chemical or electric stimulation (34). There is a *semichronic* model of seizures in the young brain represented by kindling, which is induced by repeated electrical stimulation of susceptible brain sites over 2–3 days in developing rats (29, 35). Until now, there have been only a few successful efforts to develop *chronic* models of seizures in the developing brain that would

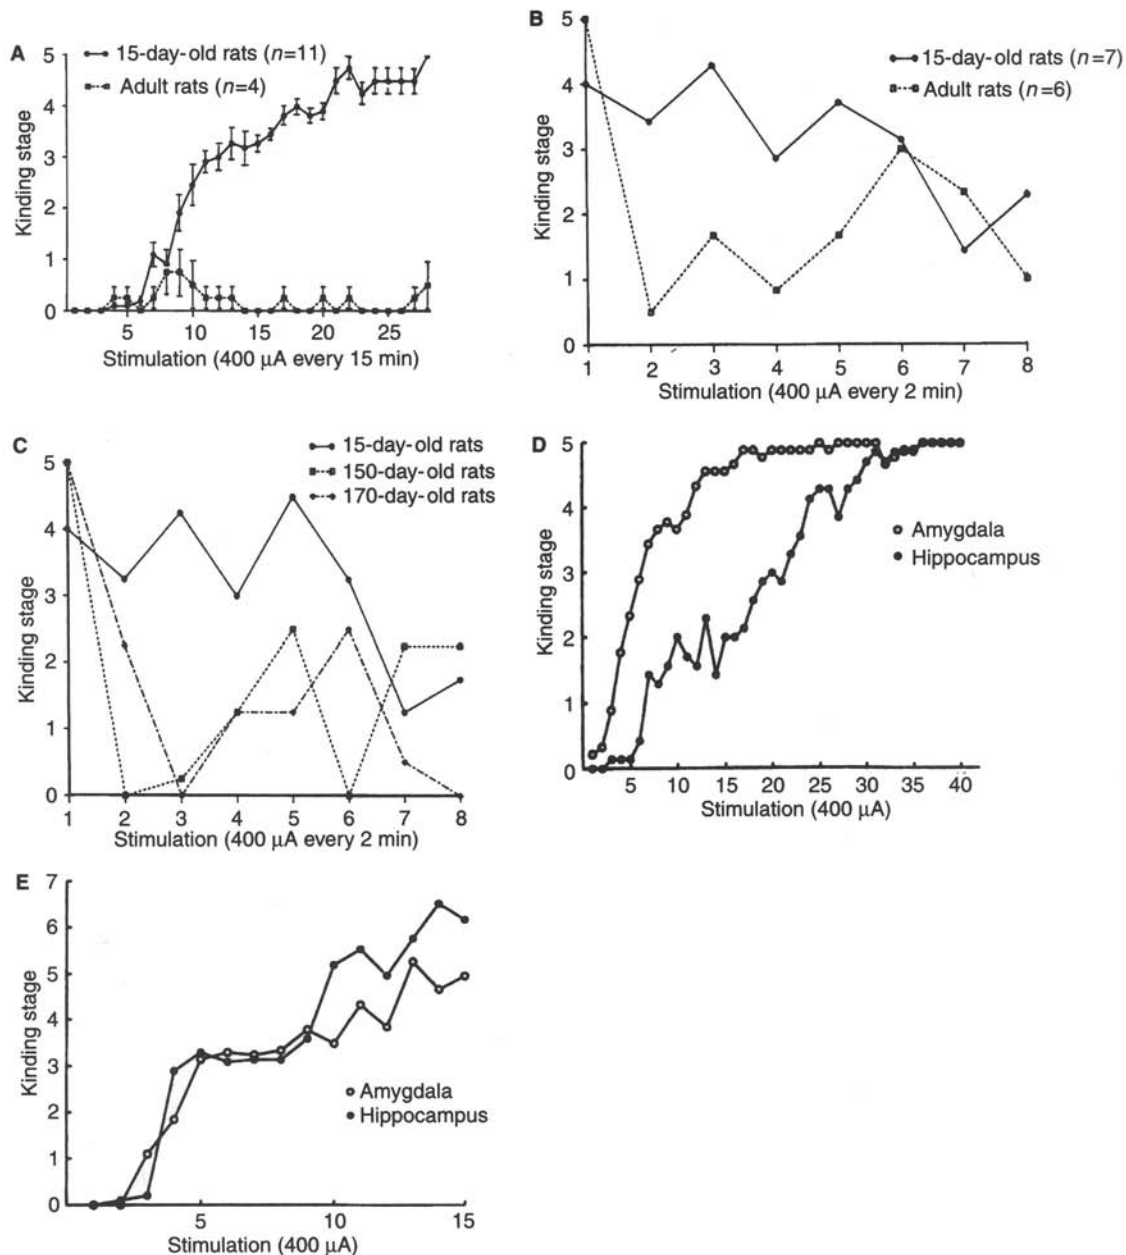

FIGURE 1-2

Increased seizure susceptibility of the immature PN15 brain to kindling-related seizures. Electrodes were implanted in the amygdala in A, B, and C and into the amygdala and hippocampus in D and E. In this composite, the x-axis depicts the severity of kindled seizures using the kindling scale of Racine (23) as modified by Moshé (24) and later on by Haas et al. (25). Kindling stages higher than 4 are secondarily generalized convulsions. Each point represents the mean behavioral kindling stage for the particular stimulation. (A) Kindling can be induced in PN15 rats using a 15-minute interstimulus interval; this stimulation paradigm fails to elicit kindling in adult rats. (B) The intensity of postictal depression is decreased in PN15 rats. In this paradigm, PN15 and adult rats that had experienced a generalized seizure received 7 additional stimuli, each delivered at 2-minute intervals. PN15 rats experienced more secondarily generalized seizures than adults, especially during the first 8 minutes. (C) The intensity of postictal refractoriness increases with age. The same rats were tested at 3 different ages: PN15, PN150 and PN170. (D) Kindling antagonism in adult rats. Kindling stimuli were delivered in the amygdala and ipsilateral hippocampus on an alternating basis, and each stimulation is plotted separately. Kindling was induced from the amygdala but not the hippocampus. (E) Lack of kindling antagonism between amygdala and hippocampus in PN16–17 rats under the same experimental conditions that induce antagonism in adults. Modified from (25–27).

better mimic human epilepsy. Examples of such studies include kindling in kittens (36) and the long-term effects of the administration of tetanus toxin in the hippocampus of young rats (37). The epileptic potential of the gamut of either chemically, physically, or genetically experimentally induced brain structural abnormalities has not been adequately explored (38–45). Why do these potentially useful models not attract more research interest? They are very expensive, labor-intensive, and time-consuming, and the data yield is relatively low. Yet this path may be required to establish models for refractory epileptic syndromes in children—catastrophic epilepsies of childhood. Recently, there has been an increase in utilization of these developmental models of pre- or perinatal brain damage, as discussed later.

This review is intended to summarize current information about the differences in the epileptogenicity of young and adult brain and to point out possible future research directions in the field of developmental epilepsy. Since the first publication of this chapter there has been a tremendous increase in the available information about developing cells, synapses, and circuits; we attempt to include all the high points in this edition.

### **NORMAL IMMATURE BRAIN: EXCITATORY PROCESSES PREDOMINATING**

Physiologic, morphologic, biochemical, and molecular biology studies have been performed to determine differences between the young and adult brain that may answer two questions: (1) What are the mechanisms responsible for the enhanced seizure susceptibility of the developing brain? (2) Why is the seizure spread less well controlled in the immature than in the adult brain?

#### **Physiology**

In vivo microelectrode studies show no evidence of inhibition in the paired-pulse paradigm in the cornu ammonis 1 (CA1) area of the hippocampus prior to PN18 in rats, after which the intensity of inhibition steadily increases to reach adult levels by PN28. In contrast, already at PN14 the measures of excitation (i.e., excitability and spike width) are at fully mature levels (46). These results indicate that in the rat hippocampus, excitatory processes are well established or fully mature within 2 weeks after birth, whereas the maturation of inhibitory processes to adult levels may not be achieved until several weeks later (46). Two additional features should be discussed here. First, in the hippocampus and other structures in the immature rats, gamma-aminobutyric acid<sub>A</sub> (GABA<sub>A</sub>) receptors have been shown to have depolarizing effects and at times mediate excitatory events (19, 47, 48). Second, in immature animals (kittens, rats, and mice), excitatory

NMDA transmission peaks early in development (49–53), with the immature form of the NMDA receptor present in rats until PN14 (54). Both these features may significantly contribute to the increased epileptogenicity of the immature brain.

The available data in seizure models support these findings. The intensity of postictal refractoriness (the period that follows a seizure) may increase with age (Figures 1-2, 1-3). Thus, in rats younger than 2–3 weeks of age, electrical kindling in the amygdala or hippocampus can be induced with stimuli (400  $\mu$ A, 60 Hz current for 1 s), given at short interstimulus intervals (26, 35, 55, 56). This is not the case in adult rats (57, 58). In younger rats, if two sites are kindled concurrently, both sites develop severe kindled seizures (25, 59). In adults, one of them develops kindling while the other site is suppressed (Figure 1-2) (60). The age-specific failure of both inter- and intrahemispheric mechanisms to suppress the development of multiple kindling foci may explain the high incidence of multifocal seizures in the immature CNS (25, 59). In PN15 rats, additional kindling stimulations easily induce severe seizures classified as stages 6–8 (25). In contrast, in adult rats, severe seizures may occur after approximately 250 kindling stimulations (61).

The increased epileptogenesis may arise from age-specific conditions for excitation and inhibition in the brain (51). Early postnatally, cortical glutamate-mediated excitation utilizes mostly NMDA receptors. This unusual role of NMDA receptors diminishes with increasing age in favor of alpha-amino-3-hydroxy-5-methyl-4-isoxazolepropionic acid (AMPA)-receptor-mediated glutamate transmission (49, 62). Additionally, early postnatally, GABA has excitatory effects through GABA<sub>A</sub> receptors in several structures, such as hippocampus, cerebral cortex, cerebellum, and spinal cord, and therefore rather supports than antagonizes glutamate excitatory actions (47, 51, 63). Thus, early in life, GABAergic inhibition may be mediated solely via GABA<sub>B</sub> receptors (51), and a fragile balance is maintained between powerful excitatory events mediated by GABA<sub>A</sub>, NMDA, and AMPA receptors (64) and inhibitory events relying solely on GABA<sub>B</sub> transmission (51). Therefore in the developing brain, it seems logical that the GABA<sub>B</sub> inhibition may be strengthened; this appears to be the case also in the site critical for control of seizures, the substantia nigra pars reticulata (65), although this enhancement probably cannot compensate for abundant excitation. This indicates that early postnatal arrangement of principal ionotropic receptors favors excitatory processes and that the rearrangement of these receptors is necessary for the decrease of seizure susceptibility in the adolescent and adult brain. It should be noted, however, that the rearrangement of the function of GABA<sub>A</sub> receptors is activity dependent and may be altered by significant early postnatal activation, including seizures (66).

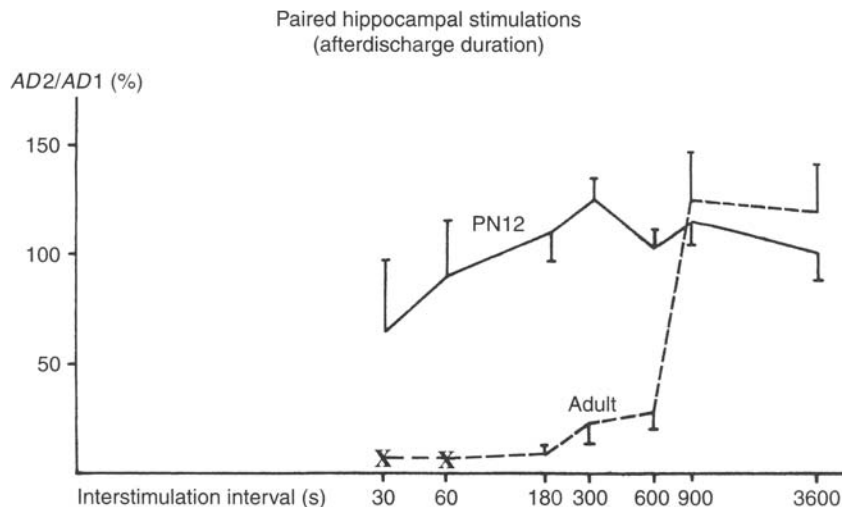

FIGURE 1-3

Insufficient postictal refractory period in the PN12 hippocampus. PN12 and adult rats were implanted with hippocampal stimulating electrodes and cortical recording electrodes. Each of two stimulations consisted of two trains of 121 constant-current rectangular pulses (8 Hz, 1 ms duration; total train length 15 s) with intensity twice as high as necessary to induce a hippocampal-cortical evoked potential using stimulation with a single pulse. Interstimulation intervals (x-axis) were in the range from 30 s to 3600 s (1 hour). The duration of the afterdischarge (AD) was recorded after each stimulation, and the results were expressed as  $AD2/AD1 \times 100$ . The postictal refractory period in PN12 rats was shorter than 30 s because already at this interstimulation interval there was no difference between the duration of the AD1 and AD2. In contrast, in adult rats the postictal refractory period lasted between 600 and 900 s because at 900 s interstimulation interval the duration of AD2 was equal to the AD1.

### Morphology

Earlier anatomical studies have suggested that there is a differential development of morphologically distinct types of synapses that can be assigned to “excitatory” and “inhibitory” functions. The classic study of Schwartzkroin showed that the “excitatory type” of the synapse is already present during the first and second postnatal week in the rabbit hippocampal area CA1, whereas the synapses of the “inhibitory type” start to occur during the third postnatal week (67). Thus, net excitation develops in parallel with the “excitatory type” of synapses, while the development of inhibition follows the occurrence of the “inhibitory type” of synapses (68). In the area CA3 of the immature hippocampus, the development of inhibition occurs earlier than in CA1. However, abundant excitatory axonal collaterals in this area form a complex network, which loses its complexity with maturation. Thus, the excessive excitatory wiring in the area CA3 may also contribute to increased epileptogenicity of the immature hippocampus and also to faster, less controlled seizure propagation early in life (69, 70). Finally, faster spread of seizures and recruitment of additional areas in the immature nervous system, compared to the adult, may be due to an extensive direct coupling of the neurons demonstrated in the neocortex of young rats lost with maturation (71). Similar findings have been reported in the PN12–18 rat hippocampus (72).

### Biochemistry and Molecular Biology

The developmental hyperexcitability of the all subtypes of glutamate receptors (49, 73) may be a function of their developmentally regulated subunit composition (74). The AMPA subtype of glutamate receptors may change their subunit composition during development from calcium-permeable isoforms in the immature brain to calcium-impermeable isoforms in adulthood (75). In this scenario, it is possible that the enhanced calcium influx into the immature neurons via fast excitatory receptor channels may be a powerful source of depolarization. Similarly, there are significant developmental differences in the expression of GABA<sub>A</sub> receptor subunit messenger RNAs (mRNAs), which also suggest age-specific composition of GABA<sub>A</sub> receptors (76). The striking correlation between the seizure-specific function and the distribution of certain GABA<sub>A</sub> receptor subunit mRNAs in certain brain areas suggests the existence of developmentally regulated GABA<sub>A</sub> receptor isoforms that may affect seizures in an opposite way compared to adult GABA<sub>A</sub> receptor isoforms (77). Molecular biology studies also indicate that ionic transporter systems such as NKCC1 and KCC2 go through maturational processes, which may affect excitatory and inhibitory features of the neurotransmitter receptors, particularly GABA<sub>A</sub> responses (78–80). One of the functional features that may comprise both the differential composition of GABA<sub>A</sub> receptors and

the ionic (chloride) environment inside the neurons is GABA-mediated tonic inhibition (81). It has been demonstrated that the spillover of GABA outside the synaptic cleft acts on extrasynaptic GABA<sub>A</sub> receptors. Addition of bicuculline would block these receptors as well as the chloride currents they control. This tonic inhibition, which may be age-specific, presets excitability of the neuronal plasma membrane and modulates the gain of the transmission (82). These extrasynaptic receptors exhibit a high affinity for GABA (hence low ambient concentrations of GABA are sufficient), and do not inactivate rapidly, thus producing a tonic form of inhibition (83). Unlike the synaptic (phasic) receptors, they do not bind benzodiazepines (84, 85). Recent studies indicate that during this “excitatory GABA” developmental period, tonic and phasic GABA activation in immature neurons may play a critical role in their synaptic integration, which is activity dependent. This process takes place in both the immature brain and newly born neurons in the adult brain (86–88).

The relatively delayed maturation of other neuromodulatory systems may contribute to the increased epileptogenicity of the immature brain. In adult rats, norepinephrine depletion accelerates the rate of kindling, decreases the intensity of postictal refractoriness levels, and permits the development of multiple seizure foci (89–91). In this respect, the norepinephrine-depleted adult rats resemble developing 2-week-old rats in which the norepinephrine transmission has not reached adult levels (29).

## NORMAL IMMATURE BRAIN: DIFFERENCES IN IONIC MICROENVIRONMENT AND GLIAL SUPPORT

### Setting the Scene

In young children, the brain is more vulnerable to insults from the external environment (92, 93). These insults may be due to epileptogenic features of exogenous or endogenous pyrogens, toxins produced by infectious agents, or reactive metabolic byproducts of the host tissues. The increased vulnerability of the young brain is probably the result of the still developing blood-brain barrier, which, in fact, reflects the development of glial cells (94). Glia have an essential role in maintaining constant extracellular environment of the nervous system (95). In the mature brain, glia contribute to neuronal stability by maintaining ion homeostasis. Almost all ions involved in synaptic transmission undergo age-specific changes, as reflected by the availability of ionic channels and the efficacy of energy-dependent ionic transporters, both in glia and in neurons (96). There is no general rule that the development of ionic channels follows; however, it seems that in the early developmental stages many ionic channels

promote calcium permeability (96). For detailed information on the role of ionic channel in epileptogenesis, see Chapter 3, this volume.

The relevant questions are these: Are the developmental changes in ionic environment powerful enough to affect age-specific seizure susceptibility? How does the maturation of transporter systems affect the development of seizures in the immature brain?

### Potassium

Potassium has an important role in the regulation of ionic fluxes early in the development of the nervous system. Intracellular concentration of potassium in neurons increases with maturation. This may be due to an increase in Na<sup>+</sup>/K<sup>+</sup>-ATPase content and probably also activity. Na<sup>+</sup>/K<sup>+</sup>-ATPase is responsible for the afterhyperpolarization of the neuron following glutamate-induced excitatory postsynaptic potentials (EPSPs) (97). During afterhyperpolarization, it is more difficult to elicit another population spike. In young rats, the afterhyperpolarization is minimal until PN11 and increases during first five postnatal weeks (97). Therefore, young neurons have more favorable conditions to generate repetitive action potentials than adult neurons have, which may further increase the susceptibility of the immature brain to seizures.

Extracellular K<sup>+</sup> efflux accompanies repetitive neuronal discharges (98). The rises in the extracellular K<sup>+</sup> as a consequence to neuronal (and epileptiform) activity are higher in the immature brain (99, 100) and the ceiling for extracellular K<sup>+</sup> concentration ([K<sup>+</sup>]<sub>o</sub>) induced by excessive neuronal activity is much lower in the adult than in the immature rats (10–12 mM versus 1420 mM) (17, 100). In any age group, accumulation of extracellular K<sup>+</sup> causes proportionate moderate depolarization of the neurons and thereby increases neuronal excitability. However, the capability of young CNS to accumulate extracellular K<sup>+</sup> is much larger than that of the adult brain, because of the immature clearance systems in the young (101). Additionally, repetitive discharges in the young brain tend to depolarize the neurons more than similar discharges in the adult brain, because the accumulation of potassium during afterdischarges is higher in the young (P9–11) rats than in older ages (101). In an environment with repeated epileptiform discharges, high [K<sup>+</sup>]<sub>o</sub> may promote a transition from interictal to ictal state. This situation is more likely to occur in the immature brain (17, 101). This is because there are several extracellular K<sup>+</sup> clearance systems, all of which are immature in the young brain and may contribute to decreased K<sup>+</sup> removal from the extracellular space. The first clearance system is Na<sup>+</sup>/K<sup>+</sup>-ATPase with a neuronal (97) and a glial (102) pool. The second system is K<sup>+</sup>-Cl<sup>-</sup> transport into astrocytes (103). The density of astrocytes

in the hippocampus during the first postnatal week in the rat is very low, while during the second postnatal week it is sparse only in hippocampal stratum pyramidale (104). The third mechanism of  $K^+$  clearance is spatial redistribution by hiding and diluting  $K^+$  in the remote and narrow processes of the extracellular space. Neurons, astrocytes, and oligodendrocytes share this function; however, the maturation of oligodendrocytes is not finished before four weeks of age (104). Therefore, in the young brain, the extracellular space is wider (105) and spatial redistribution, as measured by extracellular slow potentials (106), is slower, contributing to higher activity-dependent local concentrations of potassium. These findings demonstrate delayed maturation of various glial elements, which increases epileptogenesis of the immature brain and may support the progression of ongoing epileptiform activity (95, 107). Finally, there is a maturational pattern of potassium-chloride cotransporters (KCC), which are less significant for potassium clearance but very significant for chloride distribution (64).

The developmental features of potassium concentration and clearance as well as potassium effects on neuronal membrane excitability make potassium a good ionic candidate responsible in part for the increased seizure susceptibility in the immature brain, especially for the promotion of the transition from interictal to ictal seizure state.

### Calcium

Extracellular calcium has age-specific effects on neuronal excitability. Electrophysiological studies have shown that glutamate, and especially NMDA, receptors in the immature hippocampal pyramidal neurons are regulated by extracellular calcium instead of magnesium as in the case of mature neurons (108, 109). Therefore, in the immature brain, activity-dependent changes in extracellular calcium may have a greater influence on ion flow produced by activation of the NMDA receptor. As mentioned previously, enhanced calcium influx into the developing neurons due to the immature form of the AMPA subtype of glutamate receptor channels lacking the GluR2 subunit may be a powerful source of depolarization (75).

The role of intracellular calcium in seizure susceptibility of the immature brain is less obvious and probably indirect. Intracellular calcium affects neuronal maturation through calcium-regulated transcription (110). However, the correlation between this calcium effect and seizure susceptibility of the immature brain has not been yet systematically studied. Further, developmentally regulated intracellular calcium levels (96, 111, 112) may determine the speed by which the axon reaches its synaptic target. Thus, higher intracellular calcium levels early in the development may affect the complexity of the neuronal

network and also its excitability by delaying the “plug-in” of the inhibitory elements. Additionally, reciprocal calcium channel (T/R and L type), opening together with voltage-gated sodium channel activity, may contribute to intrinsic bursting, found in CA1 pyramidal cells during the third postnatal week of the rat (113), right after the  $GABA_A$  receptor depolarization diminishes, extending effectively the period of increased seizure susceptibility demonstrated in vivo (34).

### Chloride

Intracellular chloride can significantly affect features of the neuron and its responses to the neurotransmitter operating via chloride environment (i.e.,  $GABA_A$ ) receptors. Intracellular concentration of chloride has powerful effects on chloride fluxes out from and into the neuron (Figure 1-4). If the chloride concentration inside the cell is above electrochemical equilibrium, opening the  $GABA_A$ -operated chloride channel in  $GABA_A$  receptors leads to chloride leakage from the cell and consequent depolarization. This is the situation often found in immature neurons. The reason is the developmentally regulated expression of KCC (NKCC1 and KCC2) in the immature neurons, which results in significant intracellular accumulations of chloride (114). NKCC1 pumps all ions, including chloride, into the immature neuron. Its expression (and thus, function) significantly decreases with maturation (64, 80, 115). Therefore, blockade of this cotransporter by the specific antagonist bumetamide significantly suppresses high (8.5 mM) potassium-induced epileptiform activity in brain slices from PN7–12 old rats but is ineffective in PN21–23 rats with already decreased NKCC1 expression; and, of course, bumetamide is also ineffective in slices from NKCC1 knockout mice. Similarly, bumetamide suppresses kainic acid seizures in PN10 rats (80). KCC2 lowers the intraneuronal chloride concentration below its electrochemical equilibrium, and this function increases with maturation (116, 117). If the NKCC1 concentration is high and KCC2 concentration is low, as demonstrated in immature neurons, chloride accumulates in the neurons (78). After  $GABA_A$  receptor-operated chloride channels are opened, chloride leaks out, and the cell membrane depolarizes with possible firing of an action potential (64). In mice with disruption of the KCC2-encoding gene (118), electrophysiological recording showed hyperexcitability in the hippocampus, and heterozygotes had increased seizure susceptibility compared to those animals with uninterrupted genes (119). Additional data indicate activity-dependent and also sex-specific expression of KCC2 (79, 120). These findings may contribute to seizure modulation of consequent seizure susceptibility and to sex-differences synaptic events as well as seizure susceptibility (121).

FIGURE 1-4

Main factors affecting chloride concentrations in the immature and mature neurons. In the immature neuron, a sodium-potassium-chloride cotransporter (NKCC1) is expressed in high concentrations. As a result, chloride anions are pumped in and accumulate inside the cell, since the low expression of the potassium-chloride cotransporter (KCC2) cannot extrude them out of the cell. This chloride accumulation shifts chloride reversal potential to a more positive value than the membrane potential. After the GABA<sub>A</sub> receptor-operated chloride channel is open after GABA binding, chloride flux is directed from inside the cell outward, carrying negative charge and thus making the inside of the immature neurons more positive—membrane depolarization occurs. This depolarization can generate sodium and calcium action potentials (64).

In the mature neuron, NKCC1 expression is low, while the KCC2 expression is high. This arrangement keeps intracellular chloride concentration low, and the chloride reversal potential is more negative than the membrane potential. After GABA binding to the GABA<sub>A</sub> receptor, chloride channels open and chloride anions flow into the cell. This renders the cell more negative inside, and a membrane hyperpolarization occurs. Hyperpolarization makes firing action potentials more difficult.

## Sodium

Sodium also plays a significant role in early developmental seizures, as demonstrated by seizures resulting from sodium channel dysfunctions, which occur during infancy or early childhood and often disappear later on (122). The reasons for the developmental occurrence of seizures associated with sodium channel dysfunction are not clear. Although there are age-dependent expression patterns of sodium channel subunits (123), they do not define vulnerability windows. As an alternative, the age specificity of sodium channel defects may be a result of age-specific insults that interact with these channels. For example, increased body temperature (fever) may unmask specific deficits of mutated sodium channels (124). Consistently, sodium channel defects are particularly common in individuals with febrile seizures (125).

## NORMAL IMMATURE BRAIN: DELAYED DEVELOPMENT OF CIRCUITS THAT MODIFY THE EXPRESSION OF SEIZURES

### Spread of Metabolic Activation during Seizures

Studying the role of brain structures in the initiation and propagation of seizures has, unfortunately, serious limitations. Although several morphological and physiological methods are available, none of them can give a direct answer as to whether the seizure propagates directly from one structure to another via a specific pathway, or whether these additional structures are involved indirectly through relay areas. The best way to approach involvement of different structures is a combination of electrophysiology and imaging that may provide significant correlates of seizure spread. Electrophysiology itself provides limited findings because surface electrodes cover only superficial neocortical regions; depth electrodes record from a restricted area only, and thus many electrodes must be placed to assess the electrical activity of the brain, including the brainstem. Therefore, metabolic imaging studies are more helpful.

Metabolic studies using a radioactive glucose analog 2-deoxyglucose (2-DG) have provided significant information about changes in the metabolic activity of several structures during seizures but also during the immediate postictal period. This information points only to the metabolic activity of the structures; their actual role in seizure generation, propagation, or control, however, can only be estimated. It should be noted that, although 2-DG is an excellent source of qualitative information about brain metabolism changes, 2-DG studies in animals undergoing seizures may not provide absolute quantification because certain assumptions proposed by Sokoloff are applicable only under normal (resting) conditions (126). Additionally, 2-DG uptake informs about the activity of presynaptic

elements in the structures but cannot give a simple answer about increases in inhibition or excitation. Further, excessive motor behavior (as during seizures) can change 2-DG uptake pattern and confound the results. Therefore, the 2-DG results should be interpreted with caution.

Several 2-DG metabolic studies demonstrate age-specific metabolic involvement of brain structures in kainic acid-, kindling-, bicuculline-, and pentylenetetrazol-seizures, with somewhat limited data on flurothyl seizures (28, 127–130). The excitotoxin kainic acid, as well as kindling, induces age-specific seizures that originate focally with subsequent generalization. In addition, kainic acid-induced seizures progress into status epilepticus (28, 32, 131, 132). Pentylenetetrazol and flurothyl seizures are believed to be primarily generalized seizures and also have age-specific features; these seizures can lead to status epilepticus (20, 22, 133–138). More recently, the lithium-pilocarpine model of epilepsy has been explored (139).

In young rats until the third week of age, kainic acid-induced status epilepticus produces a rise in metabolism restricted to the hippocampus and lateral septum (28, 130). This is paralleled by paroxysmal discharges observed on electroencephalogram (EEG) that are recorded in the hippocampus, although some studies have proposed that seizures are more prominent in the neocortex (28, 130, 132, 140, 141). Starting from the end of the third week, there is a rise in labeling of other structures that are part of or closely associated with the limbic system: the amygdala complex, the mediodorsal and adjacent thalamic nuclei, the piriform, entorhinal, and rostral limbic cortical regions, and areas of projection of the fornix. These metabolic maps are thus similar to those observed in adults (130, 142). In amygdala kindling in PN15, the metabolic activation during severe seizures is restricted to limbic structures (128, 129), even when the rats experience secondarily generalized seizures. Another interesting seizure-induced difference between the metabolic activation of the young and adult brain is in the involvement of the substantia nigra pars reticulata (SNR). Whereas in the adult rats there is a significant metabolic activation of the SNR during kindling and kainic acid status epilepticus (143–147), neither kindled seizures nor kainic acid status epilepticus induce metabolic activation of the SNR in young rats (28, 148).

A series of studies on pentylenetetrazol-induced status epilepticus have shown an age-specific pattern of metabolic activity and blood flow. In young rats at PN10, there is a uniform increase in the cerebral metabolism and blood flow throughout the brain. At PN21, an age when developmentally specific pentylenetetrazol clonic seizures begin to occur (20, 22), there are significant decreases of local metabolism and blood flow in the cortex and hippocampus as well as in mammillary body, thalamic nuclei, and white matter areas. Moderate metabolic and blood flow increases are

restricted to a few structures (134, 137). In the adult rats, there is a rise in metabolism primarily in the neocortex, cerebellum, and vestibular nuclei (136). The data show consistency between metabolic rate and blood flow rate and demonstrate age-specific patterns of brain metabolic activation due to seizures.

Recently, there has been an increased interest in the brain metabolic patterns in the lithium-pilocarpine model of epilepsy. Studies have demonstrated that, in agreement with previous work, spontaneous seizures consistently develop in PN21 and older rats subjected to lithium-pilocarpine status epilepticus (139, 149, 150). No spontaneous seizures were observed in those rats subjected to status epilepticus on PN10 (139), and the spontaneous seizures developed infrequently (23%) in 2-week-old rats exposed to lithium-pilocarpine status epilepticus (150). Similarly, there was no neuronal damage and no metabolic consequences in the youngest group. Older groups than PN10 had neuronal damage in the hippocampal CA1 (2-week-old) (149) and lateral thalamus (PN12) (151). Adult rats additionally had damage in the piriform cortex and basolateral amygdala, whereas the PN21 rats displayed neuronal damage also in the entorhinal cortex.

During the latent period between the status epilepticus and development of spontaneous seizures, in PN21 and adult rats, there were decreases in metabolic activation in forebrain regions corresponding to the damaged areas. At the end of the latent period, metabolic increases in the brainstem occurred (139). Additionally, this model with lithium-pilocarpine status epilepticus induced on PN21 has been used in MRI studies for prediction of epilepsy development (152, 153). Rats with no MRI abnormalities did not develop epilepsy. Spontaneous seizures developed in two groups: with visible MRI abnormalities in one group and without visible abnormalities but with changes in T2 relaxation times in the other. These MRI changes did not correlate with neuronal damage, suggesting that subcellular changes may be responsible for the future development of spontaneous seizures (152, 153).

In flurothyl-induced moderate seizures (20% mortality) in PN15 rats, there is an activation of glucose metabolism in the midbrain and brainstem (excluding the SNR, however) and a decrease of metabolism in the neocortex. Other structures are not affected (EF Sperber, personal communication).

### Brain Structures Controlling Seizures

Several brain sites play a critical role in the control or activation of seizures. These sites involve SNR, superior colliculus, subthalamic nucleus, pedunculopontine nucleus, anterior thalamus, and area tempestas (154–163). Unfortunately, developmental data are currently available only for the SNR (77, 164).

FIGURE 1-5

Two compartments of the substantia nigra pars reticulata (SNR) that in the adult rat brain differentially control seizures. Sagittal section of the rat brain 2.4 mm lateral from midline (168) limited to parts of diencephalon, midbrain, and the brainstem. The diagram illustrates both subregions of the SNR. In the adult male brain, microinfusions of muscimol placed bilaterally and symmetrically in the light gray area (SNR<sub>anterior</sub>) have anticonvulsant effects in flurothyl-induced clonic seizures. In the adult male brain, bilaterally symmetrical microinfusions of muscimol in the dark gray area (SNR<sub>posterior</sub>) have proconvulsant effects. In the adult female brain, symmetrical microinfusions of muscimol into SNR<sub>anterior</sub> have similar anticonvulsant effects as in the adult males. However, symmetrical muscimol infusions into SNR<sub>posterior</sub> in adult female rats are without any effect on seizures. Arrows mark the main directions.

*Abbreviations:* APTD: anterior pretectal nucleus, dorsal. APTV: anterior pretectal nucleus, ventral. CA1, CA2, CA3, CA4: hippocampal cornu ammonis regions 1, 2, 3, and 4. DG: dentate gyrus. IC: inferior colliculus. LDVL: laterodorsal thalamic nucleus, ventrolateral. LP: lateral posterior thalamic nucleus. ml: medial lemniscus. Po: group of posterior thalamic nuclei. RR: retrorubral nucleus. RRF: retrorubral field. SC and the arrow mark the extent of the superior colliculus layers. STh: subthalamic nucleus. VLL: ventral nucleus of lateral lemniscus. VPM: ventral posteromedial thalamic nucleus. ZI: zona incerta.

In the adult male rat SNR, there are two GABA<sub>A</sub>-sensitive, topographically distinct functional regions localized in the anterior and posterior SNR: SNR<sub>anterior</sub> and SNR<sub>posterior</sub>, respectively (165–168; Figure 1-5). These two SNR regions mediate differential effects on clonic flurothyl seizures. In the SNR<sub>anterior</sub>, bilateral microinfusions of muscimol have anticonvulsant effects, while in the SNR<sub>posterior</sub>, muscimol microinfusions have proconvulsant effects. Similarly, microinfusions of other GABA receptor-acting drugs (such as bicuculline, ZAPA (Z)-3-[(aminoiminomethyl) thio]prop-z-enoic acid sulfate), and zolpidem) have site-specific effects on seizures in the SNR (Table 1-2) (166, 169, 170). Site-specific effects of the SNR on flurothyl-induced seizures are probably not confined only to GABAergic drugs. Infusions with different pH as an effector have differential actions in the SNR<sub>anterior</sub> and SNR<sub>posterior</sub> (171). In situ histochemistry studies have demonstrated that in adult male rats there are two SNR functional regions, which differ in the distribution of the GABA<sub>A</sub> receptor alpha-1 subunit mRNA (165). This subunit is the most abundant GABA<sub>A</sub> receptor subunit in the adult SNR (172). At the cellular level, there are a few large clusters of labeled cells with high expression of hybridization grains in the SNR<sub>anterior</sub>. In the SNR<sub>posterior</sub>, there is a high density of labeled cells that have moderate expression of the alpha-1 hybridization grains. The two SNR regions use different output pathways for their effects on seizures, as determined by 2-DG studies. In the SNR<sub>anterior</sub>, muscimol infusions decrease glucose utilization in the striatum, sensorimotor cortex, and ventromedial thalamus and increase glucose utilization in superior colliculus (165). In contrast, in the SNR<sub>posterior</sub>, muscimol infusions increase glucose utilization in the dorsal striatum, globus pallidus, and superior colliculus and decrease glucose utilization in thalamus (165). These data support the findings of the topographic and functional segregation

of the SNR-mediated systems involved in the control of seizures in adult male rats. An additional study exploring the effects of unilateral SNR muscimol injections on 2-DG uptake revealed that the activation maps in this experimental paradigm have age-, sex-, and SNR region-specific patterns (173).

However, the two regions of the SNR do not develop simultaneously. In PN15 male rats, activation of high-affinity GABA<sub>A</sub> receptors (using muscimol or gaboxadol-4, 5, 6, 7-tetrahydroisoxazolo[5, 4-c]pyridin-3-ol (THIP)) mediates only proconvulsant effects (174, 175). Thus, the organization of the SNR into two functional regions, which was described for adult male rats (165, 166), is absent in PN15 male rats (165, 166). In PN15 rats, there is only one functional region within the SNR with respect to the effects of microinfusions of GABA<sub>A</sub>ergic drug on seizures. These results suggest that the immature, undifferentiated SNR has some similarities with the SNR<sub>posterior</sub> in terms of the presence of the “proconvulsant” GABA<sub>A</sub> receptor subtype. Similarly, in situ hybridization studies have revealed that at the cellular level the silver grains of alpha-1 subunit are clustered over the labeled cells and uniformly distributed throughout the SNR with moderate amounts of the hybridization grains in these clusters. Thus, the distribution and density of these clusters resembles the pattern described in the SNR<sub>posterior</sub> in adult male rats. In PN15 male rats, muscimol infusions in the SNR also produce specific metabolic changes compared to controls. Irrespective of the site of muscimol infusion, glucose utilization is increased in the ipsilateral dorsal striatum, in the globus pallidus and superior colliculus and not changed in the sensorimotor cortex. In contrast, muscimol infusions decrease glucose utilization in the ipsilateral ventromedial thalamus (165). Thus, the data suggest that in PN15 male rats, there is only one output network, which resembles the one observed in the SNR<sub>posterior</sub> in adult rats.

**TABLE 1-2**  
*Region- and Age-Specific Effects of Nigral GABAergic Drug Microinfusions on Flurothyl Seizures in Male Rats*

DRUG	PN15 RATS		ADULT RATS	
	SNR <sub>anterior</sub>	OR SNR <sub>posterior</sub>	SNR <sub>anterior</sub>	SNR <sub>posterior</sub>
Muscimol	Proconvulsant		Anticonvulsant	Proconvulsant
Bicuculline	Proconvulsant		Proconvulsant	No effect
ZAPA	Biphasic effects		Anticonvulsant	Proconvulsant
Zolpidem	Anticonvulsant		Anticonvulsant	No effect
γ-vinyl GABA	Anticonvulsant		Anticonvulsant	Proconvulsant

Muscimol: GABA<sub>A</sub> receptor agonist on both low- and high-affinity receptors. Bicuculline: GABA<sub>A</sub> receptor antagonist on low-affinity receptors. ZAPA: GABA<sub>A</sub> receptor agonist on low-affinity receptors. Zolpidem: agonist of benzodiazepine I binding site of GABA<sub>A</sub> receptor. γ-vinyl GABA: irreversible inhibitor of the GABA degradation enzyme, GABA-transaminase.  
Based on data in (165, 166, 169, 170).

The question is, When does the differentiation of the two SNR seizure-modifying regions occur? At PN25, the SNR starts to differentiate; infusions of muscimol in the SNR<sub>anterior</sub> have no effects on flurothyl seizures, while infusions in the SNR<sub>posterior</sub> have proconvulsant effects. This maturation of the “anticonvulsant” SNR region strikingly coincides with sexual maturation (11). In male rats, there is a sudden drop in plasma testosterone levels (PN20–25) (176–178) just prior to the age when the SNR<sub>anterior</sub> assumes its “anticonvulsant” characteristics. To test the hypothesis that testosterone may play a role in formation of the “anticonvulsant” SNR<sub>anterior</sub>, male rats were castrated on the day of birth. The rats were exposed to flurothyl at ages PN15 and PN25 following bilateral infusions of muscimol in the SNR<sub>anterior</sub> or SNR<sub>posterior</sub>. In the SNR<sub>anterior</sub> in PN15 neonatally castrated male rats, muscimol infusions had no effects on seizures; in PN25, muscimol infusions had anticonvulsant effects compared to saline-infused neonatally castrated controls. Thus, in neonatally castrated male rats the emergence of the “anticonvulsant” SNR<sub>anterior</sub> shifted to an earlier time point than that observed in intact or sham-operated male rats, suggesting that the depletion of postnatal testosterone may accelerate the appearance of the “anticonvulsant” SNR<sub>anterior</sub> (170).

In female rats, a proconvulsant muscimol-sensitive SNR region does not develop. In PN15 female rats, there is only one functional region in the SNR. Infusions of muscimol into this region do not change seizure threshold. In adult female rats, the SNR<sub>anterior</sub> mediates anticonvulsant effects of muscimol similarly to the SNR<sub>anterior</sub> in adult male rats. In contrast to adult male rats, infusions of muscimol in the SNR<sub>posterior</sub> in female rats have no effects on seizure threshold. As just mentioned, maturation of the SNR regions is under control of perinatal testosterone or its metabolites. Thus, in females, postnatal administration of testosterone leads to the male SNR phenotype (170, 179). The male–female differences in seizure control seem to be associated with sex-specific differences in the GABAergic system within the SNR as well as in connectivity patterns (173). Further, it appears that the developmental control of seizures in the SNR is affected by sexually dimorphic maturation of KCC2 in this structure (79).

The data demonstrate that the age-specific susceptibility to seizures may be partly due to developmental maturation of structures controlling seizures. This maturation may be under the influence of gonadal hormones and may exert sexually dimorphic features.

### ROLE OF STRUCTURAL BRAIN ANOMALIES

Childhood epilepsies are often associated with a variety of brain anomalies. Among epileptic syndromes of childhood, catastrophic epilepsies, including West and Lennox-Gastaut

syndromes, are associated with the broadest spectrum of pathoanatomic abnormalities (180), including neuronal migration disorders and small foci of neuronal necrosis. Therefore, pre- and perinatal brain alterations become a condition *sine qua non* for the development of experimental seizures in the immature brain. The long-term goal of these studies is to induce a form of brain injury that would constitute a basis for the development of spontaneous seizures. The model, therefore, should demonstrate structural abnormalities and subsequent increased epileptogenicity in response to environmental stimuli, as well as spontaneous seizures. Until now, only few attempts have been made to approach developmental seizures in the presence of morphologic brain anomalies. How does the presence of brain anomalies or malformations lead to the development of epilepsy? Currently, data exist in four models of experimentally induced malformations: methylazoxymethanol-induced migration disorder, neocortical freezing lesions, neuronal migration disorder induced by irradiation in utero, and the double cortex mutation.

### Methylazoxymethanol-Induced Neuronal Migration Disorders

Methylazoxymethanol (MAM) is a powerful alkylating agent (181) acting during the gap 1 (G1) and mitosis (M) phases of the mitotic cell cycle. Administration of MAM on embryonic day 15 in the rat interferes with neuroblastic division and neuronal migration toward cortical layers II–V (182) and is associated with the disruption of radial glia scaffolding with premature astroglia differentiation and thickening of the marginal zone, with redistribution of Cajal-Retzius neurons to deeper layers (183). These actions result in the disruption of the cortical plate and appearance of subventricular zone nodules (183). Consistent brain alterations are present in 100% of cases (Table 1-3; Figure 1-6) (184). Young rats with MAM-induced neuronal migration disorders have indeed a modest increase in seizure susceptibility in several models. In PN14 MAM-exposed rats, hyperthermia induced seizures in 14 of 39 rats, while in age-matched controls only one rat out of 30 had a seizure (39). The higher seizure susceptibility in MAM-exposed rats exposed to hyperthermia was associated with a higher mortality rate. Young MAM rats at PN14 have a lower threshold to kainic-acid-induced seizures, in terms of seizure onset and duration of seizures, than saline-exposed controls (38, 184, 185). These effects may be associated with the alterations in AMPA receptor GluR2 flip and NMDA receptor NR1 subunit distribution in the dysplastic areas of neocortex and hippocampus (186). Additionally, brain slices from rats exposed in utero to MAM display an increased proportion of bursting cells in the hippocampal CA1 pyramidal cells compared to controls (187, 188). Spontaneous seizures have not been observed in this model.

**TABLE 1-3**  
**Prenatal Brain Injury**

MODEL	AGE OF APPLICATION	RESULTS
MAM	E14, E15	Decreased brain size, decreased cortical thickness, loss of normal lamination in layers II–V of the neocortex with abnormally migrated neurons, bilateral ectopias in the pyramidal layer of the hippocampal CA1, cell loss in the striatum and thalamus (38)
Irradiation	E16, E17	Diffuse cortical dysplasia, periventricular heterotopia, dispersion of hippocampal pyramidal cell layer, corpus callosum agenesis (40)
Double cortex	Mutation	Layers of gray matter placed inside the forebrain white matter; inverted migration pattern (42)

### Freezing Lesions

A search for a model of perinatal damage resulting in dysplastic cortex rekindled the interest in the neocortical freezing-induced focus used in adult rats by Escueta (189, 190) and in neonatal rats by Dvořák and Feit (191). In this model, a relatively restricted freezing lesion is produced by a probe (cooled usually by liquid nitrogen) in the neonatal rat neocortex on PN0 or PN1 (41). The treatment results in the loss of normal cortical lamination and results in the creation of a focal microgyrus. Moreover, there are ectopic cell clusters in the layer I of the neocortex and in the white matter (41, 192). There is no significant loss

**FIGURE 1-6**

Brain section from PN15 rat with neuronal migration disorder induced by prenatal treatment with MAM. Coronal section of hippocampus showing areas of neuronal ectopias in the CA1 subfield (arrows). Ectopic neurons are scattered in the stratum oriens (so) and stratum radiatum (sr). Reprinted from Germano IM, Sperber EF. Transplacentally induced neuronal migration disorders: an animal model for the study of the epilepsies. *J Neurosci Res* 1998;51:473–488 (184). of GABAergic neurons in the hyperexcitable tissue (193), but the GABA transmission is impaired because of loss of alpha-1, alpha-2, alpha-5, and gamma-2 GABA<sub>A</sub> receptor subunits (194). Electrophysiology reveals prominent hyperexcitability of the disorganized neocortical network in the region of focal lesion as early as on PN12 (195). In adult (4–6 months old) rats, electrical stimulation of the neocortical afferents supplying the microgyrus leads to epileptiform discharges that propagate over 4 mm in the horizontal direction, whereas in sham-operated control tissue the horizontal propagation is limited to under 1 mm (41). A metabolic study demonstrated a similar extent of 2-deoxyglucose uptake reduction (196). Although the administration of the NMDA receptor antagonist MK-801 (dizocilpine maleate) prior to the lesion can prevent the development of the discharges, it has little or no effects on an already developed focus and on its propagation (41, 197). Discharges of the already developed focus can be inhibited by the AMPA receptor antagonist 6-nitro-7-sulfamoylbenzo[*f*]quinoxaline-2, 3-dione (NBQX) (41). Optical recordings in brain slices have demonstrated high epileptogenicity of these lesions. In the low-Mg<sup>2+</sup> model in vitro, epileptiform discharges started in variable locations in control slices. In the dysplastic brains after the freeze lesion, the discharges always emerged from the dysplastic cortex (198). This finding has been confirmed in vivo, since the rats with neonatal (P1) freeze lesions developed hypothermic seizures on P10 earlier (decreased threshold) and the ictal manifestations lasted longer than in control rats (44). However, in the case of freezing lesions in developing rats, spontaneous seizures may develop (43).

### Irradiation Lesions

Exposure of embryonic day 16 (E16) or E17 rat embryos to irradiation disrupts migration patterns, resulting in the creation of numerous dysplastic lesions (40). These rats have a higher susceptibility to the development of electrographic epileptiform discharges after seizure-provoking test with acepromazine or xylazine. Similarly,

in vitro neocortical slices from adult rats exposed to irradiation in utero demonstrate more robust epileptiform activity in bicuculline-containing medium than slices from control rats (45). The results suggest that irradiation lesions express their epileptogenic potential in the environment with altered GABAergic transmission. However, spontaneous seizures have not been observed.

Recently this model has been revived. It has been demonstrated that E17 and E19 irradiation is associated with more severe pilocarpine-induced status epilepticus than E13 or E15 irradiation is (199, 200). Similarly, the survival in E13 and E15 groups was higher than in E17 and E19 groups. Interestingly, irradiation on E13 also decreased epileptogenicity of the postnatal mechanical injury inflicted on P30 (201). If the kainic acid status epilepticus model was employed, the profile was opposite to that found in pilocarpine model; that is, irradiation on E13 and E15 produced more severe symptoms than the irradiation on E17 and E19 did (202).

### GENETIC PREDISPOSITION TO SEIZURES AND EPILEPSIES

Many forms of human epilepsy are genetically determined (203). The mechanisms by which a multitude of genetic aberrations alter epileptogenicity are unclear. To date, there are several models of genetically determined epilepsy available in baboons, in rats, and many mutant mouse strains with epileptic disorders (42, 204). The major advantage of gene mutation models is the occurrence of spontaneous seizures. The disadvantages may be that there may not be any obvious human correlate, or if there is, the developmental profile may not be similar to that of human epilepsy.

#### BABOONS

There is a subpopulation of Senegalese baboon with genetically determined photosensitive epilepsy, which was one of the earliest genetic epileptic disturbances studied (205–210). Rhythmic photic stimulation induces progressing myoclonus. The model reflects a quite rare human condition of reflex myoclonus (211). These baboons do not develop their photosensitivity until prepubertal age. The model is now rarely used because of decreased availability of these baboons and the ample availability of mutant mouse models. However, spontaneous myoclonic as well as tonic-clonic seizures have been observed in other baboon subspecies such as *Papio hamadryas anubis* and *cynocephalus/anubis* (212, 213). Photosensitivity is also present in these baboons (213).

#### RATS

There is a well-established model of generalized tonic-clonic (or brainstem) seizures in the rat induced by intense

auditory stimulation. This genetically epilepsy-prone rat (GEPR) is susceptible to environmentally induced seizures that cannot be precipitated in neurologically normal subjects. Drug studies suggest that decrements in monoaminergic transmission may be one of the seizure susceptibility determinants. However, nonmonoaminergic abnormalities may also play an important role in seizure predisposition of the GEPR (214–216).

There are two rat models with spontaneous spike-and-wave discharges akin to human absence seizures: The genetic absence epileptic rat of Strasbourg (GAERS) (217) and WAG/Rij strain with spontaneous absence epilepsy from Nijmegen (218) bring potentially useful information about the mechanisms involved in the generation of absence epilepsy in humans. The age of onset of these seizures is relatively late, so these models cannot be used for study of absence seizures early in life. Thus, spontaneous seizures in GAERS begin to occur well after 4 weeks of age, and their incidence increases till adulthood (219). In the WAG/Rij strain, the seizures occur even later, around PN75 (220). This is in contrast to human absence epilepsy, which begins in childhood and by puberty may even spontaneously remit. On the other hand, the electroclinical correlation between these models and absence seizures is quite good, and thus the models may bring new information on the mechanisms of genesis of spike-and-wave rhythm and the associated behaviors (Table 1-4).

In the flathead mutant rat, the seizures develop in immature animals already during the second postnatal week. The seizure phenotype is related to cortical malformations, including microcephaly, and cellular abnormalities such as cytomegalic neurons and abnormal neuronal death with preferential loss of GABAergic interneurons (221–224). These seizures are myoclonic with loss of posture. Toward the third postnatal week, the seizures become rather tonic and lead to premature death (222).

#### Mice

A single-locus neurological mutation in mice provides a powerful genetic model system for exploration of the diversity of mechanisms that widely underlie epilepsy.

TABLE 1-4

#### *Pros and Cons of Genetic Absence Models in Rats*

##### ABSENCE SEIZURE MODELS IN GENETICALLY PRONE RATS

Positive features	Spontaneous seizures Good electroclinical correlation to human absences Good response to antiabsence drugs
Negative features	Developmental discrepancy with the onset of human absence seizures

Many spontaneous as well as engineered gene mutations were identified in mice and are now an important tool to study epilepsy syndromes, with the information well exceeding the extent of this chapter. Recently, several excellent reviews on this topic have been published (225–228); thus, we will not cover this topic in any detail, and only some models will be briefly discussed.

Significant efforts have concentrated on the search for the genes responsible for absence epilepsy. A systematic EEG survey of over 110 mapped mouse mutants revealed 5 mutant genes, located on separate chromosomes, that display a pattern of spontaneous 6–7 Hz spike-and-wave discharges accompanied by behavioral arrest, myoclonic jerks, and uniform responsiveness to treatment with ethosuximide (204). These mouse strains have been classified according to the prevalent behavioral feature such as “lethargic” (*lh/lh*), “tottering” (*tg/tg*), “ducky” (*du/du*), “mocha (2J)” (*mh<sup>2J</sup>/mh<sup>2J</sup>*), and “stargazer” (*stg/stg*) and provide a strong evidence for the genetic heterogeneity of the spike-and-wave trait in the mammalian brain. Developmentally, strains *tg* and *stg* show the onset of spontaneous seizures during a 2-day period between PN16 and PN18. Seizure frequency increases with age and reaches adult levels within one week. Seizure severity varies across the strains and is apparently also genetically linked. Thus, the rates for spontaneous seizure are greatest in *stg* and lowest in *du* mice: *stg* >> *tg* >> *lh* > *mh<sup>2J</sup>* > *du* (229). These data show that a defect at a single gene locus is sufficient to produce a spontaneous, generalized spike-and-wave seizure disorder. Additionally, the EEG trait is genetically heterogeneous and can arise from several different recessive mutations. Finally, the background cellular mechanisms responsible for these mutations are not necessarily identical, and each mutation gives rise to a distinct syndrome with a typical seizure frequency, sensitivity to antiepileptic drugs (AEDs), and severity of the associated neurological phenotype (229).

Another mouse strain, with a mutation of the *reeler* gene, has a significant brain anomaly, with layers of gray matter placed inside the forebrain white matter. Similarly, in the *scrambler* mice, mutation of the same gene pathway as in *reeler* mice leads to a disruption of the “inside-out” migration pattern of neocortical neurons during cortical development; instead, an “outside-in” pattern of migration is seen (42). Analogous situations are observed in humans, and the anomaly is termed double cortex. Like the X-linked genetically induced double cortex in humans (230), these large ectopias in mice are associated with seizures (42).

The tottering mouse exhibits intermittent focal myoclonic seizures with ataxia from the fourth postnatal week (231–233). In this model there is an increase in the axonal projections originating from the locus coeruleus, which corresponds to overproduction of norepinephrine in the terminal fields, especially within the cortex (233, 234).

The *Otx1*<sup>-/-</sup> mouse is characterized by microcephaly, with the reduction expressed especially in the

neocortex (235–238). Reduction of neuronal numbers involves mostly GABAergic interneurons. The seizures in these mice start occurring during the fourth postnatal week and are characterized by head nodding and forelimb clonus with rearing and falling.

### EXPOSURE TO EPILEPTOGENIC STIMULI (FEVER, INFECTION, HYPOXIA) DURING DEVELOPMENT

Infants are exposed to a high risk of epileptogenic stimuli, represented by greater exposure to infectious agents that lead to fever and sometimes to cerebral infections. Neonates and infants may also often suffer from perinatal hypoxia/ischemia. In susceptible subjects, these stimuli may induce seizures, and because of the higher susceptibility of the young brain to seizures, these seizures occur multiple times a day and may be difficult to control with currently available AEDs (239–245). Several investigators have begun studying the effects of high temperature or hypoxia on seizures in rats with normal and abnormal brain. The pertinent questions are the following: In the experimental models, do the stimuli, such as fever or hypoxia, induce seizures if delivered early in life? If yes, do they increase subsequent seizure susceptibility? Is this change permanent? If the stimuli do not produce acute seizures, do they alter future susceptibility anyway? To date, there are studies using hyperthermia or hypoxia as the seizure-triggering stimuli in the developing brain. So far, there are no reports on infection-induced seizures.

#### Normal Brain

Hyperthermia-induced seizures can be effectively and reliably induced in developing rats (246–249), and may be a valuable model to assess developmental seizure susceptibility as a result of preexisting alterations, such as hypoxia (250). In PN10–11 rats, hyperthermia can be induced by a stream of heated air, and the seizures are easily determined by both behavioral and electroencephalographic criteria (247). In this model, stereotyped seizures are generated in almost 95% of subjects. EEG correlates of these seizures are not evident in cortical recordings but are present in recordings from the amygdala and hippocampus. There is a low mortality (11%) and long-term survival. This model is suitable for long-term studies and appears to be extremely valuable for studying the mechanisms and sequelae of febrile seizures (247). Although hyperthermic insult produces seizures in infant rats, the question is whether this insult results in spontaneous seizures. A long-term follow-up study indicates that in normal, brief hyperthermic seizures on PN10, there is no spontaneous seizure outcome. However, if prolonged (24-min duration) hyperthermic seizures are inflicted on PN10–11, spontaneous limbic

seizures, defined by both motor and EEG patterns, occurred in about 35% of subjects at 3 months of age (251). Interictal discharges were found in 88% of rats in the hyperthermic seizure group. None of these phenomena were recorded in rats subjected to hyperthermia without seizures (blocked by pentobarbital) or in the rats removed from the cage for separation stress control (251). This was elegant experimental evidence that severe hyperthermic seizures early during development may result in development of epilepsy. An additional study demonstrated that there are sex differences in cytogenic response to hyperthermic seizures induced on PN10, determined at PN66 by counts of 5-bromo-2'-deoxyuridine (BrdU)-positive cells after BrdU administration between PN11 and PN16 (252). Male rats had significantly more BrdU-positive cells than controls, while there was no difference in female rats. The model of hyperthermic seizures in normal brain has been further developed by using a neuroimmune challenge with lipopolysaccharide to increase body temperature while concurrently a subconvulsive dose of kainic acid has been administered. This treatment resulted in seizures in about 50% of rats with no neuropathology (253).

Other studies concentrated on compromising the young brain with a hypoxic insult (254–257). In one study, rat pups, exposed to a 3% O<sub>2</sub> on PN10, were either kindled or exposed to corneal electroshock at adulthood PN70. Neither kindled seizure development from the septal nucleus or amygdala nor electroconvulsive shock profiles were significantly altered by hypoxic pretreatment (258). In another study, rat pups were subjected to 6% O<sub>2</sub> hypoxia on PN1 or PN10. In flurothyl-induced seizures and amygdala kindling, there were no differences between hypoxic rats and rats not exposed to hypoxia (255). In contrast, a study that subjected rats on PN5 to hypoxia demonstrated a slight transient increased susceptibility to seizures induced by hippocampal stimulation (256). In the hippocampal kindling model, mild or moderate hypoxia at PN15 did not change seizure susceptibility, while severe hypoxia associated with ischemia delayed the development of kindled seizures (259). Jensen et al. (254) determined the long-term consequences of exposure to hypoxia at PN10 in adult rats. While young rats exposed to hypoxia on PN10 did not perform differently in the water maze, open field, and handling tests compared to nonhypoxic age-matched controls, these rats were more susceptible to flurothyl-induced seizures in adulthood. This effect was enhanced in those PN10 hypoxic rats that had suffered from seizures during hypoxia. A detailed analysis (260) showed that global hypoxia (3–4%) induces acute seizure activity in young rats during a developmental window between PN5 and PN17 with a peak around PN10–12. Animals rendered hypoxic between PN10 and PN12 had long term decreases in seizure threshold. Hypoxia-induced seizures and long-term changes in seizure susceptibility could be prevented by excitatory amino acid antagonists. There was no apparent

histological damage in these rats, suggesting that the neuronal changes are only functional (260). Chiba (257) showed that rats suffering from severe 0% O<sub>2</sub> hypoxia on PN10 have increased susceptibility to pentylenetetrazol-induced seizures in adulthood. Moreover, 13 of 20 hypoxic rats developed status epilepticus, while none of the 20 controls experienced status epilepticus. Additionally, the amygdala kindling rate in adult rats subjected to hypoxia on PN10 was twice as fast as in controls. Although none of the hypoxia models induced spontaneous seizures, their value is in showing that hypoxia and hypoxia-induced seizures in young brain may increase (under certain circumstances) seizure susceptibility in adult brain although it may not alter other brain functions. The mechanism for increased seizure susceptibility after neonatal hypoxia may be the plastic calcium-dependent downregulation of GABAergic synaptic transmission (261). In a recent study, a combined hypoxia-ischemia was accomplished by a ligation of the right common carotid artery in PN7 rats together with 2-hour exposure to 8% oxygen. The outcome included development of spontaneous seizures in 40% of rats, along with ipsilateral hippocampal lesions and bilaterally increased Timm stain scores in the inner molecular layer of the dentate gyrus (262).

Thus, the available data suggest that febrile seizures and hypoxia-induced seizures may have model-specific consequences (254, 258). This is in agreement with epidemiological prospective studies in humans, which suggest that the outcome depends on the underlying disease rather than on the seizure itself (239).

### Abnormal Brain

There are only few attempts to study the role of elevated temperature or hypoxia in animals with abnormal brain, although this situation may be relatively frequent in neonates and infants with seizures (263, 264).

In one study, where neuronal migration disorders were induced by prenatal administration of the alkylating agent MAM, rat pups at PN14 had a higher incidence of hyperthermia-induced behavioral seizures and mortality rate than controls. Moreover, in rats with the neuronal migration disorder, hyperthermia resulted in hippocampal pyramidal cell loss independent of seizure activity (39). Similarly, neonatal (PN1) freeze lesion enhances susceptibility to hyperthermic seizures on PN10 (44), and in this case, with a long-term observation, spontaneous seizures may occur (43). However, more long-term studies are needed to better understand the long-term effects of developmental seizures.

### CONSEQUENCES OF SEIZURES

In human epilepsy as well as in epilepsy models in animals, there are frequent findings of brain anomalies (265).

In temporal lobe epilepsy in adulthood, sclerosis of the cornu ammonis (CA) is frequently found. Detrimental seizure syndromes in childhood (catastrophic epilepsies such as West syndrome and Lennox-Gastaut syndrome) are associated with a broad spectrum of pathoanatomic abnormalities involving dysraphic states, disruption of neuronal migration with pachygyria, neuronal necrosis, and microdysgenesis (180, 266). The principal questions that divide clinicians and researchers are the following: Are repeated seizures or status epilepticus the primary cause for hippocampal damage? Do severe seizures develop as a consequence of previous seizure-induced hippocampal damage? Is seizure-induced hippocampal damage developmentally regulated (267)?

### Seizure-Induced Structural Hippocampal Damage

Studies in adult animals have shown that severe or repeated seizures can indeed induce hippocampal damage (268–274). In the adult rats, kainic acid or pilocarpine administration or electric stimulation produce status epilepticus and hippocampal damage. This seizure-induced damage is more pronounced in CA3 and hilar cells than in CA1 (145, 269, 273, 274) and is accompanied by sprouting of the mossy fibers of the granule cells in the dentate gyrus to the supragranular layers (275–281). Later, after 1–2 months, this damage may facilitate the development of spontaneous seizures and may result in serious behavioral deficits (140, 282, 283). Thus, the relationship between seizures and hippocampal damage in the adult brain appears to suggest that repeated prolonged seizures induce hippocampal damage, which further deteriorates brain function and begets further seizures.

The situation in the developing brain is still under investigation. Several studies in developing animals indicate that severe seizures induced by kainic acid, pilocarpine, or flurothyl do not produce extensive damage in the dorsal hippocampus until the end of the third postnatal week (28, 284–289). In PN15 rats, minor hippocampal damage was observed after pilocarpine- (lithium/pilocarpine) induced status epilepticus (289), specific for the CA1 region (150). Similarly in this age group rats, there is no synaptic reorganization following kindling, kainic acid, or flurothyl-induced status epilepticus (284). This is in contrast with the propensity of the immature brain to develop status epilepticus, which is much higher than that of the adult brain (26, 290). However, under certain circumstances in certain models (149), damage may occur even in young rats. Already in PN15 rats, lithium/pilocarpine-induced status epilepticus may induce damage in hippocampal CA1, subiculum, neocortex, amygdala, and thalamus, demonstrating additional involvement of extrahippocampal structures (150). In weanling PN21 rats, this injury is widespread (150,

267, 291), and with time, spontaneous seizures occur in 73% of rats (149, 152). Another study determined neuron-specific enolase as a marker of neuronal damage after lithium/pilocarpine-induced status epilepticus. Interestingly, this enzyme increased in serum already in PN15 rats after status epilepticus; however, the increase was about 50% compared to controls. In contrast, there was a 500% increase in adult rats (292). Taken together, the data suggest that the immature hippocampus is more resistant to the development of seizure-induced hippocampal damage than the adult hippocampus, at least in terms of the classical pathology termed mesial temporal sclerosis (Figure 1-7) (293).

Thus, it seems that the young hippocampus is more resistant to seizure-induced damage and reorganization; however, this feature is seizure model specific. Similarly, the transfer from damage-resistant to damage-sensitive phenotype is not as abrupt as thought previously but follows an age-dependent continuum. The question why the young hippocampus is less sensitive to seizure-induced damage is still unanswered. One possible explanation may be that it is the extracellular calcium influx into adult neurons, due to excessive depolarizations (such as during status epilepticus), that induces neuronal death (294).

FIGURE 1-7

Kainic acid-induced status epilepticus produces age-related hippocampal damage. Horizontal sections from adult rat (A, C) showing extensive cell loss in the hippocampal CA3 subfield following status epilepticus. In comparison, in PN15 rat, no cell loss is apparent (B, D). It should be noted that the severity of status epilepticus was greater in the PN15 rats than in the adults. Reprinted from Sperber EF, Haas KZ, Moshé SL. Developmental aspects of status epilepticus. *Int Pediatr* 1992;7:213–222 (293) with permission.

Immature neurons receive larger loads of calcium through  $\text{Ca}^{2+}$ -permeable, GluR2-free AMPA receptors. In contrast to adult neurons, they utilize powerful enzymatic, transport, and storage systems for management of these increased calcium loads, as demonstrated in neocortical neurons (295). After status epilepticus, these systems may clear intracellular excess of calcium rapidly enough either to prevent cell damage completely (296) or to induce only transient metabolic stress (137).

### Seizure-Induced Functional Alterations

Are there any functional alterations in the immature brain as a consequence of severe seizures, similarly to those observed in the catastrophic epilepsies in childhood?

In developing rats, there are several studies with follow-up after severe seizures. An interesting difference between kainic acid- and pentylenetetrazol-induced status epilepticus in PN10 and PN25 rats has been demonstrated (297). At PN45, only status epilepticus induced by kainic acid at both juvenile groups elicited deficits in shuttle box conditioned avoidance learning although the other groups experienced pentylenetetrazol-induced status epilepticus of similar duration and intensity. Thus, the learning impairment seems to be specific for kainic acid toxin and not a consequence of status epilepticus. In a different study (140), a correlation between the age, behavioral, and morphological deficits was shown. The rats, which experienced kainic acid-induced status epilepticus on PN5 and PN10, performed normally in behavioral tasks in adulthood. Rats exposed to kainic acid on PN20 demonstrated behavioral alterations in one task, while the rats exposed on PN30 rats were incapable of completing successfully all three tests and already have hippocampal lesions. Repeated flurothyl-induced seizures in PN15 rats (three times daily for 5 days) impaired the performance of these rats in adulthood in the water maze and auditory location but did not induce any gross morphological deficits in the hippocampus (298). Indeed, seizures in immature rats also have long-term metabolic consequences, as shown by several studies (134, 299–301). An interesting insight on long-term effects of status epilepticus in young brain was recently published (134). In young rats subjected to pentylenetetrazol-induced status epilepticus at either PN10 or PN21, neurons in the neocortex, hippocampus, thalamic and hypothalamic nuclei were transiently stained with acid fuchsin, with a peak occurring at 24 hours after the seizures. This staining was accompanied by short-term increase and long term (in adulthood) decrease in the metabolic rate and blood flow rate in the respective structures, but not by cell degeneration. The study demonstrated that immature neurons, in contrast to adult neurons, were only transiently stressed by status epilepticus, without gross morphological damage but with long-term metabolic consequences (134). Several studies

have investigated properties of hippocampal neurons after a series of brief flurothyl-induced seizures during neonatal (PN1–5) period. The seizure led to permanent changes in the intrinsic membrane properties of CA1 hippocampal neurons, such as the reduction in spike frequency adaptation and afterhyperpolarizing potential following the spike train (302). Additionally, miniature inhibitory postsynaptic potentials (IPSPs) were reduced in amplitude and frequency in CA3 pyramidal cells, suggesting impairments of GABA<sub>A</sub> inhibitory transmission, although there was no change in the GABA<sub>A</sub> switch from depolarizing to hyperpolarizing effects (303). An interesting study (304) investigated in cognitive effects of multiple brief seizures, brief seizures combined with preceding status epilepticus, and status epilepticus alone elicited in the immature rats. Only the combination of the status epilepticus and brief seizures caused decrease in performance in the Morris water maze two weeks after the last seizure. Interestingly, there was no histological neuronal injury in any of the groups.

A single injection of NMDA on PN15, which produced flexion seizures but not tonic-clonic seizures, resulted in significant impairment of spatial navigation in Morris water maze task in adulthood. It should be mentioned that this treatment does not produce any gross morphological deficits (305).

These findings may suggest that although status epilepticus early in life does not produce hippocampal damage, it may impair other behaviors. The effects of seizures may be specific to the seizure type or the agent used to induce the seizures. It appears, however, that at the earlier developmental stages of the brain, the seizures must be very severe to induce at least some long-term functional alterations. It should be noted however that all these studies have been performed in normally developing rats. To better understand the impact of seizures in catastrophic epilepsies, similar studies should be performed in rats with pre- or perinatally compromised brains (39).

### Seizure-Induced Alterations in Seizure Susceptibility

Since the nineteenth century, there has been a dictum in human epilepsy that “seizures beget seizures” (306). Animal studies support this theory in adults in many models of seizures. However, the question of whether seizures beget seizures early in life is under investigation.

Prepubescent (PN30) and adult rats subjected to kainic acid-induced status epilepticus demonstrate a high incidence of spontaneous recurrent seizures and an increased susceptibility to seizures induced by kindling and flurothyl. However, kainic acid-induced seizures of similar severity in younger animals (earlier than PN20) have a low rate of spontaneous recurrent seizures in adulthood and do not differ from controls in their susceptibility to kindling- or flurothyl-induced seizures (140, 283,

290). Long-term consequences have also been determined in the pilocarpine model of epilepsy in immature rats. In adult rats, this model is characterized by an acute period of status epilepticus, a silent period, and a chronic period of spontaneous recurrent seizures. However, spontaneous recurrent seizures occurred only in the rats exposed to pilocarpine-induced status epilepticus after PN18 (307).

Kindling in developing rats has demonstrated that rat pups easily kindle beyond stage 5 (25) to severe seizures (stages 6–8) (59, 308). Similarly in kittens, the development of kindling was progressive and permanent (36). These studies demonstrated that in the young brain, kindling is permanent although there are no permanent synaptic changes in the dentate gyrus. Thus, these studies suggest that early in life there may be a dissociation between seizure-induced damage and permanence of seizures. Although permanent, the kindling seizures are still triggered by an external stimulus; however, on rare occasions few spontaneous seizures have been observed (36, 59).

Different results were obtained by unilateral intrahippocampal injection of tetanus toxin in PN9–11 rats (37). Within 24–72 hours the rat pups develop frequent, prolonged behavioral and electrographic seizures in both the injected and contralateral hippocampus and bilaterally in the neocortex with multiple independent spike foci. One week following tetanus toxin injection, the number of seizures decreases; however, interictal spiking persists. In adulthood, some of these rats develop unprovoked behavioral seizures and/or epileptiform EEG activity. Analysis of the hippocampal slices of the seizing rats in adulthood shows burst discharges and paroxysmal depolarizing shifts in CA3 neurons, suggesting long-term changes in neuronal membrane properties (37).

An interesting study investigated the relationship between numbers of hyperthermic seizures early during the development and subsequently to subconvulsant doses of pilocarpine at PN60–70. The study demonstrated that the risk of epilepsy development after the subconvulsant pilocarpine dose was parallel to the number of hyperthermic seizures experienced during the developmental period (309). This finding correlates with a recent study demonstrating that severe hyperthermic seizures on PN10–11 result in development of limbic epilepsy in adulthood (251). These findings indicate that a relatively strong epileptogenic stimulus is required during infantile period for development of seizures in adulthood. The intensity of this stimulus must be sufficient to activate both GABA<sub>A</sub> and NMDA transmission, since a collaboration of these two systems has been proposed to result in early developmental epileptogenesis (310).

Thus, the results suggest that in the normal rat, seizures that are triggered prior to the third week of life can on occasion predispose the brain to seizures in adulthood, either triggered (kindling) or spontaneous (tetanus toxin injection). It is interesting that on both occasions seizures early in life altered the subsequent seizure susceptibility

if the seizures were multiple. However, a bout of status epilepticus does not appear to beget seizures later on.

## COMMENTS ON AGE-SPECIFIC TREATMENTS

Based on clinical experience, it has been accepted that many AEDs that are effective against partial seizures in adults may also be effective against partial seizures in infancy and early childhood (311). However, the developmental neurobiology data discussed in this review suggest that the young brain is not just a small version of the adult brain. There are many age-related features, factors, and functions in the young brain that may specifically affect seizure susceptibility and seizure suppression (312). Therefore, the treatment of seizures should reflect these maturational changes. Additionally, there is the concern about the long-term effects of antiepileptic drug treatment on brain development. Thus, the relevant questions are: What are the best age-specific treatments of seizures for the young brain? How aggressive should this treatment be in terms of total seizure control, if the available drugs produce undesirable (and occasionally long-term) side effects? With this in mind, the consensus conference (311) held on the development of antiepileptic drugs in children proposed that studies for screening putative antiepileptic drugs should be performed in immature animals as well as in adult animals to identify agents that may be age-specific. In addition, the long-term effects of these drugs in the developing brain should be carefully assessed (311).

There are several developmental studies showing age-specific short-term (acute) effects of classic AEDs, GABAergic drugs, and excitatory amino acid antagonists in seizures during development (Table 1-5) (313–320). Unfortunately, for several drugs the beneficiary acute anticonvulsant effects may be associated with long-term toxicity. Some drugs may even have acute toxic effects in the young brain at doses that may be therapeutic in the adult brain.

**TABLE 1-5**  
*Age-Specific Effects of Antiepileptic Drugs in Rats*

ANTIEPILEPTIC DRUGS		
EFFECTIVE AT ALL AGES	HIGHLY EFFECTIVE IN DEVELOPING BRAIN, LESS EFFECTIVE OR INEFFECTIVE IN ADULT BRAIN	EFFECTIVE IN ADULT BRAIN, INEFFECTIVE OR TOXIC IN DEVELOPING BRAIN
Carbamazepine	Vigabatrin	Phenytoin
Phenobarbital	Baclofen	Pyridoxine
Midazolam	MK-801	
Clonazepam		

### Drugs Effective against Seizures at All Ages

Carbamazepine as well as AEDs that enhance GABA<sub>A</sub>-mediated inhibition, such as phenobarbital and benzodiazepines (i.e., clonazepam and midazolam) are approximately equipotent in both young and adult rats in several seizure models (316, 321–324). However, in PN12 rats in pentylenetetrazol-induced seizures, phenobarbital and carbamazepine can suppress tonic-clonic seizures and at the same time increase the incidence of clonic seizures (322, 323). This suggests that these drugs may have differential effects on various seizure types within a single model. Acute administration of phenobarbital prior to kainic acid inhibits clonic seizures in both PN12 and adult rats (321). However, chronic daily administration of phenobarbital after the kainic acid challenge may have more detrimental effects on memory, learning, and activity level than kainic acid–induced seizures per se (325).

### Drugs Effective against Seizures in the Developing Brain but Ineffective or Less Effective in Adults

Systemic administration of vigabatrin (gamma-vinyl GABA; an irreversible inhibitor of the GABA-degrading enzyme GABA-transaminase) 24 hours prior to seizure testing is effective in PN15 but not in adult rats in the flurothyl seizure model (316). Baclofen (a GABA<sub>B</sub> receptor agonist) administered systemically is also much more effective in PN15 than in adult rats against flurothyl-, pentylenetetrazol-, and kindling-induced seizures (316, 326, 327).

Most of the excitatory amino acid antagonists, such as MK-801 (dizocilpine; noncompetitive antagonist of NMDA receptors) and 2-amino-7-heptanoic acid (competitive antagonist of NMDA receptors) are more effective in PN12 rats against pentylenetetrazol- and flurothyl-induced seizures than in adult rats (317, 328, 329), an effect that may be associated with blood-brain barrier maturation. In contrast, MK-801 exacerbates kainic acid–induced seizures in neonatal and PN11–12 rats and, in higher doses, induces ictal electrographic and behavioral manifestations (330). Repeated administration of MK-801 in neonatal rats induces a significant decrease in brain size and weight (331, 332). In humans MK-801 has significant

behavioral effects, which are the reason for its withdrawal from clinical trials (333).

### Drugs Effective against Seizures in Adults but Less Effective or Toxic in Developing Brain

There are drugs with acute toxic effects in the young brain after doses that may be therapeutically effective or even inactive in the adult brain. Phenytoin, which is an effective antiepileptic drug in both adult and young patients (334, 335), may be toxic in high doses (336). Whereas in the pentylenetetrazol model of seizures, phenytoin is anticonvulsant throughout development (337), high doses of phenytoin per se may be toxic and proconvulsant in young rats (319). Similarly, high doses of pyridoxine may be toxic in PN12 and PN18 rats (338).

With certain drugs, such as the NMDA receptor antagonist CGP39551, the anticonvulsant activity is much stronger in adult than in PN12 rats (315). There may be several reasons for this effect, such as the existence of an active metabolite of the drug preferentially synthesized in the adult brain (339) or the delayed maturation of brain uptake mechanisms for the drug. Additionally, an important study revealed that, in fact, some of the anticonvulsant drugs commonly used in children, such as valproate, phenobarbital, phenytoin, and vigabatrin, may significantly increase apoptosis in the therapeutic concentration range (340). The reason for this effect may be a therapy-induced significant decrease in neuronal activity during the developmental period of synaptogenesis, with disruption of the timing and sequence of synaptic connections. This causes nerve cells to receive an internal signal to undergo apoptosis (341).

## FUTURE RESEARCH DIRECTIONS

### The Need to Create Models of Spectrum of Brain Anomalies and Determine Pathology-Specific Epileptogenicity

Table 1-6 (180, 342) summarizes brain anomalies found in catastrophic epilepsies of childhood. This wide variety of anomalies may have a pre-, peri- or even postnatal

**TABLE 1-6**  
*Brain Anomalies Associated with Catastrophic Epilepsies of Childhood*

SYNDROME	BRAIN ANOMALIES
West syndrome	Neuronal migration disruptions, pachygyria, brain weight reduction, neuronal necrosis, dysgenesis, dysraphic states (180)
Lennox-Gastaut syndrome	Small foci of neuronal necrosis in the cortical and subcortical structures of forebrain, also in the cerebellum (342)

origin. Experimentally, there are two models of prenatally induced neuronal migration disorder available: methylazoxymethanol-induced DNA alkylation and prenatal irradiation resulting in severe neuronal migration disorders in the affected offspring (Table 1-3). There is a model of epileptogenic perinatal damage with microgyria induced by neocortical freezing (41) as well as genetically produced models of brain anomalies (42).

There is a need to develop, experimentally, additional severe migration disorders that should involve prenatal and perinatal neuronal alterations, alterations of radial glia, and pre- or perinatal to determine the epileptic potential and consequences of these disorders.

### The Need to Create a Model of Chronic Epilepsy/Catastrophic Epilepsy

In the rat, infancy and childhood last a mere 5-week period until the onset of puberty. In cats (36) the process is slower and can be studied for months (with puberty arriving at 7–9 months). Although the developmental models of seizures and progressive epileptic state (kindling) may bear certain similarities to many therapy-responding epileptic seizures in childhood, there are no models of intractable childhood seizures (or catastrophic epilepsies of childhood, such as early infantile epilepsies or West and Lennox-Gastaut syndromes). The available models of severe seizures that eventually express spontaneous seizures have an early developmental limit: they do not occur if the inducing condition (status epilepticus) occurs before PN18 in the rat—that is, later than the age corresponding (7, 9) to the ages of West and Lennox-Gastaut syndrome in infants.

Therefore, in the rat, there should be a search for age-specific seizures within the age window between PN10 and PN20 with intractable features that would be similar to catastrophic childhood epilepsies and would provide a model to screen putative AEDs and to determine mechanisms of these therapy-resistant syndromes. In this respect, there may be promise in the tetanus toxin model, which results in the development of spontaneous seizures. NMDA receptor agonists also produce age-specific, intractable flexion seizures with certain features of the West and Lennox-Gastaut syndromes, although without the development of spontaneous seizures (21, 343, 344). These seizures produce long-term cognitive deficits (305). Additional recent data demonstrate that the flexion spasm model induced by systemic injection of NMDA in the brain prenatally exposed to corticosteroids is sensitive to ACTH therapy (345). However, further research in this area is still justified.

### The Need for Further Investigations on Gender Differences in Seizure Susceptibility

Historic data from patients suggest that there may be significant gender-related differences in seizure susceptibility (306). These differences have been studied in several animal models of seizures (346–349). The results are mostly in favor of the anticonvulsant action of progesterone and its derivatives and the proconvulsant action of estrogens. However, these conclusions are not supported by all studies. There are many factors involved, including the dose and duration of estrogen effects, estrogen type, and gender of the recipient (Table 1-7). In particular, low doses of beta-estradiol in females may have beneficial effects, especially

**TABLE 1-7**  
*Factors Affecting Effects of Estrogens on Seizures and Seizure-Induced Damage*

FACTORS	ANTICONVULSANT (NEUROPROTECTIVE) OR NO EFFECT	PROCONVULSANT EFFECT
Sex	Females	Males
Estrogen dose/level	Low/physiological	High/supraphysiological
Pretreatment	Chronic	Acute
Estrogen type	Beta-estradiol	All other
Brain region/nuclei	Ventral hippocampus Amygdala	Dorsal hippocampus
Seizure model	Flurothyl Pilocarpine Kainic acid NMDA Picrotoxin	Pentylenetetrazol Electroshock
Hormonal status in females	Estrogen replacement Normally cycling	Ovariectomy Aging

It should be emphasized that for the proconvulsant effect to occur, one proconvulsant factor is enough and in a combination of factors, the proconvulsant factor is prevailing.

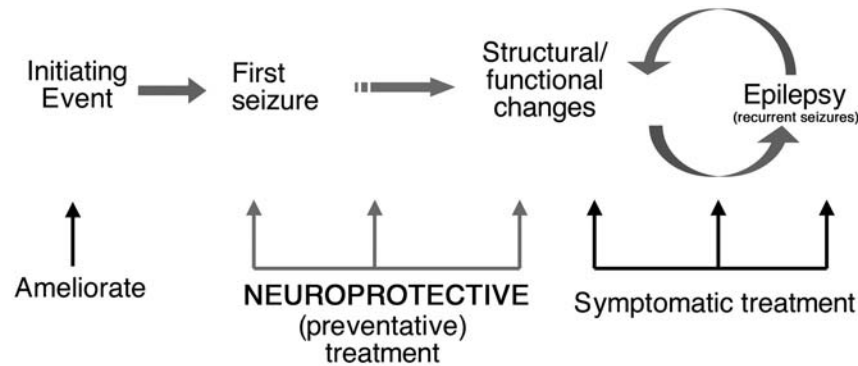

FIGURE 1-8

Simplified scheme of possible treatment interventions during epileptogenesis. The current view is that epileptogenesis proceeds from the initiating (precipitating) event to the first seizure (status epilepticus), which may induce structural and/or functional changes. These changes make the condition permanent and contribute to further generation of recurrent seizures; that is, epilepsy develops. The best treatment opportunity is to ameliorate the initial event; however, this event can be only infrequently diagnosed and rarely predicted, which is a condition for successful amelioration. However, after the first seizure occurs, anti-epileptic therapy can be combined with neuroprotection so that the permanent fixation of changes is prevented. This is probably the most promising area for therapy development. Symptomatic (current) treatment, unfortunately, cannot reverse already established morphological changes.

as means of neuroprotection against seizure-induced damage (350–352). Furthermore, Holmes showed that anticonvulsant effects of progesterone in kindling occurred only in developing, but not in adult, rats (353, 354).

Additional studies show that gender differences, as reflected in the control of seizures, may be operant before puberty as a result of sexually dimorphic brain organization (355–358).

### The Need to Develop Age-Specific Antiepileptogenic and Neuroprotective Treatments

Though antiepileptic drugs have mostly antiseizure effects, by their mechanisms of action some of these drugs may interfere with both principal mechanisms of neuronal death: necrosis and apoptosis (Figure 1-8). Some of the current AEDs indeed have this potency (359). However, use of phenobarbital with neuroprotective and antiepileptogenic intent in children with febrile seizures may be associated with a decrease in cognition (360). The question is how much this effect is associated with the aforementioned phenobarbital-induced increase in apoptosis (340). Similarly, there are other drugs with neuroprotective potential (such as felbamate) that may be harmful for the developing brain. In this regard, use of those add-on

neuroprotective treatments that would not be associated with negative cognitive impacts may be advantageous.

The question remains as to how much this neuroprotective effect of antiepileptic therapy is associated with functional antiepileptogenic effect (361). Here, the data are still controversial. Several authors demonstrate that in animal models, neuroprotective therapy during the window immediately after the status epilepticus reduces the percentage of animals that develop spontaneous seizures (362, 363). On the other hand, recent data indicate that even though several antiepileptic drugs or other compounds (e.g., MK-801) (364) are neuroprotective, none of them are antiepileptogenic in experimental models or in humans (365).

With the rapid expansion of knowledge in basic disciplines such as neurobiology, cell physiology, molecular biology, and neurochemistry, there is hope that appropriate developmental models of epilepsy will be created to deal with epilepsies of infancy and childhood.

## Ion Channels, Membranes, and Molecules in Epilepsy and Neuronal Excitability

*Laxmikant S. Deshpande*  
*Robert J. DeLorenzo*

**I**mportant advances have been made in molecular neurobiology that enhances understanding the regulation of neuronal excitability in epilepsy and other brain functions. This research typically has involved antiepileptic drugs (AEDs) and other pharmacologic probes that have defined different mechanisms affecting neuronal excitability. The investigation of AEDs in these systems has also shed new light on the molecular basis of epilepsy and on the mechanisms of AED action (1–5).

This chapter provides the scientific background to assist the clinician in keeping abreast of several rapidly advancing fields. It highlights issues that influence neuronal excitability and seizures with emphasis on the mechanisms of sustained repetitive firing (SRF), sodium channels, the gamma-aminobutyric acid (GABA)–chloride channel complex, potassium channels, excitatory transmission, regulation of metabotropic receptors, carbonic anhydrase inhibition, neuromodulators, calcium-mediated regulation of neuronal function, and inhibition of epileptogenesis. In considering these quite different mechanisms, this chapter brings together many of the concepts considered in Chapters 4 and 30.

### SUSTAINED REPETITIVE FIRING (SRF)

Sustained high-frequency repetitive firing is an important property of vertebrate and invertebrate neurons that correlates with the excitability state of the neuron (6–10). Many central nervous system (CNS) neurons exhibit SRF. Although no direct evidence has demonstrated the link between SRF and epilepsy, information from *in vitro* studies on isolated neurons may have some bearing on altered neuronal excitability and anticonvulsant action.

Sustained repetitive firing is a nonsynaptic property of neurons. The relevance of limitation of SRF to AED action is strengthened by several important observations. The therapeutic efficacy of each AED in controlling seizures in animals and humans is similar to that for controlling SRF in isolated, cultured neurons. These results indicate (7) that therapeutic levels of AEDs in cerebrospinal fluid (CSF) correlate with the concentrations that are most effective against SRF. The effects of anticonvulsants in limiting SRF have been shown in a variety of neurons from different regions of the mammalian CNS maintained in culture. This argues that this effect is not unique to specific regions or cell types. Anticonvulsants prevent bursting in the epileptic focus and restrict the spread of

epileptic activity from the focus to normal surrounding tissue. Thus, suppression of SRF by anticonvulsants may inhibit excitability by inhibiting the spread of seizure activity. Membrane properties of nonepileptic neurons may be important in understanding drug mechanisms of action and may have a special relationship to the properties of SRF. SRF is an important model for studying the excitability of isolated neurons.

### **SUSTAINED REPETITIVE FIRING AND SODIUM CHANNEL REGULATION**

In studying SRF, several properties of neuronal excitability and seizure phenomenon have been recognized. Voltage-gated sodium channels are responsible for the rising phase of neuronal action potentials. Upon neuronal depolarization to action potential threshold, the sodium channel undergoes a conformational change that results in the channel opening for a few milliseconds from its closed (resting), nonconducting state to permit sodium flux. The channel inactivates within a few milliseconds to terminate sodium ion influx. The membrane must repolarize before it can be activated again by a subsequent depolarization. Brain sodium channels can rapidly cycle through the conducting and nonconducting stages, allowing neurons to fire tonic high-frequency action potentials, as is required for both normal brain function and for the expression of epileptic activity characterized by SRF. Several agents block sodium channels to produce an antiepileptic effect. They include phenytoin, lamotrigine, carbamazepine, zonisamide, felbamate, topiramate, and valproate. The AEDs that block SRF have several properties in common. Blocking of SRF is voltage-dependent, and the anticonvulsant effect is use-dependent. Research on the role of the sodium channel in regulating SRF indicates that the drug effects on SRF are mediated through a use-dependent blockage of the sodium channel. Thus the block accumulates with SRF, inhibiting only the pathological high-frequency discharges but not the excitatory or inhibitory synaptic processes essential for normal brain functioning (11). Phenytoin and carbamazepine can reduce the amplitude of the sodium-dependent action potential in a use-dependent fashion (12). Phenytoin is thought to induce a nonconducting state of the sodium channel that is similar to channel inactivation (11, 13). These studies indicate that modulation of sodium channels by anticonvulsants, and possibly endogenous anticonvulsant-like molecules, may play an important role in the regulation of neuronal excitability in seizure discharge. Newer compounds such as safinamide, which is in clinical trials, are thought to produce anticonvulsant effect, at least in part, through inhibition of sodium and calcium channels, stabilizing membrane excitability and inhibiting transmitter release (14). Investigating the heterogeneity of sodium channels

and their relationship to altered neuronal excitability is an area of important research.

### **BENZODIAZEPINE RECEPTORS AND MEMBRANE EXCITABILITY**

In the 1970s use of radioactively labeled benzodiazepine derivatives allowed the detection of specific nanomolar benzodiazepine receptor sites in brain membrane (15–17). These sites have a very high affinity for the benzodiazepines, binding in low (nanomolar) concentration ranges. Binding to these receptors is reversible, saturable, and stereospecific. Nanomolar benzodiazepine receptors have now been identified in human brain, where they are widely distributed. The specific membrane protein that accounts for the majority of nanomolar benzodiazepine binding has a molecular weight of approximately 50,000 daltons and has been purified from animal and human brain (18).

High-affinity benzodiazepine binding has also been observed in peripheral, nonneuronal tissue (19). A different class of benzodiazepine receptor molecules causes this binding, because both the potency and the tissue distribution of this binding are different from that at the central-type receptor. This second class of high-affinity benzodiazepine binding sites was designated “peripheral type receptor” (19), but it was subsequently shown that the peripheral-type benzodiazepine receptor is also present in neuronal tissue. Thus, both peripheral and central high-affinity benzodiazepine receptors exist in the brain.

High nanomolar and low micromolar benzodiazepine binding sites have been identified more recently in brain membranes (20, 21). In addition, another benzodiazepine receptor that binds in the high nanomolar range has been identified in brain cytosol (21). These novel benzodiazepine-binding sites are stereospecific and have potencies for benzodiazepine binding that correlate with the ability of these compounds to inhibit maximal electric shock-induced seizures. Benzodiazepine bound to micromolar benzodiazepine receptors is displaced by phenytoin. These results indicate that high nanomolar and low-micromolar-affinity benzodiazepine receptors may represent important anticonvulsant binding sites in brain membrane that mediate some of the effects of benzodiazepines in high concentration in curtailing status epilepticus, generalized tonic-clonic seizures, and maximal electric shock-induced seizures.

Benzodiazepines are effective in nanomolar concentrations in blocking pentylenetetrazol-induced seizures in animals and in treating absence seizures. In addition, benzodiazepines in high nanomolar and low micromolar ranges inhibit maximal electric shock-induced seizures in animals. Furthermore, benzodiazepines are effective

in humans in stopping generalized tonic-clonic seizures and status epilepticus when given in intravenous doses that produce low micromolar serum concentrations. The potency of the benzodiazepines in blocking maximal electric shock-induced seizures, however, correlates in neither time nor consequence with their ability to inhibit pentylenetetrazol-induced seizures or bind to the nanomolar central benzodiazepine receptor (20). Thus, other mechanisms appear to underlie this generalized anticonvulsant property of the benzodiazepines in high concentration ranges. Lower-affinity benzodiazepine binding sites in the high nanomolar and low micromolar ranges have also been described (20, 22). These lower-affinity receptor sites come into play in the concentration ranges in which benzodiazepines produce effects on maximal electric shock-induced seizures in animals, on generalized tonic-clonic seizures in man, and on SRF in cultured neurons.

Diazepam and clonazepam reduce SRF in high nanomolar and low micromolar concentrations (7). These concentrations are above therapeutic free-serum concentrations achieved in ambulatory patients treated with benzodiazepines but are within the ranges of free-serum concentrations achieved in patients treated for status epilepticus or acutely for generalized tonic-clonic seizures. In addition to the discrepancy in concentration ranges, the potency of benzodiazepines for suppressing SRF does not correlate with benzodiazepine binding to the nanomolar central receptor or with their ability to inhibit pentylenetetrazol-induced seizures but does correlate with binding to the lower-affinity benzodiazepine binding system.

### THE GABA SYSTEM, NEURONAL EXCITABILITY, AND SEIZURE ACTIVITY

Gamma-aminobutyric acid is the major inhibitory neurotransmitter in brain. It has been extensively characterized and plays a major role in regulating neuronal excitability by controlling chloride permeability (23–25). Specific binding sites for GABA molecules have been identified in neuronal membrane. Although not all GABA receptors are linked to the chloride channel, a large proportion of these receptors are directly involved in regulating chloride channel function. The major inhibitory effect of GABA on the nervous system is mediated through its ability to regulate chloride channel permeability. GABA binding to the GABA receptor potentiates the opening of the chloride channel, allowing chloride ions to flow more easily into the cell. This causes cellular hyperpolarization and inhibits neuronal firing, because chloride ions increase the internal electrical negativity of the cell. This is believed to be the major mechanism by which GABA produces its inhibitory effect on neurons.

Functions of GABA in neuronal systems have been closely linked with the effects of the benzodiazepines (23–25). Significant portions of the nanomolar benzodiazepine receptors in the brain are associated with the GABA-binding sites and are thereby functionally linked to the chloride channel in neuronal membranes. The GABA–nanomolar benzodiazepine receptor/chloride ionophore macromolecular complex is an important example of the interrelationship between membrane receptors and neuronal excitability (25). The ability of AEDs and the benzodiazepines to modulate chloride conductances is a major molecular mechanism regulating neuronal excitability.

### The GABA–Chloride Channel Complex Regulates Seizure Discharge

The chloride channel is surrounded by a GABA receptor, a nanomolar central benzodiazepine receptor, and a receptor site that binds picrotoxin and related convulsants as well as barbiturates and related depressants. This channel and its properties, related to the benzodiazepines, GABA, and convulsant and barbiturate molecules, have been characterized in detail (26). Picrotoxin binds to the proposed site and modulates benzodiazepine and GABA receptor binding in a way that inhibits chloride channel permeability, therefore making the cell more excitable. Barbiturate binding potentiates benzodiazepine receptor binding and thus indirectly potentiates the GABA effect on opening the chloride channel and enhancing neuronal inhibition. This complex interaction between GABA, benzodiazepines, picrotoxin and related convulsants, and the barbiturates and related depressants is a prime example of how pharmacologic agents modulate the function of ion channels through specific receptor binding.

Benzodiazepines are an important class of compounds that have antianxiety or anxiolytic effects and sedative, muscle relaxant, and anticonvulsant properties (15, 23–25, 27). As anticonvulsants, these compounds are effective in blocking both pentylenetetrazol-induced seizures in animals and, at higher concentrations, maximal electric shock-induced seizures. Benzodiazepines are the most commonly prescribed drugs for the initial treatment of generalized tonic-clonic seizures and status epilepticus in hospital emergency rooms. The anticonvulsant properties of the benzodiazepines, therefore, not only are of academic importance but also have widespread clinical use. The research characterizing this benzodiazepine receptor (16–19, 28, 29) demonstrates AED receptor-mediated regulation of neuronal excitability. Benzodiazepine binding to the nanomolar receptor site potentiates GABA effects on neuronal inhibition, providing one clear mechanism by which these compounds regulate neuronal excitability. Correlative neuropharmacologic studies have indicated

that the anxiolytic and anti-pentylentetrazol-induced anticonvulsant activity of these compounds are mediated through the high-affinity benzodiazepine nanomolar receptors. The effects of benzodiazepines on maximal electric shock-induced seizures and on generalized convulsions, however, cannot be clearly explained by these nanomolar actions.

Stiripentol is a novel antiepileptic compound that is structurally unrelated to any of the other currently marketed antiepileptic drugs (30). Studies in animal models have demonstrated that it produces anticonvulsant effect by increasing GABAergic transmission by enhancing the duration of opening of GABA<sub>A</sub> receptor channels (31). However, its clinical development was halted because of its inhibitory effect on cytochrome P450 enzymes. Despite this, it has been found to be beneficial for the treatment of early childhood epilepsy, and clinical trials are under way to further characterize its beneficial effect in pediatric patients (30).

Recently two types of GABA<sub>A</sub> receptor-mediated inhibition have come to the forefront: phasic and tonic. Synaptically released GABA, acting on postsynaptic GABA<sub>A</sub> receptors, produces “phasic” inhibition, whereas ambient GABA continually present in the extracellular space produces persistent activation of extrasynaptic GABA<sub>A</sub> receptors, resulting in “tonic” inhibition (32). Elegant studies by Istvan Mody’s group strongly indicate that distinct GABA<sub>A</sub> receptor subtypes mediate these tonic and phasic receptor-mediated inhibitions (32–34). They found that the alpha-4 GABA<sub>A</sub> receptor subtype were extrasynaptically located and were responsible for tonic inhibition (34). These results suggested that alpha-4/beta/delta and alpha4/beta/gamma subunit-containing GABA<sub>A</sub> receptors may be present exclusively extrasynaptically, have a higher affinity for GABA, and not desensitize on the prolonged presence of agonist (35). On the other hand, alpha-1/beta/gamma-2 or alpha-2/beta/gamma-2 receptors are thought to mediate phasic inhibition, since the synaptic currents are known to be sensitive to benzodiazepines (36, 37). These studies provide another mechanism for GABA<sub>A</sub> regulation of synaptic activity.

### GABA<sub>A</sub>- and GABA<sub>B</sub>-Mediated Neuronal Inhibition

As described previously, the best-characterized inhibitory effect of GABA on the nervous system is to open chloride channels and hyperpolarize the membrane, an effect that is mediated through GABA<sub>A</sub> receptors. In addition to GABA<sub>A</sub> receptors, scientists have characterized GABA<sub>B</sub> receptors that primarily open potassium channels in the membrane either pre- or postsynaptically. Opening potassium channels also results in hyperpolarization of the cell. Any alteration or decrease in GABA-mediated inhibition through GABA<sub>A</sub> or GABA<sub>B</sub> receptors can

lead to seizures. Thus GABA<sub>B</sub> knockout mice exhibit spontaneous seizures (38). These data clearly indicate that GABA receptors in the regulation of chloride and potassium channels can regulate seizure discharge.

### Potassium Channels

Potassium channels play a major role in regulating neuronal excitability. Although more than 20 types of potassium channels have been identified by biophysical studies, there are four major groups: calcium-activated, voltage-gated, sodium-activated, and inwardly rectifying potassium channels. These different types of potassium channels are regulated by neuromodulators, ions, and second messenger systems. The opening of potassium channels has the effect of hyperpolarizing neurons or reversing depolarizing actions that exist during the transmission of the action potential or the neuroexcitatory input. Following depolarization, several calcium-activated potassium channels play a major role in the after-hyperpolarization that occurs to restore the resting potential of a neuron (39). Electrographic studies on hippocampal neurons from patients undergoing temporal lobectomies have demonstrated alterations in potassium channels in epileptic tissue (40). In addition, compounds that can block potassium channels and prevent the effect of these channels on hyperpolarization are potent convulsants. Fluoraminopyridine and dendrotoxin-I are potent convulsants that have been used in numerous animal models to cause seizures (41, 42). In addition, compounds that are currently used as antihypertensive drugs, including chromakalim, minoxidil, diazoxide, and penicidil, act as potassium channel openers in muscle membranes and may have potential for use as anticonvulsant compounds (43, 44). The possibility of developing new classes of compounds that can activate or potentiate potassium channel activity may play an important role in increasing hyperpolarization following excessive excitatory activity and may serve to reverse the decreased levels of some potassium channels observed in patients with epilepsy.

Some anticonvulsant compounds may also play a role as potassium channel openers. Carbamazepine has been found to enhance potassium conductances in neurons (45). Other potential anticonvulsant compounds are being evaluated that may also potentiate potassium channel activation. Investigation of anticonvulsant drugs regulating potassium channels is a major frontier in the development of new anticonvulsant compounds. The small conductance Ca<sup>2+</sup>-activated K<sup>+</sup> (SK) channels inhibit epileptiform bursting in hippocampal CA3 neurons. Compounds activating or inhibiting voltage-gated potassium channels formed by KCNQ2, KCNQ3, and KCNQ5 assembly (M-channels) are undergoing clinical trials for epilepsy, stroke, and Alzheimer’s disease (46). Mutation in KCNQ2/3 causing mild reduction of M-channel activity is

thought to enhance neuronal excitability associated with benign neonatal seizures. On the other hand, M-channel openers decrease the hyperexcitability responsible for epileptic seizures and migraine. Indeed, retigabine is thought to produce antiepileptic effect by opening the KNCQ2/3 channels (47, 48). This is a promising area for novel anticonvulsant drug development.

It is only in the recent past that scientists have begun to decipher the role of the hyperpolarization-activated cation (HCN) channel or h-channel ( $I_h$ ) in regulating neuronal excitability and modulating seizures. The HCN family of genes consists of four subtypes and encodes HCN or  $I_h$  (49). HCN1 and HCN2 are the most prevalent subtypes in cortex and hippocampus, and HCN2 and HCN4 predominate in the thalamus. HCN3 is modestly expressed in brain (50). HCN has the unique capacity of being able to produce opposite biophysical effects. Thus, it can be either excitatory or inhibitory with respect to its influence on action potential firing. For example,  $I_h$  can diminish the effect of excitatory inputs, or it can set normal resting membrane potential, depolarizing the membrane from the  $K^+$  reversal potential toward the firing threshold, thereby producing an excitatory effect (51). There is a growing body of evidence implicating HCN in epileptogenesis (51–54). For example,  $I_h$ - and GABA-mediated inhibition is increased in febrile seizures (55, 56). Moreover, genetic deletion of HCN2 resulted in a mouse phenotype that exhibited spontaneous absence seizures as well as cardiac sinus arrhythmias, indicating that the absence of HCN2 is proconvulsive (57). There is conflicting pharmacologic evidence for the role of HCN in epilepsy (51). Certain AEDs, such as lamotrigine, act beyond their normal target—the  $Na^+$  channels—and upregulate  $I_h$ , and they reduce action potential firing that is initiated from dendritic depolarization but not from somatic depolarization (52). On the other hand, other  $Na^+$  channel blockers, such as carbamazepine or phenytoin, did not lower dendritic excitability (52). Thus, the action of lamotrigine on HCN may constitute an important, novel anticonvulsant mechanism. The role of the HCN channel in epilepsy is an important area for further investigation.

## EXCITATORY TRANSMISSION

Glutamate is the major excitatory neurotransmitter in the brain. Understanding the role of excitatory transmission and its overactivation in epilepsy is an important area for anticonvulsant drug development. Only since the early 1980s has the role of glutamate, aspartate, and other compounds that serve as excitatory transmitters been clearly identified. Several important receptors have been identified in the brain that respond to glutamate and other excitatory neurotransmitters (58). The major

glutamate receptors that regulate ion channels include the N-methyl-D-aspartate (NMDA), quisqualate or alpha-amino-5-methyl-3-hydroxy-4-isoxazolepropionic acid (AMPA), and kainate channels. In addition, there are other, more recently identified subcategories of excitatory amino acid ion channels regulated by glutamate (59).

NMDA receptor-regulated ion channels are an important class of excitatory amino acid coupled channels in the brain that not only play a role in neuronal excitability but also have long-term effects on long-term plasticity changes in the brain. NMDA receptor-activated channels are permeable to sodium, potassium, and calcium. They can be voltage-blocked by magnesium, which indicates that they can be in an operative form only when the cell is partly depolarized by other excitatory receptor activation. This type of modulation allows for complex regulation of NMDA receptor activity. For an NMDA channel to be activated, it is necessary for either the excitatory amino acid transmitter glutamate or aspartate to bind to the NMDA receptor site and for the molecule glycine or D-serine to bind at the neuromodulatory site on the receptor. Antagonists of either glutamate or glycine at their respective recognition sites can block this channel. Regulation of NMDA receptors may play an important role in the development of anticonvulsant drugs. In addition, long-term changes in NMDA channel expression may accompany epileptogenesis. Properties of NMDA receptor channels are altered in neurons from kindled rats (60). Furthermore, NMDA receptor antagonists are anticonvulsants in several models of epilepsy (61). Glutamate (62) and glycine site competitive antagonists (63, 64) also have anticonvulsant activity. Noncompetitive channel blockers that work when the channel is open can also inhibit NMDA channels. These drugs include dizocilpine (MK-801) and phencyclidine. Although both of these compounds are good anticonvulsants, both have major side effects when used in anticonvulsant doses (65). Nevertheless, the possible role of glutamate/NMDA-channel regulation is an important area for the development of anticonvulsant compounds and those that may prevent epileptogenesis. Although there is a plethora of evidence from preclinical in vivo and in vitro models of epilepsy regarding the AED potential for glutamate receptor blockers, use of selective NMDA agents as AEDs has been rather disappointing in the clinical setting. However, there is evidence that some of the clinically used AEDs, such as felbamate, can block NMDA receptor at therapeutic concentrations (66).

AMPA receptors are major excitatory amino acid receptors that play an important role in the fast depolarizing actions of glutamate, contributing to the fast excitatory transmission in the CNS. They are thought to be essential for seizure spread and are thus attractive targets for development of novel AEDs. During epilepsy the AMPA receptors are responsible for the early component of the

discharges involved in spike discharges and paroxysmal depolarizing shifts. The later elements of these phenomena are primarily related to NMDA receptor activation. Quinoxalinediones (67) were one of the first AMPA receptor antagonists that were found to have anticonvulsant property in several models of epilepsy (62, 68). Several classes of AMPA channel inhibitors have also been developed that have anticonvulsant activity. Both indirect AMPA antagonists and noncompetitive allosteric inhibitors of AMPA receptors have anticonvulsant property in several animal models (68). The AMPA receptor has several molecular subtypes that are differentially expressed in different neurons (69). Receptors containing the GluR2 subunit have a much lower permeability to calcium and show a component of their activation that has a linear rectifying current-voltage relationship. Receptors lacking the GluR2 subunit are different and show significant calcium permeability and an inwardly rectifying property (70). Evidence indicates that differential expression of the GluR2 subunit may play an important role in epileptogenesis and altered neuronal excitability. Thus, the ability to selectively modify AMPA receptors containing GluR2 subunits may play an important role in the development of anticonvulsant compounds. Selective AMPA receptor antagonists are under intense investigation as potential AEDs, but no currently marketed AEDs act through this mechanism (11).

Kainate channels also play an important role in fast depolarizing actions of glutamate in the CNS. However, only a few drugs have been identified as primary kainate antagonists, although some of the AMPA antagonists also inhibit kainic acid channels (71). At the present time it is not clear whether selective inhibition of kainate channels has any advantage in terms of anticonvulsant development over the development of AMPA channel inhibitors. Sodium ion-permeable kainate receptors not only contribute to the postsynaptic excitation, but the presynaptically located kainate receptors can modulate release of glutamate from excitatory terminals and, interestingly, can also prevent release of GABA from inhibitory interneurons (72). Kainate receptor antagonists have been demonstrated to block seizures in the *in vivo* and *in vitro* epilepsy models (73). In fact, among topiramate's multiple actions that contribute toward its being a potent AED, kainate receptor blockade is a participating mechanism of action (74, 75). The possible role of kainate glutamate receptors in modulating seizure discharge and anticonvulsant drug development is an important frontier for further research.

## METABOTROPIC RECEPTORS

Metabotropic receptors are glutamate- or excitatory amino acid-activated receptors that are not coupled to ion channels. These excitatory amino acid receptors are

coupled to second messenger systems in the membrane that have an important role in regulating cellular metabolism and function (76). Metabotropic receptors are coupled to G proteins and enzymes that regulate adenylate cyclase or guanylate cyclase. Regulating these enzymes by metabotropic receptor activation changes levels of cyclic adenosine monophosphate (cAMP) or cyclic guanosine monophosphate (cGMP). Metabotropic glutamate receptors are classified into eight different types (mGluR1–mGluR8). These mGluRs are further classified according to the second messenger systems to which they are linked. Class I mGluRs consist of mGluR1 and mGluR5, are most potently activated by quisqualate, and are coupled to phospholipase C (PLC) activation. Class II mGluRs, consisting of mGluR2 and mGluR3, are activated by 2R,4R-4-aminopyrrolidine-2,4-dicarboxylate (APDC), and inhibit adenylate cyclase activity. Class III mGluRs (mGluR4 and mGluR6–mGluR8) are most potently activated by L-amino-4-phosphonobutyrate and inhibit adenylate cyclase activity, but to a lesser extent. Metabotropic glutamate receptors are found both on the presynaptic and postsynaptic membranes. Presynaptic mGluRs decrease neurotransmitter release, while mGluRs on the postsynaptic membrane regulate the function of ligand-gated ion channels, including all three subtypes of ionotropic glutamate receptors, as well as inhibit the function of voltage-gated  $\text{Ca}^{2+}$  channels (VGCCs) and some potassium channels. Thus, metabotropic glutamate receptors can act to modulate synaptic transmission in the CNS (77). Modulating the activation or inhibition of metabotropic receptor activation by excitatory transmission plays an important role in modifying neuronal function over both short- and long-term periods relative to seizure activity. Metabotropic receptors play an important role in producing sustained changes in neuronal excitability that may have implications in epileptogenesis and the development of seizure discharges. In patients with temporal lobe epilepsy (78) or focal cortical dysplasia patients (79), up-regulation of mGluR5 immunoreactivity has been described. In the pilocarpine-induced epilepsy model, mouse strains with differential susceptibility exhibit different expression of mGluR4 receptors, with up-regulation in the dentate gyrus of mice with attenuated seizure phenotype and down-regulation in mice with enhanced seizure susceptibility (80). Evidence has accumulated for a possible role of glutamate metabotropic receptors in the development of epileptogenesis (81). Inhibition of metabotropic receptor activation during epileptogenesis in several models has blocked the development of long-term epilepsy. Competitive antagonists of group I mGluRs have shown efficacy against seizures induced experimentally in several epilepsy models. Metabotropic receptor inhibitors, therefore, are possible future areas for the development of novel AEDs (80, 82, 83).

## CARBONIC ANHYDRASE INHIBITION

Carbonic anhydrase (CA) is a major enzyme system that has been found to regulate GABA-mediated inhibitory potentials and therefore has important anticonvulsant or antiepileptic effects (84). GABA receptor ion channels are permeable to both chloride and bicarbonate ions. Bicarbonate ions normally move outward through the GABA receptor, producing a depolarizing effect that is normally smaller than the hyperpolarizing action of the inward movement of chloride ions. The movement of bicarbonate ions out of the neuron following entry of chloride ions can produce a potential depolarizing effect that can be mediated by the GABA-receptor channel. Inhibitors of CA play a role in blocking this effect. Thus, blocking the depolarization effects mediated by the GABA receptor through bicarbonate ion movement may be an important role of CA inhibitors in increasing the hyperpolarizing effect of the GABA receptor in the neuron. There may be other actions of CA inhibitors that go through other mechanisms, but this is another area of research for the development of anticonvulsant drugs. CA inhibitors such as sulthiame and acetazolamide (AZM) have previously been shown to lower neuronal intracellular pH (pHi), which effectively reduced epileptiform activity in epilepsy model systems in vitro (85). Topiramate (86) is shown to produce carbonic anhydrase inhibition that reduces the steady-state pHi of cornu ammonis field 3 (CA3) neurons in slices, thereby inhibiting epileptiform activity.

## NEUROMODULATORS

There are many classes of neuromodulators, but two major classes have been widely studied that have significant implications in regulating seizure activity: adenosine and the monoamines. Both adenosine and monoamines influence seizures and epileptogenesis in several models of epilepsy. Adenosine is released during seizure activity and acts as an endogenous anticonvulsant (87, 88). One form of the adenosine receptor (A1 receptor) is coupled to the G protein system in a similar mechanism, as is the metabotropic receptor. Activation of the A1 adenosine receptor stabilizes the resting membrane potential presynaptically and blocks glutamate release but not GABA release (89). Several analogs of adenosine acting at the A1 receptor exhibit good anticonvulsant effects in several models of epilepsy (90, 91). These compounds, however, have significant adverse cardiovascular effects, and their potential role as anticonvulsants needs further investigation. Another major type of adenosine receptor is the A3 receptor. Selected antagonists of the A3 receptor have also been recently shown to have anticonvulsant activity (92).

Regulation of adenosine receptors, both chronically and during seizure activity, may play important roles in developing new anticonvulsant drugs. The major challenge in this area, however, is to develop compounds that do not have complicating side effects, such as cardiovascular alterations or effects on other aspects of the nervous system.

Monoamines are important classes of neurotransmitters that play important roles in modulating both excitatory and inhibitory neurotransmission. Abnormalities in monoaminergic transmission in several animal models and in human epileptic foci taken from patients following epilepsy surgery have indicated that there may be a role for monoamine receptor activation in chronic epilepsy. Pharmacologic manipulation of monoaminergic neurotransmission plays a role in the development of several seizure syndromes, such as the reflex epilepsies (93). Noradrenaline agonists, such as  $\alpha_2$  agonists, are protective against seizure activity, and antagonists act as convulsant compounds. These effects have been well studied in amygdala kindling in rats and kittens (94, 95). Dopamine antagonists have also been shown to be protective in photosensitive epilepsy in animals and humans (96, 97). Monoamine oxidase B inhibitors play a role as anticonvulsants in several seizure models.

There is a growing body of evidence implicating the serotonergic system in the etiology of seizures. For example, depletion of brain 5-hydroxytryptamine (5-HT, serotonin) levels by *p*-chlorophenylalanine (98) and the serotonergic neurotoxin 5,7-dihydroxytryptamine (99) appears to exacerbate seizures, indicating that experimental manipulations that attenuate serotonergic neurotransmission can induce and/or augment epileptic seizures. In contrast, experimental manipulations that enhance serotonergic function, such as treatment with 5-HTP (100), fluoxetine (101), or stimulation of dorsal raphe nuclei (102–104) has been shown to inhibit seizures. Already there is conflicting evidence regarding the role of selective serotonin reuptake inhibitors (SSRIs) in seizures (105), with fluoxetine reported to elevate hippocampal seizure threshold in rats (106). In light of these findings, the role of 5-HT receptor subtypes is being actively investigated in epilepsy.

Some clinicians consider vagus nerve stimulation (VNS) as an alternative in drug-resistant epilepsy. It is only in the recent past that we have begun to understand the mechanisms underlying VNS-mediated seizure suppression. One of the best indications regarding VNS's mechanisms of action has come from Krahl et al (107). They chemically lesioned the locus coeruleus (LC) to chronically deplete rats of norepinephrine or acutely inactivated LC with lidocaine. Under both circumstances, VNS-induced seizure suppression was attenuated when tested in the maximal electroshock (MES) model. These studies indicate that the LC was necessary for the VNS-mediated anticonvulsant effects. Their

studies also suggest that noradrenergic agonists could enhance VNS-induced seizure suppression. Thus, the possible role of monoamines in relation to monoamine receptors in epilepsy is another potential area for development of future anticonvulsants.

## CALCIUM REGULATION OF NEURONAL FUNCTION

Calcium plays a major role in modulating normal activity and function of the nervous system (108, 109). One of its most widely recognized roles is modulating synaptic neurotransmission. A host of studies have demonstrated the importance of calcium in stimulus-secretion coupling (110). In addition to its important effects on neurotransmission, calcium plays a major role as a second messenger in neuronal and non-neuronal tissues.

Several lines of evidence indicate calcium's importance in regulating neuronal excitability and producing anticonvulsant effects. Because of calcium's importance as a second messenger, it is reasonable to assume that alterations in the normal function of calcium-regulated processes may underlie some of the abnormalities of neuronal excitability seen in seizure disorders.

Accumulating evidence suggests that abnormalities in major calcium-regulated enzymatic processes or ion channels underlie alterations in neuronal excitability and result in seizure activity (111). The role of calcium in antiepileptic drug action and in regulating seizure excitability has been recently reviewed (111, 112). Certain anticonvulsants have been shown to regulate the entry of calcium into cells through both voltage-regulated and transmitter-regulated calcium channels. In addition, anticonvulsants inhibit important calcium-mediated enzyme systems that play important roles in cell function and neuronal excitability. These mechanisms may also be significant for some anticonvulsant effects.

### Calcium Channels and Neuronal Excitability

The entry of calcium into a cell triggers many biochemical and biophysical actions (113, 114). This major second-messenger effect of calcium has been clearly linked to the regulation of neuronal excitability and cell metabolism (109, 114, 115). Thus, controlling calcium entry into the cell is the first major step in regulating the effect of calcium as a second messenger.

Depolarization-dependent action potentials are typically mediated by large sodium currents into the cell. Calcium simultaneously enters the cell during depolarization. Recently, the importance of this calcium entry during action potential generation has been more clearly understood. Accumulation of increased concentrations of calcium within a neuron is related to SRF of neurons,

which can occur *in vitro* or during epileptic activity. Calcium entry is also regulated by specific excitatory amino acid receptors. This type of calcium channel is opened or closed in response to binding of excitatory amino acids (EAA) to specific calcium channel-linked receptors. The ability of these channels to produce tonic, long-lasting excitability changes in hippocampal neurons and in other cortical neurons has implications for long-term potentiation, memory, and excitability.

In conceptualizing the role of calcium in neuronal excitability and anticonvulsant drug action, one must consider both voltage-regulated and excitatory amino acid-modulated calcium channels. The regulation of calcium channels, like the regulation of the chloride channel, by the benzodiazepines, barbiturates, and convulsant drugs may play an important role in modifying neuronal excitability.

### Voltage-Gated Calcium Channels

Voltage-regulated or gated calcium channels affect neuronal excitability. As an action potential arrives at a nerve terminal, depolarization of the nerve terminal membrane causes entry of calcium through voltage-gated calcium channels with subsequent release of neurotransmitters. This is the classic paradigm for calcium-mediated neurotransmitter release and was the initial observation that demonstrated the importance of calcium in neuronal excitability, but little was understood about the specific mechanisms of calcium channels in brain.

Early insight into the neuropharmacology of calcium channels came from studies of smooth muscle and cardiac cells during the 1970s. The dihydropyridine type of calcium channel blocker and related molecules were shown to be effective in blocking calcium channels in peripheral tissue (112, 116, 117). These compounds were classified as "organic calcium channel blockers" and represented a major advance in pharmacology. Numerous analogues were developed, and specific binding sites for the dihydropyridines and other analogs were identified and characterized. This led to the first molecular characterization of calcium channels and their regulation by specific receptor sites. A major controversy developed based on the observation that the organic calcium blockers, effective in inhibiting calcium entry into non-neuronal tissue, seemed to be ineffective in blocking voltage-gated calcium entry into neurons (118). Numerous investigators demonstrated that calcium entry as a result of neuronal activity was not significantly inhibited by therapeutic or relevant concentrations of the organic calcium channel blockers (112). Because there was at that time no clear evidence for more than one type of calcium channel, this dichotomy was not well understood and was attributed to unusual properties of the neuronal membrane and to specific differences in drug penetration into the nervous

system. More recent studies using benzodiazepines and phenothiazines (119–122) demonstrated that these compounds in fact could significantly block voltage-gated calcium channels in neurons. These results indicated that calcium channels in brain were distinct from calcium channels in peripheral tissue.

With the development of patch and voltage clamp technology, more sophisticated characterization of calcium channels has been possible. It is now clear that there are at least three, and possibly more, types of calcium channels in neurons (118, 123, 124). One type of voltage-gated calcium channel is insensitive to dihydropyridines, while a second type of calcium channel is sensitive to these compounds. A third type of brain membrane calcium channel has also been postulated that is different from the first two types of channels. Although a set terminology has not been developed for these different channels, initial classification by Tsien (124) is currently in use and describes these channels as the T-, N-, and L-type channels, respectively.

The heterogeneity of calcium channels provides a major insight into different mechanisms of regulating calcium excitability in the nervous system. These observations also explain the fact that the major voltage-gated calcium channels in brain that were insensitive to dihydropyridines were a different class of channel from those found in peripheral tissues. In certain regions of the nervous system and at certain sites on the cell body, however, there are calcium channels that are sensitive to dihydropyridines and are similar to those calcium channels in non-neuronal tissue. The different types of calcium channels are distributed in characteristic patterns over the surface of a neuron. Some channels may be localized at the synapse, while others may be present at a higher density at the cell body. The heterogeneity and individual functions of specific types of calcium channels are important areas for further investigation, such as the development of specific drugs to regulate each type of channel.

Several anticonvulsant compounds block or alter calcium entry through voltage-gated calcium channels. Ferrendelli and coworkers (125, 126) described the ability of phenytoin, phenobarbital, carbamazepine, but not ethosuximide, to block voltage-dependent calcium entry into isolated nerve terminal preparations. Subsequent studies have demonstrated that benzodiazepines, as well as phenytoin and barbiturates, can regulate calcium entry into isolated neurons. However, the concentrations of antiepileptic drugs that are required to block calcium entry are in the low micromolar range, concentrations that are approximately one order of magnitude higher than the therapeutic levels of these drugs achieved in spinal fluid. Although these concentrations may be relevant to anticonvulsant actions, they are more likely related to toxic side effects.

Thalamic relay neurons fire in two different modes: burst and tonic. T-type  $\text{Ca}^{2+}$  channels underlie the burst firings. When activated, T-type channels produce low-threshold  $\text{Ca}^{2+}$  currents that lead to the generation of a burst of action potentials (127). Burst firing of thalamic neurons have been implicated to play an important role in the pathogenesis of absence epilepsy (128). Ethosuximide, a known antiepileptic drug, is known to block T-type  $\text{Ca}^{2+}$  channels in thalamic relay neurons (129). Analysis of knockout mouse for the  $\alpha 1\text{G}$  gene coding for a subtype of T-type  $\text{Ca}^{2+}$  channels demonstrated absence of low-threshold, T-type,  $\text{Ca}^{2+}$  currents and an inability to induce burst firing in the thalamic relay neurons (130, 131).  $\alpha 1\text{G}$  knockout mice were resistant to GABA<sub>B</sub> receptor agonists; baclofen and gamma-hydroxybutyrate (GHB) induced seizures (132). T-type  $\text{Ca}^{2+}$  channels represent a novel pharmacologic target for development of drugs for the treatment of epilepsy.

### Excitatory Amino Acid Receptors and Calcium Channels

L-glutamate was proposed as an excitatory neurotransmitter over 30 years ago (133). Recently, excitatory amino acids (EAA) have been found to play important roles in epilepsy, neuronal excitability, and learning (133–135). The two main excitatory neurotransmitters currently known are glutamate and aspartate (136). Many pathways in the brain use these neurotransmitters, including hippocampal afferents and major cortical output tracts that are widely activated during convulsions.

Excitatory amino acids bind to specific membrane receptors (58, 137). Currently, four major types of EAA receptors have been characterized. One major EAA receptor is characterized by binding of the EAA analog NMDA. The NMDA receptor has now been well studied and represents a specific type of excitatory amino acid receptor. Three types of non-NMDA receptors that bind other analogs of excitatory amino acids but have different properties from the NMDA receptor have also been identified. The non-NMDA receptors bind EAAs but not NMDA. The non-NMDA receptors include binding sites for kainic acid, quisqualate, and 2-amino-4-phosphonobutyrate (2-APB).

Excitatory transmission regulated by EAA receptors plays a major role in synaptic transmission in the CNS. Excitatory amino acids regulate specific ion channels that allow calcium and sodium to enter the cell when the channel is activated by the EAA receptor (58, 137). These specific channels are actually opened or gated by the EAA. The currents activated by EAA receptors are both rapid and long lasting. The postsynaptic localization of these receptors, as well as their presence over the cell body, have been implicated in explaining how EAAs alter neuronal excitability, causing rapid depolarization

in some situations and long-lasting neuronal changes in other cells. Thus, this type of calcium entry is activated by specific EAAs and has been implicated in many neuromodulating effects in the brain. Important convulsants, such as kainic acid, alter neuronal excitability by binding to these receptor sites and activating calcium and sodium channels. Compounds that bind to EAA receptors but do not activate the channel can inhibit EAA effects on these receptors. Several of these compounds have potent anticonvulsant actions and are very effective in maximal electric shock-induced seizure models (58).

Because of their potential importance to epileptogenesis, EAA receptors and the calcium channels that they regulate have been the focus of extensive research (134, 138). These receptor sites are responsible for mediating some of the effects of kainic acid in producing convulsant discharge in the brain. NMDA receptors have been implicated in the phenomenon of long-term potentiation and in long-term alterations of neuronal excitability. The EAA analog 2-amino-7-phosphonoheptanoate (APH, AP7), is a potent anticonvulsant in various seizure models. These and other investigations provide strong evidence that EAA receptors and their regulation of calcium channels are important mechanisms in regulating neuronal excitability and, potentially, in AED actions. It is anticipated that several new anticonvulsant compounds will be developed that act specifically through this mechanism.

### **Modulating the Calcium Signal in Controlling Neuronal Excitability**

The discovery of a calcium-binding protein, calmodulin (CaM), was the first major breakthrough in understanding the molecular mechanisms that mediate calcium second messenger effects (139, 140). Evidence now suggests that many of the effects of calcium on cell function are mediated by calmodulin (120, 121, 141–143). Several important calcium-regulated processes are mediated by calmodulin and by a major calmodulin target enzyme system, calmodulin kinase II (144–146). Evidence from several laboratories has now confirmed the original calmodulin hypothesis of neurotransmission and substantiated the role of calmodulin in mediating some of the effects of calcium on neuronal excitability. Antiepileptic drugs, including phenytoin, carbamazepine, and the benzodiazepines, antagonize calcium-mediated effects and inhibit calmodulin activation of calmodulin kinase II (113, 147). Concentrations required to inhibit CaM kinase II are in the low micromolar concentration ranges for antiepileptic drug effects on the protein kinase. This enzyme plays an important role in mediating calcium-dependent protein phosphorylation of membrane and soluble proteins.

CaM kinase II has been implicated by several investigators to be a major molecular mechanism mediating some of the second-messenger effects of calcium in the

cell. Thus, control of this important calcium-mediated event by phenytoin, carbamazepine, and diazepam may be a major action of these drugs. The precise relationship of this particular effect to clinically useful anticonvulsant activity remains to be elucidated.

The importance of calmodulin kinase II in regulating neuronal excitability is widely recognized. Injection of CaM kinase II into invertebrate neurons regulates potassium and calcium currents (148). In addition, CaM kinase II levels in hippocampal neurons are chronically altered during the long-term alteration of neuronal excitability that occurs in kindling (149). CaM kinase II activity is inhibited by specific anticonvulsants (111, 121), and the subunits of CaM kinase II are a major protein component of the postsynaptic density, localizing this important enzyme system directly at the synapse (150, 151). Further understanding the role of CaM kinase II in the pathophysiology of epilepsy and in controlling neuronal excitability is clearly important.

Another major molecular mechanism regulating the effects of calcium on neuronal excitability and cell function is the major enzyme system protein kinase C. Protein kinase C has been implicated in many of the effects of calcium on cell function and has been implicated in some of the effects of calcium in regulating specific ion conductances (108). Although no direct studies have been performed to investigate the effects of anticonvulsant drugs on the C-kinase system, this too is an important area for investigation. Modulation of these calcium target enzyme systems by anticonvulsant drugs is a potential area for new drug development.

Calcium is a ubiquitous signaling molecule with significant regulatory function in neurons (152, 153). As a result even slightest changes in  $[Ca^{2+}]_i$  could sustain alterations in  $Ca^{2+}$ -dependent enzyme systems that could contribute to the generation of epileptiform activity. It has been demonstrated that levels of protein kinase C (alpha) isozyme are decreased after kindling epileptogenesis (154), and the activity of the  $Ca^{2+}$ /calmodulin-dependent phosphatase calcineurin is increased after pilocarpine-induced status epilepticus (SE) (155, 156). Further, the activity of CaM kinase II is depressed in human epileptic tissue (157) and in various *in vivo* models of epilepsy (158–162). Epileptic neurons in culture also manifest some of the biochemical, electrophysiologic, and molecular changes observed in animal models. Thus, decreased CaM kinase II activity and its alpha subunit expression are observed in the low- $Mg^{2+}$  hippocampal neuronal culture model of epilepsy (163). As in epileptogenesis, these changes are dependent on activation of the NMDA receptor (162, 163). Further, mice lacking active CaMKII manifest epileptiform activity after subconvulsive stimulation (164), implicating decreased CaMKII activity in epileptogenesis. In addition, hippocampal neuronal cultures, treated with antisense oligonucleotides to

the CaMKII alpha subunit, express decreased levels of CaMKII and exhibit epileptiform discharges similar to the low-Mg<sup>2+</sup> and glutamate injury-induced epileptogenesis models (165, 166).

### Anticonvulsants that Inhibit Vesicular Neurotransmitter Release

SV2A, a synaptic vesicle protein, has recently been identified as a likely target for antiepileptic action. SV2A is a protein component of synaptic vesicles that is structurally similar to 12-transmembrane-domain transporters. SV2A is not essential for synaptic transmission, but mice in which the protein has been deleted by gene targeting exhibit seizures (167). This finding led to a search for compounds acting on SV2A as probable anticonvulsant agents. Levetiracetam (Keppra®) is thought to bind with SV2A and disrupt synaptic release mechanisms to produce an anticonvulsant effect (168). It is also speculated that levetiracetam binding enhances a function of SV2A that inhibits abnormal bursting in epileptic circuits, a function whose loss in the SV2A knockout models results in seizures (168). It is also suggested that a reduction of potassium currents may contribute to the antiepileptic effect(s) of levetiracetam (169). Newer analogs of levetiracetam, such as seleteracetam and brivaracetam, are currently investigated for probable anticonvulsant actions (170). Levetiracetam at clinically relevant concentrations is also reported to inhibit Na<sup>+</sup>-dependent Cl<sup>-</sup>/HCO<sub>3</sub><sup>-</sup> exchange, lower neuronal pH<sub>i</sub>, and thereby contribute to its anticonvulsive activity (85).

### Anticonvulsants that Target the Endocannabinoid System

Recently the endocannabinoid system—an inhibitory neurotransmitter system—has generated considerable interest as a novel locus of anticonvulsant activity in brain (171–174). This unique system consists of at least two cannabinoid receptors (CB1 and CB2), the endogenous agonists (endocannabinoids: anandamide and 2-Arachidonyl Glycerol (2-AG)), and the protein machinery for their synthesis, transport, and degradation (175). Cannabinoids such as those naturally occurring in marijuana (*Cannabis sativa*) possess anticonvulsant properties (176, 177) and have been used since antiquity for the treatment of seizures (178). Recently synthetic cannabinoids such as WIN 55,212-2 have been demonstrated to produce an anticonvulsant effect in a CB1 receptor-dependent manner (179, 180). Emerging evidences have indicated that the endocannabinoid system controls seizure threshold, duration, and seizure frequency (171, 181).

Endocannabinoids regulate neuronal excitability via depolarization-induced suppression of excitation (DSE) (182) or inhibition (DSI) (183, 184). In response to

Ca<sup>2+</sup>-mediated depolarization of the postsynaptic membrane, endocannabinoids are synthesized “on demand” and then diffuse in a retrograde fashion and activate presynaptic CB1 receptors to inhibit neurotransmitter release and thus modulate neuronal excitability (185). Intense synaptic activity caused by seizure discharges stimulates 2-AG synthesis (171). Such an “on-demand” synthesis of endocannabinoids is thought to produce anticonvulsant effects, ultimately terminate seizures, and regulate seizure duration and frequency in the pilocarpine model of epilepsy. There is also evidence that the endocannabinoids, such as anandamide and 2-AG, dampen epileptiform activity in hippocampal brain slice preparations (186). Cannabinoids and endocannabinoids have also been demonstrated to block seizure spread via a CB1 receptor-dependent mechanism in the MES model of short-term seizure and the rat pilocarpine model of temporal lobe epilepsy (171, 179, 181). This plethora of evidence indicates that an active endogenous cannabinoid tone maintains chronic activation of presynaptic CB1 receptors that play an important role in dampening persistent excitation in epilepsy and may prevent the transition of a single seizure into SE. In the pilocarpine model of acquired epilepsy, inhibiting endogenous cannabinoid tone using a CB1 receptor antagonist caused a marked increase in seizure frequency and duration and produced SE-like activity (171), suggesting that the endocannabinoid system was playing an important role in preventing the development of SE. Thus, the endocannabinoid system appears to be the brain’s endogenous mechanism that guards against persistent epileptic neuroexcitation and prevents the transformation of single seizure to SE.

### New Frontiers in Epilepsy Treatment: Inhibition of Epileptogenesis

More than half of the epilepsies are described as symptomatic or acquired. These types of epilepsy are acquired through environmental stress or injuries to the nervous system that result in the permanent alteration of neuronal function, resulting in epilepsy (187). Conditions such as stroke, head trauma, metabolic disease, prolonged seizures, tumors, or other neurologic insults can permanently alter the brain and trigger mechanisms of neuronal plasticity that eventually result in the development of epilepsy (188). Because of the diversity of causes of epilepsy, epilepsy is not considered a disease but rather a condition. In addition to the acquired causes as described previously, other idiopathic forms of epilepsy may have a genetic basis (187).

The process of epileptogenesis means the development of spontaneous recurrent seizures in a previously normal brain (188). Symptomatic epilepsy, representing a significant number of patients that develop epilepsy, occurs through the process of epileptogenesis. This is an

important area to consider for anticonvulsant drug development. Compounds that prevent the development of epileptogenesis may have important clinical ramifications. If specific antiepileptogenic drugs can be administered following a brain injury, symptomatic epilepsy may be prevented. Although these compounds may not be true anticonvulsant drugs, they would be the ultimate AEDs by preventing the development of epilepsy. This is a new and important area for future research.

Molecular genetics has set the stage for major advances in studying neurologic diseases, and initial advances have been made in understanding specific mutations that are associated with epilepsy and other neurologic conditions (189). In addition to specific mutations, permanent alterations in brain function and

diminished expression are associated with epileptogenesis. In symptomatic epilepsy, normal brain tissue is permanently altered and develops spontaneous recurrent seizures. These changes entail long-lasting changes in gene expression at both transcriptional and posttranscriptional levels in association with the induction of epileptogenesis.

Understanding the effects of severe environmental stresses on the multiple sites of transcriptional and posttranscriptional regulation of gene expression is likely to provide important insights into how altered neuronal function develops and point to novel strategies that will prevent epileptogenesis. This important area for future research represents a frontier in the development of AEDs.

## Channel Mutations in Epilepsy: A Neurodevelopmental Perspective

*Edward C. Cooper*

**S**earches for genes mutated in several hereditary forms of epilepsy affecting infants and children have resulted in the identification of epileptic channelopathies: that is, epilepsies resulting from mutations in ion channel genes. This is a rapidly evolving field, and reviews of recent progress appear frequently in journals. This chapter attempts to take a broader view and provide background that may serve as an introduction to this ongoing literature for interested pediatricians and pediatric neurologists. In particular, I attempt to make explicit key background, assumptions, and hypotheses underlying this relatively new field and explore (even at the risk of speculation) some of its current directions and promise.

### **WHY HAVE INVESTIGATORS PURSUED A GENETIC STRATEGY FOCUSED ON RARE MENDELIAN FORMS OF EPILEPSY?**

Only a small minority of seizure patients encountered in the clinic have family histories of epilepsy. Why, then, focus on the even smaller group of patients in which pedigree analysis suggests inheritance of epilepsy resulting from effects of mutation in single genes? Investigators have chosen this approach partly out of recognition of the difficult nature of the problem. Seizures and epilepsy

are complex phenomena. Seizures emerge suddenly from the brain's interictal activity, often producing elaborate ictal behaviors and myriad consequences for development. During a seizure, normal neuronal firing patterns are replaced by synchronized rhythms that are excessively prominent and widespread. We know that the capacity to seize is latent in normal brain—convulsions can be provoked in any child or adult as a symptom of metabolic disturbances (e.g., hypoglycemia, hypocalcemia, uremia) or acute injury. What is different about the brains of people with epilepsy, who have seizures without such provocations? Furthermore, why do most syndromic forms of epilepsy exhibit distinctive developmental profiles, affecting individuals at particular periods of their lives? These are tough questions.

Genetics is an approach to these questions that has unique advantages. Genetic research can lead to the identification of a responsible gene (or genes), even when no other biologic information about the cause of a disorder is available. So a successful genetic study offers the potential to “think outside the box” by identifying mechanisms previously completely unknown or unsuspected of being involved with a particular disease process (e.g., the nicotinic receptor, KCNQ channel and Lgi1 proteins, discussed subsequently). Genetics is relatively unbiased by preconceptions born from prevailing models and currently available technical approaches. Such

an approach is extremely valuable for scientists confronting a process as complex, heterogeneous, and poorly understood as epilepsy. Furthermore, even when the genetic form of a particular disorder is rare, there is a strong possibility that the mechanism revealed may be involved in pathogenesis of more common forms of the disease.

Because of these potential advantages, over the last two decades efforts have been made to identify families in which epilepsy has occurred in patterns suggesting Mendelian inheritance—that is, in patterns suggesting that the epileptic trait resulted from mutations in a single gene. In the last dozen years, with a burst of success aided by tools derived from the Human Genome Project, hundreds of such mutations have now been discovered (Table 3-1). Remarkably, nearly all of the mutations causing idiopathic epilepsy discovered so far lie in genes encoding ion channels, and the exceptions are primarily in genes for proteins that interact directly with channels and regulate their activity. Some types of hereditary epilepsy associated with other features, such as episodic or progressive motor

dysfunction and cognitive impairment (i.e., symptomatic or cryptogenic in traditional classification schemes), have also been found to be due to channel mutations. The primary and direct role of ion channels in the pathogenesis of Mendelian forms of idiopathic epilepsy has rapidly gone from hypothesis to irrevocable fact.

The forging of this sturdy conceptual link between epilepsy and channel genes has occurred coincidentally with a period of revolutionary progress in our understanding of channels themselves, coming from basic neuroscience. Very recently, investigators have begun to systematically explore the functions played by the newly identified “epilepsy genes.” They have used neurobiologic techniques to analyze with the requisite detail how mutations in particular channels alter the excitability of individual neurons and neural networks, ultimately resulting in epilepsy. These studies of the epileptic channelopathies are revealing important and previously unknown mechanisms controlling brain excitability at particular stages of development that represent novel targets for therapeutic drugs.

**TABLE 3.1**  
*Epileptic Channelopathies with Onset in Infancy, Childhood, or Adolescence (Identified as of January 2007)*

SYNDROME	GENE(S)	PROTEIN	CHANNEL TYPE
Benign familial neonatal seizures (BFNS)	KCNQ2 (KCNQ3) <sup>1</sup>	Kv7.2 Kv7.3	M-channel; axonal Ks channel; voltage-gated K <sup>+</sup> channel
Benign familial neonatal-infantile seizures (BFNIS)	SCN2A (KCNQ2)	Nav1.2	Axonal voltage-gated Na <sup>+</sup> channel
Generalized epilepsy with febrile seizures plus (GEFS+)	SCN1A (SCN1B)	Nav1.1 Nav beta1	Interneuron voltage-gated Na <sup>+</sup> channel (?); <sup>2</sup> voltage-gated Na <sup>+</sup> channel accessory subunit
	(GABRG2) (GABRD)	GABA <sub>A</sub> gamma2 and delta subunits	Ligand-gated (GABA) Cl <sup>-</sup> channel subunit
Severe myoclonic epilepsy of infancy (SMEI)	SCN1A	Nav1.1	Interneuron voltage-gated Na <sup>+</sup> channel (?)
Cortical dysplasia-focal epilepsy syndrome (CDFE)	CNTNAP2	Caspr2	Axonal K <sup>+</sup> channel interaction protein
Generalized epilepsy with paroxysmal dyskinesia (GEPD)	KCNMA1	BK subunit	Large conductance Ca-dependent K <sup>+</sup> channel
Childhood absence epilepsy (CAE)	GABRG2	2 GABA <sub>A</sub> gamma subunit	Ligand-gated (GABA) Cl <sup>-</sup> channel subunit
Autosomal dominant nocturnal frontal lobe epilepsy (ADNFLE)	CLCN2 CHRNA4 (CHRNA2) (CHRN2)	CLC-2 α4, α2, and β2 subunits of acetyl-choline receptors	Voltage-gated Cl <sup>-</sup> channel Neuronal nicotinic acetylcholine receptor subunits (?inhibitory presynaptic terminals)
Autosomal partial epilepsy with auditory features (ADPEAF)	LGI1	Lgi1	K <sup>+</sup> channel interaction protein (?); glutamate receptor interaction protein (?)
Autosomal dominant juvenile myoclonic epilepsy (ADJME)	GABRA1α2	GABA <sub>A</sub> subunit	Ligand-gated (GABA) Cl <sup>-</sup> channel subunit

<sup>1</sup>Where one gene accounts for most mutations in a disorder, rarely mutated genes are shown enclosed in parentheses.

<sup>2</sup>Where uncertainty exists as to channel function, (?) is shown.

## ION CHANNEL FUNCTION, STRUCTURE, DISTRIBUTION, AND DIVERSITY

What are ion channels? Ion channels are membrane proteins, tiny molecular machines about 10 nanometers in size, that allow ions to enter or leave the cell interior at very high rates—usually  $10^6$  to  $10^7$  ions per second per channel (1). These ion fluxes through individual channels cause transient, local changes in neuronal membrane potentials that represent the smallest units of brain electrical signaling. All neurons possess different classes of channels that are selectively permeable to the cations sodium ( $\text{Na}^+$ ), potassium ( $\text{K}^+$ ), and calcium ( $\text{Ca}^{2+}$ ) or the anion chloride ( $\text{Cl}^-$ ). Because of the activity of pumps and co-transporters,  $\text{Na}^+$ ,  $\text{Ca}^{2+}$ , and  $\text{Cl}^-$  are usually more concentrated extracellularly and  $\text{K}^+$  more concentrated intracellularly. To maintain these concentration differences, the pumps consume energy in the form of adenosine triphosphate (ATP). As a result, when channels permeable to  $\text{Na}^+$  or  $\text{Ca}^{2+}$  open, these ions enter the cell, depolarizing the membrane potential. When channels selective for  $\text{K}^+$  or  $\text{Cl}^-$  open, the membrane is made more hyperpolarized as  $\text{K}^+$  leaves or  $\text{Cl}^-$  enters the cell interior. So, at the simplest level,  $\text{Na}^+$  or  $\text{Ca}^{2+}$  channel activity leads to increased excitation, whereas  $\text{K}^+$  or  $\text{Cl}^-$  channel activity reduces excitation.

Although the function of an individual channel type may appear quite simple, groups of such channels can readily underlie complex, dynamic changes in the membrane potential, producing oscillations and rhythmic activity in neurons and neuronal networks. Grouping together even two channels capable of causing opposing changes in the membrane potential in a neuronal membrane creates a mechanism for generating membrane potential oscillations. The propagated action potential, mediated by sequential opening of voltage-gated  $\text{Na}^+$  channels (depolarizing phase) and  $\text{K}^+$  channels (repolarizing and/or hyperpolarizing phase) grouped along nerve axons, is the best-studied example of such signaling.

We now know, however, that other channel groupings occur everywhere in nervous tissue. Particular channel types are deployed at specific locations, for specialized purposes. Indeed, humans possess several hundred genes encoding ion channel types that differ in key functional properties such as opening and closing rates (kinetics), the types of ions passed (ion selectivity), and the signals that bring about channel opening and closing (gating and modulation) (2). This allows different neurons to express distinct subsets of ion channels and for different channel types expressed by a neuron to be localized at specific sites in the cell membrane with great precision. For example, some channels are expressed at synapses. Some channels are specifically expressed on dendrites, but others are found at particular locations along axons or at presynaptic terminals. Some channels

are preferentially expressed on inhibitory or excitatory neurons within a brain region, or on glia. Along with cell shape, cell-specific differences in ion channel expression contribute to each cell's particular electrical "personality," enabling neurons to perform distinctive functions in local networks, and underlying the differences between the network properties of different brain regions. It is important to note that the expression levels of many ion channels are not static during development; instead, ion channel genes exhibit distinctive developmental profiles. One goal of current research is to improve the current fragmentary understanding of how the roles played by different ion channels change in parallel with the achievement of motor, sensory and cognitive development milestones during infancy and childhood.

So, when we learn that an ion channel mutation causes seizures, this leads to functional questions at several levels. At the level of the channel molecule, we seek to learn how the mutation alters intrinsic channel properties such as kinetics, selectivity, gating, and modulation. At the cellular level, we want to know how the mutation affects channel abundance and distribution. At the local network level, we need to know how the mutation alters the rhythmic properties and synchronization of firing occurring in networks of neurons in particular brain regions, since it is at this level that the seizure phenotype is manifest. Finally, we seek understanding of how the channel's roles change during development, seeking clues from the age of onset and natural history of the clinical syndrome.

### Ion Channel Structure

Many channel mutations exert their effects by disrupting the normal structure of the encoded channel proteins. Here we introduce some key common aspects of channel structure/function relationships most relevant to the epileptic channelopathies; more detailed reviews are available elsewhere (3–6).

Cellular membranes are bilayers with polar surfaces facing the aqueous cytoplasmic and extracellular spaces and a  $\sim 50$ -angstrom-thick hydrophobic core (Figure 3-1A). Although seemingly thin and fluid, the oily core of biologic membranes represents a formidable barrier for ions, which are even tinier ( $\sim 1$  angstrom) and highly charged. Furthermore, ions in solution attract an admiring "entourage"—a surrounding shell of water molecules that are also repulsed by the hydrophobic core of the membrane. Thus, transport across the membrane requires each ion to be sequentially bound by the channel, dehydrated (stripped of surrounding water molecules), carried across the inhospitable membrane core, rehydrated, and released. These steps must all happen very quickly. It takes the electrical charge from about 10,000 ions to depolarize a  $1 \mu\text{m}^2$  patch of membrane by

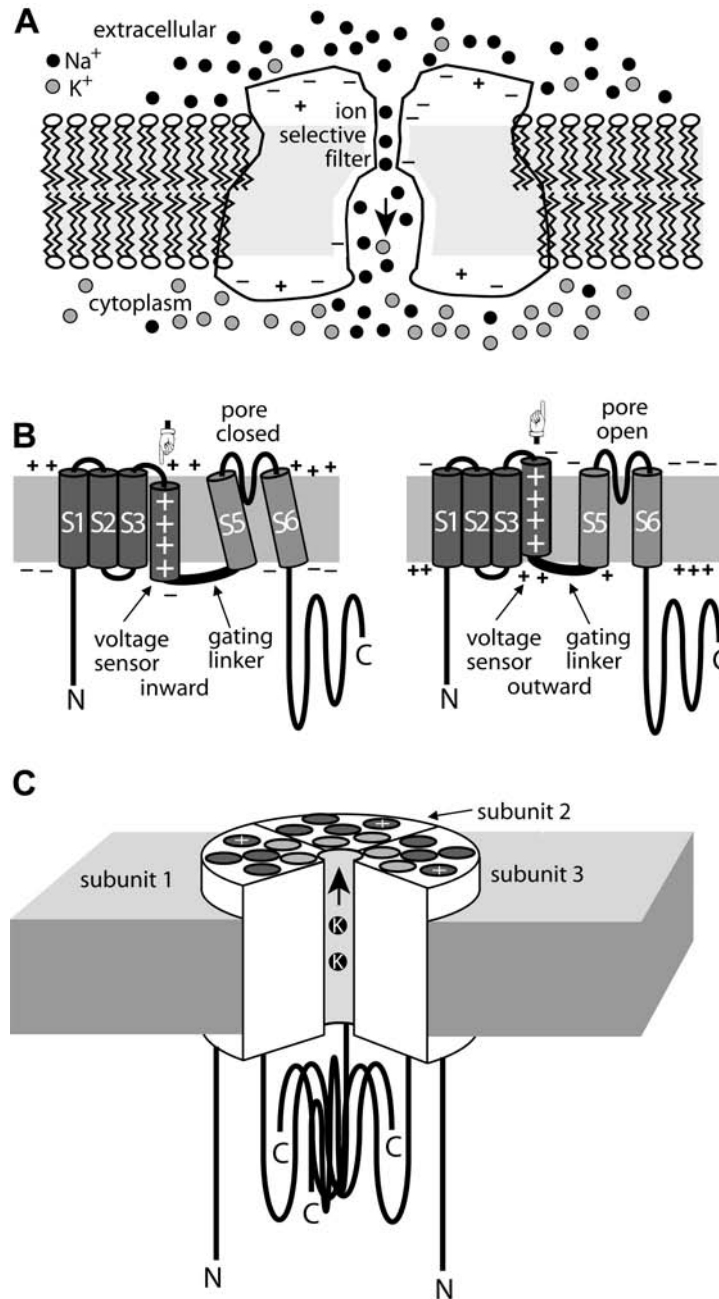

FIGURE 3-1

Structure and gating mechanism of representative ion channels. (A) Cartoon showing a cross-sectional view through the center of a model ion channel. The channel has hydrophobic surfaces facing the membrane lipid core (gray area) and hydrophilic surfaces with charged residues (indicated by +’s and -’s) facing the internal and external solution and lining the centrally located transmembrane ion path. At the narrowest part of the pore, permeant ions bind preferentially to the “ion selective filter.” The channel depicted is selectively permeable to Na<sup>+</sup> ions, which are shown moving through the channel from the extracellular solution to the cytoplasm. (B) Transmembrane topology, functional subdomains, and molecular movements of a voltage-gated K<sup>+</sup> channel subunit. The subunit polypeptide has intracellular amino and carboxy terminal domains, and six segments (S1 through S6) that traverse the membrane. S1–S4 form the voltage sensor domain. S5–S6, and the loop that connects them and is folded partly into the membrane, form the pore domain. The S4 domain possesses positively charged residues (indicated by +’s), and as a result, undergoes molecular movements in response to changes in the transmembrane electrical potential, moving outward when the membrane is depolarized (indicated by pointers). Outward movement of the S4 domain pulls the pore at the cytoplasmic end of S5–S6, allowing ion flow (right panel). (C) Cartoon showing K<sup>+</sup> channel subunits arranged around the central pore of an assembled channel—the fourth (front) subunit has been removed to reveal the ion path. Positions of transmembrane segments are indicated as in part B (gray, S5 and S6; dark gray, S1 to S4).

100 mV (the height of a typical action potential). For this to occur within a millisecond, ions must enter this small area of the membrane at a rate approaching 10 million per second. Ion channels routinely achieve this amazing feat, but how?

Ion channel polypeptide chains traverse the membrane several times and assemble into proteins shaped like doughnuts embedded at their midsection in the membrane (Figure 3-1). The surfaces of the channel that face the extracellular and intracellular aqueous solution are hydrophilic and may contain charged residues and sugars that attract ions, whereas the circumferential band touching the oily membrane core is made up of hydrophobic amino acids. Ions traverse the membrane through a centrally located pore (the doughnut's hole). The channel pore is water filled except for a narrow segment known as the selectivity filter. The selectivity filter possesses a row of sites where individual ions are briefly bound and released. The selectivity filter is equally accessible to ions from the intracellular and extracellular sides of the membrane. The net direction of flow is influenced by the fact that randomly moving ions are more likely to access the filter from the side where they are more highly concentrated, and less likely to return once released from the side where they are more dilute. In addition, once ions enter the channel pore, they come under the influence of the electrical potential difference between the two sides of the membrane— $\text{Na}^+$ ,  $\text{Ca}^{2+}$ , and  $\text{K}^+$  are attracted towards the negative side of the membrane, and  $\text{Cl}^-$  towards the positive side. The balance between these concentration- and voltage-driven forces determines the direction of net ion flow.

In addition to the pore-forming parts themselves, all ion channels have additional components that control the opening and closing of the ion pathway. Regulatory domains include voltage sensors embedded in the membrane (Figure 3-1B). Alternatively, some channels have parts that bind and respond to intracellular second messengers and metabolites (e.g.,  $\text{Ca}^{2+}$ , ATP, cyclic adenosine monophosphate [cAMP], or polyamines), and extracellular sites for binding neurotransmitters. The best understood regulatory mechanism is that of voltage-gating mechanisms common to  $\text{Na}^+$ ,  $\text{K}^+$ , and  $\text{Ca}^{2+}$  channels, which has been revealed through detailed studies combining electrophysiology and X-ray crystallography. A cluster of positive charges on one transmembrane segment (S4) cause it to move inward or outward, depending on which side of the membrane is more negatively charged (Figure 3-1B). In the closed state (inside-negative membrane potential), the S4 is pulled inward, forcing the pore-lining part of the channel into an angled position, so that the inner mouth of the pore is too small for ions to pass (Figure 3-1B, left). When the membrane is depolarized, the voltage sensor moves towards the extracellular space, pulling the pore-lining residues away from the center axis

of the pore and opening the inner pore mouth sufficiently to allow ions to flow (Figure 3-1A, C).

### Ion Channel Diversity and Nomenclature

Successive waves of technical advance over the last 20 years have left a wake of very confusing nomenclature for ion channel currents, proteins, and genes. First, electrophysiologic methods of improved sensitivity have allowed previously overlooked subtypes in the channel currents to be recorded from neuronal membranes. This led to a new nomenclature subclassifying various voltage- and ligand-gated channel types based on their kinetics, pharmacology, and other functional properties. Next, the advent of methods for isolating messenger RNAs from neural cells led to the identification of a large number of complementary DNAs (cDNAs) encoding channel subunits. Finally, the sequencing of the genomes of humans and various model organisms led to the identification of many additional channel genes. The process of correlating the channels actually expressed in neurons with specific genes and proteins is slow and painstaking, in part because most native channels are heteromeric—that is, formed by the coassembly of the protein products of two or more different genes. Only rarely do channels appear to be homomeric—that is, formed by multiple copies of the same subunit type. As a result, the exact subunit composition of most of the channels expressed in most brain neurons is not yet known—particularly in humans. The changes in channel composition and expression that occur during normal human development and in disease states are even less understood; with a few exceptions, such developmental changes have not yet been studied.

Although much remains to be learned about the function of particular channel genes, genomics has revealed how ion channel diversity has been generated and, by implication, why. All human channels are derived from a very small number of ancestral genes, already present in the genomes of ancestral prokaryotes over a billion years ago (1, 2, 7). Just as genes are subject to random mutations, it is now known that all genes are subject to random duplication, albeit very rarely, as the result of errors occurring during DNA replication; indeed the rate of such gene duplications is estimated to be one per hundred million years (8, 9). Each gene duplication event creates a “surplus” gene that is relatively free to evolve new functional properties, since the original gene is still present and performing any essential functions. In the vast majority of cases, a duplicate gene does not evolve a novel useful function but instead accumulates inactivating mutations over time and, eventually, disappears from the genome. Rarely, the duplicate gene evolves a new function that provides a survival advantage to the organism—in such cases, both duplicate genes become “fixed” in the genome. The related genes produced by

duplication (called “paralogs”) can then themselves be subsequently duplicated. The human ion channel families are incredibly large—for example, one such family consists of 80 K<sup>+</sup> channels, 10 voltage-gated Na<sup>+</sup> channels, 11 voltage-gated Ca<sup>2+</sup> channels, and an additional 42 cation channels of various classes, all derived from the same ancestral K<sup>+</sup> channel (2)! The two other major families of channel genes, encoding voltage-gated Cl<sup>-</sup> channels and the ligand-gated channels, were produced by the same process of duplication and subsequent functional divergence (10–12). Because a duplicated neuronal channel gene must provide a survival advantage to first establish itself in its species of origin and remain stably present over the course of evolutionary time, gene survival alone is an indication that a duplicate gene has acquired a needed, novel role. That role may be restricted—for example, to particular neuronal cell types, or to a particular stage of development. Many of these roles remain poorly understood. Indeed, analysis of the phenotypes produced by disease-causing mutations in individual channel genes is an important source for clues regarding these unknown functions.

## EPILEPTIC CHANNELOPATHY SYNDROMES

A first expectation, based on earlier studies of channel defects in hyperexcitability disorders of skeletal muscle (e.g., myotonia) and heart (long QT syndrome), would be that channel mutations leading to epilepsy would be associated with increases in Na<sup>+</sup> or Ca<sup>2+</sup> channel activity (since such activity leads to membrane depolarization) or with reductions in K<sup>+</sup> or Cl<sup>-</sup> channel activity (since these currents prevent membrane depolarization) (13, 14). As will be discussed subsequently, we have learned that this expectation is often, but not always, fulfilled. To facilitate further reading, we have provided the listing for each disorder in the National Library of Medicine’s Online Mendelian Inheritance in Man (OMIM) database (<http://www.ncbi.nlm.nih.gov/omim/>), which is frequently updated.

### Channel Mutations in Epilepsies with Onset in Neonates and Infants

*Benign Familial Neonatal Seizures (BFNS; OMIM 121200).* Benign familial neonatal seizures (BFNS, also termed benign familial neonatal convulsions) is a syndrome characterized by recurrent, brief generalized or partial seizures that begin on about the fourth day of life and remit after 1–3 months (15). In the classic syndrome, first described by Rett and Teubel (15), infants otherwise grow and develop normally, without subsequent epilepsy, although affected persons carry a 10–16% risk

of experiencing one or more seizures again later in life (16, 17). In 1989, Leppert et al. linked the disease gene to chromosome 20 (18). Later, investigators identified additional families linked to chromosome 8, a first example of genetic heterogeneity in epilepsy (19, 20).

The two BFNS genes on chromosome 20 and 8 encode highly homologous potassium channel subunits, KCNQ2 and KCNQ3 (21–23). These neuronal channel subunits are relatives of a cardiac channel, KCNQ1, which previously was shown to be mutated in both dominantly and recessively inherited forms of the long QT syndrome (24, 25). Four KCNQ1 subunits combine to form the channels in the heart. In neurons, some channels are KCNQ2 tetramers, but many are composed of a combination of KCNQ2 and KCNQ3 subunits (26–31). Some disease-causing missense mutations in KCNQ2 and KCNQ3 are associated with only modest reductions (20–30%) in current magnitude (32). This may imply the critical dependence of neuronal excitability on the absolute magnitude of KCNQ2/KCNQ3 potassium channel activity, especially during the neonatal period. KCNQ channels underlie an extensively studied potassium channel, found in central and autonomic neurons, known as the M-channel (26). The name “M-channel” comes from the fact that these channels are important effectors for acetylcholine acting via muscarinic receptors. Indeed, many neurotransmitters that activate intracellular G proteins increase neuronal excitability by reducing the openings of KCNQ channels (33). These channels open occasionally at the resting membrane potential and are slowly activated by membrane depolarization. Because of their slow kinetics, M-channel activation causes a period of membrane hyperpolarization after a cell receives excitatory input. As a result, neurons expressing M-channels tend to fire one action potential after receiving excitatory input, then become transiently quiescent. Inhibition of the M-channel by neurotransmitter receptors causes these neurons to become slightly depolarized and to fire multiple action potentials rhythmically after receiving excitatory inputs. Thus, M-channels may serve as a general brake on excess neuronal excitation, a brake that can be selectively removed when the cell receives input from neurotransmitters such as acetylcholine.

KCNQ2 subunits are widely expressed in circuits implicated in generation of epileptic seizures (30, 34, 35). Interestingly, one conspicuous localization of KCNQ2 expression is in inhibitory neurons important for synchronization of the firing of excitatory neurons, including the reticular thalamic neurons and several populations of interneurons in the hippocampus and cortex (34). A second important localization of KCNQ2 and KCNQ3 is at spike initiation zones at the beginning of axons, including those of pyramidal cells in the hippocampus and neocortex (30, 36). This localization may allow them to powerfully control the neuronal threshold, since each neuronal

action potential originates in the proximal axon (37). In transfection experiments, some BFNS mutations strongly disrupt proper traffic at the axonal initial segment; if this disruption occurs *in vivo*, it could be the main contributing factor in the BFNS phenotype (38).

Recent studies have identified patients in BFNS pedigrees with KCNQ2 mutations and more severe epilepsy, impaired cognition (39–42) and myokymia (43, 44). KCNQ2 and KCNQ3 have been found at nodes of Ranvier of peripheral nerves and at the axonal initial segments of spinal motor neurons, and loss of their activity likely causes the aberrant impulse initiation in the nerve that is manifest as myokymia (30, 31, 36). It is not clear whether environmental or genetic factors underlie the more severe cognitive, motor, and epileptic phenotypes seen in some BFNS patients.

Retigabine is a novel anticonvulsant, initially identified in the National Institute of Neurological Disease and Stroke (NINDS) antiepileptic (AED) drug screening program, that is effective in preventing seizures induced by electrical shock or by a broad range of chemical convulsants (pentylenetetrazole, N-methyl-D-aspartate [NMDA], 4-aminopyridine, and picrotoxin, but not bicuculline or strychnine) (45). BMS-204352 is another drug initially developed as a potential therapy for acute stroke (46). Remarkably, recent studies have revealed that both these agents are potent activators of neuronal KCNQ channels (47–50). The discover of retigabine's novel mode of action has contributed to new interest in its potential clinical usefulness, and it is currently undergoing stage III trials for adult partial epilepsy (50). Although these agents have not yet been shown to be of clinical usefulness, it is clear that the cloning of the KCNQ channels has revealed an important potential new target for drug screening studies.

*Benign Familial Neonatal-infantile Seizures (BFNIS; OMIM 607745).* Kaplan and Lacey (51) and Shevell et al. (52) first described families in which nonfebrile seizures, like those seen in BFNS but with a somewhat later onset ranging from the first week of life to 3.5 months, were inherited in an autosomal dominant pattern. This delayed onset led to the suspicion of a distinctive etiology, which was affirmed when the two BFNS loci on chromosomes 8 and 20 were excluded by genetic linkage analysis, and another location on chromosome 2, harboring a cluster of genes encoding several Na<sup>+</sup> channel proteins, was implicated (53–55). Screening of the chromosome 2 genes in BFNIS patients revealed mutations in SCN2A, encoding the Na<sup>+</sup> channel subunit, Nav1.2.

Cell biologic studies using rodents indicate that Nav1.2 channels play an important, transient role on neuronal axons in the developing brain and peripheral nerve (56). In rats and mice, Nav1.2 is at birth the predominant sodium channel at the spike initiation zone in the proximal axon (i.e., the axonal initial segment), but it

is largely replaced at this location during the second and third postnatal week. A similar Nav1.2 to Nav1.6 switch occurs at the nodes of Ranvier of many newly myelinating fibers. Based on studies of other proteins, it seems likely that similar subunit switches occur in humans, but over a slower time period of several months (57). The observation that the channels mutated in BFNS and BFNIS are expressed in similar axonal locations during early development is certainly intriguing—but available data do not yet explain why KCNQ2/3 mutations would produce an earlier onset than SCN2A mutations.

*Generalized Epilepsy with Febrile Seizures Plus (GEFS+; OMIM 604233), Severe Myoclonic Epilepsy of Infancy (SMEI; OMIM 607208), Intractable Childhood Epilepsy with Generalized Tonic-clonic Seizures (ICEGTCS; OMIM 607208).* Febrile seizures occur in 3–5% of all children. When febrile seizures occur in isolation, between age 3 months and 5 years, in children who are otherwise developing normally, the risk of later epilepsy is low (see Chapter 19). For a minority of cases, however, febrile seizures herald epilepsy of a variety of forms and degrees of severity.

In a seminal clinical study, Scheffer and Berkovic (58) described an exceptionally large multigenerational family in which typical febrile seizures of infancy and early childhood were common, but a variety of nonfebrile seizure types also occurred. This spectrum of other seizure types represented in the pedigree included nonfebrile convulsions, absences, myoclonic seizures, atonic seizures, and severe myoclonic-astatic epilepsy with developmental delay. Scheffer and Berkovic argued that this heterogeneity represented variable phenotypes associated with the dominantly inherited trait and introduced the term “generalized epilepsy with febrile seizures plus” (GEFS+) to describe the new seizure syndrome. They further noted that such phenotypic heterogeneity would make this syndrome difficult to detect in smaller families, obscuring its frequency in the clinic. They concluded that molecular studies of large pedigrees such as the one they had analyzed might reveal the underlying genetic mechanism(s). Follow-up studies by the authors and others have confirmed all these predictions.

Mutations in four channel genes have thus far been identified in patients with GEFS+. By far the largest numbers of them are in SCN1A, a close relative of SCN2A, also encoding a voltage-gated Na<sup>+</sup> channel pore-forming subunit. In addition, a few mutations have been found in SCN2A, SCN1B (encoding Nav β1, a voltage-gated Na<sup>+</sup> channel single-transmembrane accessory subunit) and GABRG2 and GABRD (encoding gamma-aminobutyric acid [GABA] receptor subunits).

The single mutation identified in Nav beta1, C121W, has been described in two Anglo-Australian pedigrees (59, 60). C121 is located in the extracellular domain of

Nav beta1, where it forms a disulfide bridge that plays a critical role in the proper assembly of the extracellular domain into an immunoglobulin-like folding pattern (61). Nav beta1 subunits have multiple roles, enhancing surface expression of the pore-forming alpha subunits, participating in protein-protein interactions within the extracellular space that are important for channel clustering at key sites such as the nodes of Ranvier, and enhancing rates of channel inactivation (62). Careful biochemical and electrophysiologic studies using coexpression with neuronal alpha subunits in mammalian cells have revealed two rather subtle effects of C121W (63). The mutation prevents protein-protein interactions mediated by the extracellular domain of Nav beta1 and shifts inactivation to hyperpolarized potentials, thereby increasing the number of channels available for opening.

The discovery of a second GEFS+ locus on chromosome 2q (64, 65), a region that harbors a cluster of three genes encoding sodium channel alpha subunits, led to a search for mutations within these genes in GEFS+ pedigrees. Sequencing of patient DNA revealed many different mutations in SCN1A and a single mutation in SCN2A, all resulting in single amino acid substitutions (missense mutations) in the resulting alpha subunit polypeptides (66–70). Interestingly, these studies have revealed a high frequency of partial seizures in members of some pedigrees that otherwise fit the original GEFS+ profile (60, 69, 70). The electrophysiologic properties of many of the mutant alpha subunits have now been studied fairly intensively in heterologous cells. A subset of the mutations show defective inactivation mechanisms, as observed first in studies of the C121W mutation in beta1 discussed in the preceding paragraph. For example, Lossin et al. found three mutations that exhibited a persistent current during prolonged depolarizations due to an apparent failure of inactivation gating (71). However, other mutations seem to show reduced current amplitudes or changes in gating that are predicted to reduce current flow, without a defect in inactivation (72, 73). Thus, only some GEFS+ mutations appear to be associated with enhanced channel activity similar to the mutations in heart and skeletal muscle Na<sup>+</sup> channels that cause disorders of hyperexcitability and excessive synchrony (myotonia, long QT syndrome) in those tissues (74, 75).

This issue has been further complicated by genetic and clinical evidence that an additional epilepsy syndrome, severe myoclonic epilepsy of infancy (SMEI), represents a severe form of the GEFS+ spectrum (76–78). SMEI, first described by Dravet in 1978, is a progressive syndrome of refractory seizures and cognitive decline. After a normal early infancy, patients present with prolonged generalized or unilateral febrile seizures at 5–12 months of age. Other seizure types, including myoclonic, absence, partial, and atonic seizures, begin between 1 and 4 years of age. Psychomotor slowing becomes apparent during the

second year of life, and the patient may also experience obtunded states associated with myoclonus and develop ataxia, pyramidal dysfunction, and refractory generalized tonic-clonic and partial seizures. Intellectual outcome is generally poor. Although a family history of epilepsy had been previously recognized as common in SMEI, the nature of the seizure disorder in family members had not been systematically explored until recently. Singh et al. (76) described 12 SMEI pedigrees within which other family members exhibited forms of epilepsy consistent with the GEFS+ spectrum. Subsequent screening of additional SMEI patients for mutations in SCN1A has identified more than 100 additional mutations. The majority of SMEI mutations are de novo frame-shift, nonsense, or splice-donor mutations predicted to result in markedly aberrant, truncated forms of the channel protein. In contrast to the modest changes in gating seen with GEFS+ mutations that cause single amino acid changes, the SMEI truncations would be expected to produce proteins incapable of conducting ions. Most recently, an additional clinical syndrome, intractable childhood epilepsy with generalized tonic-clonic seizures (ICEGTCs), which is quite similar to SMEI except that patients do not show myoclonic seizures, has also been shown to result from mutations in SCN1A (79).

These clinical and genetic observations are perplexing and lead to many questions concerning genotype-phenotype relations in the GEFS+/SMEI patients. How could gain-of-function mutations (i.e., the impaired inactivation seen in some GEFS+ patients) cause a mild syndrome, if loss-of-function mutations cause a severe phenotype (in SMEI and ICEGTCs). Cell biologic studies are beginning to shed light on this. In early studies, SCN1A was described as widely expressed by excitatory and inhibitory neurons, with Nav1.1 proteins observed on neuronal somata and proximal dendrites (80). Very recent experiments are revising this view, however. In hippocampus, both the protein and mRNA are reportedly much more expressed in inhibitory neurons than in excitatory pyramidal cells, leading to the suggestion that the severe phenotype of null mutations reflects a simple loss of inhibition (81). Furthermore, careful immunohistochemical studies have revealed Nav1.1 channels clustered in the initial segments of some cortical interneurons (82).

In short, the localization and relative importance of various subpopulations of Na<sup>+</sup> channels is incompletely understood but is rapidly being addressed by current studies. Studies using transgenic mouse models that allow mutant channels to be studied *in vivo* are critical to future success, as are correlative studies of channel distribution in human tissue.

Screening of large clinical populations suggests, however, that amino acid coding mutations in SCN1A, SCN2A, and SCN1B account for only about 20% of familial cases of GEFS+ and a far lower percentage of cases of idiopathic

generalized epilepsy (67, 68). This implies that other genes may be involved, and the search has begun. Recently, mutations in the GABRG2 and GABRD genes, which encode the gamma2 and delta subunits of the GABA<sub>A</sub> receptor, were also identified as causes of GEFS+ (83, 84). GABA<sub>A</sub> receptors are ligand-gated Cl<sup>-</sup> channels (85). GABA released at inhibitory synapses binds to sites on the extracellular side of the channel, leading to channel opening and Cl<sup>-</sup> influx and generating a fast inhibitory postsynaptic potential (IPSP). There are 16 human genes for subunits of GABA receptors: alpha1–6, beta1–4, gamma1–3, delta, epsilon, and theta. Each GABA receptor is a pentameric complex consisting of two alpha subunits, two beta subunits, and single subunit of class gamma, delta, epsilon, or theta. Although receptors containing a variety of different subunit combinations are represented *in vivo*, the most abundant and widely distributed form of the receptor is formed by alpha1, beta2, and gamma2 subunits. The known gamma2 subunit mutations range widely in the severity of their effects on channel function and the associated clinical phenotype. One mutation (R43N), found in a pedigree with a relatively mild seizure phenotypes (febrile seizures and childhood absence epilepsy), introduces a point mutation in the site for channel modulation by benzodiazepines such as diazepam and lorazepam (86). R43N mutant channels expressed in *Xenopus* oocytes exhibited only 10% reductions in GABA current amplitudes, though responsiveness to benzodiazepines was abolished completely. A second missense mutation (K289M), in an extracellular loop between the M2 and M3 transmembrane segments, was associated with a ~90% reduction in GABA currents and a more severe phenotype of febrile seizures and afebrile generalized tonic-clonic seizures (83). Finally, a truncation mutation in GABRG2 was found in a patient with SMEI within a branch of a large GEFS+ pedigree with bilineal inheritance of epilepsy (87). When expressed in oocytes or cultured mammalian cells, this truncation mutation (Q351X) acted as a potent dominant negative, coassembling with normal GABA receptor subunits and preventing them from leaving the endoplasmic reticulum (87). Beyond these direct effects on GABA receptor functioning, three of the GEFS+ mutations has been shown to impair channel transport to the membrane when expressed in cells maintained at elevated temperature (40°C); by contrast, wild-type channels did not show temperature dependence (88).

Very recently, a fourth GABRG2 mutation was found in a small pedigree with febrile seizures and no other forms of epilepsy (89). The mutation described (R139G) was located in the extracellular portion of the subunit, near the location where benzodiazepines bind and thereby enhance channel openings. R139G had a slight effect on function, speeding the rate of channel closing after an opening elicited by GABA. Although the

number of families is very small, so far there is a direct correlation between the severity of epilepsy and the severity of the effects on channel gating observed in the four known GABRG2 mutations.

A single GEFS+ pedigree with four affected patients has been linked to a mutation in GABRD. Channels including the delta subunit encoded by GABRD are located at nonsynaptic sites on the soma and dendrites (90). Although delta-containing receptors are present at low density, they make important contributions to regulation of neuronal responsiveness because of their long-lasting openings (91).

*Recessive Cortical Dysplasia—Focal Epilepsy Syndrome (CDFE; OMIM 610042).* An Amish family was described in which 9 children were affected by a syndrome of cortical dysplasia, focal epilepsy, relative macrocephaly, and diminished deep-tendon reflexes (92). Intractable focal seizures began at 14–20 months of age. Subsequently, autism-like features, including language regression, hyperactivity, impulsive behavior, and mental retardation, developed in all children. Attempts to treat the refractory epilepsy by surgical removal of focal dysplastic cortical regions did not prevent the recurrence of seizures. Pathologic studies of dysplasias showed abnormal neurons, altered neuronal migration, and gliosis. All affected children were found to be homozygous for a mutation in CNTNAP2, encoding the protein contactin-associated protein-like 2 (Caspr2). Caspr2 is a single transmembrane protein possessing a large extracellular domain with multiple protein-protein interaction modules. Remarkably, Caspr2 is localized on axonal membranes at the axon initial segments and the nodes of Ranvier (93, 94). Caspr2 is required for targeting the Kv1 subclass of voltage-gated potassium channels to these important axonal subdomains (95–97).

The Kv1 channel pore-forming subunits are encoded by KCNA genes. Six genes, KCNA1–6, are known to be expressed in the CNS, produced by gene duplication from a single ancient, ancestral gene. Indeed these genes are the homologs of a single fly gene, called *Shaker*. Flies with mutations in *Shaker* are hyperactive when undisturbed and, if exposed to low levels of anesthetic vapors, develop rapid shaking movements of their wings, legs, and abdomen that prevent normal behavior (98). Recordings from *Shaker* flies show failure of action potentials propagated along neuronal axons to repolarize normally (99). In mammals, the role played by Kv1 channels on axons undergoes a developmental switch during myelination (96, 100). Kv1 channels arrive near the node as it begins to form, and they play a key role in axonal action potential repolarization during the early stages of myelination. Once myelination is complete, Kv1 channels have a diminished role at nodes, because they are sequestered beneath the myelin sheath. However, they

are also present on unmyelinated portions of the axon both proximally (i.e., the initial segments) and distally (at presynaptic terminals), and in these locations they contribute to control of initiation and neurotransmitter release (93, 101). The basis for epilepsy based on recessive inheritance of Caspr2 mutations is not established, but the connection with axonal excitability is particularly provocative in view of the better-established axonal roles of Nav and KCNQ subunits mutated in neonatal and infantile forms of epilepsy. This family study is also the first human example of recessive inheritance of epilepsy involving channel regulation. A large number of recessive epileptic channelopathies have been identified in inbred strains of laboratory mice (102); the relative lack of such mutations detected in human epilepsy reflects the uncommonness of consanguinity required for the rare pathogenic mutations to become symptomatic, and the difficulty of identifying mutations in small families.

*Axonal Hyperexcitability: An Emerging Theme in the Hereditary Epilepsies of Neonates and Infants.* From the foregoing discussion, it is clear that recent evidence has linked KCNQ channels, Nav1.2, Nav1.1, and Caspr2 mutations to forms of epilepsy involving neonates and/or infants. In parallel, cell biologic studies have revealed that all of these proteins have major roles in regulation of intrinsic axonal excitability in the developing nervous system. It seems clear that in these early-onset forms of epilepsy, disturbance of the ion channels that mediate the actual initiation and firing of action potentials is centrally important. It is not yet known why, for example, mutations in KCNQ2 should cause onset of seizures at an earlier age than mutations in Nav1.2. Further experiments should help to clarify the specific age-dependent phenotypes associated with various mutations and, in the process, the precise functions played by these channel types.

### Channel Mutations in Epilepsies with Onset In Childhood and Adolescence

*Autosomal Dominant Nocturnal Frontal Lobe Epilepsy (ADNFLE; OMIM 600513).* In 1994, Scheffer et al. described a new epilepsy syndrome characterized by clusters of brief nocturnal motor seizures (103, 104). The attacks began in childhood (median age 8 years) and persisted throughout life, often misdiagnosed as night terrors, nightmares, hysteria, or paroxysmal nocturnal dystonia. Video-EEG recordings revealed that the nocturnal attacks were epileptic seizures heralded by frontally predominant sharp- and slow-wave activity (104), usually arising from stage 2 non-REM sleep. In spite of improved understanding of the disorder, clinical differentiation from parasomnias and other paroxysmal disorders

of sleep can be challenging and may require video-EEG monitoring and polysomnography (105, 106).

Initial analysis of ADNFLE pedigrees suggested autosomal dominant inheritance with incomplete (~70%) penetrance. Subsequent molecular genetic studies have revealed mutations in genes for three subunits of neuronal nicotinic acetylcholine receptors (nAChRs) in affected individuals: CHRNA4 on chromosome 20, CNRNB2 on chromosome 1, and CHRNA2 on chromosome 8 (107–111).

Central nAChRs are pentameric cation channels, closely related to the well-studied nAChRs at skeletal muscle endplates, but are composed of alpha and beta subunits expressed only (or at least, primarily) by neurons. Binding of acetylcholine to sites on alpha subunits leads to channel opening and membrane depolarization. Although there are distinct genes for seven neuronal nAChR alpha subunits and three beta subunits, heteromeric channels formed by coassembly of alpha4 and beta2 subunits appear to be the most abundant form expressed in brain. The subunits share a common basic structure, with a large, extracellular amino-terminal domain and four transmembrane alpha-helices. The second (M2) helix lines the transmembrane ion pathway and is believed to undergo a twisting conformational change after acetylcholine binding that allows ions to flow.

The ADNFLE mutations in alpha4 or beta2 described so far all result in single amino acid changes at key positions within the pore-lining helices and might therefore be expected to cause changes in gating or ion conductance properties. Indeed, electrophysiologic experiments using the mutant subunits expressed in experimental cells such as *Xenopus* oocytes or mammalian cultured cells have revealed marked, albeit complex, changes in these properties (108, 112, 113). The  $\alpha 4$  S248F mutant AChR responses showed faster desensitization, slower recovery from desensitization, less inward rectification, and virtually no  $\text{Ca}^{2+}$  permeability as compared with wild-type  $\alpha 4/\beta 2$  AChRs (112). Although these effects would all tend to reduce channel activity, this mutation also caused use-dependent up-regulation of activity and was more strongly activated by low levels of agonist, effects that might result in enhanced activity in vivo. Studies of the two known CNRNB2 mutants show differing effects: The V287M mutation shows normal kinetics but 10-fold increased Ach sensitivity (110), whereas the V287L mutation shows normal Ach sensitivity but 30-fold slower kinetics (109). The alpha2 mutation, I279N, is in the first transmembrane segment (M1) that links the extracellular ligand-binding domain to the pore-lining segment (M1). Recordings of transfected cells expressing either the mutant or the wild-type receptor showed that I279N markedly increases the receptor sensitivity to acetylcholine (109).

Immunolocalization studies show that the alpha4 subunit is widely expressed and is localized on neuronal

somata and dendrites in cortical and subcortical structures, and it is particularly highly expressed by dopaminergic neurons in the substantia nigra (114). Labarca et al generated CHRNA mutant mice harboring a point mutation in the pore near the position of the ADNFLE mutations (115). This mutation caused 30-fold increased Ach sensitivity and is partially activated by choline at levels that are normally present in cerebrospinal fluid. Mice exhibited early lethality and loss of nigral dopaminergic neurons. More recently, investigators generated two lines of transgenic mice expressing different ADNFLE mutations and found, paradoxically, a 20-fold increase in nicotine-induced GABAergic *inhibitory* postsynaptic currents in cortical neurons, with no change in excitatory currents (116).

How could increased inhibition lead to seizures? Because cortical GABAergic interneurons project widely to large numbers of neighboring pyramidal cells, they are powerful synchronizers of cortical output. Neurons in basal cholinergic nuclei project to the thalamocortical circuits that mediate transitions between sleep and wakefulness; acetylcholine release in these circuits contributes to arousal and alertness (117). Excessive cholinergic responsiveness during a critical stage of desynchronization of this circuit appears to be sufficient to cause seizures. The frontal lobe predominance of the semiology and epileptic discharges in ADNFLE patients is not explained by the distribution patterns of the receptors, which are widespread, but may reflect the importance of the physiologic contribution made by the frontal lobes to the critical arousal transition that is disrupted in the disorder.

*Episodic Ataxia with Myokymia (and Partial Epilepsy) (EA-1; OMIM 160120).* EA-1 is a dominantly inherited disorder involving both the brain and peripheral nerves (118–120). Patients experience recurrent attacks of unsteady gait and loss of limb coordination lasting minutes to hours. This phenotype suggests an intermittent derangement of cerebellar function. In some cases, transient cognitive deficits accompany the motor symptoms. Attacks may be provoked by a sudden stress or startle. Myokymia is continuously present in many EA-1 patients. This myokymia is unaffected by pharmacologic block at the proximal portion of peripheral nerves but is reduced by distal nerve block and abolished by inhibition of neuromuscular transmission. This observation suggests that, unlike myotonia or epilepsy, myokymia results from abnormal hyperactivity in the peripheral nerve. However, patients with EA-1 have about a 10-fold greater risk of epileptic seizures compared to the general population (118, 121).

In 1994, Browne et al linked EA-1 to missense mutations in KCNA1 (120). KCNA1, one of the mammalian *Shaker* homologs, encodes voltage-gated potassium Kv1.1 channels that, as discussed previously in connection with the severe CDFE syndrome, are targeted to axons by

interaction with Caspr2. Extensive further work, including physiologic studies of the mutant channels, anatomical studies of KCNA channel localization in the central nervous system and peripheral nerve, and studies of knockout and knockin mice, gives useful clues for understanding the basis of the EA-1 phenotype in the brain and peripheral nerve (14). Studies in *Xenopus* oocytes indicate that the mutations causing EA-1 result in reductions in KCNA1 expression and current magnitude (121–123). In some cases, EA-1 mutant channels in heterologous cells exhibit clear “dominant negative” effects, interacting with coexpressed normal channels and preventing them from functioning normally or trafficking to the cell surface. Other EA-1 mutants exhibit simple loss-of-function properties in vitro. As discussed previously, Kv1 family channels have been localized along axons and on presynaptic terminals (101, 124–126). Smart et al. generated knockout mice lacking KCNA1 (127). Interestingly, mice heterozygous for the knockout allele appear normal; this is in contrast to the dominantly inherited effects of EA-1 mutations in humans. Mice that are homozygous for the knockout allele have subtle defects in cerebellar function (128), but the most obvious aspects of their phenotype are very frequent generalized epileptic seizures and associated premature death (127). It has proved difficult to identify the alterations in cellular physiology that cause frequent spontaneous seizures in the Kv1.1 knockout mice; hippocampal slices prepared from the knockouts exhibit remarkably normal intrinsic neuronal and synaptic properties (127). A possible explanation for this was that channels containing the subunit are often localized to small axons and presynaptic termini, which are difficult to study directly using currently available physiologic methods (126). An interesting clue to the pathophysiology of EA-1 is the responsiveness of the condition in some but not all pedigrees to treatment with the carbonic anhydrase inhibitor acetazolamide (129). To further understand the EA-1 phenotype, Herson et al generated knockin mice bearing a human EA-1 point mutation (130). Heterozygous mutant mice exhibited stress-induced loss of coordination that was ameliorated by pretreatment with acetazolamide. Recordings from brain slices suggest that expression of the mutant subunits results in increased neurotransmitter release at presynaptic terminals after invasion by action potentials. Seizures were not reported in the knockin heterozygous mutants, and the homozygous state was lethal early in embryonic development.

As a larger number of patients with EA-1 have been identified, it has become clear that they differ in the severity of their symptoms over a broad spectrum and that more severe forms of the disorder are often associated with epilepsy. Zuberi et al described a family containing five patients with episodic ataxia and myokymia, two of which additionally had partial complex seizures (121). Eunson et al described a second

family with this combination of symptoms, as well as families with severe and acetazolamide-resistant ataxia, or isolated myokymia (131). When studied in heterologous cells, the mutations associated with severe ataxia and epilepsy caused severe reductions in channel activity (132). In some cases, the EA-1 plus epilepsy mutant subunits were capable of dominant-negative interactions with wild-type subunits; that is, they were capable of coassembling with the wild-types, but the resulting channels were hypofunctional because of failure of intracellular trafficking or lack of intrinsic channel activity (132). Trafficking defects are likely to be particularly critical in neurons, because the KCNA channel proteins are normally localized to sites along myelinated and nonmyelinated axons and at presynaptic terminals, which are very distant from their sites of translation and assembly in the endoplasmic reticulum (125, 126, 133).

*Autosomal Dominant Juvenile Myoclonic Epilepsy (JME; OMIM 606904).* JME is characterized by the onset, usually during adolescence, of bilateral single or repetitive myoclonic jerks, occurring most commonly upon morning awakening (134). A majority of patients have at least one generalized tonic-clonic seizure, and about 15% have absences. A characteristic EEG finding is frontally predominant bilateral 4–6 Hz polyspike-wave discharges. JME is not uncommon and represents approximately 4–6% of all patients with epilepsy (134). Nevertheless, identifying genes for JME has been particularly difficult, likely as a result of the genetic heterogeneity and complexity underlying the syndrome. Recently, mutations in genes for a GABA receptor subunit and a subtype of voltage-gated Cl<sup>-</sup> channel were identified.

Cossette et al. ascertained a large family in which epilepsy, with characteristic clinical and electroencephalographic features of common JME, was inherited in an autosomal dominant pattern (135). A missense mutation was found in GABRA1, resulting in an A322D change in a conserved site in the third transmembrane helix of the GABA receptor alpha1 subunit. Two alpha subunits are present in each pentameric GABA receptor; each of these subunits contributes both to a binding site for GABA and to the transmembrane pore. Peak currents mediated by receptors that included the A322D GABA alpha1 mutants were only 10% of those of wild-type receptors, and this weak response required 200-fold higher concentrations of GABA. Accordingly, the epileptic phenotype would be expected to be associated with greatly reduced responsiveness to inhibitory neurotransmission. It is unclear why this mutation results in epilepsy of the JME type.

A genomewide linkage analysis of 130 families with idiopathic generalized epilepsy (IGE) identified a susceptibility locus on chromosome 3q (135). The gene CLCN2, encoding a voltage-gated Cl<sup>-</sup> channel protein

(called ClC-2 or CLC-2), was identified within the linked region and sequenced for mutations in samples from 46 families (137). Three mutations were identified among these families, one in a small family with 5 patients with JME. CLC-2, like other members of the chloride channel family, forms dimeric channel complexes. Heretically, each chloride channel subunit possesses its own transmembrane ion path, and gating of the two pores within each channel is regulated by allosteric interactions within the protein (10). The JME mutation identified in the single family produced a truncated form of the protein that was unable to conduct ions itself or coassemble with wild-type subunits.

*Epilepsy with Grand Mal Seizures on Awakening (EGMA, OMIM 607628) and Childhood Absence Epilepsy (CAE; OMIM 600131).* JME overlaps with another syndrome, termed “awakening epilepsy” or “epilepsy with grand mal seizures on awakening.” Patients with EGMA have difficulty falling asleep, abnormal sleep architecture, and the vast majority of their seizures occur clustered within the first minutes after awakening from sleep (irrespective of the time of day) (138). A CLCN2 mutation encoding a nonfunctional channel was identified in a large family with EGMA (137).

A subset of JME and EGMA patients experience absence spells. A third CLCN2 mutation was found to segregate in a small family in which three children had typical childhood absence epilepsy (CAE) (137). This CAE-linked mutation resulted in a single amino acid change (G715E); mutant channels were reported to be functional but were reported to exhibit altered voltage dependence. This finding has been contradicted by two subsequent investigations showing activity of the mutant indistinguishable from wild type, further weakening the modest genetic evidence provided by the small family studied (10). A more recent survey of 55 families with IGE failed to identify additional CLCN2 mutations (138). At present, the strongest evidence linking CLCN2 to generalized epilepsy is provided by the large EGMA pedigree.

*Autosomal Dominant Partial Epilepsy with Auditory Features (ADPEAF, OMIM 600512).* In 1995 Ottman et al described a large family in which partial seizures associated with unusual auditory auras were inherited in an autosomal dominant pattern linked to a gene on chromosome 10 (140). Several additional families with this distinctive syndrome were subsequently identified (141, 142). The age of seizure onset was typically at 9 to 12 years of age. Seizures are heralded by a variety of stereotyped, but in nearly all cases nonverbal, auditory hallucinations (141). Mutations were subsequently identified in the gene Lgi1, a gene of unknown function previously shown to be disrupted in some patients with primary brain tumors (143). This set in motion efforts

to understand the function of the Lgi1 protein in brain development, auditory processing, and epileptogenesis.

At present, evidence supporting two conflicting models has been described. One set of experiments shows that the Lgi1 protein is physically associated with and enhances the activity of Kv1 family voltage-gated potassium channels whose pore-forming subunits are encoded by the KCNA genes (144). In this model, Lgi1 is a cytosolic protein that binds to the intracellular portion of channels that contain both pore-forming subunits and previously described channel intracellular accessory units, called beta subunits. The beta1 subunit causes Kv1 channels to close after a period of milliseconds of membrane depolarization. This time- and voltage-dependent closing, called inactivation, is similar to the fast inactivation of sodium channels that helps terminate each action potential. However, inactivation of K<sup>+</sup> channels will generally tend to increase neuronal excitability. Wild-type Lgi1 proteins antagonize this inactivation, prolonging channel opening. Mutations derived from ADPEAF patients, which produce truncated proteins, all abolish the ability of the Lgi1 protein to prolong the K<sup>+</sup> channel opening. This model is consistent with previously discussed findings that loss-of-function KCNA1 mutations that cause epilepsy in some patients with EA-1, and mutations in Caspr2 that disrupt Kv1 channel targeting in the recessive focal epilepsy.

The alternative, and very different, model is based on the recent report that Lgi1 protein is packaged in secretory vesicles and released into the synaptic cleft, where it binds tightly to a cluster of proteins linked to postsynaptic glutamate receptors (145, 146). Lgi1 binds directly to ADAM22, and is thereby linked to PSD-95 and stargazin, all of which are components of the excitatory postsynaptic density. Application of soluble Lgi1 proteins to brain slices *in vitro* results in enhancement of alpha-amino-3-hydroxy-5-methylisoxazole-4-propionic acid (AMPA)-type glutamate receptor currents. Lgi1 applied to neurons grown in dissociated culture increases the number of AMPA receptors at the cell surface. Mutations in stargazin and ADAM22 that are capable of disrupting the protein complex are associated with epilepsy in mice (although human mutations in these genes are unknown) (146–148). Effects of Lgi1 mutations on this complex and the implications for receptor function are incompletely known, but the implication is that mutations would tend to reduce postsynaptic excitatory currents.

How can the two proposed functional roles of Lgi1 be reconciled? Immunoblots of proteins separated by sodium dodecyl sulfate (SDS) gel electrophoresis reveal two forms of Lgi1 that differ by 3–5 kDa, indicating that the protein is either alternatively spliced or post-translationally processed (150). Moreover, the larger form localizes to the cytoplasm, whereas the smaller is found in a microsomal fraction containing secretory vesicles. Although it

is not clear which form is most important for epilepsy, hippocampal and cerebellar cortex (areas with particularly high densities of AMPA-type glutamatergic synapses) showed predominantly the smaller, presumed secreted form. The highest percentage of the cytosolic, high-molecular-weight form was present in temporal neocortex (150). This result favors the idea that the cytoplasmic interaction with potassium channel contributes to the auditory auras and seizures in ADPEAF, but additional studies are needed.

*Generalized Epilepsy with Paroxysmal Dyskinesias (OMIM 609446).* Clinical studies have noted patients, sometimes in familial groups, with a combination of generalized epilepsy and paroxysmal dyskinesia (151, 152). Du et al. described an unusual family with 16 affected individuals in five consecutive generations, strongly indicating dominant inheritance. Seven had paroxysmal non-kinesogenic dyskinesias, four developed epilepsy only, and five exhibited both symptoms. The symptom onset age ranged broadly from 3 to 15 years, with one patient developing seizures before 6 months. After establishing linkage to chromosome 10, the investigators identified a mutation in KCNMA1, which encodes a pore-forming alpha subunit of a type of calcium-activated potassium channel called BK (“Big-K”; also “Maxi-K”) because these channels pass ions at higher rates than other K<sup>+</sup> channel types. BK channels are activated synergistically by membrane depolarization and elevated intracellular Ca<sup>2+</sup> (1). Their opening rates are very fast, enabling them to speed repolarization of action potentials, shortening the sodium channel refractory period and thereby facilitating rapid neuronal bursting. The pathogenic mutation in BK identified increases channel activity (153). Interestingly, a knockout mutation in a BK accessory subunit has also recently been shown to cause epilepsy in transgenic mice (154). Careful electrophysiologic analysis of these mice indicates that this mutation also increases the activity of BK, leading to increased neuronal firing. The detailed biophysical mechanism whereby excitability is increased in the mice is intriguingly indirect. First, the enhanced BK activity and associated shortened action potential duration causes a reduction in Ca<sup>2+</sup> entry during each spike. This diminishes the activation of a second type of Ca<sup>2+</sup>-activated K<sup>+</sup> channel, known as SK (“small-conductance K<sup>+</sup> channel”). Despite their name, SK channels very potently limit excitability by means of their long-lasting openings. So preventing SK activation (by increasing BK openings) leads to markedly increased cellular excitability. In effect, the cell must balance BK and SK activity precisely to maintain the desired overall level of excitability. This elegant electrophysiologic analysis again illustrates the importance of transgenic mouse models for current studies of the epileptic channelopathies, and it begins to hint at how very indirect the effects of a mutation can be.

## CONCLUSIONS AND IMPLICATIONS FOR THERAPEUTICS

Although the first identification of a channel gene mutation in epilepsy occurred only in 1994, many such mutations have now been identified in 15 different channel subunits and channel-associated proteins. What do these efforts reveal about the causes of epilepsy and potential for novel treatments? One remarkable result is that many of the mutations have been found in subunits of voltage-dependent Na<sup>+</sup> channels and GABA receptors, important targets of the majority of currently approved drugs, all developed through in vivo pharmacologic screening. Many (but not all) Na<sup>+</sup> channel mutations in GEFS+, for example, result in increased Na<sup>+</sup> channel activity; by contrast, such drugs as phenytoin, carbamazepine, and lamotrigine act by blocking Na<sup>+</sup> channel activity. Similarly, in autosomal dominant JME and some cases of GEFS+, mutations in GABA receptor subunits that reduce activity are implicated, whereas benzodiazepines and barbiturates potentiate GABA receptor activity. This is satisfying, but is also potentially a cause for concern. If genetics were only to lead us back to the therapeutic targets we know about, it would be informative but of little practical use. In this regard, the stories of the identification of the KCNQ channel mutations in BFNS, nicotinic acetylcholine receptor mutations in ADNFLE, and Lgi1 mutations in ADPEAF are exciting and reassuring counterexamples. The neuronal KCNQ channels and the functions of Lgi1 regulating K<sup>+</sup> channels and glutamate receptors were unknown before these mutations led to the recent mechanistic studies discussed in this chapter. It seems possible that a new class of KCNQ opener drugs may be developed, with patterns of clinical usefulness that are quite different from available agents. The Lgi1-dependent augmentation of K<sup>+</sup> channel activity is another potential target for future drug development. As neurobiologic studies allow us to understand the mechanistic pathways through which individual mutations lead to seizures, additional targets will be revealed beyond the mutated gene itself. An example of this is the unexpected observation that nicotinic receptor mutations in ADNFLE may cause seizures through enhanced inhibition during arousal from deep sleep. Interestingly, low doses of picrotoxin, a GABA antagonist that is strongly convulsant at higher doses, blocked epileptiform EEG activity and

spontaneous seizures in transgenic mice bearing ADNFLE mutations (116).

Although many aspects of genotype-phenotype relationships remain poorly understood, recent years have brought considerable progress, encouraging optimism that the pathogenic mechanisms in these disorders can be understood in detail. Examples of such progress are the identification of the role for KCNQ channels in setting thresholds by targeting to the axonal spike initiation zone, the discovery that SCN1A subunits are preferentially expressed on inhibitory interneurons, and the analysis showing how KCNM1 mutations increasing the activity of BK channels can paradoxically increase neuronal excitability (30, 81, 155). However, it remains unclear whether, in GEFS+ families, the variable phenotype seen within pedigrees may reflect differences in genetic background between individuals, environmental exposures, or both. The spectrum of phenotypes associated with SCN1A mutations, ranging from normal gene carriers or patients with only FS in GEFS+ pedigrees to SMEI patients with severe refractory seizures and progressive motor and cognitive decline, is impressive and requires further study. It remains unclear whether the more severe phenotypes in GEFS+ pedigrees and SMEI should be seen as a part of the GEFS+ spectrum, since they are almost certainly associated with secondary changes in brain structure and function (e.g., cell death, network reorganization, changes in the levels of expression of other channels and signaling proteins) that do not occur in mildly affected individuals. Finally, as pathogenic mechanisms in these Mendelian forms of epilepsy become clearer, efforts will focus on understanding to what extent these mechanisms contribute to the common, non-Mendelian forms of epilepsy. Already, the epileptic channelopathies fit poorly with our traditional classification of the epilepsies as idiopathic (i.e., hereditary, with normal function except for seizures) versus symptomatic (associated with cognitive, motor, and other deficits). Not only can different mutations in the same channel cause varying degrees of impairment—the same mutation can have variable effects within a pedigree.

Resolving these and unforeseen questions arising with the identification of novel epilepsy mutations should be extremely fruitful both in terms of a better understanding of basic mechanisms underlying seizures and epileptogenesis and for drug development.

## Metabolic and Pharmacologic Consequences of Seizures

*Michael V. Johnston  
John W. McDonald*

The electrical discharge of neurons associated with seizure activity stimulates a marked rise in cerebral metabolic activity. Estimates from animal experiments indicate that energy utilization during seizures increases by more than 200 percent, while tissue adenosine triphosphate (ATP) levels remain at more than 95 percent of control, even during prolonged status epilepticus (1, 2). Cerebral metabolic activity can be measured using 2-deoxy-2-[<sup>18</sup>F]-fluoro-D-glucose positron emission tomography (FDG PET) (3), and magnetic resonance spectroscopy (MRS) can be used to measure the turnover of glutamate, the major excitatory neurotransmitter (4). Comparison of FDG PET and MRS in patients with seizures indicates that glucose metabolism and the turnover of glutamate are tightly coupled (3). This is because the transporters that remove glutamate as well as gamma-aminobutyric acid (GABA), the major inhibitory neurotransmitter, from the synaptic cleft require substantial energy (5). These transporters are located on astroglia that surround synapses, and they remove glutamate and GABA soon after their release from presynaptic nerve terminals to terminate their activity. The transporters are linked to a Na<sup>+</sup>/K<sup>+</sup>-ATPase, which in turn is powered by anaerobic metabolism of glucose (4). The brain generally withstands the metabolic challenge of seizures quite well because enhanced cerebral blood flow delivers

additional oxygen and glucose. Mild to moderate degrees of hypoxemia that commonly accompany seizures are usually harmless. In addition, the immature brain is less vulnerable to injury from seizures than the adult brain (6, 7). However, status epilepticus can sometimes produce an imbalance between metabolic demands and cerebral perfusion, especially if severe hypotension or hypoglycemia is present. Injury can also occur through a direct effect on synapses known as excitotoxicity (8, 9).

Excitotoxicity refers to a process of injury triggered by excessive activation of neuronal receptors for the excitatory amino acid (EAA) neurotransmitters glutamate and aspartate. Under normal circumstances, activation of EAA receptors mediates more than half of the neuronal communication in the brain (10). Seizures initiate release of EAA neurotransmitters from nerve terminals into the synaptic cleft, where they bind to specific neuronal receptors and cause postsynaptic excitation. In the developing brain, EAA receptors serve an additional role as regulators of neuronal development (11). During a prolonged seizure, if the EAA neurotransmitter release continues unabated to raise the synaptic concentration of glutamate, excessive EAA receptor stimulation may damage and eventually kill neurons.

An important component of the excitotoxicity theory holds that EAAs cause intracellular calcium overload, which intoxicates neurons (12–14). Calcium

and sodium are allowed to enter neurons through pores or ionophores controlled by EAA receptors. The concentration of calcium within the neuron is normally 10,000 times lower than in the extracellular fluid, and calcium entry is tightly controlled. The neuron has several mechanisms for protecting itself from excessive calcium influx, including sequestration of calcium within mitochondria and endoplasmic reticulum and energy-dependent pumps that move calcium outward across the cell membrane. Continued bombardment of the neuron by EAA neurotransmitters can overwhelm these protective mechanisms, allowing calcium to poison the metabolic machinery of the neuron (15). The EAA theory proposes that excitatory neurotransmitters are a major direct link between excessive seizure activity and neuronal injury; however, metabolic derangements such as hypoxia may play a contributing destructive role by reducing the efficiency of energy-dependent protective mechanisms and hastening EAA-stimulated metabolic exhaustion (16).

### PHARMACOLOGY OF EXCITATORY AMINO ACID RECEPTORS

Glutamate is released from presynaptic nerve terminals, but the synaptic concentration is quickly reduced by an active reuptake process mediated by its specific, energy-dependent reuptake pump. Impairment in the activity of the EAA reuptake pump may play an important role in EAA neurotoxicity in disease states. In experimental hypoxia-ischemia, synaptosomal uptake of glutamate is transiently reduced, contributing to marked elevations in extracellular glutamate concentrations, which may reach the micromolar range (17). Metabolic disorders may contribute to EAA neurotoxicity by this mechanism.

The excitatory responses to glutamate are mediated by several receptor subtypes that may be classified into two broad categories as either N-methyl-D-aspartate (NMDA)-type or non-NMDA-type EAA receptors (18, 19) (Figures 4-1 and 4-2). Glutamate is a relatively flexible amino acid molecule that can assume several different conformations, and NMDA is a rigid glutamate analog that represents one of them (20). NMDA maximally activates a glutamate receptor that is linked to an ion channel. Together the receptor and its channel are referred to as the NMDA receptor/channel complex (see Figure 4-1). Molecular cloning of NMDA receptors showed that their diverse characteristics are related to variations in specific combinations of subunits (21). The NMDA channel is permeable to cations such as sodium and calcium, and at normal membrane potential the channel is blocked by magnesium ions (22). Partial depolarization of the membrane potential is necessary for the magnesium block to be removed. As a result, the NMDA receptor/channel

FIGURE 4-1

Current understanding of the components of the NMDA receptor/channel complex, based on biochemical and electrophysiological evidence, is outlined in this schematic diagram. The NMDA recognition site is coupled to a cationic channel that is permeable to  $\text{Ca}^{2+}$  and  $\text{Na}^{+}$ . NMDA receptor activation is modulated by several regulatory sites. Activation of a closely associated glycine recognition site is required for channel activation and markedly enhances responses to NMDA. Physiological concentrations of  $\text{Mg}^{2+}$  block the NMDA-associated ionophore, and membrane depolarization relieves this blockade. Thus, NMDA receptor/channel activation requires activation of both NMDA and glycine receptors and concurrent membrane depolarization. NMDA-receptor channel activation also can be modulated by  $\text{Zn}^{2+}$  and polyamines (not illustrated). Noncompetitive NMDA receptor antagonists, such as phencyclidine and its thienyl derivative TCP, block NMDA responses by binding within the NMDA-operated ionophore. Cerebral events that impair the mechanisms that regulate  $\text{Ca}^{2+}$  homeostasis can produce a prolonged elevation of intracellular  $\text{Ca}^{2+}$  concentration and cytotoxicity.

complex is not generally involved in ordinary rapid impulse flow.

Several antagonists of the NMDA receptor/channel complex have been developed, some of which block the NMDA receptor (competitive NMDA antagonists) and others that block the associated cation channel (noncompetitive antagonists). Drugs such as 3-(2-carboxypiperazin-4-yl)-propyl-1-phosphonic acid (CPP), CGS-19755, and 2-amino-5-phosphonovaleric acid (AP5) are competitive blockers at the NMDA receptor (23). The channel binding site is sometimes referred to as the phencyclidine receptor. Two potent preclinical noncompetitive channel-blocking drugs are MK-801 and phencyclidine (24, 25). The clinically approved anesthetic ketamine (26) and the antitussive dextromethorphan (27), as well as the anticonvulsant felbamate, are also NMDA channel blockers. Memantine, an "un-competitive" NMDA channel blocker, has recently been approved by the Food and Drug Administration for use in Alzheimer disease. It differs from noncompetitive NMDA blockers in that it binds more avidly to open channels, rather than indiscriminately blocking all channel conformations (28). This

FIGURE 4-2

This schematic diagram outlines the synaptic components that contribute to EAA-mediated synaptic transmission, second-messenger generation, and calcium homeostasis. (1) EAAs such as glutamate are released from presynaptic terminals in a calcium-dependent process by presynaptic depolarization. (2–4) Glutamate in the synaptic cleft depolarizes the postsynaptic membrane by binding to at least three subsets of EAA receptors. Activation of (2) the NMDA receptor/channel complex, (3) AMPA receptors, and (4) kainate receptors, produced calcium ( $\text{Ca}^{2+}$ ) and sodium ( $\text{Na}^+$ ) entry through receptor-associated ionophores. Furthermore, activation of a subset of metabotropic receptors that are linked to phospholipase C produces phosphoinositol hydrolysis and generation of the second messengers inositol triphosphate and diacylglycerol. (5) The excitatory action of synaptically released EAA is terminated by a presynaptic, high-affinity, energy-dependent transport process.

mechanism may be associated with fewer psychotomimetic side effects than are associated with more complete channel blockade.

The NMDA receptor/channel complex also includes several regulatory sites. One receptor is specific for the simple amino acid glycine (29, 30). Unlike the inhibitory glycine site in the spinal cord, this site is not sensitive to strychnine, and activation facilitates opening of the

NMDA channel by glutamate. Recognition sites for zinc and polyamines also appear to regulate NMDA receptor/channel complex activity (13). Drugs that block the glycine site on the NMDA receptor are being developed to attempt to avoid the psychotomimetic side effects of noncompetitive NMDA antagonists (31). Non-NMDA receptors were initially identified because they were activated preferentially by the glutamate analogs quisqualic

acid and kainic acid (19). Kainic acid is a very potent neurotoxic and convulsant agent in the adult brain (32, 33). Currently, two major types of non-NMDA receptor are recognized: one that is linked to an ion channel that fluxes sodium and to a lesser extent calcium, and another that is linked to stimulation of phosphoinositide (PPI) turnover or downregulation of cyclic-AMP production (20). The so-called ionotropic non-NMDA receptors are now divided into kainate receptors and AMPA (alpha-amino-3-hydroxy-5-methyl-4-isoxazole propionate) receptors. Molecular studies indicate that these two receptors have similar molecular characteristics, with AMPA receptors made up from combinations of GluR1-4 receptor subunits, and kainate receptors made up of GluR5-7 subunits. AMPA receptors mediate most of the fast excitatory activity in the brain, and they include most of the receptors previously referred to as quisqualate receptors (20). The anticonvulsant topiramate is an AMPA receptor blocker. Kainate receptors stimulate presynaptic release of glutamate as well as activating postsynaptic receptors. The glutamate receptors linked to second messengers are called metabotropic receptors. A marked increase in glutamate release, which occurs during a prolonged seizure, is likely to result in the activation of all types of glutamate receptors.

### DEVELOPMENT OF EXCITATORY AND INHIBITORY SYNAPTIC MARKERS

Synaptic markers for EAA neurotransmitters undergo marked changes during postnatal development (34–37). Studies of the ontogeny of NMDA and AMPA-sensitive receptor subtypes during postnatal development indicate that NMDA-type and non-NMDA-type glutamate receptors have a unique ontogenetic profile in the hippocampal formation (37). When receptors for NMDA-sensitive  $^3\text{H}$ -glutamate binding, strychnine-insensitive glycine binding, and  $^3\text{H}$ -N-(1[2-thienyl]cyclohexyl)3, 4-piperidine (TCP) binding to the channel were examined independently, all were found to be overexpressed in the neonatal period relative to the adult. NMDA-sensitive binding exceeded adult levels by 50 to 120 percent in all regions of the hippocampus examined, with peak densities occurring between postnatal days 10 and 28. The ontogenetic profiles of the glycine modulatory site and the phencyclidine receptor were similar to each other but were delayed with respect to the timing of the NMDA recognition site. The physiologic relevance of overexpression of NMDA recognition sites relative to other components of the NMDA receptor/channel complex is unclear. However, the temporal expression of NMDA recognition sites correlates with the molecular changes in receptor subunits and synaptogenesis (38–40). Studies of NMDA receptors in human cerebral cortex in early life have also

demonstrated enhanced levels and different characteristics compared to adults (39, 41).

The ontogeny of NMDA receptor binding also appears to correlate with physiologic changes. Long-term potentiation, a synaptic correlate of memory, is enhanced during the neonatal period in rats, at the same time that NMDA-mediated neurotransmission predominates over AMPA-mediated activity (42). Postsynaptic excitation appears to predominate over inhibition during the first postnatal weeks of hippocampal development, as does enhanced seizure susceptibility (43). In CA3 of the hippocampus, superfusion with NMDA elicits recurrent synchronized burst activity, and the epileptogenic effect of NMDA increases from postnatal days 1 to 10 (44). Also, the susceptibility to epileptiform activity increases from postnatal days 4 to 6 to postnatal day 14 (45). This activity is blocked by specific NMDA receptor antagonists (46). The development of NMDA receptors tends to lag behind the development of sensitivity to NMDA neurotoxicity, which transiently peaks on day seven.

AMPA receptors also undergo developmental changes that make them more calcium permeable and more likely to mediate seizures and excitotoxicity in infancy and childhood (47). AMPA receptors that lack GluR2 subunits are calcium permeable, while AMPA receptors that include GluR2 subunits flux only sodium. Jensen and colleagues have studied the development of AMPA receptor subunits in rats and human postmortem tissue and found a correspondence between the expression of GluR2-lacking receptors and regional susceptibility to brain injury and seizures (48–50). GluR2-lacking AMPA receptors appear first in radial glia and oligodendrocytes in the periventricular white matter at 25–32 weeks gestation in humans (49). Their expression is delayed to around 40 weeks gestation in pyramidal neurons and nonpyramidal neurons of the cerebral cortex, persisting into early infancy and beyond in selected regions (49). These ontogenetic changes in AMPA receptors are consistent with experimental evidence that AMPA-receptor antagonists provide protection against seizures and damage at these stages in development (51).

The development of markers for GABAergic inhibitory synapses also undergoes major changes in the postnatal period and tends to lag behind development of excitatory synapses (52–54). GABA<sub>A</sub> receptor antagonists cause prolonged seizure-like discharges in the hippocampus of 2–3-week-old rats (43). However, during early life, extending to the end of the first week postnatal in rats, stimulation of GABA<sub>A</sub> receptors paradoxically produces excitation rather than inhibition, as a result of a lag in the development of the chloride KCC2 transporter, which maintains low intracellular Cl<sup>-</sup> levels (55–58). Without this transporter, high concentrations of Cl<sup>-</sup> accumulate within the dendrite, resulting in depolarization when the

Cl<sup>-</sup> channel is opened by GABA. This is consistent with the theme that excitatory neurotransmission is enhanced early in development to support activity-dependent neuronal development and plasticity and becomes more balanced with inhibitory neurotransmission later in life (59). These developmental programs contribute to the higher incidence of seizures in infants and children.

### DEVELOPMENTAL CHANGES IN GLUTAMATE NEUROTOXICITY

The immature brain is quite sensitive to neurotoxicity from glutamate and certain of its analogs (33, 60). Olney discovered a number of years ago that feeding monosodium glutamate to neonatal mice produced characteristic lesions in the hypothalamus (33). More recently, it has become clear that the receptors that mediate glutamate neurotoxicity respond differently in the immature brain compared with the adult brain. These observations have important implications for the EAA neurotransmitter hypothesis of epileptic brain injury in children.

In adults, kainic acid is the most potent neurotoxic analog of glutamate, but in neonatal rodents NMDA is the most toxic analog (60–62). Although kainic acid produces seizures in the immature brain, it produces little cytotoxicity (63). In contrast, NMDA injected into the 7-day-old rat brain produces prolonged seizures and extensive neurotoxicity. At 7 days of age, the relative neurotoxicity of several glutamate analogs is NMDA >>> AMPA > kainic = zero, whereas in the adult kainic acid >> NMDA ≥ AMPA. The severity of brain injury produced by direct injection of NMDA into the 7-day-old rat brain is approximately 60 times greater than in the adult (60). There is a relatively sharp peak of sensitivity to NMDA neurotoxicity at 7 days of age in the rat, with less sensitivity at times before and after, suggesting a potentially important effect of age on sensitivity to EAA-mediated injury. The shift in sensitivity to NMDA neurotoxicity parallels developmental changes in genetic expression of NMDA subunits that make up the receptor channel complex (40, 64). These changes appear to be programmed to mediate activity-dependent neuronal plasticity during early development (11). NMDA receptor activity is needed to promote normal development, and excessive blockade of these receptors leads to neuronal apoptosis (65). The NMDA receptor is a potential Achilles heel for the developing brain: both overstimulation and blockade can produce damage under certain circumstances (11).

The susceptibility of the developing brain to NMDA-induced brain injury parallels the susceptibility to hypoxic-ischemic brain injury. Olney's studies suggest that the acute neurohistologic picture of NMDA-induced injury in the 7-day-old rat brain is virtually identical to

that from a hypoxic-ischemic injury at the same age (66). NMDA may induce metabolic changes similar to hypoxia-ischemia. Studies using <sup>31</sup>P MRS in brain slices indicate that NMDA produces a rapid exhaustion of phosphocreatine stores and nucleotide triphosphate levels following its application (67). The noncompetitive antagonist MK-801 protects against hypoxic-ischemic damage in the 7-day-old rat brain (68). These studies suggest that overactivation of NMDA receptors may be a final common pathway for hypoxic-ischemic injury, as well as other types of developmental brain injury.

### EVIDENCE THAT EAA NEUROTRANSMITTERS PLAY A ROLE IN SEIZURE-RELATED INJURY

The link between excessive EAA neurotransmitter activity and epileptic brain injury was initially strengthened by Meldrum's pioneering studies in subhuman primates (9). These studies showed that seizures alone could damage the brain and that the EAA analog kainic acid produced sustained seizures and brain injury with a regional histologic pattern resembling epileptic brain injury. Similar studies of selective injury in the hippocampus from kainic acid injection into the brain have been performed in rodents by Nadler and colleagues (69). Two additional models in adult animals have also provided additional, more direct experimental evidence.

In experiments conducted by Sloviter, electrical stimulation of the perforant pathway that projects into the hippocampus from the entorhinal cortex leads to neuronal degeneration in hippocampal zones innervated by perforant pathway fibers (70). The perforant pathway is the major excitatory glutamatergic afferent pathway into the hippocampus (71). The acute neuropathologic changes produced by the persistent stimulation resemble the histopathology seen when glutamate analogues or other convulsant substances are injected into the hippocampus (72).

The pathology replicates the typical "epileptic" pattern of injury with damage to dentate basket cells, hilar cells, and CA3 and CA1 pyramidal cells of the hippocampus. CA2 neurons are typically spared. Electron microscopy shows acutely swollen dendritic segments distributed in a laminar pattern corresponding to the neuronal-receptive fields of EAA pathways in the perforant projection. Somatostatin-containing neurons are especially vulnerable, whereas GABA neurons are relatively spared (73).

In a second model of epileptic brain injury developed by Collins and Olney, persistent focal seizure activity is induced by focal application of the GABA receptor-blocking drug bicuculline onto the cerebral cortex (8). The seizure activity causes acute neurodegenerative changes in specific thalamic regions innervated by the

corresponding corticothalamic pathway. This model also produces acute neuropathologic changes that resemble glutamate-like neuronal degeneration. Using this model, Olney's group demonstrated that ketamine and MK-801, two powerful blockers of the action of NMDA-type EAA receptors, completely abolish the thalamic damage caused by the focal seizure activity (74). MK-801 reduced but did not prevent the electrical seizure activity itself, suggesting that the neuroprotective action resulted from blockade of NMDA-type EAA receptor activation rather than from a reduction in neurotransmitter release. The results of these experiments, along with the electrical stimulation studies, support the hypothesis that EAA receptor stimulation plays an important role in seizure-induced neuronal injury. They also suggest that the neurotoxic effects of seizures can be dissociated from effects of excessive electrical activity.

### MECHANISMS FOR SEIZURES AND INJURY IN THE IMMATURE BRAIN

The immature brain, especially the seven-day-old rat brain, is quite sensitive to seizures produced by NMDA as well as to NMDA-mediated neurotoxicity, but the relationship between the two is not clear. The models of prolonged direct electrical stimulation of the perforant pathway and of bicuculline-induced focal seizures described for adult animals have not been examined in the infant. However, both perforant pathway stimulation and the lithium-pilocarpine model of status epilepticus have been shown to produce neurotoxicity in the hippocampus of 15-day-old rodents (75). In our experiments, anticonvulsants such as phenytoin, diazepam, and pentobarbital markedly reduced NMDA-induced seizure activity but did not reduce the neurotoxic effects of injected NMDA (76). MK-801 and other NMDA antagonists produce significant levels of neuroprotection at doses that do not block behavioral seizures. Seizures induced by injection of NMDA in immature animals have some similarity to electrographic and behavioral changes seen in infantile spasms, and this is an active area of investigation (77, 78).

Activation of non-NMDA receptors also could contribute to seizure-related injury. A model in which kainic acid is injected into immature rodents has been extensively studied for its effects on brain injury as well as on long-term behavior. This is a useful model for trying to understand subtle effects of seizures themselves, as opposed to direct pathologic effects of neurotoxicity (79). Stimulation of AMPA receptors also produces seizures and brain injury in the immature rat (80). Metabotropic receptor stimulation may also contribute to effects of seizures because seizures stimulate phosphoinositide turnover and release of free fatty acids (81).

EAA mechanisms also could play a role in epileptogenesis and seizure expression (82). In an *in vitro* model of electrographic seizures in hippocampal slices, NMDA antagonists such as AP4 and MK-801 prevented the progressive development of seizures but did not block previously induced seizures (83). This suggests that the process of establishing a long-lasting seizure-prone state depends on the NMDA receptor/channel complex, whereas the expression of seizures does not. AMPA receptor-mediated mechanisms also appear to play an important role in seizure susceptibility that follows exposure to hypoxia in rodents (84). This suggests an important distinction between antiepileptogenic and anticonvulsant pharmacologic agents (85).

It is also possible that EAA receptors play a role in other more subtle developmental sequelae of seizures (43). In addition to their role in transmembrane signaling, EAA neurotransmitters participate in a variety of neurodevelopmental events. These include promotion of neuronal survival, growth, and differentiation of neurons; regulation of neuronal circuitry and cytoarchitecture; regulation of activity-dependent synaptic plasticity; and certain forms of learning and memory (86). Excitotoxic amino acids may act as neurotrophic factors promoting neuronal survival growth and differentiation during development. The NMDA receptor/channel complex appears to play a critical role in visually determined plasticity in the visual cortex (87). Drugs that block the NMDA receptor/channel complex may block the physiologically determined ocular dominance shifts that normally occur with monocular deprivation. The NMDA receptor/channel complex also appears to play a critical role in the formation of long-term potentiation, an electrical model of learning and memory (88). Disturbances in these normal developmental mechanisms by excessive EAA neurotransmitters released during repeated seizures could potentially be a mechanism for a variety of neurobehavioral disturbances in patients with seizures. Seizure-induced disturbances in EAA mechanisms involved in memory in the hippocampus might be responsible for disturbances in learning and memory in patients with frequent or prolonged seizures. This encephalopathic disturbance might occur in the absence of permanent injury.

Synaptic inhibitory mechanisms also play an important role in both short- and long-term changes that result from seizures. Short-term changes in GABA receptors appear to reduce the efficacy of anticonvulsant drugs that target these receptors after extended periods of status epilepticus (89–93). Injection of tetanus toxin into the hippocampus of immature rats produces selective impairment of GABA neurotransmission and seizures, and this treatment has been shown to induce long-term behavioral and learning deficits as well as changes in the expression of NMDA receptor subunits (43). These experimental results reflect the plastic responses

of developing excitatory and inhibitory synaptic mechanisms to seizures.

## METABOLIC AND PHARMACOLOGIC CONSEQUENCES OF SEIZURES

### Excitatory Amino Acid Mechanisms in the Pathogenesis of Partial Epilepsy

Whether excitotoxic mechanisms play a role in the pathogenesis of childhood temporal lobe epilepsy associated with hippocampal damage is the subject of debate (94, 95). Although laboratory evidence discussed earlier suggests this is likely, human epidemiologic evidence suggest that prolonged seizures are usually harmless in children (7). Although a history of febrile status epilepticus is frequently obtained in patients undergoing temporal lobectomy surgery for partial complex seizures, magnetic resonance imaging (MRI) studies suggest that many patients have hippocampal malformations that predated onset of seizures (96). However, recent serial MRI has identified a few children who acquired hippocampal sclerosis following very prolonged febrile seizures (97). This suggests that EAA pathways may have a role in the pathogenesis of certain forms of chronic epilepsy.

Partial complex seizures following hippocampal injury or malformation are sometimes progressive, suggesting that further seizures lead to progressive injury and synaptic reorganization that promotes more seizures (98). EAA mechanisms could contribute to progressive metabolic disturbances and injury that could perpetuate this process. Studies of epileptogenic hippocampus using intracerebral microdialysis in patients undergoing monitoring prior to surgery showed high basal levels of glutamate, a low glutamate/glutamine ratio, and high lactate levels, which suggest poor glucose utilization (99). This is consistent with the observation that FDG PET commonly shows hypometabolism in epileptogenic hippocampi (100, 101). Interictal energy deficiency could contribute to impaired glutamate reuptake, persistently elevated glutamate, and EAA neurotoxicity. Abnormal recurrent sprouting of excitatory mossy fibers in the hippocampus that have lost their targets in the CA3 region has also been implicated in this process (102). Autoradiography studies of tissue resected from patients with temporal lobe epilepsy shows reduction in binding to the phencyclidine site of the NMDA receptor/channel complex and a relative increase in associated NMDA receptor sites (100). This resembles the ratio of receptor to channel binding found in the immature rat brain (37). Elevations in non-NMDA receptors have also been reported in human hippocampal tissue from patients with partial complex seizures (103). Studies of human hippocampal AMPA and NMDA messenger RNA and protein levels

in brain tissue from temporal lobe epilepsy patients also found elevated levels for AMPA GluR1 and NMDA NR2 subunits (104, 105), as well as up-regulation of metabotropic mGluR5 receptors (106). These results suggest that alterations in glutamate receptor levels and subunit composition contribute to neuronal hyperexcitability and seizure generation in temporal lobe epilepsy.

These observations suggest a hypothetical mechanism for progressive epileptic change in certain patients with complex partial seizures (Figure 4-3). In this hypothesis, a severe insult such as prolonged status epilepticus or hypoxia-ischemia leads to EAA release and a glutamate type of injury to neurons in the hippocampus and other susceptible regions. This form of injury causes loss of some pyramidal neurons, but those that remain have stunted dendritic arbors (8, 43, 107). Perhaps in response to a reduced surface area of dendrites, post-synaptic NMDA receptor/channel complexes adjust by up-regulating their NMDA receptors. This would compensate for the reduced dendritic surface area available for excitatory input to the neuron. In addition, a reduction in the number of inhibitory GABA receptors might also serve to increase excitatory tone (100, 108).

An increased ratio of NMDA receptors per channel might sensitize the neuron to enhance excitability and further injury from physiological amounts of synaptic glutamate. Potentially, the seizure threshold might be lower, and further dendritic injury might result from excitatory events that are only mildly superphysiological. This additional injury in turn leads to a cycle of repeated seizures and injury. An important implication of this model is that pharmacological attempts could be made to prevent further EAA-mediated injury and thereby halt the progression of the disorder. Based on studies suggesting that there is a distinction between epileptogenesis and epileptic expression, drugs might be developed that would reduce the progressive epileptic process, although they themselves might not be good antiseizure agents (83, 85, 109).

## CONCLUSION

Although seizures dramatically raise the brain's metabolic activity during the ictal event, they generally do not have any long-term damaging effect. However, data from animal models of status epilepticus and supraphysiological stimulation of specific excitatory pathways indicate that neuronal injury in sensitive areas such as the hippocampus can occur through a glutamate-mediated excitotoxic mechanism. Although children appear to be less affected by this mechanism than adults, recent experiments in animals suggest that the effects of prolonged seizures may be more injurious than previously thought (110). Studies in children suggest that hippocampal sclerosis occasionally

FIGURE 4-3

A speculative proposal of the mechanisms that contribute to the progressive epileptic changes observed in patients with complex partial seizures. (A) Schematic illustration of a typical pyramidal cell from Ca1–3 hippocampal subfields. Glutamatergic input (open triangles) from the perforant path originates in the entorhinal cortex and synapses on distal pyramidal cell dendrites and GABAergic interneurons. A severe focal cerebral insult causes overactivation of EAA receptors and produces excitotoxic injury, localized mainly to dendritic regions of the pyramidal cells. (B) The dendritic regions of surviving pyramidal cells are stunted, and the number of functional NMDA recognition sites (solid circles) and corresponding TCP channels (solid squares) is reduced. Moderate loss of functional GABA<sub>A</sub> sites occurs. As a result of impaired EAA synaptic transmission, the level of pyramidal cell excitation is reduced, as depicted by the large arrow of the emerging axon. In response to reduced pyramidal cell excitation, a series of compensatory synaptic alterations take place. (C) Dendritic zones regenerate, EAA neurotransmission is enhanced by up-regulating NMDA recognition sites, and the level of functional inhibition is reduced by down-regulating GABA<sub>A</sub> sites. These changes in turn would compensate for the reduced pyramidal cell excitation that results from cerebral injury by increasing excitatory tone. However, these compensatory changes could produce enhanced susceptibility to seizure and seizure-related excitotoxicity by lowering the seizure threshold. The compensatory epileptogenic events lead to a cycle of repeated seizures and injury.

may be caused by prolonged febrile status epilepticus. Analysis of hippocampal tissue removed at surgery from patients with temporal lobe epilepsy indicate that levels of specific neuronal glutamate and GABA receptors are

altered, which may contribute to epileptogenicity and a progressive cycle of further excitotoxic injury. A better understanding is needed of the factors that contribute to epileptic excitotoxicity.

## Neuropathologic Substrates of Epilepsy

*Carolyn R. Houser*  
*Harry V. Vinters*

### INTRODUCTION

The purpose of this chapter will be to review selected neuropathologic substrates of intractable epilepsy, including lesions that cause seizures in infants and children, as well as adults. We will not consider the pathologic findings in (usually low-grade) neoplasms that are especially common as a cause of intractable epilepsy.

### PATHOLOGY OF TEMPORAL LOBE EPILEPSY

Temporal lobe epilepsy (TLE) is the most common form of epilepsy across all age groups, and hippocampal sclerosis is the most consistent pathology in this disorder. Although TLE is often diagnosed in adolescence or adulthood, the processes leading to epilepsy may have begun earlier and, in many cases, during childhood. In this context, we will consider the patterns of neuronal loss, as well as preservation, in hippocampal sclerosis; evidence for plasticity of remaining neurons, including the reorganization of their axons and synaptic connections; and a disorganization of the granule cells of the dentate gyrus that could be related to alterations in basic developmental programs for neuronal migration.

### Neuronal Loss and Resultant Circuitry

Hippocampal sclerosis is characterized by a well-recognized and intriguing pattern of neuronal loss. This typically includes extensive loss of neurons in three major regions of the hippocampal formation—the hilus or polymorph layer of the dentate gyrus, CA3 and CA1 (1–3) (Figure 5-1). In contrast, granule cells of the dentate gyrus and neurons of CA2 and the subiculum are comparatively well preserved (Figure 5-1), even though some cell loss often occurs in these regions also. The cell loss is accompanied by gliosis, and the combined changes lead to a smaller than normal hippocampus (Figure 5-1A, B).

Despite extensive neuronal loss, a functional circuit through the hippocampal formation is likely to remain. Even in the neuron-depleted CA1 and CA3 fields, some neurons are frequently present, either locally, within a hippocampal slice, or at different anterior-posterior levels of the hippocampus. It is presumed that such neurons continue to form a functional hippocampal circuit. Importantly, major input and output regions of the hippocampal formation, the dentate granule cells and subicular neurons, respectively, remain relatively intact. However, the normal inputs to both regions are often severely reduced as a result of cell loss in other hippocampal regions. Loss of both inhibitory gamma-aminobutyric acid (GABA) neurons and

**FIGURE 5-1**

Hippocampal formation of human temporal lobe epilepsy (A) and normal autopsy (B) specimens that are stained with cresyl violet to demonstrate neuronal cell bodies. (A) The epilepsy specimen exhibits hippocampal sclerosis that is characterized by the smaller size of the hippocampus (compare to control in Panel B) and severe depletion of neurons in the dentate hilus (H), CA3 and CA1. Granule cells of the dentate gyrus (DG) and neurons in CA2 and the subiculum (S) are comparatively well preserved. (B) In a control specimen, neurons are abundant throughout the hilus (H) of the dentate gyrus (DG) and in the pyramidal cell layer of all hippocampal fields (CA3, CA2, CA1) and the subiculum (S). Specimens are shown at the same magnification.

excitatory mossy cells in the hilus reduces their control of the dentate granule cells, and such loss of neurons in the hilus (sometimes referred to as CA4) is one of the most consistent findings in TLE (1, 4, 5). Likewise, the severe depletion of CA1 neurons considerably reduces

the normal input to the subiculum. Yet the subiculum remains active and constitutes a major output of the hippocampal formation. Activity from the subiculum can be propagated to the entorhinal cortex and from there to widespread regions of the brain as well as back to the dentate gyrus in a reentrant excitatory path. Thus, despite neuronal loss, a hippocampal circuit persists, and alterations of this remaining basic circuit are likely to form the morphological substrates for the excessive, hypersynchronous activity of epilepsy.

### Reorganization of Remaining Neurons

*Axonal Reorganization as a Basic Feature of TLE Pathology.* Although, for many years, the focus of pathological studies of TLE has been on neuronal loss, it has become increasingly clear that remaining neurons and their connections are a critical part of the “pathology of epilepsy.” When the initial cell loss occurs in childhood, remaining neurons are present during a period when the nervous system has the capacity for the greatest developmental plasticity. In particular, processes such as axonal growth and synaptogenesis could be stimulated. Indeed, numerous studies now suggest that reorganization of the synaptic connections of remaining neurons is a central feature of the morphological changes in TLE. This axonal reorganization appears to occur in both principal cells (granule cells of the dentate gyrus and pyramidal cells of the hippocampus) and GABAergic interneurons.

*Reorganization of Principal Cells.* The reorganization or sprouting of mossy fibers that originate from dentate granule cells is one of the most striking alterations in the hippocampus of humans with TLE. Since the early descriptions of mossy fiber sprouting in human epilepsy (6–8), numerous studies have confirmed the findings in a very high percentage of cases (e.g., 9, 10).

The mossy fibers and their axon collaterals normally innervate neurons in the hilus and CA3, but in many patients with TLE, the mossy fibers are distributed aberrantly in the inner molecular layer, where they form a distinct band above the granule cell layer (Figure 5-2A, C). The inner molecular layer is normally innervated by excitatory mossy cells of the hilus, and these neurons are frequently lost as part of the extensive cell loss in the hilus. Loss of mossy cells may serve as a major stimulus for reorganization of mossy fibers into these regions because, through their loss, many of the normal targets of the granule cells in the hilus are missing (7). Also, synaptic sites on granule cells in the inner molecular layer are vacated as a result of degeneration of mossy cell terminals.

The reorganized mossy fibers in human TLE appear to develop completely and form synaptic contacts in the molecular layer (8, 11, 12). The time course of mossy

**FIGURE 5-2**

Dynorphin labeling of mossy fibers in the human hippocampus. (A) In a human temporal lobe epilepsy (TLE) specimen, a dense band of labeled fibers (arrows) is present in the inner molecular layer of the dentate gyrus and indicates an aberrant distribution of mossy fibers from dentate granule cells (G). Normally, such mossy fibers are restricted to the dentate hilus (H) and CA3. (B) In a control autopsy specimen, dynorphin-labeled mossy fibers are concentrated around neurons in the hilus (H) and are not present in the granule cell (G) and molecular (M) layers. (C) In a TLE specimen, dynorphin-labeled mossy fibers are concentrated in the inner molecular layer (M), and the normal labeling around cell bodies in the hilus (H) is reduced due to loss of neurons in this region. (D) In an electron micrograph of a TLE specimen, a dynorphin-containing mossy fiber terminal (MF) in the inner molecular layer contains numerous clear synaptic vesicles as well as several dense core vesicles. The terminal forms distinct, asymmetric synaptic contacts (arrows) with several dendritic profiles (D). The size of the mossy fiber terminal is considerably larger than that of another terminal (T) in the region.

fiber reorganization in humans cannot be determined, but in surgical specimens from patients with chronic epilepsy, the reorganized terminals appear morphologically mature (12). If the mossy fiber terminals had remained in an immature state, they would likely resemble developing mossy fiber terminals in rodents, in which synaptic vesicles are sparse and mitochondrial profiles are few (13). Remarkably, in human TLE, the reorganized mossy

fiber terminals are packed with clear synaptic vesicles (Figure 5-2D), presumably containing glutamate, and contain numerous mitochondrial profiles, suggesting that the terminals are functional and capable of strong, excitatory influences. Many of the terminal profiles in humans are relatively large (Figure 5-2D), with a mean major diameter of 2.3  $\mu\text{m}$ , and this exceeds the size of most other axon terminals in the region (12).

Whether the reorganized mossy fibers form synaptic contacts with inhibitory neurons or other granule cells is important for determining their function, and the predominant target of sprouted mossy fibers in animal models continues to be debated (14–16). However, in humans, granule cell dendrites appear to be the most common target, with the vast majority of synaptic contacts being formed with dendritic spines and the remainder with dendritic shafts of granule cells (8, 11, 12).

The morphological features of the reorganized mossy fiber synapses suggest that they could exert strong excitatory influences. The reorganized mossy fiber terminals in humans establish distinct, asymmetric synapses that are characteristic of excitatory synapses, and a single terminal often establishes multiple synaptic contacts (Figure 5-2D). The large aberrant mossy fibers are indented and invaginated by multiple spines (12), and such patterns are characteristic of the final stages of normal mossy fiber development in CA3, when complex spines are formed (13). Thus, reorganized mossy fibers in the human dentate gyrus appear to have progressed through their full development and show synaptic organization that is consistent with a powerful, aberrant, reexcitatory circuit among granule cells.

Reorganized mossy fibers provide the clearest example to date of axonal reorganization and new synapse formation in the human central nervous system (CNS). However, axonal reorganization of other excitatory neurons is also likely to occur in TLE. In the dentate gyrus, the normal projection from the supramammillary region to the inner molecular layer appears to have increased, as indicated by an expanded band of calretinin labeling (17). Thus growth and reorganization of extrinsic as well as intrinsic excitatory projections may occur in the dentate gyrus in TLE and contribute to enhanced excitability in the region.

Axonal reorganization may also occur in CA1 and other regions where there is partial loss of principal neurons. Aberrant collateral sprouting of CA1 pyramidal cell axons into the pyramidal cell layer and stratum radiatum has been described in human TLE following injections of fluorescent tracers in hippocampal slices (18). This network reorganization could contribute to increased excitability and synchrony among the CA1 neurons.

*Loss and Reorganization of GABA Neurons.* The general histological view of neuronal loss and preservation in TLE emphasizes the principal, excitatory neurons that form the basic circuitry through the hippocampal formation. The fate of GABA neurons that control activity within the circuit has been more difficult to determine. Indeed, early reports appeared to be contradictory, with some studies suggesting that GABA neurons are preserved in the

hippocampus of humans with TLE (19) and others demonstrating loss of specific groups of peptide-containing neurons (20, 21) that are known to be subgroups of GABA neurons.

Current findings indicate that the changes in GABA neurons in human TLE are indeed complex but fascinating. First, different classes of GABA neurons appear to have different vulnerabilities, according to whether they innervate dendritic regions or perisomatic sites that include cell bodies and axon initial segments (5, 22). Within the dentate gyrus, neurons that terminate in dendritic regions are among the most vulnerable to damage, and many of these neurons are labeled with somatostatin and neuropeptide Y (NPY). Loss of these neurons was demonstrated initially by de Lanerolle and colleagues and others (20, 23), and their loss has been confirmed in subsequent studies (24). Because many of the cell bodies of somatostatin- and NPY-containing neurons that innervate dentate granule cells are located in the hilus, the loss of hilar neurons in TLE provides additional support for degeneration of these groups of neurons, perhaps as a result of an initial precipitating event (25, 26). This would be consistent with the extreme vulnerability of somatostatin neurons in animal models following status epilepticus, ischemia, and traumatic head injury (27–31). These hilar neurons normally project to the dentate molecular layer, where they help regulate the responses of granule cells to excitatory input from the entorhinal cortex, and loss of these GABA neurons could increase granule cell excitability in response to this input.

Despite the marked loss of hilar neurons, a plexus of somatostatin- and NPY-containing fibers can still be observed in the molecular layer at chronic stages of epilepsy (20). Such findings have suggested that remaining GABA neurons, either within the hilus or other regions of the hippocampus, may have reorganized their axonal connections. This potentially reorganized plexus no longer exhibits a normal laminar pattern in the molecular layer and, instead, is distributed throughout the layer (20, 32). Despite the potential sprouting of these axons, their laminar distribution and associated specificity are altered, and thus it is unlikely that they will compensate fully for loss of the normal GABAergic innervation of the dendritic region.

In contrast to a severe loss of hilar GABA neurons that innervate granule cell dendrites, those that innervate perisomatic regions in the dentate gyrus and hippocampus may be relatively well preserved (33, 34). Many of these neurons normally express the calcium-binding protein parvalbumin, and several studies of human TLE have reported a decrease in parvalbumin labeling (33, 35–37). Although this could reflect a loss of these GABA neurons, electron microscopic studies have found that many GABAergic axon terminals

around the cell bodies and axon initial segments, presumed to originate from parvalbumin-containing neurons, are preserved (33, 34, 37). Thus the decreased parvalbumin labeling has been interpreted by some investigators as a decrease in parvalbumin content in persisting interneurons (34). In regions such as the dentate gyrus, the number of terminals and complexity of the innervation around the cell bodies and along the axon initial segments are even increased (33, 38). Such alterations have again suggested sprouting of remaining GABA neurons.

While such changes could be viewed as compensatory, Maglóczy and Freund have suggested that the maintained or increased GABAergic innervation on the cell bodies and axon initial segments of projection neurons could contribute to enhanced, abnormal synchronization of neuronal firing (22). This is consistent with current views of GABAergic function, in which GABAergic innervation at perisomatic locations is considered to be critical for the normal synchronization of ensembles of principal cells (39).

The complexity of changes in GABAergic innervation in TLE has been emphasized in detailed studies of axo-axonic cells by deFelipe (37) and others (38). Despite what appeared to be a general preservation of perisomatic GABAergic innervation in human TLE, a loss of GABAergic terminals along the axon initial segments of some granule cells was identified (38). When a loss was observed, it was often extreme and could be sufficient to severely decrease inhibitory influences at the axon initial segment, which strongly influences the final output of the projection neurons (38). These findings suggest that loss of even a small number of GABA neurons could severely deplete the GABAergic innervation at critical locations on remaining principal cells, and such projection neurons could feasibly become sites of seizure initiation.

Calbindin-containing interneurons are an additional group of GABA neurons that may be preserved in several regions of the hippocampal formation (17, 35). However, these persisting neurons undergo numerous morphological changes that include increased numbers of spines and increased GABAergic innervation (40, 41). Increased inhibitory control of inhibitory interneurons could potentially limit their output and lead to decreased inhibitory control of the principal cells.

Finally, although no loss of GABA neurons and their terminals has been observed in the subiculum (38), functional alterations in GABAergic signaling have recently been described in this region. In a subgroup of pyramidal cells of the subiculum of human TLE specimens, GABA had unexpected depolarizing actions, and the resultant activity contributed to rhythmic interictal discharges (42). These responses are reminiscent of GABA-mediated excitation that occurs

during early development and is related to late expression of the potassium-chloride cotransporter (KCC2) that normally extrudes  $\text{Cl}^-$  from the cell (43). Further studies have demonstrated both down-regulation of the KCC2 transporter mRNA and up-regulation of the  $\text{Na}^+\text{-K}^+\text{-2Cl}^-$  (NKCC1) transporter mRNA, a transporter that facilitates accumulation of  $\text{Cl}^-$  within neurons, in the subiculum in human TLE (44). Interestingly, similar changes were not found in the hippocampus or temporal neocortex. A functional reversion of some neurons in TLE to earlier developmental stages, when GABA has excitatory actions, could substantially alter GABAergic influences and possibly contribute to seizure activity (45–47).

Current findings thus suggest that GABA neurons and their function can be altered in multiple ways in TLE. Clearly some groups of GABA neurons are vulnerable to damage, and their loss could reduce GABAergic control of principal cells at dendritic sites, where they receive their major excitatory input. In contrast, many GABA neurons remain viable, may exhibit substantial axonal reorganization, and could contribute to enhanced neuronal synchronization. Finally, some remaining GABA neurons could exert excitatory influences in specific regions of the hippocampal formation.

Reorganization of the axons and synaptic connections of both principal cells and GABAergic interneurons now appears to be a central component of hippocampal pathology in TLE. Interestingly, the sprouting of excitatory neurons, as well as inhibitory neurons that innervate perisomatic sites, could contribute to enhanced synchrony of the projection neurons of the circuit, although through different mechanisms (22, 48). Determining the “rules” that govern such reorganization and its time course is critical for developing interventions that could limit the formation and maturation of aberrant synaptic connections that are likely to contribute to seizure activity.

### Granule Cell Disorganization

*Altered Patterns of Dentate Granule Cells.* In many patients with TLE and hippocampal sclerosis, the granule cells of the dentate gyrus are one of the most persistent groups of neurons. However, in a subpopulation of these patients, the granule cells have a disorganized appearance that contrasts sharply with the compact, relatively narrow band of granule cells in the normal hippocampus (Figure 5-3A). The most common altered pattern has been described as granule cell dispersion (49) and is characterized by a wider than normal granule cell layer, increased space between many of the granule cells, and poorly defined laminar borders (Figure 5-3B). The granule cells are often aligned in vertical rows that extend into the

**FIGURE 5-3**

Granule cell organization in the human hippocampus of control autopsy (A) and temporal lobe epilepsy (TLE) (B, C) specimens as demonstrated by NeuN immunolabelling. (A) In control tissue, the granule cells of the dentate gyrus are closely approximated and form a relatively narrow, compact granule cell layer (G). (B) In a TLE specimen, granule cells (G) are dispersed, creating a widened layer with uneven borders. Granule cell somata are more widely separated than normal, particularly in the outer part of the layer. (C) In another TLE specimen, the granule cells (G) form a bilaminar pattern with a relatively cell-free zone between the two layers of neurons. Severe loss of neurons is evident in the hilus (H), CA3 and CA1.

molecular layer to varying extents and create an irregular outer border of the granule cell layer (Figure 5-4A). The vertical alignment of dispersed granule cells and their elongated appearance are remarkably similar to those of developing neurons as they migrate along radial glia (49) (Figure 5-4A). Recent studies have demonstrated a close approximation between dispersed granule cells and radial glia fibers and found that the length of the glial fibers increased with the severity of granule cell dispersion (50).

In several series of TLE patients, granule cell dispersion has been found in approximately 40% of TLE cases (9, 10, 51, 52). Thus, this alteration is not an essential feature of hippocampal sclerosis. However, it is of interest because it suggests alterations in the normal development of the dentate gyrus that could be associated with

altered circuitry and contribute to abnormal function of the region.

A second altered pattern is a bilaminar distribution of granule cells in which two layers of granule cells are separated by a clear region that is relatively devoid of neuronal cell bodies (49, 53) (Figure 5-3C). The bilaminar pattern is observed less frequently than generalized dispersion and has been found in approximately 10% of TLE cases (10). Within dispersed and bilaminar regions, granule cells are numerous, and the laminar alterations do not appear to result primarily from granule cell loss. However, distinct regions of granule cell loss can sometimes be found in the granule cell layer (Figure 5-3C).

*Possible Mechanisms of Granule Cell Dispersion.* The basic mechanisms responsible for granule cell dispersion in

**FIGURE 5-4**

Granule cell organization in human temporal lobe epilepsy (TLE). (A) In a TLE specimen with granule cell dispersion, many of the NeuN-labeled granule cells have elongated cell bodies (examples at arrows) with vertically oriented processes and often appear to be aligned in columns. Numerous granule cells extend beyond the granule cell layer (G) into the molecular layer (M). Dispersed neurons are also evident in the hilus (H). (B) In a TLE specimen, neurons are identified specifically as granule cells by immunolabeling for Prox1 in their nuclei. Numerous labeled granule cells are evident in the molecular layer (M) as well as in the granule cell layer (G). Some ectopic granule cells (examples at arrows) are also present in the hilus (H). (C) In another TLE specimen, Prox1-labeled neurons in the granule cell layer (G) form a normal, compact layer. However, ectopic granule cells (examples at arrows) are concentrated near a blood vessel (BV) in the hilus (H).

human TLE have not been determined, but recent studies of human tissue and various animal models have suggested several interesting possibilities. Two general hypotheses are being explored. The first is that the alterations reflect an intrinsic, developmental migration disorder. The second is that the altered positioning of the granule cells is acquired as a result of an initial precipitating event such as severe febrile convulsions, status epilepticus, or, possibly, repeated seizure activity. Support can be found for both hypotheses.

The presence of granule cell dispersion has generally been restricted to patients with TLE and has seldom been

reported in autopsies of neurologically normal individuals or those with other neurological disorders. However, Harding and Thom (54) recently described bilateral granule cell dispersion in autopsy studies of three pediatric cases. In one case, the child presented with a severe seizure disorder, and bilateral hippocampal sclerosis accompanied the granule cell disorganization. In two other cases, no seizures were documented, and the remainder of the hippocampal formation appeared intact. In all three cases, heterotopias or polymicrogyria were also present. The presence of bilateral granule cell dispersion and other

migrational defects suggested that granule cell dispersion could be an independent developmental disorder in at least a small subgroup of cases (54).

Disorganization of dentate granule cells has also been observed in several mouse models with genetic mutations, and these include the Reeler mouse, which lacks the reelin protein, and the p35-deficient mouse. However, some differences exist between the patterns of neuronal lamination in human TLE and those in the mutant mice. In genetic models with altered neuronal migration, multiple groups of cortical and hippocampal neurons are often affected. Yet, in most TLE cases with granule cell dispersion, other regions of the hippocampal formation do not show noticeable laminar disruption (Figure 5-3C). In addition, granule cell dispersion in human TLE is frequently accompanied by severe cell loss in other regions of the hippocampus, and similar patterns of cell loss are not found in the mutant mice.

The association between granule cell dispersion and neuronal loss suggests that either an initial precipitating event or recurrent seizures could have influenced the positions of the granule cells. In several studies of human TLE, a strong association has been found between neuronal loss in the hilar (polymorph) region and the presence of granule cell dispersion (49, 52, 55). Similarly, in a recent study of a large number of TLE cases, Thom and colleagues found that granule cell dispersion correlated more closely with the extent of neuronal loss throughout the hippocampal formation than with any other variables examined (10).

This relationship, when viewed in conjunction with findings from mutant mice with altered granule cell lamination, suggests that the initial precipitating event could have produced specific cellular and molecular changes that, in turn, cause the altered patterns of granule cells. Several potential candidate molecules have recently been identified.

Reelin is an extracellular matrix protein that is important for the proper lamination of the cerebral cortex and hippocampus, and loss of reelin, as occurs in the Reeler mutant mouse, leads to a severely disordered cortex and hippocampus, including nearly complete loss of a compact granule cell layer (56, 57). In the hippocampus, reelin is synthesized and secreted by Cajal-Retzius cells, which are located in the outer molecular layer of the dentate gyrus and are particularly prominent during development (58, 59).

Recent studies by Frotscher and colleagues have found that reelin mRNA expression in Cajal-Retzius neurons of the dentate gyrus is reduced in some patients with TLE (60). Furthermore, the amount of loss of reelin mRNA-labeled cells was correlated with the extent of granule cell dispersion into the molecular layer. These findings are consistent with suggestions that reelin may be providing positional clues for migrating granule cells

or controlling their detachment from radial glia and that, following loss of reelin, a compact granule cell layer cannot be established or maintained (50, 60).

The association between neuronal loss and granule cell dispersion suggests further that excitotoxic damage that produces cell loss in the hilus and other regions of the hippocampus could also cause loss of Cajal-Retzius cells and thus reelin. Findings that Cajal-Retzius neurons in rodents are sensitive to damage by glutamate agonists are consistent with this idea (59). While some investigators have found a loss of putative Cajal-Retzius cells (17), others have described a preservation or increase in these neurons, as identified by calretinin labeling, in human TLE (10, 61). Methodological differences may account for some of the discrepancies, or it could be that reelin expression is decreased within persisting neurons.

Granule cell positioning could also be influenced by brain-derived neurotrophic factor (BDNF). In a mouse model of TLE that is produced by the intrahippocampal injection of kainate, granule cells become severely dispersed and enlarged (62). In this model, levels of BDNF are significantly elevated and could have stimulated migration of the granule cells as well as their increased size (63, 64). Injection of BDNF into the hilus in rodents also leads to increased numbers of ectopic granule cells in the region, possibly due to aberrant migration from the subgranular layer (65). Interestingly, increased BDNF mRNA and protein levels also have been found in humans with TLE (66, 67).

The p35 signaling pathway, involved in neuron-specific activation of cyclin-dependent kinase 5 (Cdk5), could also be involved in granule cell dispersion and mossy fiber sprouting. In p35-deficient mice, lamination of the dentate gyrus is altered, and the distribution of granule cells closely resembles that of granule cell dispersion in TLE patients (68). Furthermore, these mice demonstrated spontaneous seizures (69).

Altered migration of granule cells along radial glia or failure of the neurons to leave the scaffold could be a common mechanism underlying granule cell dispersion, through either the reelin or p35 signaling pathway (50, 70). Similarly, immature astrocytes and increased expression of several neural cell adhesion, and related, molecules could contribute to the altered cellular architecture of the dentate gyrus in TLE (71–73).

Finally, evidence for the development of granule cell dispersion following an initial insult, rather than from an intrinsic developmental abnormality, has come from a study of the effects of limbic-like seizures in normal immature monkeys (74). Following a unilateral infusion of bicuculline in the entorhinal cortex and the production of limbic-like seizures, histological changes that resembled hippocampal sclerosis developed, and these included granule cell dispersion, in addition to hippocampal cell loss and mossy fiber sprouting (74). Thus many of the

changes observed in humans with TLE can be produced by an initial episode of status epilepticus in a normal, immature primate brain. Although spontaneous seizures were not detected up to 1 year after the initial seizure episode in these animals (74), it seems plausible that a longer postseizure period (years) might be required for such seizures to develop.

*Possible Contributions of Neurogenesis.* Renewed interest in neurogenesis in the dentate gyrus during postnatal life and evidence that this process can be stimulated by seizure activity (75, 76) have led to speculation about the possible contributions of newborn neurons to granule cell disorganization as well as mossy fiber sprouting. The results of recent studies to determine whether newly generated neurons contribute to granule cell dispersion in patients with TLE have differed. In some studies, immunohistochemical markers of neural stem cells and progenitors, as well as immature glia, have been observed in the dentate gyrus and in regions of dispersion (77, 78). In contrast, other investigators, using similar markers for newly generated neurons in human surgical tissue, have found no evidence for such neurons in regions of dispersion (50) and have concluded that displacement of mature neurons, rather than newly generated neurons, leads to granule cell dispersion in the epileptic hippocampus (50, 79).

The human studies cannot, however, rule out the possibility that increased neurogenesis at earlier times might have contributed to the altered distribution of dentate granule cells. The finding that the number of neurons within regions of dispersion is often greater than that in regions without dispersion is consistent with a contribution of seizure-stimulated neurogenesis to these regions (77). Likewise, in the pilocarpine model of recurrent seizures, some adult-generated granule cells have been identified in ectopic locations in the molecular layer as well as in the hilus (80). Also, in this model, newly generated granule cells in the subgranular zone disperse more rapidly than normal into outer parts of the granule cell layer, but further movement into the molecular layer was not detected (81).

Although observed less frequently than granule cell dispersion in human TLE, clusters of granule cells in the hilus (Figure 5-4C) are consistent with generation of new neurons in a region that is a secondary germinal zone for granule cells during normal development (82). These and other dispersed neurons have been conclusively identified as granule cells by immunohistochemical labeling of Prox1, a homeobox gene that is specific for differentiated granule cells in the dentate gyrus (Figure 5-4B, C) (80). Interestingly, when aberrant clusters of granule cells are found in the hilus in human TLE, they are often located immediately adjacent to blood vessels (Figure 5-4C), and thus these regions have similarities to the vascular niche

that has been described in the dentate subgranular zone of rodents and is considered to be a key site for adult neurogenesis (83). More diffusely distributed granule cells in the hilus also could be generated locally or could migrate into the hilus after being generated in the subgranular zone (80).

When considering neurogenesis as well as other types of morphological plasticity in TLE, a distinction between changes that occur at the time of an initial precipitating event and those that may occur as a result of later, spontaneous seizures could be particularly important. The initial event, such as a severe, prolonged seizure, is likely to stimulate neurogenesis acutely, as has been demonstrated in several animal models (76, 84, 85). Although the extent of neurogenesis in humans appears to be considerably less than that in rodents (86), any increased production of granule cells could be significant. The newly generated neurons may then require a period of time to mature and become completely integrated into the hippocampal circuitry, that is, several months in rodents (87, 88) and perhaps longer in humans. Events during this period could be of considerable importance for the functional integration of the newborn neurons (89) and could determine whether granule cells reach normal or abnormal positions, form proper or aberrant connections, and thus compensate for or contribute to an epileptic state.

The effects of spontaneous seizures might differ from those of the acute events. Indeed, several studies have suggested a reduction of neurogenesis in the chronic pilocarpine and intrahippocampal kainate models of recurrent seizures (79, 90, 91), as well as in human pediatric patients with frequent extratemporal seizures (92). Nevertheless, ongoing spontaneous seizures could promote additional changes such as increased production of growth and trophic factors that could continue to influence neuronal migration and circuitry, leading to ectopic positioning of granule cells and the stimulation of axonal sprouting and new synapse formation.

### NEOCORTICAL LESIONS ASSOCIATED WITH SEIZURES

Structural lesions (aside from TLE, see previous discussion) associated with epilepsy can be grouped into the following categories: (a) malformative, (b) neoplastic, (c) familial metabolic, (d) vascular/traumatic, and (e) infectious/inflammatory (93, 94). Investigators have suggested that some of these pathologic processes may overlap in epilepsy patients (95, 96) and “dual pathology” (e.g., a cortical resection specimen showing features of *both* a malformative and destructive lesion) is occasionally encountered (97). Some causal lesions—as with TLE, see previous discussion—are amenable to

definitive surgical treatment (e.g., low grade neoplasms, malformations of cortical development). This section will focus on developmental malformations and destructive or inflammatory lesions of the neocortex that account for the majority of structural lesions seen in infants and children with intractable epilepsy, especially those with infantile spasms (IS). More subtle malformations are also recognized with increasing frequency in adults with epilepsy; on rare occasions, severe dysplastic lesions may, for unknown reasons, present to a neurologist or epileptologist in adulthood.

### MALFORMATIONS OF CORTICAL DEVELOPMENT

Malformations of cortical development (MCDs) have usually been considered to represent disorders of neuronal migration (or vascular formation) and have variously been classified with regard to morphology or putative etiology (98–100). The classification of these lesions is increasingly being modified by (1) the availability of high-resolution multimodality neuroimaging techniques that can be used to predict pathologic abnormalities in a given patient (101–103), and (2) molecular genetic clues to pathogenesis, based upon techniques such as gene expression profiling following laser capture microdissection of surgical specimens (104). The genetic basis of some types of lissencephaly (e.g., Miller-Dieker syndrome, obviously not a surgically treatable lesion) is now well understood (104, 105). They can be categorized as follows: (a) cortical dysplasia (CD), which accounts for the majority of malformations associated with pediatric epilepsy and encompasses the full spectrum of neuronal migration disorders (NMDs), ranging from the most subtle to the most severe; (b) CNS structural lesions associated with tuberous sclerosis complex (TSC); (c) Sturge-Weber-Dimitri syndrome (SWDS), or encephalotrigeminal angiomatosis; (d) neurofibromatosis type II, which may be associated with meningio-angiomatosis; and (e) vascular malformations.

#### Clinicopathologic Considerations

Seizure disorders have traditionally been subdivided into syndromes based on clinical presentation and electroencephalographic (EEG) findings. However, there is often a marked discrepancy between the clinical phenomenology of a seizure disorder and its neuropathologic substrate(s). Infantile spasms (IS; West syndrome) and Lennox-Gastaut syndrome can be seen with a wide range of cerebral lesions (106–108). The clinical form of epilepsy seen in a given patient appears to depend more on *when* during cerebral development the lesion occurred than on the specific *type* or topographic distribution of

lesions (106, 109). It has been suggested that the CNS lesions associated with IS can be functionally categorized into three groups: (a) diffuse, (b) focal or multifocal cerebral lesions, and (c) cases with minimal neuropathologic change (108). Diffuse hemispheric lesions include hemimegalencephaly (HME), agyria/pachygyria-lissencephaly, and Aicardi syndrome (110). Focal and multifocal lesions include CD/MCD and destructive lesions (vascular and infectious), as well as cortical tubers seen in patients with TSC.

MCDs can be viewed as a spectrum of CD resulting from derangement of the normal process of cortical development (111–115). This spectrum consists of a range of morphologic features associated with multiple putative etiologic factors, including genetic and environmental (e.g., destructive) influences. CD encompasses a broad range of neocortical malformations, ranging from the most subtle (“microdysgenesis”) to the most severe (HME), and includes such conditions as agyria/pachygyria-lissencephaly, polymicrogyria (PMG), and focal CD. The resultant neuropathologic features may reflect abnormalities that probably occur within well-defined time windows during brain development. Clinically there is an inverse correlation between the size and severity of CD and the age at clinical presentation (102, 111), supporting the notion that there is a predominance of pathologically severe CD in neonates and infants with seizures, including those with IS (116). Although CD accounts for the majority of malformations associated with pediatric epilepsy, other malformative lesions are also capable of producing these epilepsy syndromes, and they frequently show neuropathologic changes that overlap significantly with those seen in patients with CD. Jellinger (106) has noted that the clinical severity of a given seizure disorder appears to be more closely related to the *timing* of the insult (whether genetic or environmental) and its effect on the processes of development than to the nature of the lesion itself. This may explain some of the heterogeneity of neuropathologic lesions seen in children with epilepsy, as the clinical phenotype results not only from the lesion or putative “insult” to the developing CNS but also from the developmental processes it subsequently affects.

A puzzling feature noted in pediatric epilepsy is the finding in cases of IS of *diffuse* and transient suppression of cortical activity in the presence of *focal* or *multifocal* lesions (108). This diffuse cortical suppression has not been linked to particular distributions or types of neuropathologic change. Rather, some have suggested that this feature of IS is associated with neocortical *immaturity*. The pattern of evolution of IS from transient and diffuse suppression of cortical discharge to ultimately focal or generalized seizures may represent a maturation of the malformed cortex (108).

### Nosologic Considerations

Understanding of the full clinicopathologic spectrum of CD is currently evolving and reflects a progressive elucidation of the basis of these complex lesions (109–125). Cortical malformations have historically been described largely by their gross characteristics (i.e., agyria/pachygyria-lissencephaly, HME, microgyria). As investigators discovered the range of microscopic cortical malformations that produce epilepsy but show no (or relatively mild) gross abnormalities, additional terms such as microdysgenesis (109, 117, 118), dysplastic cortical architecture (not otherwise specified) (119), focal cortical dysplasia (FCD) (120, 121), and generalized or diffuse cortical dysplasia (122, 123, 124a) came into use. The nomenclature of CD has evolved through several schema of classification, each intended to provide correlations with morphology of seizures or to reflect etiologic mechanisms (98, 99, 111). The term *FCD* was initially used to specify lesions in which cytomegalic neurons were present (121), although its frequent use to describe a localized region of CD renders the term slightly ambiguous. Some investigators prefer to use a traditional classification of migrational disorders into four main groups: (a) agyria/pachygyria-lissencephaly, (b) microgyria-polymicrogyria, (c) dysplastic cortical architecture, and (d) heterotopias (119). Others, to denote the belief that these lesions are related and reflect developmental abnormalities along a continuous spectrum, have chosen to refer to them as neuronal migration disorders (NMDs) (98, 113, 114) or cerebral or synaptic dysgenesis (124, 125). A recent consensus conference resulted in a proposal to subclassify CD or grade its severity (in surgical resection specimens) using simple morphologic criteria identifiable by any experienced neuropathologist, for example, presence or absence of cortical disorganization, enlarged or dysmorphic neuronal cell bodies, and “balloon cells” (see following) (126).

### Development of the Neocortex

The neuropathologic changes seen in infants and children with epilepsy frequently represent the end result(s) of insults to a rapidly developing brain. Several reviews have summarized the historical evolution in our understanding of the immensely complex molecular and neurobiologic processes that occur to create a normally functioning cerebral cortex (127–131). Neocortical development after neural tube formation can be roughly considered to be the end result of a series of overlapping processes: (a) cell proliferation in the ventricular and subventricular zones (VZ/SVZ), (b) early differentiation of neuroblasts and glioblasts, (c) programmed cell death of neuronal precursors and neurons, (d) migration of neuroblasts (both radially from the VZ/SVZ and tangentially) to form the mature

cortical plate, (e) late neuronal migration, (f) organization and maturation of the cortex, and (g) synaptogenesis/synaptic pruning (98, 110, 119, 132). A discussion of how derangement of these processes contributes to CD is beyond the scope of this review, but can be found elsewhere (133). Most developmental disorders of the brain associated with epilepsy are thought to originate from the perturbation of developmental events after the embryonic period, that is, after 6 weeks' gestation, when cell proliferation starts along the wall of the neural tube. This generates a group of “matrix cells” (134), or precursor cells for all neuroblasts and glioblasts, forming the VZ/SVZ in the pallium, as well as the ganglionic eminence in the subpallium. Programmed cell death (PCD, apoptosis) is also an essential mechanism in normal brain development, determining the cellular constituents of the CNS. In normal brain development, there is a 25% to 50% overproduction of neuroblasts, many of which will undergo physiologic PCD (125). Synapse elimination is intimately intertwined with the remodeling of cortical connections and is a highly dynamic process (135), demonstrated both in vivo and in vitro (136).

As the neocortex develops, the marginal zone, future molecular layer or cortical layer I, is composed largely of Cajal-Retzius cells. As previously discussed, they secrete the extracellular glycoprotein reelin, required for the normal inside-out positioning of neurons as they migrate from the ventricular zone along radial glia. Human Cajal-Retzius cells, characterized by the combined expression of reelin and p73, are transient cells, present from the preplate stage at 8 weeks' gestation, and gradually increase in number (by tangential migration) until they disappear by the end of gestation (137, 138, 138a). In mice carrying mutations in *RELN* (Reeler mice) and in *disabled-1* (*Dab1*), as well as in mice carrying double mutations of both very low-density lipoprotein receptor (*VLDLR*) and apolipoprotein E receptor 2 (*ApoER2*), normal neuroblast migration with an inside-out fashion is inverted (139). This suggests a role for these genes in the control of cell positioning in the developing CNS and predicts a pattern of cytoarchitectural alteration in patients carrying alterations in the reelin/lipoprotein receptor/*Dab1* pathway, as well as *RELN* mutations causing lissencephaly (140). *LIS1* also appears to have important effects on neuronal migration, and significant interactions with Cajal-Retzius cells (141). The superficial or subpial granular layer (SGL) is a transient cell layer; it appears beneath the pial surface between 13 and 24 weeks' gestation (93, 142). Cells in the SGL originate from the basal periolfactory subventricular zone (142–144) and migrate tangentially beneath the pia to cover the neocortical marginal zone. Cells in this layer express interneuron markers such as calretinin, calbindin, and GABA (145). The biological significance of the SGL, however, remains to be elucidated. PCD may, at least in part, contribute to its elimination (146). The human subplate contains large multipolar

neurons. These neurons in the developing cerebrum, though they are transient and most disappear in early postnatal life, are thought to be important in organizing cortical connections in the developing cerebrum and are thought to act as pioneer corticofugal axons (147–150).

### Neuropathologic Significance of Cortical Dysplasia

The Pediatric Epilepsy Surgery program at UCLA Center for the Health Sciences, active for over 20 years, has enabled us to examine more than 500 surgically resected specimens from infants and children with intractable seizures, including a spectrum from partial lobectomies to complete and partial (functional) hemispherectomies. The most common morphologic substrate was CD, this being of etiologic importance as a cause of intractable pediatric seizures in more than 80% of children younger than 3 years of age. The extent of CD neuropathology can often be predicted by high-resolution neuroimaging studies. Such neuroimaging allows for stratification of CD cases into those that show hemimegalencephaly (HME), with diffuse enlargement of the gray and white matter, including thickening of the cortical ribbon, within an entire cerebral hemisphere; hemispheric CD, with multifocal CD affecting one cerebral hemisphere (though not causing enlargement of that hemisphere); or multilobar, lobar, or focal CD, the latter affecting as few as one gyrus or two adjacent gyri. The magnetic resonance imaging (MRI) findings of HME include an enlarged cerebral hemisphere and markedly thickened gyri, with loss of sulcation, deformity, and enlargement of the ipsilateral ventricle. Palmini type IIB CD is also easily identified by MRI, with focal thickness of the gyrus (gyri) and associated hyperintense T2-weighted signal changes in the adjacent white matter. It is as yet difficult to visualize Palmini type I CD by MRI; however, combining this with other modalities, such as positron emission tomography (PET) and magnetic source imaging (MSI), it is likely that the detectability of this lesion will increase.

In resection specimens from such patients, macroscopic heterotopia and polymicrogyria (PMG) are occasionally seen. Loss of the normal cortex–white matter junction, best appreciated with a Klüver-Barrera or other myelin stain, is a frequent accompaniment and excellent predictor of severe microscopic CD. Many specimens, however, exhibit no striking gross cortical abnormalities even when severe microscopic lesions are present. CD can be further characterized with regard to specific and easily identifiable microscopic abnormalities, including cortical laminar disorganization, frequent single heterotopic white matter neurons, excess neurons in the neocortical molecular layer, marginal glioneuronal heterotopia, white matter neuronal heterotopia, neuronal cytomegaly with or without associated dysmorphic features of the

cytoplasm (the latter often accompanied by cytoskeletal abnormalities and balloon cell change) (111). These microscopic features can be used as the basis for a grading system for CD, for example, one presented recently by Palmini et al (126).

Cortical laminar disorganization is a defining histopathologic feature of CD. As neocortical architecture is the end result of the developmental processes of proliferation of neuronal precursors, migration, terminal differentiation, PCD, and cortical remodeling, abnormalities in any of these processes may result in abnormal cortical architecture. Cortical disorganization (as well as cytologic abnormalities in individual neurons) can be highlighted using immunohistochemistry that incorporates primary antibodies to neurofilament epitopes (104). Although many neurons still reside in the intermediate zone/white matter in the last trimester of pregnancy and even into postnatal life (151, 152), the phenomenon of single heterotopic neurons in the white matter is accentuated in CD (109). It has been demonstrated in other series using morphometric techniques (153). It has been suggested that injury to the radial glial fibers leads to a “stranding” of the migrating neuroblasts within the white matter, where they further differentiate into mature neurons (125). Alternatively, overproduction of neurons late in neurogenesis may lead to crowding of migrating neurons toward the cortical surface (154). Morphometric analysis has demonstrated a statistically significant increase in the number of neurons within the molecular layer of the cortex in epileptic patients (118); this is considered to be evidence of a slight maldevelopment of the neocortex, sometimes described as microdysgenesis (108, 126). Persistence of the superficial granular layer (SGL) has been seen in association with many cortical malformations (111). Marginal glioneuronal heterotopia consists of excrescences of disorganized neuroglial tissue extending from the pial surface into the subarachnoid space. They are often found in association with persistent SGL. These lesions may be associated with a failure of the glia limitans. White matter neuronal heterotopia consists of disorganized masses of neurons in the white matter that usually occur in a periventricular position with a nodular morphology, although rare instances of laminar subcortical bands of heterotopic gray matter have been known to produce the appearance of a double cortex. These lesions may be associated with injury to a group of radial glia, leading to failure of a group of neuroblasts to migrate normally (125). Alternatively, a defect in genes controlling, neuroblast proliferation, neuroglial interactions, and PCD has been suggested as being causal (119).

PMG denotes small, meandering gyri, often with bridging of the sulci by fusion of the molecular layers. It consists of two histologic types. Four-layered PMG is most frequently considered to result from a destructive lesion occurring at approximately 20 to 24 weeks

FIGURE 5-5

Cytologic neuronal changes in severe cortical dysplasia (CD). Panel A (stained with the Bielschowsky technique) shows many neurons with cytoskeletal abnormalities, and some with cytoplasmic vacuolization (circled neuron). The neuronal changes resemble neurofibrillary tangles (NFTs) seen in neocortex of patients with Alzheimer disease, although at the ultrastructural level paired helical filaments (typical of Alzheimer NFT) are not present in CD. Nissl techniques (Panel B, stained with Kluver-Barrera) also highlight neuronal disorganization, enlargement of neuronal cell bodies (e.g., neuron in the middle), and clumping of perinuclear Nissl together with clearing of peripheral cytoplasm.

of gestation, and an unlayered form is thought to result from an insult earlier in brain development (at approximately 13–16 weeks) (154).

Neuronal cytomegaly denotes enlarged neurons, some of which may also be dysmorphic (Figure 5-5); these were first described in association with seizure-producing focal cortical malformations by Taylor et al. (121). Nerve cell hypertrophy was convincingly shown using quantitative histochemistry in a case of HME (155). The differentiation of cytomegalic vs. dysmorphic neurons is of importance in assigning a Palmini grade to a given lesion. Neurons that show enlargement of their cell bodies only are, in association with cortical architectural disorganization, typical of Palmini type IB lesions, whereas corticectomies that also contain dysmorphic neurons are characteristic of Palmini type II CD. When balloon cells are absent, the lesion is described as Palmini type IIA; when they are present, it becomes Palmini type IIB. (Palmini IIB CD corresponds to what has been described as Taylor-type focal cortical dysplasia, or T-FCD.) Dysmorphic neurons bear an extremely complex dendritic arborization as well as an abundance of perisomatic synapses and a paucity of axosomatic synapses (156, 157). Increased neuronal size has been associated with an increased DNA and RNA content, as well as increased nuclear and nucleolar volume suggestive of heteroploidy (124, 158). Argyrophilic, neurofibrillary-like tangles and cytoplasmic vacuoles have been demonstrated within many such neurons (Figure 5-5) (159), as has the existence of paracrystalline intracytoplasmic structures visible on ultrastructural examination (160). These neurofibrillary-like cytoplasmic inclusions differ from the neu-

rofibrillary tangles of Alzheimer's disease in that they do not contain paired helical filaments (161).

Balloon cells, showing similarity to gemistocytic astrocytes, have eccentric nuclei and ballooned, glassy, or opalescent eosinophilic cytoplasm (Figure 5-6). They often demonstrate binucleation or dysmorphic nuclei, sometimes showing bridges of nucleoplasm between two separate islands of nuclear material within a cell. They may cluster at the cortex–white matter junction or be abundant within subcortical white matter (94, 104). Frequently they are admixed with dysmorphic and enlarged neuronal cell bodies. Ultrastructurally, they are packed with filaments ranging in size from 400 to 600 nm in length and 30 nm in thickness, interspersed with non-membrane-bound, electron-dense, helical structures (162). Vinters et al. (159) and others have demonstrated dual staining of many cells in dysplastic cortex (including some balloon cells) with antibodies to both neuronal and glial markers, implying either a failure of the cells to commit to a specific phenotype or dedifferentiation. The resemblance of balloon cells to cells found within the cortical tubers of TSC has suggested the possibility that cases of CD harboring balloon cell change may represent a forme fruste of TSC (104, 113, 114, 162, 163).

### Pathogenesis of Cortical Dysplasia

Although it is accepted that cortical dysplasia involves abnormal cerebral cortical development, it is unclear when this occurs and how it produces seizures. Most MCD classification systems are based on speculating

**FIGURE 5-6**

Changes of CD, Palmini type IIB. All panels are from sections stained with hematoxylin and eosin. Panel A shows marked neuronal disorganization. At higher magnification (Panel B) balloon cells are identified (arrow), as are dysmorphic neurons. Arrowheads highlight a cell with typical neuronal nucleus, but opalescent balloon-like cytoplasm, at the periphery of which Nissl-like substance is seen. Other neurons in this field show changes similar to those in Figure 5-5B. Panel C shows several balloon cells, with glassy eosinophilic cytoplasm (arrows) scattered throughout a surgical resection specimen.

when the first developmental steps involving cell proliferation, neuronal migration, and cortical organization become deranged to produce the malformed cortex. Previously, the presumed mechanisms of CD pathogenesis have been thought to be defects in neuronal migration, as one explanation for subcortical heterotopic neurons, and altered periventricular neuroglial differentiation to account for cytomegalic and dysmorphic neurons and balloon cells (164–166). Although such mechanisms appear to be operant in genetic forms of MCD, clinicopathologic investigations (using corticectomy specimens) have challenged this singular interpretation (98, 101, 102, 167, 168).

In recent studies, the UCLA group has found evidence that surgically treated CD seems to involve retention of cells of the human pre- and subplate, along with an overproliferation of cortical neurons. Prenatal human

subplate cells have morphologic similarities to dysmorphic neurons found in postnatal CD tissue (168). Normal human subplate contains large multipolar neurons similar to cytomegalic neurons, and polymorphous and fusiform neurons with thick primary dendrites along with inverted pyramidal-shaped neurons, a feature noted in dysmorphic CD neurons (151). Most human subplate cells degenerate in the 4 to 6 weeks before birth (147, 169), which coincides with increasing definition of the gray-white matter junction and secondary gyral folding (170). Toward the end of normal neurogenesis, periventricular radial glial cells attach themselves to the tailing processes of the last produced cortical pyramidal neurons and migrate toward the cortex, where they detach and eventually transform into protoplasmic astrocytes (171–173). This may explain why balloon cells in CD tissue have some characteristics similar to those of radial glia (174–176).

The UCLA group has proposed that CD pathogenesis probably involves partial failure of the later phases of neocortical formation. As a consequence, subplate and radial glial degeneration and transformation would be reduced or prevented, giving the appearance of abnormal dysmorphic cells in postnatal CD tissue. A failure of late cortical maturation could explain the presence of abnormally thickened gyri with indistinct cortical gray-white matter junctions in the MRI scans of CD patients (101). The precise timing of these events during cortical development would explain the different forms of CD identified by MRI as well as the severity of CD assessed by histopathology. Developmental alterations during the late second or early third trimester would account for severe CD, such as hemimegalencephaly, whereas events occurring closer to birth might explain milder forms of CD. In addition, there appears to be an overproduction of neurons in the later phases of cortical development. Cerebral hemispheric volumes assessed by MRI were normal or increased in the case of hemimegalencephaly, and cortical thickness was the same or slightly increased (103, 154). Furthermore, neuronal densities were increased in the upper gray matter, molecular layer, and subcortical white matter. The location of excess neurons would be consistent with the idea that this process occurred in later periventricular cell cycles (i.e., ones occurring toward the end of neurogenesis). Thus, heterotopic subcortical white matter neurons are likely the result of excessive late generated pyramidal neurons trying to migrate toward the already overly crowded cortical ribbon, in combination with residual prenatal subplate neurons that failed to degenerate before birth.

### Cortical Tubers of the Tuberous Sclerosis Complex (TSC)

Tuberous sclerosis complex (TSC) is an autosomal dominant, multisystem disorder in which the CNS, eyes, kidneys (Figure 5-7), skin, and heart are most commonly affected by malformative, hamartomatous, or neoplastic lesions (177–182). It has an incidence of 1:9,400 to 10,000 births (177, 178); however, accurate estimates are difficult to ascertain, and a high rate of spontaneous TSC gene mutations has been described (177, 183). The clinical presentation of an individual with TSC may be with infantile spasms, autism, or mental retardation. Approximately 85% of TSC patients who come to medical attention have experienced a seizure at some time. Because genetic analysis to confirm the diagnosis of TSC remains unavailable to most physicians, diagnostic criteria for TSC have been enunciated (184, 185). In the 1998 criteria, some clinical features previously thought to be pathognomonic for TSC were considered less specific, whereas clinical or radiographic features of the disease were subdivided into major and minor categories, based

FIGURE 5-7

Angiomyolipoma, a tumor characteristic of TSC, is seen in the sectioned kidney of a patient who came to autopsy.

upon their apparent degree of specificity for TSC. Using these newer revised criteria, a definitive diagnosis of TSC was made by the confirmation of two or more distinct types of lesion in a patient, rather than multiple lesions of the same type (e.g., tubers) in the same organ system. Thus no single lesion defines the disease.

*Neuropathology of Cortical Tubers as a Cause of Seizures.* Individuals with TSC may rarely present with HME. However, the characteristic brain abnormalities of TSC include neocortical tubers (Figure 5-8), subependymal nodules (SENs), and subependymal giant cell astrocytomas (SEGAs). Cortical tubers are often associated with IS and intractable epilepsy in children. The lesions manifest as enlarged gyri in which the cortex–white matter junction has become blurred, resembling sporadic, severe cortical dysplasia (104, 111). Histologically the lesions show disorganized neocortex, with a variety of dysmorphic, markedly enlarged neurons, and bizarre

FIGURE 5-8

Tuber of tuberous sclerosis complex. All panels are micrographs from the same specimen, examined using different stains. Panel A (from a hematoxylin and eosin–stained section) shows features akin to those seen in Palmini type IIB cortical dysplasia. Note a markedly disorganized, crowded collection of dysmorphic neurons, and balloon-like cells. Panel B is from a section labeled with a digoxigenin-labeled probe for the *TSC2* gene product. Note differential expression of the gene in various cells, but especially prominent expression within cells of neuronal phenotype. (For details, see M. Menchini, J.K. Emelin, PS Mischel, TA Haag, MG Norman, SH Pepkowitz, CT Welsh, JJ Townsend, HV Vinters. Tissue and cell type specific expression of the tuberous sclerosis-related gene, *TSC2* in human tissues. *Modern Pathology* 1996; 9:1071–1080). Panel C is from a section stained (immunoperoxidase technique) with primary antibodies to the *TSC1* gene product, hamartin. Note prominent immunoreactivity of clusters of cells (with uncertain phenotype, arrows) and perivascular cells (arrowheads). This tuber originated from a patient in whom it was unknown whether a mutation was present in the *TSC1* or *TSC2* gene. (For details of methodology, see MW Johnson J.K. Emelin, S-H Park, H.V. Vinters. Co-localization of *TSC1* and *TSC2* gene products in tubers of patients with tuberous sclerosis. *Brain Pathology* 1999; 9:45–54.)

gemistocytic astrocyte-like “balloon cells” having eccentric nuclei containing relatively coarse chromatin and glassy, eosinophilic cytoplasm (Figure 5-8). Balloon cells seen in TSC are almost identical to those seen in severe cortical dysplasia (CD). This observation has raised the possibility that cases of CD with balloon cell change represent a forme fruste of TSC (113, 114, 162, 163). Balloon cells, such as those in FCD, show morphological and immunohistochemical features of both neurons and astrocytes, suggesting a failure of commitment in neuroglial differentiation. Tubers may show prominent calcification. Giant cells within TSC tubers show halos of synaptophysin

immunoreactivity around neurons, resembling those noted in gangliogliomas, as well as strong immunostaining with antibodies to the microtubule-associated protein 2 (MAP-2) (186). Alpha B-crystallin, a member of the heat shock protein family of peptides, is found within dysgenetic cells of tubers, and within both SEGAs and SENs (187). Dysmorphic cytomegalic neurons express high levels of tuberin, as do individual cells within SEGAs and SENs. Tuberin appears to be present in most neuronal populations of the CNS from at least 20 weeks’ gestation, with an apparent up-regulation of its expression after 40 weeks of gestation (181). Hamartin was found, albeit

with a weaker signal, in the same cell types during CNS development.

Although architectural disarray is a defining feature of a tuber, cellularity of a lesion may be extremely variable. When high cell density is noted, a tuber may resemble a ganglioglioma (181, 188, 188a). Although the proliferative potential of these lesions appears low, as judged by immunohistochemistry for Ki-67, other markers of cellular proliferation (e.g., collapsin response mediator protein 4/CRMP4, doublecortin/DCX) are expressed within giant cells of cortical tubers and SEGAs, suggesting that they may represent newly generated cells that have migrated into tubers from the SVZ (188).

Our current understanding of the molecular pathogenesis of TSC represents a triumph of multidisciplinary, multicenter collaborations focused on characterizing the complex gene defects that cause this disorder (189–192). TSC results from mutations in one of two nonhomologous tumor suppressor genes, *TSC1* (192) on chromosome 9 (9q34) encoding a 130-kDa protein, hamartin, and *TSC2* (189) on chromosome 16 (16p13.3) encoding a 200-kDa protein, tuberin. About one-half of TSC families show linkage to each of these two genes. *TSC1* mutations, accounting for a minority of mutations identified, are slightly less common in sporadic TSC patients, and are more common in familial cases (13–50%) (193). Putative functions of both *TSC1* and *TSC2* gene products have been studied using mostly *Drosophila* and rodent models of TSC, but also using human tissues. This work initially suggested that both *TSC1* and *TSC2* gene products had growth suppressor properties (194–196). Significant interactions of the TSC gene products with each other, and with intracellular signaling pathways, have been implicated in disease pathogenesis.

Hamartin may also interact with the ERM (ezrin, radixin, and moesin) family of actin-binding proteins to activate small GTPases of the Rho subfamily (Rho GTPases) (197). Rho GTPases are important regulators of the actin cytoskeleton and may be involved in neuronal developmental processes including migration, establishment of polarity, synapse formation, etc. (198). ERM proteins belong to the band-4.1 superfamily of membrane-cytoskeleton linking proteins (199), thought to function in multiple different fashions according to their interaction with various membrane proteins, Ras superfamily GTPases, and the actin cytoskeleton; they may be involved in the formation of microvilli, cell-cell adhesion, maintenance of cell shape, and motility (200). The observation that hamartin binds to ezrin in vivo and can modulate the activity of RhoA (Ras homologous member A) (197), suggests that tuberin and hamartin may be attached to the membrane-cytoskeletal cortex through activated ERM proteins (201, 202). Evidence suggests that ERM proteins function at a position upstream and downstream of Rho GTPases to regulate cellular adhesion

and motility (203, 204). ERM proteins (ezrin and moesin) are expressed in germinal matrix cells, migrating cells, and radial glial fibers in the developing human brain (201), correlating with RhoA expression in proliferating and migrating cells in the developing rat brain (205). Dysfunction of tuberin and hamartin may perturb communication between ERM proteins and Rho GTPase to cause abnormal neuronal migration, polarity, and morphology, resulting in the formation of dysplastic cortex. Hamartin and tuberin are coexpressed within a population of abnormal neuroglial cells (206), and both TSC gene products and ERM proteins are also coexpressed within a subpopulation of abnormal neuroglial cells in TSC tubers (201). Abnormalities of radial glia have also been implicated in the pathogenesis of brain lesions of TSC (206a).

Tuberin contains a conserved 163-amino acid carboxy-terminal region that exhibits sequence homology to the catalytic domain of a GTPase-activating protein (GAP) for the small molecular weight GTPase Rap1 (207) and for Rab5 (208). Using in situ hybridization, *TSC2* mRNA was found to be widely expressed in various cell types throughout the body, including epithelia, lymphocytes, and endocrine organs; within the CNS, it was prominently and selectively expressed within neurons, especially motor neurons (209). Widespread expression of the *TSC2* gene within developing and adult nervous system was noted in another study using various techniques (210). A study in mice showed that tuberin localized to the perinuclear region of cerebellar Purkinje cells, whereas hamartin was noted to distribute along neuronal or astrocytic processes (211). *TSC2* mRNA and tuberin were found in abundance in many CNS cell types, including neurons and ependymal cells (212).

*TSC1* and *TSC2* gene products colocalize within tubers (and sometimes within individual dysmorphic cells) of patients with TSC (206). Tissue culture experiments in various cell types show that both hamartin and tuberin interact with the G2/M cyclin-dependent kinase CDK1 (213). It has also been suggested that hamartin and tuberin have separable and presumably distinct functions in mammalian cell cycle regulation (214); that is, hamartin has the ability to modulate cell proliferation independent of the presence of functional tuberin, and binding to hamartin is not always essential for tuberin to affect cell proliferation. *Tsc1* and *Tsc2*, *Drosophila* homologs of *TSC1* and *TSC2*, function together in vivo to negatively regulate cell size, cell proliferation, and organ size in the insulin signaling pathway (PI3Kinase-Akt/PKB-mTOR-S6K-S6) at a position downstream of *dAkt* (*Drosophila Akt*) and upstream of *dS6k* (*Drosophila S6 kinase*) (215). This has been clearly confirmed in surgically resected TSC tubers by means of quantitative immunohistochemical evaluation using tissue microarray methodology (216); constitutive activation of S6K has been observed in TSC

tubers but not in focal cortical dysplasia of Taylor type (T-FCD or CD Palmini type IIB), suggesting one difference between these MCDs (216, 217).

### STURGE-WEBER-DIMITRI (SWD) SYNDROME/ENCEPHALOTRIGEMINAL ANGIOMATOSIS

This rare, nonfamilial, neurocutaneous syndrome of unknown etiology (218–220) is encountered in surgical specimens from infants and children with intractable epilepsy, although much less commonly than destructive and malformative/hamartomatous lesions. Its frequency is estimated to be 1 per 50,000 live births (221); 75% to 90% of affected children develop partial seizures by 3 years of age (222). Clinicopathologic reports describe the association of the cerebral lesion, usually localized to the occipital cortex, with facial capillary hemangioma

(port-wine stain) in the distribution of the ophthalmic division of the trigeminal nerve (220, 223, 224). Neuroimaging features are highly characteristic. Neuropathologic abnormalities in cortical resection specimens (Figure 5-9) are easily appreciated at low magnification. Soft tissue radiographs of the sliced specimen may show the characteristic “tram-track” pattern of neocortical calcification. Leptomeningeal angiomas are a key diagnostic feature of the syndrome (225), characterized by some authors as a venous angioma (224), consisting of dilated and tortuous thin-walled blood vessels within the subarachnoid space and pia, which may extend into the underlying cerebral cortex and subcortical white matter. The cortex itself shows calcifications centered on microvessels, with associated neuronal loss, astrocytic gliosis, and cortical atrophy (218, 219) that is assumed to result from ischemic phenomena secondary, at least in part, to the meningeal angiomas. Associated malformations such as polymicrogyria, agyria/pachygyria, heterotopias, and cortical

FIGURE 5-9

Sturge-Weber disease (surgical specimens stained with hematoxylin and eosin). (A) A portion of occipital lobe showing barely visible punctate and granular calcification in the superficial cortex (arrows). (B) Venous angioma-like structure in meninges of another case (arrows; cortex is at top of the image).

disorganization may also be seen (220). Ultrastructural studies of the parenchymal calcifications in Sturge-Weber brain have suggested that the earliest calcium deposits occur within perithelial cells (pericytes) of small blood vessels, and that the underlying cause of the calcification may be anoxic injury to endothelial, perithelial, and glial mitochondria (226, 227).

### NEUROFIBROMATOSIS AND OTHER NEURO CUTANEOUS SYNDROMES

Central neurofibromatosis (NF-2) is a genetic disorder characterized by neoplastic and dysplastic lesions of Schwann cells, meningeal cells, and glia (182, 228). It is associated with (a) central and peripheral schwannomas, including bilateral acoustic schwannomas, (b) meningiomas, (c) gliomas, and (d) glial hamartomas. It is inherited as autosomal dominant, with a high rate of sporadic mutations. The *NF-2* gene, postulated to be a tumor-suppressor gene, has been localized to chromosome 22q12 and encodes a widely expressed protein, merlin (moesin, ezrin, radixin-like protein) or schwannomin, a new member of the protein 4.1 family of cytoskeleton-associated proteins (228, 229). Although seizures can develop in patients with NF-2, these are usually caused by a primary neoplasm rather than a malformative lesion. The most frequent malformations seen in association with NF-2 are meningio-angiomas and glial hamartomas. Meningio-angiomas (230, 231) is a rare epilepsy-associated lesion of the cerebral cortex of unknown etiology, with puzzling and rather dramatic vascular, malformative, and neoplastic elements (232, 232a). Rare neurocutaneous syndromes, such as epidermal nevus syndrome and hypomelanosis of Ito (233), have also been associated with pediatric epilepsy. The pathologic changes seen within the cerebral cortex of these patients are virtually identical to those seen in patients with CD.

### BRAIN INFLAMMATION AND EPILEPSY

One of the most common inflammatory lesions encountered in corticectomies performed for intractable epilepsy is the chronic inflammatory reaction (often with a giant cell or granulomatous component) that is left by depth electrodes implanted for preoperative monitoring purposes within brain parenchyma. Leaving aside the obvious fact that any inflammatory disorder of the brain (especially viral encephalitides, e.g., caused by *Herpes simplex*) may be accompanied by seizure activity, evidence is emerging of an increasingly important role for brain inflammation in epilepsy. Steroids and adrenocorticotropic hormone (ACTH) have powerful anticonvulsant effects, especially in children with infantile spasms

or West syndrome. Seizure activity is regularly associated with a cerebrospinal fluid (CSF) pleocytosis and elevated CSF proinflammatory cytokines. Emerging evidence suggests that patients who develop temporal lobe epilepsy with hippocampal sclerosis (TLE-HS) following febrile convulsions may have been at risk for developing TLE-HS because of polymorphisms in the interleukin (IL)-1 $\beta$ -511T allele (234). Temporal lobes resected from patients with TLE have demonstrated overexpression of NF $\kappa$ B, a transcription factor involved in acute inflammation (235). There is indirect evidence that new-onset refractory status epilepticus (NORSE) may have an inflammatory basis in that many patients have an antecedent inflammatory or infectious illness and CSF usually shows a pleocytosis (236).

### Rasmussen Syndrome (RS)

Rasmussen syndrome (or Rasmussen encephalitis, RE) is characterized by intractable focal seizures (usually epilepsy partialis continua) with progressive hemiparesis, symptoms attributed to chronic (pathogen-free) inflammation of gray and white matter, with progressive unihemispheric atrophy (237–239). A recent European consensus meeting on RS has formulated diagnostic criteria, which incorporate clinical, EEG, MR, and pathologic findings (240). Although the pathologic appearances of brain tissue affected by RE suggest a chronic viral infection, no virus has ever been consistently isolated from RS brain tissue or discovered within it using modern molecular or microbial culture techniques (241, 242). Circulating anti-glu-R3 antibodies were reported to be of etiologic importance in some patients with RS (243, 244), but subsequently these antibodies were found to occur in other seizure disorders (245, 246). Very recently, autoantibodies against the N-methyl-D-aspartate glutamate receptor (NMDA-type GluR) epsilon2 subunit and its epitopes were reported in RS patients (247). However, although the initial report is highly promising, the diagnostic specificity of GluRepsilon2 for RS remains to be confirmed. Any explanation for RS will ultimately have to account for its unihemispheric topography. Rarely have pathologic studies demonstrated bihemispheric involvement (248).

The neuropathologic findings of RS/RE (Figure 5-10) are said to comprise four merging stages (240, 249, 250), the earliest of which is characterized by inflammation, especially perivascular lymphocytes, and microglial nodule formation within brain parenchyma, but little morphologic evidence of neuronal injury. In stage 2, lymphocytic infiltration increases in density and both astrocytes and microglial cells become more widespread, tending to involve all cortical layers—a “panlaminar” pattern of cortical inflammation and gliosis. Patchy neuronal loss may be present. In stage 3 the neuronal population is depleted in either a patchy or panlaminar pattern, with

**FIGURE 5-10**

Histopathology of Rasmussen encephalitis (RE). All panels are from sections stained with hematoxylin and eosin. (A) Extensive cystic cavitation (gyrus at left, arrowheads) and extreme laminar necrosis (gyrus at right, arrows) in a resection specimen from a severely affected child. (B) Large cortical scar, seen in the center of this image, running vertically. (C) Perivascular inflammation by mononuclear inflammatory cells (arrows), accentuated in one part of the vessel wall. (D) Patchy meningeal inflammation (arrows) by mononuclear inflammatory cells.

severe cortical degeneration and gliosis. In stage 4 there is profound cortical atrophy with gliosis and vacuolation of the neuropil, with cystic cavitation in many cases (Figure 5-10). Frequently, areas of relative cortical normality surround zones of badly scarred cortex. This geographically defined severe pathologic change, often seen a few micrometers away from relatively normal brain parenchyma, means that a negative brain biopsy taken with the intent of establishing the diagnosis of RE never truly excludes the diagnosis. Occasionally, dual pathology including malformative elements of cortical dysplasia

or vascular malformations and chronic inflammation are seen in a corticectomy originating from an epilepsy patient, suggesting that the two lesions may be etiologically connected (251).

There is some interlobar variation in severity of the neuropathologic change, although usually the occipital cortex is less severely involved than the others. Subcortical white matter may show evidence of axonal injury in the form of neuroaxonal spheroids, although whether this is secondary to Wallerian degeneration or represents a separate cytotoxic attack on axons is uncertain. The

**FIGURE 5-11**

Immunohistochemical features of Rasmussen encephalitis. The panels represent three parallel fields from a severe case (cortectomy specimen) stained with hematoxylin and eosin (A), or primary antibodies to a T-cell marker (CD3, Panel B) or microglial/macrophage marker (CD68, Panel C), highlighting the heterogeneity of the angiocentric infiltrate. (B lymphocytes are, however, usually few in number.)

inflammation or neuronal destruction varies in its timing and progression from one region to another. Early changes consisting of inflammation only may be located adjacent to areas showing intense neuronal loss and gliosis. The almost unique unilateral nature of RS/RE separates it from all other immune-mediated disorders of the nervous system. Ultrastructural studies of RE/RS have failed to demonstrate viral particles consistently in brain biopsies/resections from affected patients, although rarely measles virus-like particles have been noted; rare cerebral endothelial cells in one case contained tubuloreticular

inclusions (252). Gene expression profiling of a brain specimen from an RE patient has shown a dramatic increase in expression of several genes related to inflammation, and a pronounced down-regulation of several GluRs, especially GluR4 (253).

The inflammatory infiltrate in RS brain consists predominantly of CD8-positive T cells (254, 255). The lymphocytes lie adjacent to MHC class I(+)-expressing neurons and contain granzyme B, which has been suggested as the local mediator of T cell-mediated cytotoxic neuronal death in RS (254). There is little evidence to support a humoral

FIGURE 5-12

Severe intrauterine/perinatal brain injury (hematoxylin and eosin-stained section) usually manifests as cystic encephalomalacia, with variably severe involvement of the cortex (arrows) or subcortical white matter (section is from an autopsy rather than a surgical specimen).

process in that B cells, immunoglobulin and complement are rarely found in RS brain tissue. The T cell infiltrate is of relatively restricted clonality (256). Abundant microglia and macrophages may also be present (Figure 5-11).

## DESTRUCTIVE LESIONS/ ENCEPHALOMALACIA

Destructive lesions, with the neuropathologic appearance of regions of cystic encephalomalacia, are commonly encountered in corticectomies for epilepsy, especially in infants and children (162). They are presumed to represent sequelae of intrauterine, perinatal, or (rarely) postnatal brain infarcts (Figure 5-12) or hemorrhages, the etiology of which is multifactorial, extremely complex, and beyond the scope of this chapter. For excellent recent monographs on pathophysiologic mechanisms important in the evolution of destructive brain lesions in the developing human brain, including ones that may cause seizures, see the works by Kalimo (232) and Golden and Harding (232a).

## Epileptogenic Cerebral Cortical Malformations

*Annapurna Poduri  
Bernard S. Chang  
Christopher A. Walsh*

**N**euroimaging has become a standard part of the evaluation of patients with localization-related epilepsy or with any type of epilepsy in the setting of abnormal cognitive development. In this setting, malformations of cortical development are recognized more and more frequently as the etiology of epilepsy in children.

The more aggressive pursuit of detailed neuroimaging in children with epilepsy is due in part to the more accepted role of focal resective epilepsy surgery as a treatment option in medically refractory localization-related epilepsy. Neuropathological data from patients undergoing surgical resection of epileptogenic foci have shed further light on the prevalence and histopathological properties of cerebral cortical malformations, even among some patients with normal magnetic resonance imaging (MRI). As such, the role of these malformations is proving to be substantial in the pathogenesis of refractory epilepsy in children.

We use the terms “cerebral cortical malformation” and “malformation of cortical development” interchangeably in this chapter to discuss malformations that represent known or presumed disruptions of brain development. We reserve the term “disorders of neuronal migration” for disorders in which there is radiological, pathological, or other evidence implicating the abnormal migration of cortical neurons during development. In addition, whereas “cortical dysplasia” can refer to the broad range

of cerebral cortical malformations (1, 2), we restrict our use of this term to discussions of focal cortical dysplasia (FCD), since to some readers the term may connote a specific, pathologically confirmed entity.

We begin by highlighting the important role of malformations of cortical development in pediatric epilepsy. We discuss mechanisms of epileptogenesis in cerebral cortical malformations, with examples drawn from several types of malformations. In the second half of the chapter we review what has become a well-established framework for the understanding and classification of these disorders, taking into account central nervous system ontogeny and the genes that regulate it.

### **CEREBRAL CORTICAL MALFORMATIONS IN PEDIATRIC EPILEPSY**

#### **Type of Seizures and Epilepsy Associated with Cerebral Cortical Malformations**

The majority of patients with malformations of cortical development and epilepsy have symptomatic, localization-related epilepsy. This classification applies to any patient with a cerebral cortical malformation and seizures that originate in a focal region of cortex, regardless of whether the malformation itself is a focal lesion, such as a focal

cortical dysplasia, or whether it represents a more widespread abnormality affecting the entire cortex, such as lissencephaly.

An individual with a cerebral cortical malformation may have seizures that appear generalized; such a patient most likely has secondarily generalized localization-related epilepsy, but symptomatic generalized epilepsy is also possible. In these cases, under the most recent semiology-based International League against Epilepsy (ILAE) classification of seizures and epilepsy, the seizure phenomenology is classified as “generalized,” and the etiology should be specified as the malformation of cortical development (3).

### **Epidemiology of Cerebral Cortical Malformations in Pediatric Epilepsy**

½ to 1% of children are estimated to have epilepsy (4–6). About one-third of children with epilepsy do not respond to medication and are considered medically refractory (7), and it is in this group that malformations of cortical development are most frequently encountered.

The role of cortical malformations has been widely recognized in cases of refractory localization-related epilepsy in children and adults, with malformations ranging from small heterotopia to large hemispheric malformations such as hemimegalencephaly (8–12). 10% to 20% of patients seen in subspecialty epilepsy centers are estimated to have cerebral cortical malformations by some authors (13). In an observational study of patients aged 15 years or older with localization-related epilepsy, only 70% of whom had any form of imaging performed, 3% of patients were found to have cerebral cortical malformations by MRI (14). In one series of adults with refractory epilepsy, 12% malformations of cortical development on MRI (15).

Epidemiological studies performed in the era preceding the routine use of MRI do not reflect the role of malformations of cortical development in pediatric epilepsy, but there are several reports suggesting that their role is even greater in children than in adults with epilepsy. Kuzniecky and colleagues reported that one-quarter of a series of 44 children who underwent surgical resection for treatment of epilepsy demonstrated cortical malformations (16). Pasquier and colleagues described 230 consecutive children and adults undergoing epilepsy surgery, the majority of whom had childhood-onset epilepsy; nearly one-quarter had some form of cerebral cortical malformation, including FCD, tubers suggesting tuberous sclerosis complex (TSC), and dysembryoplastic neuroepithelial tumor (DNET) (17). Sinclair and colleagues described a series of 42 children undergoing temporal lobectomy, in whom four had pathological evidence of FCD and four had tubers; additionally, of 13 patients who had temporal lobe tumors, eight fell into the spectrum of developmental malformations (seven gangliogliomas and one DNET) (18, 19).

In the subgroup of children undergoing epilepsy surgery for refractory infantile spasms, malformations of cortical development are a leading cause (20–22). Furthermore, there is a growing body of pathological evidence from epilepsy surgery series demonstrating that many adults and children with intractable localization-related epilepsy *without* MRI abnormalities have malformations of cortical development that are currently appreciated only microscopically (12, 23–28) or identified using [<sup>19</sup>F]2-fluoro-2-deoxy-D-glucose ([<sup>19</sup>F]2-FDG) (29).

To our knowledge, large population-based studies of children with epilepsy have yet to fully capture the role of cerebral cortical malformations as a common etiology. Nonetheless, the accruing evidence and our personal experience lead us to conclude that malformations of cortical development account for a substantial portion of children with refractory localization-related epilepsy.

### **EPILEPTOGENESIS OF CEREBRAL CORTICAL MALFORMATIONS**

The discussion of the epileptogenesis of malformations of cortical development draws on observations regarding the pathological, electrophysiological, and molecular properties that may underlie their propensity to generate seizures. Many features suggest the persistence of fetal patterns, suggesting a disruption of the early process of neuronal and glial precursor proliferation, which in turn may lead to perturbations of the later processes of neuronal migration, lamination, and later cortical organization. The mechanisms of epileptogenesis may differ among malformations of cortical development according to the stage at which development was disrupted (30). We will consider epileptogenesis as a phenomenon common to all of the malformations together, because specific influences of the timing of disruption have yet to be elucidated.

#### **Pathology of Cerebral Cortical Malformations**

Pathological studies provided an initial understanding of developmental malformations of the brain. Despite advances in neuroimaging, there are still patients with relatively subtle disturbances of cortical development that are manifest only as pathological changes; it is only on the basis of accurate neuropathological analysis that these patients' lesions can be appropriately characterized and classified. Even in those patients with malformations evident by neuroimaging, the pathological abnormalities continue to provide insight into the developmental origin of these lesions.

Both neurons and glia may appear abnormal in location and morphology in malformations of cortical development, as described by Taylor and colleagues in focal cortical lesions, now referred to as FCD with balloon cells or Taylor-type FCD (8). They and others since have

reported the following abnormalities in neurons in these developmental lesions: (1) neurons may be abnormally large and clustered; (2) many abnormal neurons are located in cortical layer I and sometimes heterotopically in the white matter; (3) the malformations contain bizarrely shaped cells of presumed glial origin; and (4) there is potential for severe disorganization of the cortex in these lesions (8, 31, 32). Similar pathological changes have been described in many other types of cerebral cortical malformations, including hemimegalencephaly (33, 34). Figure 6-1 depicts these abnormal neuronal and glial features from a child

**FIGURE 6-1**

Abnormal neuronal and glial features from the hemisphere involved in hemimegalencephaly in a child who underwent hemispherectomy for refractory epilepsy. (a) Hematoxylin and eosin staining shows neurons with abnormal morphology, size, and orientation in the gray matter. The arrow indicates two abnormally shaped neurons with abnormal orientation and clustering. (b) Glial fibrillary acidic protein (GFAP) staining depicts abnormal astrocytes in the white matter (arrow) as well as intermediately stained cells with mixed neuronal and glial morphological properties (asterisk).

with hemimegalencephaly who underwent hemispherectomy for seizure control. Beyond these cellular and architectural findings, Sankar and colleagues described severe dysmyelination underlying regions of pathologically abnormal cortex in cerebral cortical malformations, suggesting a more prominent role of white matter in the pathogenesis as well as epileptogenesis (23).

One feature shared by many malformations of cortical development is disruption of the cortical architecture, which can be profound in such examples as double cortex syndrome and pachygyria, or more subtle in cases with only mild dyslamination. In some cases, the distinction between gray matter and white matter can be difficult to discern (35). Palmieri and colleagues grouped the histopathological abnormalities seen in cerebral cortical malformations into four categories, listed by increasing degree of abnormality (36):

1. Isolated architectural abnormalities, including dyslamination and columnar disorganization.
2. Architectural abnormalities with the predominant abnormal cell type of giant neurons (pyramidal-shaped neurons that are larger than normal layer V neurons).
3. Architectural abnormalities with predominant dysmorphic neurons (neurons with abnormal cytoplasmic neurofilament accumulation leading to abnormalities in shape, size, orientation, and processes), along with which giant neurons may also be present.
4. Architectural abnormalities with dysmorphic neurons and balloon cells (large cells that have thin cell membranes and eosinophilic cytoplasm, may be multinucleated, and typically display immunoreactivity to markers of both neurons and glia).

The third and fourth of these categories correspond to what is often termed Taylor-type FCD (36).

An additional feature sometimes seen in malformations of cortical development is the immature neuron, which is neither enlarged nor dysmorphic but has a large, immature-appearing nucleus and relatively sparse cytoplasm (36). From a pathological perspective, the abnormal cells seen in malformations of cortical development can be arranged from least to most severe in the following order: heterotopically placed but morphologically normal neurons, immature and giant neurons, dysmorphic neurons, and balloon cells (listed in Table 6-1). There is some evidence to suggest that pathological severity may reflect the severity of the associated epilepsy (37, 38).

Pathological analysis of malformations of cortical development clearly demonstrates that the neurons and glia within these lesions display unusual morphological properties. One might expect that neurons with abnormal morphological features and cell surface properties would display abnormal connectivity that would give rise to

**TABLE 6-1**  
*Range of Abnormal Cells Identified  
 in Cerebral Cortical Malformations,  
 from Least Severe to Most Severe*

TYPE OF NEURON	CHARACTERISTICS
Normal-appearing neurons	Located in abnormal locations (most commonly layer I)
Immature neurons	Normal shape and size, abnormally large nucleus
Giant neurons	Normal shape, abnormal size
Dysmorphic neurons	Abnormal shape, size, orientation, clustering
Balloon cells	Abnormal shape, size, orientation, clustering, neuronal and glial features

epilepsy (39). Some cells seen in malformations of cortical development recall features of neuronal-glia progenitor cells or immature neurons, suggesting the abnormal persistence of a fetal-like state. These and other features may contribute to the proclivity of cerebral cortical malformations to engender seizures. Efforts to understand these malformations on a molecular level should render further insight into the precise means of epileptogenesis, both in and around the malformations and in epileptogenic foci in general.

#### **Persistence of Immature Patterns of Expression in Cerebral Cortical Malformations**

Analogous to the pathological features of cerebral cortical malformations, the abnormalities observed at the protein level are also reminiscent of immature patterns. Immunohistochemical study of neurons in malformations of cortical development reveals excessive reactivity to the neurofilament protein SMI311 and the microtubule associated protein MAP2, which are typically expressed early in the immature brain (32, 35). Immunoreactivity to the cell adhesion molecule L1, which usually peaks in expression near the end of normal human gestation, has been found in excess in abnormal neurons from samples of hemimegalencephaly (40). The simultaneous neuronal nuclei (NeuN) and glial fibrillary acidic protein (GFAP) immunoreactivity of some cells corresponds to their morphological ambiguity and suggests absent or aberrant differentiation of neuronal-glia precursors and possible arrest in, or return to, a pre-differentiated state.

The immature and undifferentiated features of many of the cells seen in cerebral cortical malformations

certainly suggest a dysregulation of the processes of cell fate determination among neurons and glia. The mechanisms leading to these common features of many malformations of cortical development are not yet known, so it is not possible to state precisely which stage of cortical development is first disrupted. It is conceivable that a disruption during cell proliferation results in a more profound pathological picture, whereas a milder defect influencing neuronal migration may lead to more subtle ultrastructural changes with preserved neuronal maturation and cellular architecture. Until we discover the fundamental inciting events leading to each type of malformation, hypotheses based on the pathology and immunohistochemistry remain speculative.

#### **Abnormal Neurotransmitter Receptor Subunits in Cerebral Cortical Malformations**

An imbalance of excitatory and inhibitory synaptic activity can be implicated in any discussion of epileptogenesis. One approach to this issue in the realm of cerebral cortical malformations has been the study of expression of excitatory and inhibitory neurotransmitter receptor subunit proteins in surgical specimens from epilepsy surgery in humans as well as in animal models of malformations of cortical development. A thorough description of the role of excitatory and inhibitory neurotransmission in normal synaptic activity and epileptogenesis is provided elsewhere in this text. We concentrate here on the neurotransmitters for which there are data specific to malformations of cortical development.

##### *Glutamate Receptors*

Two classes of excitatory glutamate receptors that have been implicated in the epileptogenesis of malformations of cortical development are the *N*-methyl-D-aspartate (NMDA) and  $\alpha$ -amino-3-hydroxy-5-methyl-4-isoxazole propionic acid (AMPA) receptors. A functioning NMDA receptor comprises of a four-part complex of NMDAR1 (or NR1) and NMDAR2 (or NR2) subunits, which have eight and four different forms, respectively; although the NMDAR2 subunits do not alone function as ion channels, they potentiate the conductance of NMDAR1 currents when the two subunits are combined (41, 42). Immunohistochemical studies of abnormal neurons from human malformation of cortical development have shown alterations in expression of the NMDAR2 type A and B subunits (43–45). Crino and colleagues evaluated mRNA expression in individual abnormal neurons from regions of focal cortical dysplasia and reported increased expression of NMDAR2 type B and C subunits but decreased expression of NMDAR2 type A subunits in abnormal neurons from FCD (46). The relatively increased NMDAR2 subunit expression correlates with hyperexcitability in neurons in malformations of cortical

development; electrocorticography within malformations has revealed abnormal electroencephalographic (EEG) activity in regions subsequently found to have abnormal NMDA receptor profiles (42, 44).

The AMPA receptor complex is formed by four subunits: GluR1 through GluR4. Immunohistochemical studies have shown increases in GluR2 and GluR3 subunit expression in giant neurons and dysplastic neurons from human malformations of cortical development (45). In contrast, mRNA expression studies have shown decreased GluR1 and increased GluR4 expression in abnormal neurons from cerebral cortical malformations, compared to normal neurons from control samples (46). Some authors suggest that the functional implications of any or all of these deviations from normal AMPA receptor subunit expression may involve altered subunit stoichiometry, leading to neuronal hyperexcitability (42), but the precise mechanisms have yet to be worked out.

### ***GABA Receptors***

Gamma-aminobutyric acid (GABA) is the chief inhibitory neurotransmitter in the mature central nervous system. Assaying regions of FCD with immunohistochemical markers that identify GABAergic neurons, Ferrer and colleagues reported a decrease in the number of GABAergic neurons (47). In the study mentioned in the preceding section, Crino and colleagues reported a decrease in mRNA expression of the alpha-1, alpha-2, beta-1, and beta-2 subunits of the [GABA-A] receptor (46). During early brain development, there is limited GABA-mediated inhibitory activity (48), and the role of GABA evolves over time from excitatory to inhibitory (49). Abnormalities in GABA receptor expression in malformations of cortical development must therefore be considered against the backdrop of this developmental shift in GABA function (see also Chapter 1). If abnormalities in GABA receptor subunit expression represent yet another recapitulation of an immature state, the persistence of GABA-mediated excitability could contribute to the epileptogenicity of malformations of cortical development (50).

Clearly, in a patient with a cerebral cortical malformation or any predisposition to epilepsy, there are dynamic factors mediating the excitatory-inhibitory balance and establishing an electrophysiological threshold that is intermittently crossed, allowing a seizure to be generated and propagated. While the available data from neurotransmitter receptor subunit expression studies do not provide a complete model for epileptogenesis in malformations of cortical development, the pattern seen in these lesions appears to represent a developmental dysregulation of the balance of excitatory and inhibitory activity. Further study into the unique receptor properties in cerebral cortical malformations may not only shed further light onto the developmental aspects of the malformations but also

lead to the targeting of specific pharmacological treatment strategies for patients with malformations of cortical development. Given the important role of glutamate and other neurotransmitters in learning and memory, a more complete understanding of neurotransmitter dysfunction in cerebral cortical malformations may also ultimately provide insight into the cognitive difficulties that often accompany the seizures in patients with malformations of cortical development.

### **Genomic Study of Focal Cerebral Cortical Malformations**

The publication of the human genome, coupled with advances in informatics, allow us to study mRNA expression profiles and to conduct genome-wide studies to assay for deletions, duplications, and chromosomal rearrangements in the malformations of cortical development resected during epilepsy surgery. Kim and colleagues identified upregulation of genes associated with apoptosis and downregulation of other genes associated with apoptosis in tissue from focal malformations of cortical development (51). Immediate early genes have been similarly found to be upregulated in tissue from focal cerebral cortical malformations as well as in epileptic tissue not associated with malformations (52). In such studies, it is difficult to implicate the involvement of the identified genes in the causality of either the malformation or the epilepsy, because the abnormalities seen may represent an effect of electroclinical or electrographic seizures that have occurred. Using evidence from targeted microarrays, Yu and colleagues reported increased expression of genes encoding growth factors and transcription factors in tissue from hemimegalencephaly lesions, pointing to several potential pathways that may be involved in the aberrant growth responsible for these malformations (53). These latter studies may point to the very mechanisms that underlie the formation of malformations of cortical development, and the role of the genes identified in the lesions' epileptogenicity remains to be studied.

In our own study of tissue from epilepsy surgery samples, we have used single-nucleotide polymorphism-based copy number analysis and quantitative polymerase chain reaction to identify three copies of chromosome 1q in two cases of large hemispheric malformation; in one case, there was no evidence of this duplication in the patient's leukocytes, suggesting that a somatic event occurred in the brain (55). Further study is required to determine the implications of chromosomal aneuploidy in the development of focal malformations of cortical development and epilepsy. Although these DNA-based strategies may lead to further understanding of the genetic mechanisms underlying development of cerebral cortical malformations, they may not fully explain their epileptogenic potential.

**TABLE 6-2**  
*EEG Characteristics of Cerebral Cortical Malformations*

TYPE OF RECORDING	EEG CHARACTERISTICS
Scalp EEG	<ul style="list-style-type: none"> <li>• High-amplitude (&gt;100 <math>\mu</math>V) rhythmic theta and delta activity (55)</li> <li>• High-amplitude sharp-slow waves, alpha and beta activity (52)</li> <li>• Fluctuating amplitude theta and delta activity, faster than expected for age, possibly asynchronous (55)</li> <li>• High-amplitude or fluctuating amplitude &gt;15 Hz beta activity, in bursts or continuous (55)</li> <li>• Localized slowing and epileptiform spikes (37)</li> <li>• Repetitive or nearly continuous spikes or seizures (60, 61)</li> </ul>
Subdural extraoperative EEG	Continuous epileptiform discharges (60)
Intraoperative corticography	<ul style="list-style-type: none"> <li>• Repetitive bursts of alpha and beta activity (&gt;10 Hz) (61)</li> <li>• "Recruiting/derecruiting pattern" of spikes increasing in rhythmicity and frequency up to 12–16 Hz followed by focal slowing (61)</li> <li>• Continuous or nearly continuous rhythmic spiking (61–63)</li> </ul>

### **Epileptogenic Activity Arising in and around Cerebral Cortical Malformations**

Electroencephalographic data from scalp, subdural, and depth electrode recordings suggest intrinsic epileptogenicity of neurons within malformations of cortical development as well as the regions that surround them (9, 55–59). Table 6-2 (60–63) presents electrophysiologic characteristics that have been described in association with various types of cerebral cortical malformations based on routine or prolonged scalp EEG, subdural EEG recorded outside of the operating room with the intent of localizing seizure onset, and intraoperative corticography, the last of which is almost exclusively interictal (37, 55, 60–63). The common theme that emerges from all of these methods of recording is excessive rhythmicity, with higher than expected amplitudes and frequencies for age. Notably, investigators have reported abnormal electrophysiological properties and seizure onset zones in the regions immediately surrounding focal malformations of cortical development (9, 60, 64, 65). These latter findings have important implications for the treatment of cerebral malformations with resective surgery; the epileptogenic capacity of the tissue surrounding the regions of malformation that are visible macroscopically and by MRI suggest that subdural EEG recording may be required to establish seizure onset firmly, since it may not be restricted to the malformation.

### **CLINICAL PRESENTATION AND CLASSIFICATION OF CEREBRAL CORTICAL MALFORMATIONS BY STAGES OF CORTICAL DEVELOPMENT**

The process of brain development, which follows a sequence that is under genetic regulation, provides a

framework for understanding the variety of cerebral cortical malformations encountered in patients with pediatric epilepsy. The classification presented by Barkovich and colleagues has evolved to include an ever-expanding list of genetic etiologies for many cerebral malformations (1, 19, 66). The importance of its emphasis on genetic causes cannot be overstated; even when epilepsy is not the presenting symptom of a cerebral malformation, clinicians must address important questions regarding possible genetic etiologies. Table 6-3 presents the major categories of malformations of cortical development according to the stage that is thought to be first or primarily disrupted in brain development.

We begin this section with some general clinical observations regarding patients with epilepsy caused by cerebral cortical malformations. We briefly review the normal sequence of cortical development before discussing representative examples from each major group according to the first stage of brain development known or thought to be disrupted.

### **General Clinical Observations**

The focus of this chapter is the relationship between malformations of cortical development and epilepsy, so we provide estimates of the prevalence of epilepsy among patients with specific malformations when this information is available. In general, though the prevalence of epilepsy in each group is not 100 percent, we recommend advising patients with cerebral cortical malformations and their families that epilepsy is a common symptom of any structural brain malformation.

Apart from the minority of patients with cerebral cortical malformations who are asymptomatic, many patients with malformations of cortical development have what some clinicians term a "chronic static encephalopathy,"

**TABLE 6-3**  
*Cortical Malformations Classified by Stages of Cortical Development*

STAGE OF DEVELOPMENT	ASSOCIATED MALFORMATIONS
Neuronal and glial proliferation	Net decrease in neurons and glia—primary microcephaly <ul style="list-style-type: none"> <li>• Normal or simplified gyral pattern</li> <li>• Normal or thin cortex</li> <li>• Microlissencephaly (thick cortex)</li> <li>• With or without polymicrogyria</li> </ul> Net increase in neurons and glia—macrocephaly <ul style="list-style-type: none"> <li>• Abnormal proliferation</li> <li>• Cortical tuber</li> <li>• Focal cortical dysplasia with balloon cells, including transmantle dysplasia</li> <li>• Hemimegalencephaly</li> </ul> Tumors—DNET, ganglioglioma, gangliocytoma
Neuronal migration and cortical lamination	Abnormal radial migration, including arrested migration <ul style="list-style-type: none"> <li>• Lissencephaly (formerly type I lissencephaly)</li> <li>• Subcortical band heterotopia</li> <li>• Other subcortical heterotopia</li> <li>• Subependymal, periventricular heterotopia</li> </ul> Abnormal radial migration, including overmigration <ul style="list-style-type: none"> <li>• Cobblestone lissencephaly (formerly type II lissencephaly)</li> </ul> Abnormal radial and tangential migration <ul style="list-style-type: none"> <li>• X-linked lissencephaly with abnormal genitalia</li> </ul>

Adapted with permission from Dr. AJ Barkovich.

manifest not only as epilepsy but also varying degrees of developmental delay or mental retardation as well as other neurological problems. It is helpful to frame the individual patient's neurological problems, including the epilepsy, as stemming from the malformation of cortical development and to attribute the malformation itself, along with any associated nonneurological sequelae, to the underlying genetic etiology whenever possible. The likelihood and typical age of onset of epilepsy vary among syndromes, and the most precise characterization of patients' conditions will aid in the prognosis of their epilepsy as well as their neurodevelopmental outcome. In Table 6-4 we present a list of genes known to be associated with specific malformations of cortical development at the time of the writing of this chapter (67–86). Note that most of the conditions described thus far have been associated with autosomal recessive or X-linked patterns of inheritance, which is important when providing counseling to families about recurrence risk in subsequent children.

The treatment of epilepsy caused by malformations of cortical development is beyond the scope of this chapter, and general principles of treatment of epilepsy

are covered in depth elsewhere in the text. Patients with refractory epilepsy due to cerebral cortical malformations and well-localized anatomical and seizure foci are often considered candidates for epilepsy surgery, and the outcome has been reported to be favorable in one-third to two-thirds of patients with brain malformations undergoing resective surgery for the treatment of seizures (87–89).

### **Classification by Stage of Cortical Development Disrupted and Presentations**

#### *Normal Cortical Development*

The processes underlying normal cortical development in the human continue to be elucidated in increasing detail. The currently accepted paradigm for the formation of the human cortex was outlined elegantly by Sidman and Rakic in 1973 (90) and includes in the following sequence of events: (1) proliferation of progenitor cells in ventricular zone, (2) neuronal migration along a radial glial scaffold, leading to the establishment of the six layers of the neocortex, and (3) further organization, including formation

**TABLE 6-4**  
**Genes Responsible for Malformations of Cortical Development and Epilepsy**

MALFORMATION OF CORTICAL DEVELOPMENT	IDENTIFIED GENE(S)	INHERITANCE
Disorders of neuronal and glial proliferation		
Primary microcephaly	<i>MCPH1</i> , <i>ASPM</i> (67, 68)	AR
With seizures	<i>ASPM</i> (69)	AR
Microcephaly with bilateral periventricular heterotopia	<i>ARFGEF2</i> (70)	AR
Disorders with macrocephaly		
Neurofibromatosis type 1	<i>NF1</i> (71)	AD or sporadic
Sotos syndrome	<i>NSD1</i> (72)	AD or sporadic
Cowden syndrome	<i>PTEN</i> (73)	AD
Tuberous sclerosis complex	<i>TSC1</i> , <i>TSC2</i> (74, 75)	AD or sporadic
Disorders of neuronal migration and lamination		
Lissencephaly, male or female	<i>LIS1</i> (76)	AD or sporadic
Lissencephaly with cerebellar hypoplasia	<i>RELN</i> (77)	AR
Lissencephaly, male	<i>DCX</i> (76, 78)	X-linked
with abnormal genitalia	<i>ARX</i> (79)	X-linked
Double cortex syndrome, female	<i>DCX</i> (78, 80)	X-linked
Pachygyria	<i>DCX</i> , <i>LIS1</i> (76, 78, 80)	X-linked, AD, or sporadic
Cobblestone lissencephaly	<i>POMT1</i> (81) <i>POMT2</i> (82) <i>POMGnT1</i> (83) others	AR
Bilateral periventricular heterotopia	<i>FLNA</i> (84)	X-linked
Disorders of later organization		
Bilateral fronto-parietal polymicrogyria	<i>GPR56</i> (85)	AR
Schizencephaly	<i>EMX2</i> (86)	AD or sporadic

AR = autosomal recessive, AD = autosomal dominant

of gyri and sulci of the appropriate size and orientation, synaptic organization, and myelination. Figure 6-2 presents a schematic version of cortical development.

This model for cortical development provides an excellent general framework and continues to be refined. Evidence that cortical neurons and the radial glia that guide their migration arise from a common neuronal-glial progenitor pool (91, 92) suggests that there are other elements between steps (1) and (2) in the aforementioned sequence that may be affected to produce malformations of cortical development, including the processes of cell fate determination and formation of the radial glial scaffold, which must occur before migration can begin. There is evidence from studies in *Drosophila* that neuronal differentiation occurs after a progenitor cell undergoes an asymmetric mitotic division, dividing into one “daughter” cell that eventually becomes a neuron and another “daughter” cell that continues to divide, maintaining the pool of progenitor cells; this process is directed and regulated by the action of a number of intrinsic and extrinsic proteins (93–96). Aberrations in these aspects of neuronal differentiation would also result in disorders of proliferation, though they have not yet been identified as such in humans.

Another development that has added complexity to the paradigm of brain development as outlined above is the phenomenon of nonradial neuronal migration (97), characterized as tangential migration from the ventral telencephalon, giving rise predominantly to interneuron populations (98). If they lead to deficiencies of GABAergic interneurons in the cortex, abnormalities of tangential migration may be particularly likely to lead to cortical hyperexcitability and epileptogenesis. Advances in basic neuroscience will continue to shed light on the complex processes that may be disrupted to produce the broad range of known malformations of cortical development, and new clinical syndromes will likely invoke mechanisms that are yet to be described.

#### *Disorders of Neuronal and Glial Proliferation*

Disorders of neuronal and glial proliferation most likely result from abnormal proliferation of the undifferentiated progenitor of neurons and glia. These disorders may reflect an imbalance between proliferation of progenitor cells and apoptosis, or programmed cell death. This category includes those conditions thought to be a result of relative underproduction of neurons and glia or, conversely, those with a relative overproduction, as

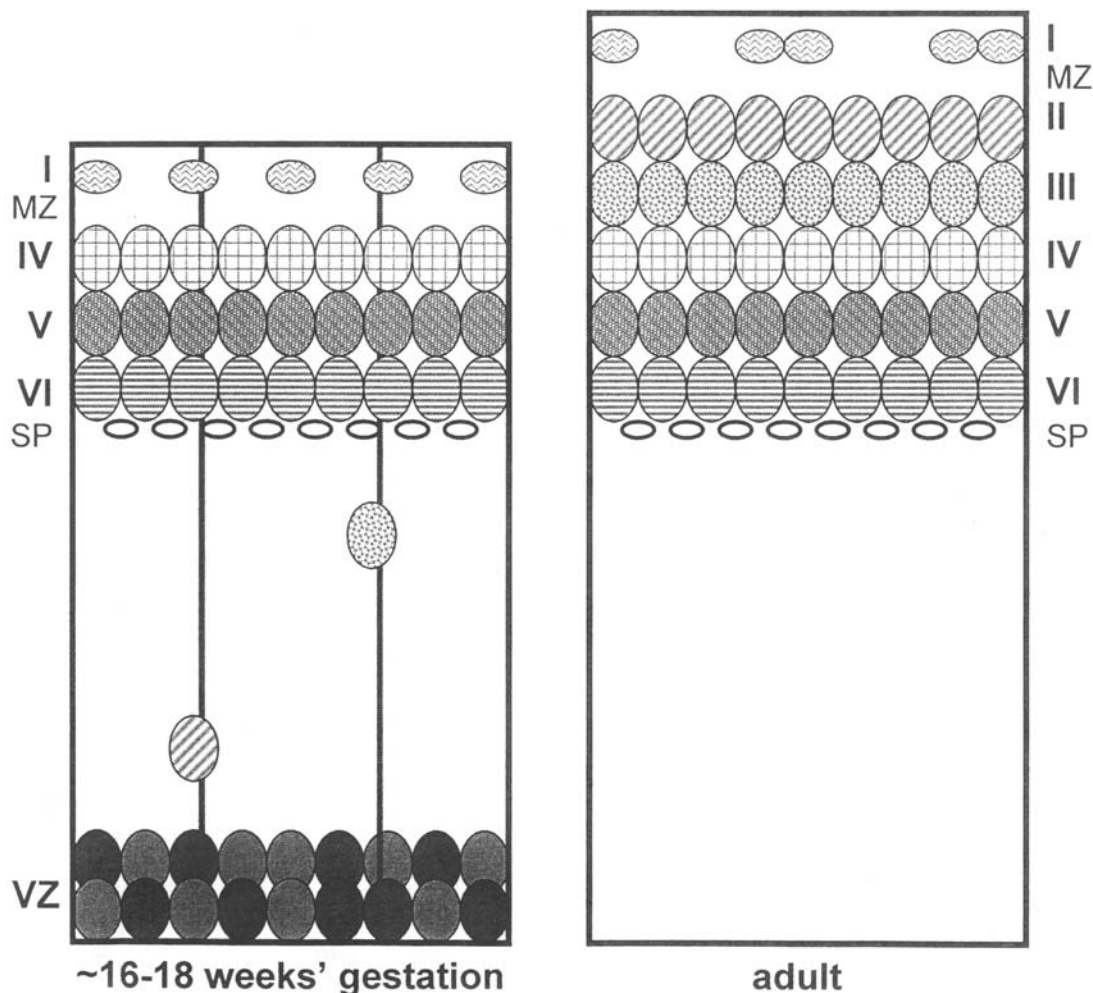

FIGURE 6-2

The formation of the cerebral cortex in humans involves the proliferation of progenitor cells (light gray ovals) in the ventricular zone (VZ); establishment of a radial glial scaffold (vertical lines) following differentiation of some progenitors into glial cells (cell bodies shown as dark gray ovals) and others into neurons (patterned ovals); and (3) neuronal migration along the radial glial scaffold. The panel on the left depicts the stage of approximately 16 to 18 weeks' human gestation, by which time the layer I Cajal-Retzius neurons have migrated to the pial surface (represented by the top of the panel) followed by layer VI, layer V, and layer IV; representative neurons from layers III and II are shown migrating along radial glia. The panel on the right represents the adult six-layer cortex after neuronal migration is complete; note that the cortical plate has expanded with the addition of layers III and II. Not shown are the final stages of further cortical organization, including formation of gyri and sulci of the appropriate size and orientation, synaptic organization, and myelination. (MZ: marginal zone; SP: subplate neurons.)

outlined in Table 6-3. Conditions resulting in the production of abnormal cell types are also included in this group, with both nonneoplastic and low-grade neoplastic subgroups (19). It is important to note that any perturbation at this early stage of development is likely to have downstream effects on the later stage, and it is therefore not surprising that cortical lamination and further organization also appear abnormal in this group of disorders.

*Net decrease in neurons and glia—microcephaly.* Microcephaly can be the result of a number of etiologies, including hypoxic-ischemic injury and exposure to viral

pathogens in utero that result in an underproduction, excessive apoptosis, or abnormal destruction of neurons and glia during gestation. When microcephaly is seen in the absence of such factors, it is considered primary microcephaly. At least seven genetic loci have been associated with autosomal recessive forms of primary microcephaly (99). Nonsense mutations in the gene *ASPM* have been found to be responsible for a particular familial form of microcephaly with seizures (69), reinforcing the connection between this structural brain malformation and epilepsy.

The MRIs of patients with primary microcephaly, as described above, typically have normal or mildly simplified

gyral pattern (100). Microcephaly can also be associated with a markedly simplified gyral pattern (101) and with polymicrogyria and other structural abnormalities, such as agenesis of the corpus callosum (102). Generally speaking, the more severe the associated gyral abnormality, the more severe the neurodevelopmental prognosis and the higher the chance of seizures will be (100).

*Net increase in neurons and glia—macrocephaly.* Macrocephaly, or megalencephaly, is seen in isolation or in association with syndromes associated with general dysregulation of growth in multiple tissues, including neurofibromatosis type 1, Cowden syndrome, and Sotos syndrome (72, 103, 104). Some but not all individuals with these syndromes have epilepsy, but it is a less prominent feature than in those with most of the other malformations described (72, 105, 106). Orstavik and colleagues report a syndrome of macrocephaly, epilepsy, autism, and dysmorphic features in two sisters, the genetic basis of which is not yet known (107). In these cases of primary macrocephaly of known or likely genetic etiology, epilepsy may be one of many clinical manifestations but generally does not dominate the clinical picture.

*Abnormal proliferation—TSC, FCD, and hemimegalencephaly.* Abnormalities at the time of proliferation of neuronal-glia progenitor cells are thought to be responsible for the formation of cortical tubers in TSC, FCD with balloon cells, and hemimegalencephaly, all of which share many pathological features (31, 33).

Eighty to 90% of individuals with TSC have epilepsy; seizures typically begin during childhood and often are refractory to medical treatment (108). In particular, children with TSC have a particular propensity for developing infantile spasms (109).

FCD with balloon cells is a common pathological finding in epilepsy surgery series, as previously discussed in the section on Epidemiology in this chapter. Subtypes of FCD with balloon cells include transmantle dysplasia (shown in Figure 6-3), extending from the ventricle through the white matter and into the gray matter, and the “bottom of the sulcus” cortical dysplasia (19). MRI features include thickening of the gray matter and blurring of the gray-white matter junction (110). FCDs that have ultimately been found to have balloon cells on pathological analysis have been far more likely than those without balloon cells to be associated with abnormal MRI T2 signal in the white matter underlying the cortical lesion (111). FCD with balloon cells is typically diagnosed by MRI after an individual has presented with epilepsy. Although some such individuals are assessed as cognitively normal, mild to severe mental retardation is also reported, with younger age of onset of epilepsy (particularly under one year) associated with worse cognitive outcome (110).

The other characteristic malformation of cortical development in the category of abnormal proliferation

FIGURE 6-3

This coronal T2 fast spin echo inversion recovery (FSEIR) image is from the MRI of a patient with focal seizures due to a transmantle dysplasia, a subtype of focal cortical dysplasia (arrow). This malformation of cortical development likely reflects a focal abnormality at the proliferative stage of brain development.

is hemimegalencephaly, an example of which is shown in Figure 6-4. These lesions are large, hemispheric malformations with varying degrees of macroscopically disrupted architecture. As reviewed by Flores-Sarnat and colleagues, the presence of a unilateral malformation, with its characteristic appearance and associated pathological findings, strongly suggests a disruption early in the proliferative stage of brain development (34). Hemimegalencephaly can occur as an isolated entity or as part of a syndrome with somatic components, such as linear sebaceous syndrome, hypomelanosis of Ito, and, rarely but not surprisingly, other neurocutaneous syndromes such as TSC and neurofibromatosis type 1 (112). Why such a profound change occurs primarily unilaterally in the developing brain of patients with hemimegalencephaly is not yet understood. There is a report of microscopic evidence of abnormal development on the side contralateral to the large hemispheric malformation (113), the reason for which is also not known. Epilepsy inevitably occurs in patients with hemimegalencephaly, with a large number of infants presenting with severe neonatal seizures, and hemispherectomy is often a necessary component of seizure management (100).

*Abnormal neoplastic proliferation—developmental tumors.* As listed in Table 6-3, DNET, ganglioglioma, and gangliocytoma are the developmental tumors associated with abnormal proliferation of progenitor cells and

FIGURE 6-4

This axial T2 MR image from a child with intractable localization-related epilepsy shows right-sided hemimegalencephaly. The entire right hemisphere is larger than the left, and there are abnormalities involving the gray and white matter (R: right, L: left).

associated with epilepsy. As previously detailed in the section on Epidemiology, they are reported with varying frequency in series of children undergoing epilepsy surgery (17–19). The line between such nonneoplastic lesions as FCD and this group of neoplastic lesions remains to be better defined by detailed comparative pathological and molecular studies of the two groups.

#### *Disorders of Neuronal Migration and Cortical Lamination*

Disorders of neuronal migration include a group of disorders with macroscopic disruptions in cortical architecture, resulting in either absent or profoundly abnormal cortical lamination. Classic examples in this category include lissencephaly as well as the X-linked conditions of double cortex syndrome and periventricular heterotopia, discussed in detail subsequently. In Table 6-3 we have subdivided this category slightly differently from Barkovich and colleagues (19) to highlight that disrupting the two different streams of migration—radial and tangential—can result in different phenotypes.

Theoretically, a disruption at the earlier stage of proliferation could establish an abnormal substrate of neurons and glia, leading to abnormalities in migration and lamination. For the disorders in this group, it is helpful to conceptualize them as those with a dominant defect in migration

with possible origin from an earlier defect or with defects at both the proliferation and migration stages. Indeed, molecular evidence from studies of *LIS1*, a gene classically associated with neuronal migration, demonstrates a role for the gene at the stage of progenitor proliferation in the developing mammalian brain (114). That these disorders that are primarily attributed to defects in radial migration are also associated with abnormalities in gyral folding emphasizes that defects in early stages of development will result in disruption of later stages.

*Abnormal radial migration—classical lissencephaly and subcortical heterotopia.* Classic examples of these malformations of cortical development include the conditions of lissencephaly and double cortex syndrome, representing abnormal radial migration of neurons. Lissencephaly, meaning “smooth brain,” affects the entire cortex but can do so variably depending on the underlying genetic etiology. It is helpful to think of classical, or type I, lissencephaly as agyria-pachygyria with either an anterior-posterior or posterior-anterior gradient of smoothness (115). Epilepsy and severe mental retardation are nearly universal features of classical lissencephaly. On the other hand, females with double cortex syndrome, or bilateral subcortical band heterotopia, typically have mild to moderate mental retardation and epilepsy that is generally less severe than in individuals with lissencephaly (116, 117)

Classical lissencephaly occurs in both males and females. When a genetic cause can be identified, it is most often a deletion or mutation in the *LIS1* gene (120). Figure 6-5 presents the MRI from a patient with lissencephaly due to a mutation in the *LIS1* gene and symptomatic generalized epilepsy. The posterior-predominant agyria accompanied by anterior pachygyria is typical of *LIS1*-associated lissencephaly. When there is a deletion of *LIS1* and other genes in the 17p13.3 region, the affected individuals have not only lissencephaly and its consequences but also the dysmorphic features that are characterized as the Miller-Dieker syndrome (119).

Classical lissencephaly in males also occurs as a result of mutations in the *DCX* gene (78, 79). Females with *DCX* mutations typically display double cortex syndrome, and their male offspring have a 50% risk of inheriting a mutated form of *DCX* and presenting with classical lissencephaly. Mutations include single amino acid substitutions as well as protein-truncating mutations, and somatic and germline mosaicism have been observed (120, 121). More recently, Guerrini and colleagues have shown that another phenotype, anteriorly predominant pachygyria and mental retardation, can be associated with *DCX* mutations as well; pharmacoresistant epilepsy occurred in all of the affected boys described (122). Figure 6-6 shows a range of patients with mutations in the *DCX* gene, including classical lissencephaly in a boy, pachygyria in a boy, and double cortex in a girl.

FIGURE 6-5

An example of a disorder predominantly due to a defect in radial neuronal migration is shown in this MRI from a patient with lissencephaly due to a *LIS1* mutation and symptomatic generalized epilepsy. An axial T2 image (a) and a sagittal T1 image (b) are shown.

Focal abnormalities of migration, such as focal subcortical heterotopia, are also seen in association with refractory epilepsy (123). An example is shown in Figure 6-7, which shows an image from the MRI of a patient with subcortical heterotopia, adjacent abnormal cortex, and also focal regions of periventricular heterotopia in the contralateral hemisphere. Genetic causes of subcortical heterotopia have

yet to be identified, and the focal nature of these lesions makes them attractive candidates for epilepsy surgery, though long-term outcome data are not available.

*Abnormal radial overmigration—cobblestone lissencephaly.* Type II lissencephaly, or cobblestone lissencephaly, may resemble classical lissencephaly radiologically

FIGURE 6-6

These axial images show a range of MRI abnormalities in patients with epilepsy and mutations in the *DCX* gene range from (a) lissencephaly in a boy, (b) pachygyria in a boy, and (c) double cortex in a girl. These cases illustrate global disruptions of neuronal migration.

FIGURE 6-7

MRI is shown from a patient with localization-related epilepsy due to a large subcortical heterotopia with abnormal overlying cortex (arrowheads). The patient also had a small contralateral region of heterotopia (arrow), so these lesions appear to represent separate and asymmetric focal disruptions of neuronal migration.

but represents a different pathophysiological entity that arises from an overmigration of neurons beyond the pial surface. There is a strong clinical association with cobblestone lissencephaly and congenital muscular dystrophy in conditions such as Walker-Warburg syndrome, muscle eye brain disease, and Fukuyama muscular dystrophy (124–126). Epilepsy is often an early component of these syndromes, which are also associated with other MRI abnormalities, varying degrees of mental retardation, and hypotonia. The pathophysiology of this group of disorders involves abnormal glycosylation of alpha-dystroglycan, as described in a recent review by Endo (127).

*Abnormal radial migration—periventricular heterotopia.* X-linked bilateral periventricular heterotopia (PH) provides another example of abnormal radial neuronal migration, in this case with the appearance of arrested or minimal migration of a subset of neurons from the ventricular zone during cortical development. Figure 6-8 is an MRI from a female patient with this form of malformation due to a mutation in the *FLNA* gene on the X chromosome, the typical genetic abnormality associated with bilateral PH (84, 128). Females with bilateral PH usually have epilepsy, with age of onset in their teens or twenties and milder severity than patients with the other disorders of migration; cognition is often

FIGURE 6-8

This axial T1 spoiled gradient recalled (SPGR) MR image shows bilateral periventricular heterotopia in a female with a *FLNA* mutation, representing a disorder of radial neuronal migration.

normal, though specific defects in reading ability have been identified (129). Less commonly, this condition can occur in males with a similar overall phenotype (128). Not all females with bilateral PH harbor mutations in *FLNA* (128); another gene that has been associated with PH is *ARFGEF2*, described in autosomal recessive pedigrees with PH and microcephaly (70) and classified by Barkovich and colleagues as a disorder of neuronal proliferation (19).

*Abnormal radial and tangential neuronal migration—XLAG.* The last example in this section represents a disorder in which both radial and tangential migration of neurons is affected. X-linked lissencephaly with abnormal genitalia (XLAG) is the most severe phenotype described in association with mutations in the *ARX* gene (79). The lissencephaly is posterior-predominant, similar to classical lissencephaly seen with *LIS1* mutations, and may be accompanied by agenesis of the corpus callosum and basal ganglia abnormalities (130). Also notable are *ARX* mutations in nonsyndromic boys with infantile spasms *without* lissencephaly (131) but presumably with disrupted migration at a microscopic level.

#### *Disorders of Later Cortical Organization*

Disorders of later cortical organization chiefly include polymicrogyria (PMG) and schizencephaly. FCD without balloon cells, and lesions that are evident only by

**FIGURE 6-9**

Bilateral fronto-parietal PMG (BFPP) is often associated with mutations in the gene *GPR56*, as in the patient whose axial T2 MRI is shown here. Note the increased apparent cortical thickness in the regions of polymicrogyria in both frontal and parietal lobes. PMG is classified as a disorder of cortical organization.

microscopic analysis, are included in this category as well. All of these conditions are associated with epilepsy.

PMG can be created experimentally by freeze lesions in rodent cortex (132), suggesting that local disruptions of either genes or the environment during human brain development could produce similar focal lesions in humans. PMG has also been associated with disorders of peroxisome function and with in utero exposure to cytomegalovirus (133, 134). Epilepsy has been a defining feature of the bilateral PMG syndromes, occurring in the vast majority of cases, and these conditions bear further discussion. It is the bilateral PMG syndromes that most strongly suggest a genetic etiology for PMG, and a representative example is shown in Figure 6-9. Bilateral generalized polymicrogyria affects most or all of the cortex and is associated with epilepsy in almost all patients; nearly half of the patients have macrocephaly (135), suggesting a possible disruption as early as the stage of proliferation. The bilateral perisylvian PMG (BPP) syndrome consists of epilepsy and a characteristic oromotor apraxia; epilepsy occurs in nearly 90% of affected individuals (136). Genetic linkage studies of familial BPP suggest a locus on the X chromosome (137), and studies of pedigrees also suggest an autosomal dominant mode of inheritance

(138). BPP has also been described in association with deletions of the 22q11 locus (139). Thus, BPP is clearly a genetically heterogeneous syndrome. The bilateral fronto-parietal PMG (BFPP) syndrome—which includes epilepsy, mental retardation, dysconjugate gaze, and pyramidal signs—has been associated with mutations in the gene *GPR56* (85, 140). Interestingly, in a series of 13 patients with a form of bilateral PMG restricted to the frontal regions, only five had epilepsy (141).

Schizencephaly is a cerebral malformation consisting of one or more clefts that span the depth of the cortex, from the lateral ventricle to the pial surface, and that are lined by gray matter (142). Similarly to polymicrogyria, schizencephaly can occur unilaterally or bilaterally and can result from a variety of viral, vascular, or genetic abnormalities (86, 142, 143). About half of the individuals affected are reported to have epilepsy, and as yet there is not a clear correlation between the type of schizencephaly and the occurrence or severity of epilepsy in these patients (144).

## CONCLUSIONS

The majority of patients with cerebral cortical malformation will experience clinical epilepsy, often with onset during childhood. The clinical neurologist treating any patient with localization-related epilepsy or treating any child with presumed symptomatic epilepsy, should have a high index of suspicion for a malformation of cortical development as the etiology.

Understanding the mechanisms through which malformations of cortical development occur will continue to teach us about normal brain development and will allow us to provide better explanations of causality to patients and their families. A detailed understanding of the genetic underpinnings of these malformations and the molecular basis of their epileptogenesis should ultimately lead to more refined and individualized approaches to treatment.

## Genetic Influences on the Risk for Epilepsy

**Asuri N. Prasad**  
**Chitra Prasad**

### INTRODUCTION

Of the many neurologic disorders affecting humans, epilepsy has been recognized since antiquity, with well-documented references in records dating back to the Mesopotamians. The word *epilepsy* is derived from the Greek verb *epilambanein*, which means “to seize or attack”; that is, a seizure was taken to mean that the patient was being literally seized by gods or demons, and hence the condition was given the status of a “sacred disease” in medical writings that date back to 400 B.C. However, in lay society the diagnosis of epilepsy has spelt fear, hopelessness, social stigma, and isolation.

Epilepsy is a heterogeneous disorder with diverse etiologies, affecting nearly 1% of the world population (1). In the last century, epidemiological studies of families and twins with epilepsy have provided incontrovertible evidence in support of a genetic contribution to the risk of developing certain epilepsies. The discovery of the first single-gene defect underlying idiopathic epilepsy was made in 1995 (mutation in a gene coding for a neuronal nicotinic cholinergic receptor, leading to autosomal dominant nocturnal frontal lobe epilepsy). The subsequent identification of other gene defects has provided added

evidence to support the role played by genetic susceptibility in the development of human epilepsy.

The relatively recent breakthroughs in gene-sequencing technologies, accompanied by development of animal models and bioinformatics, have speeded up the identification of new gene defects underlying the many epilepsy syndromes. These have been summarized in several reviews in recent years (2–4). Though a long list of gene defects and mutations associated with human epilepsy is presently known, these are mostly monogenic disorders that are rare; a complete understanding of the genetic basis of the more common epilepsies remains a distant goal. The large majority of individuals affected with epilepsy do not have affected relatives, nor do they have a family pedigree that is consistent with the traditional Mendelian patterns of inheritance. Epileptic disorders such as those currently considered under the umbrella of idiopathic generalized epilepsies (IGE) are now considered as genetically complex as to their inheritance patterns and expression. In this chapter we explore the implications of considering human epilepsy as a complex disorder and how genetic studies can shed light on our understanding of the risk of developing epilepsy in the clinical setting.

## MENDELIAN VERSUS COMPLEX INHERITANCE: HISTORICAL BACKGROUND

Before proceeding to a discussion of the genetic influences in human epilepsy, it might be useful to introduce readers to the basic issues on how inheritance plays a role in epilepsy. Mendel in 1866 had worked out inheritance patterns and rules applicable to the segregation of distinct features termed “traits.” The traits Mendel studied focused on were qualitative differences (nature of the skin on the seeds, or color of the flowers); it soon became evident that many traits in the general population did not follow these rules of segregation. Galton and Pearson in the 1900s observed that quantitative traits (e.g., growth parameters and IQ scores) followed a Gaussian (normal) distribution among offspring, thus raising contradictions to Mendel’s conclusions. The work of Sir Ronald Fisher was instrumental in providing an explanation to this apparent contradiction. His work showed that the observed effects in the case of quantitative traits could be explained through the involvement of multiple genes that carried small effects, which acted in an additive manner (5). The influence of environmental factors was also recognized, and the cumulative additive effects of the combination tended to nudge the resultant effect toward a normative (Gaussian) distribution. This model, called “multifactorial and polygenic,” was extended to explain disorders such as epilepsy by Falconer. He postulated a normal distribution of risk in the form of a nonmeasurable quantity termed “liability” that led to people being affected if the liability crossed a particular “threshold.” In the case of epilepsy this could be considered as a “seizure threshold” (6). Other factors such as age, sex, puberty, or pregnancy can influence this threshold. Idiopathic epilepsy occurs with higher frequency in relatives of affected individuals; yet the different types do not conform to the expected frequencies for Mendelian traits. In these epilepsies, inheritance is considered to be multifactorial, where intrinsic susceptibility genes interact with environmental factors, producing a particular seizure phenotype (7).

## CAUSES OF EPILEPSY

Broadly, epilepsy can be categorized on the basis of etiology (Figure 7-1) as symptomatic (a clear etiology can be demonstrated, such as a tumor, cortical dysplasia, or scarring), cryptogenic (a cause is suspected on the basis of associated neurologic features but remains hidden), or idiopathic (the individual appears to be normal on neurologic assessment, and no cause other than a hereditary predisposition established). Etiologies in the symptomatic category can be attributed to chromosomal aberrations (Angelman syndrome, Wolff-Hirschhorn syndrome) or single-gene defects for conditions such as tuberous sclerosis or lissencephaly.

Though the epilepsy phenotypes encountered here are highly variable, these disorders display typical Mendelian inheritance patterns, wherein mutations at a single locus can explain the pattern of segregation of the disease within families. It is possible to list a large number of disorders of this type, but these conditions are uncommon in clinical practice and account for <1% of cases of genetic epilepsies.

At least 40–50% of all epilepsies are considered to belong to the category of idiopathic epilepsy (i.e., with a presumed genetic basis). In the case of idiopathic epilepsies, it is now clear that inheritance patterns can involve a monogenic (single-gene defects), oligogenic (few genes), or polygenic (many genes) models. Even within the monogenic epilepsies the relationship between gene defect and clinical phenotype is susceptible to modification by “epigenetic factors.” These factors modify the penetrance of the gene, often resulting in fewer than expected recurrences within families. The disorders displaying polygenic or a complex inheritance pattern display marked phenotypic variability (intrafamilial as well as interfamilial), and recurrence of the trait and its expression within families is much harder to predict.

Genetic inheritance patterns not conforming to classic Mendelian inheritance have also been recognized in the epilepsies. The mechanisms of genetic transmission in these conditions include triplet and dodecamer expansions and mitochondrial inheritance involving non-nuclear (mitochondrial) genome.

## GENETIC INFLUENCES IN EPILEPSY

The importance of heredity in epilepsy has been recognized for more than a century. Gowers estimated a figure of around 30% in his case series as having a heritable form of epilepsy in his treatise on *Epilepsy and Other Convulsive Disorders* (8). In the early part of the twentieth century this idea was further explored in family studies using electroencephalography (EEG) in the identification of individuals with an epileptic trait (9). By the end of the twentieth century, different lines of evidence came to strongly support a genetic basis to several forms of common epilepsies. These lines of evidence included (1) linkage analysis and positional cloning of susceptibility genes as well as candidate genes, (2) molecular studies of single-gene defects associated with human epilepsy, and in animal models, (3) aggregation studies in families and twins, and finally (4) association studies (10).

### Linkage Analysis

Linkage studies have traditionally provided the lead in the identification of susceptibility genes in monogenic as well as complex phenotypes of epilepsy (11). Typically, classic linkage analysis requires large family sizes, with multiple

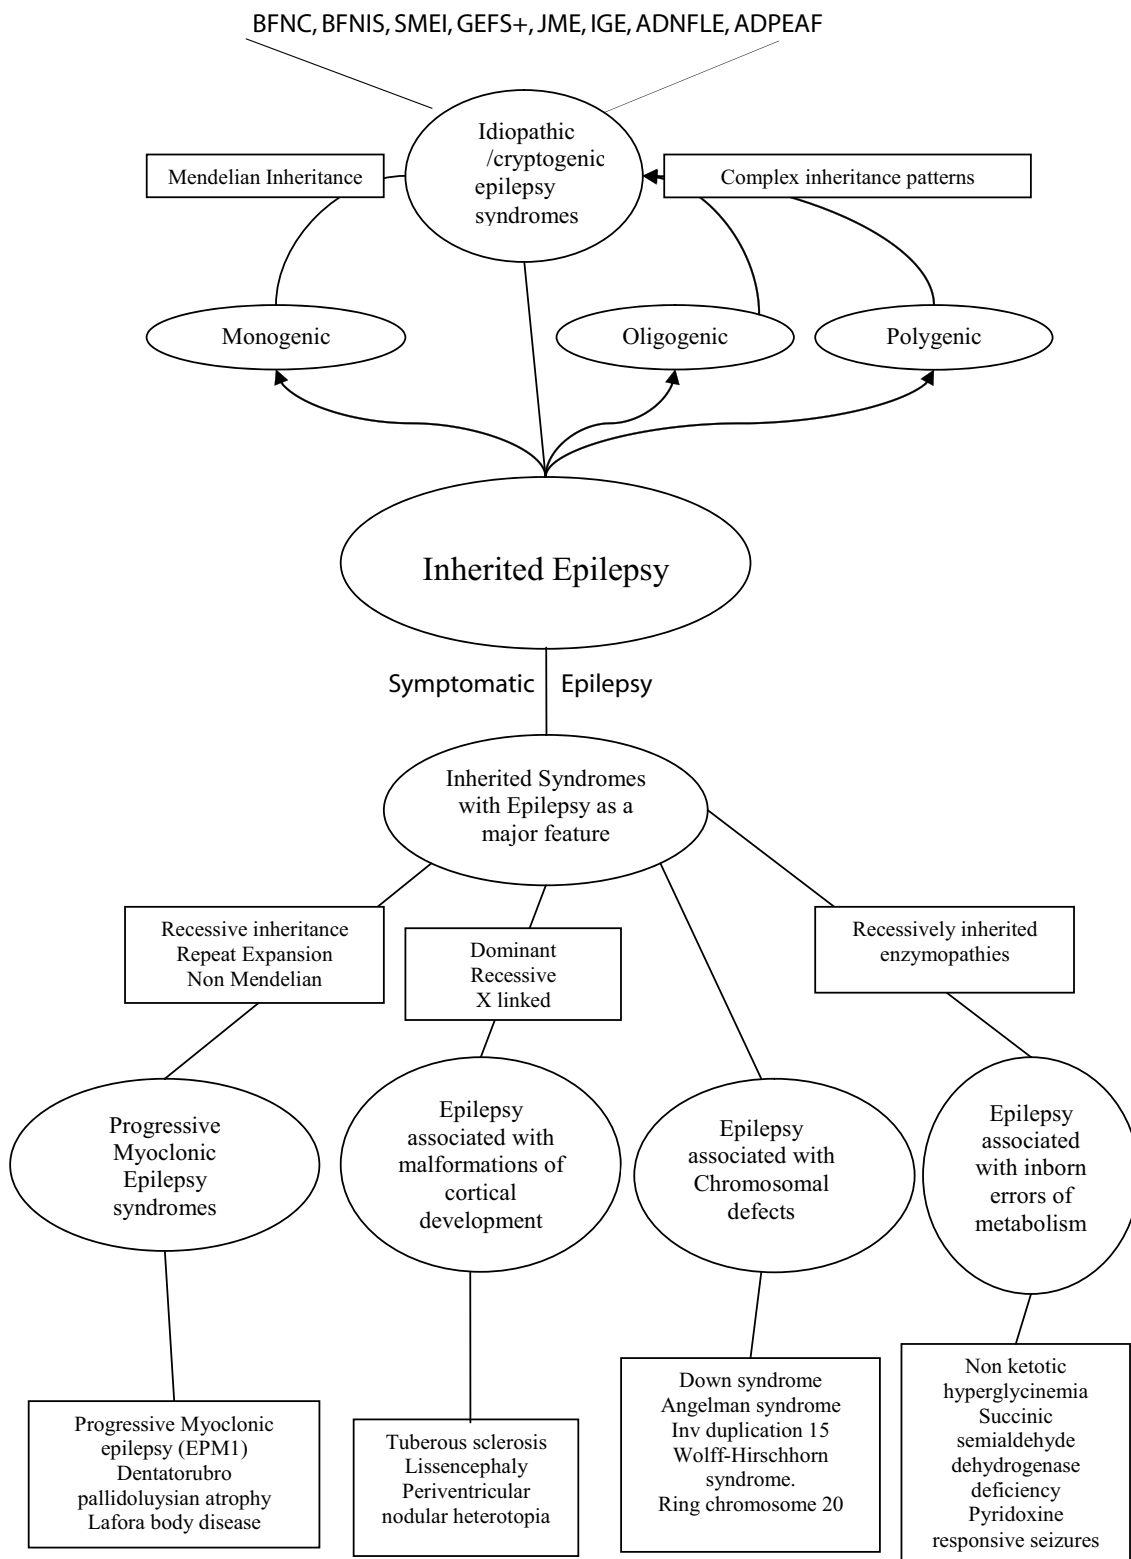

FIGURE 7-1

Genetic influences in human epilepsies; modes of inheritance and examples. BFNC = benign familial neonatal convulsions, BFNIS = Benign Familial Infantile Seizures, SMEI = Severe Myoclonic Epilepsy of Infancy, GEFS+ = Generalized Epilepsy with Febrile Seizures+, JME = Juvenile Myoclonic Epilepsy, IGE = Idiopathic Generalized Epilepsy, ADNFLE = Autosomal Dominant Nocturnal Frontal Lobe Epilepsy, ADPEAF = Autosomal Dominant Partial Epilepsy with Auditory Features.

affected individuals (multiplex families) or many families that may share the same mutation and clinical phenotype. Using this approach several loci have been linked with different partial epilepsy syndromes for, for example, nocturnal frontal lobe epilepsy (NFLE), autosomal dominant partial epilepsy with auditory features (ADPEAF), and the syndrome of benign familial neonatal convulsions (BFNC).

However, this approach seems to work less well for the situations where there may be incomplete penetrance or presence of multiple phenocopies (relatives with epilepsy caused by etiologies other than genetic). Although it is possible to adopt nonparametric approaches, studies carried out lacked sufficient power to detect the weaker susceptibility genes in the complex epilepsies. Thus, success with this approach has been limited.

### Single-Gene Defects in Human Epilepsy, Animal Models, and Molecular Studies of Mutations

Single-gene defects are rare as causes of epilepsy and constitute a heterogeneous group of metabolic, degenerative conditions or malformations of cortical development in which epilepsy is often part of a much wider disorder. However, identification of single-gene defects in selected forms of idiopathic epilepsy has provided useful insights into epileptogenesis. The concept of epilepsy as a “channelopathy” was supported by the identification of mutations in voltage- and ligand-gated ion channels underlying BFNC; generalized epilepsy with febrile seizures plus (GEFS+) and severe myoclonic epilepsy of infancy (SMEI) as discussed later in this chapter. Genotype-phenotype correlations in these disorders have led to the conclusion that genetic heterogeneity is considerable, even in single-gene defects leading to inherited epilepsy. Mutations in different genes have been found to cause the same epilepsy syndrome (locus heterogeneity), while mutations in the same gene have been known to be associated with completely different epilepsy phenotypes (allelic heterogeneity) (Figure 7-2).

Additional insight has been gained through studies of the molecular aspects of epileptogenesis in these monogenic disorders, and the study of animal models of epilepsy. The structure and subunit composition of membrane channels, synapses, neurotransmitters, and receptors (proteins involved in cell signaling and transport) have yielded and confirmed several targets affected by gene mutations leading to epilepsy.

Mouse models of epilepsy (both transgenic models and mice with spontaneous seizures) have led to the identification of many epilepsy genes. Broadly these genes are involved in the regulation of (1) neuronal differentiation, migration, and cerebral morphogenesis; (2) membrane excitability (ion- and ligand-gated channels, neurotransmitter biosynthesis, release and reuptake) (3) intracellular pathways of intermediary metabolism, protein synthesis, degradation, and cellular homeostasis) (12).

### Aggregation Studies

Strong support for a genetic basis for several epilepsies is also provided by studies of concordant rates of epilepsy in twin pairs. The concordance rate for IGE among monozygotic twins is up to 95% (13). The risk of occurrence of IGE in first-degree relatives of affected individuals is about 8–12%, and shows a significant drop to 1–2% in second-degree relatives. These risk assessments are very suggestive of an oligogenic pattern of inheritance (14).

Whereas monozygotic twins share an identical genotype, dizygotic twins are as different in genotype as siblings. However, both types of twinning share a similar environment in utero. So if two cotwins (in a monozygotic pair) share a given disorder at a greater frequency than two cotwins of a dizygotic pair, the inference drawn supports a strong role for genetic factors in disease causation. Concordance rates for both febrile and afebrile seizures are consistently higher in monozygotic twins as compared to dizygotic twins (13, 15–17) (Table 7-1).

Using the Danish population-based twin registry at the University of Southern Denmark, 34,076 twins were screened for epilepsy. A total of 214 pairs with epileptic seizures (single seizure events, febrile seizures included), and 190 pairs with epilepsy (recurrent unprovoked seizures, 2 or more events) were identified. Higher concordance rates were found in monozygotic over dizygotic twins for epileptic seizures (0.56 vs. 0.21,  $p < 0.001$ ) and for epilepsy (0.49 vs. 0.16,  $p < 0.001$ ). In terms of epilepsy syndromes, concordance rates were higher for monozygotic twins for both generalized epilepsy (0.65 vs. 0.12) and for localization related epilepsy (0.30 vs. 0.10), but significantly more for the former (17, 18). Similar findings of higher concordance rates in monozygotic twins over dizygotic twins for seizure are reported in a larger recent multinational study combining data from twin registries of Denmark, Norway, and the United States (18a). The data from this larger sample is likely to provide even stronger support for a genetic basis for epileptic seizures.

### Association Studies

Association studies permit the examination of the association of different alleles at different loci between unrelated individuals using a genetic marker such as single nucleotide polymorphisms (SNPs). An allele can be considered to be associated with the disease if its frequency in cases is higher than in controls, greater than predicted through chance alone. Such an association favors linkage disequilibrium (LD). Association studies have the ease of case collection and enabling greater statistical power. However, there are limitations to this approach, because mere association does not imply causation. The findings have to be replicable and have to fulfill biological plausibility in order to be

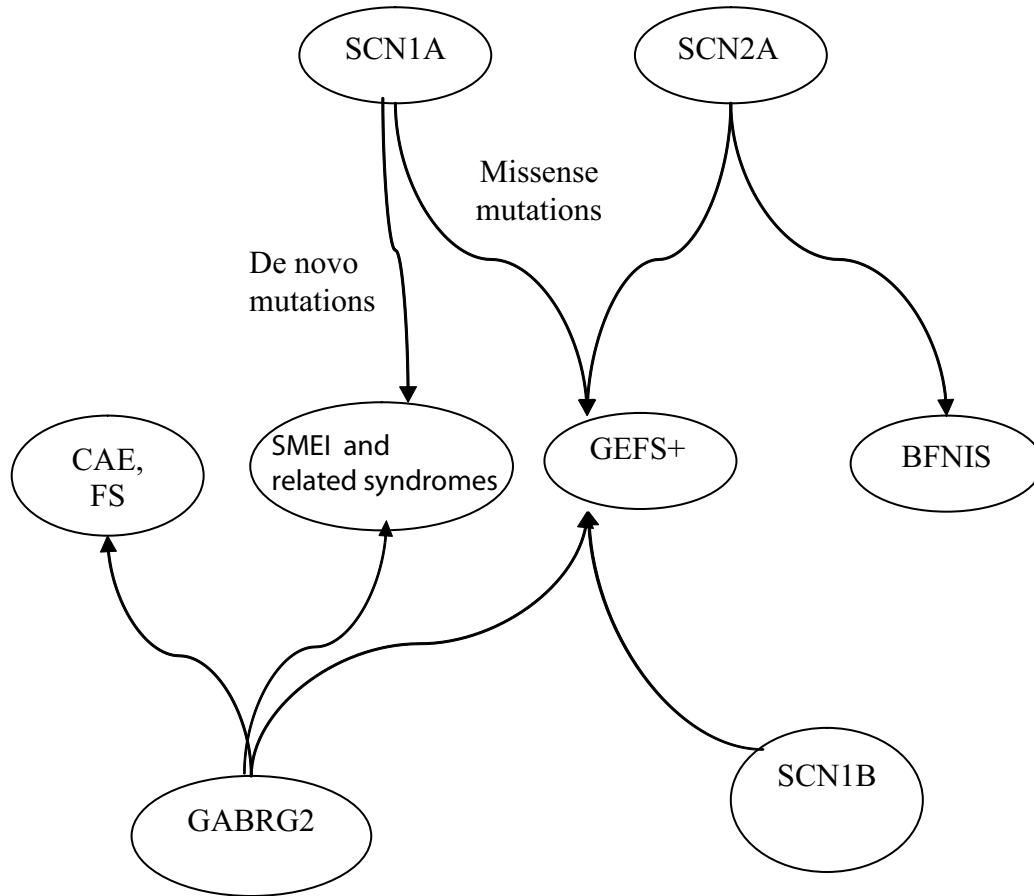

FIGURE 7-2

SCN1A (Sodium channel, alpha 1 subunit), SCN2A (Sodium channel, alpha 2 subunit), GABRG2 (GABA receptor gamma2 subunit), SCN1B (Sodium channel, beta 1 subunit), CAE (Childhood Absence Epilepsy), SMEI (Severe Myoclonic Epilepsy of Infancy), GEFS+ (Generalized Epilepsy with Febrile Seizures plus), BFNIS (benign familial neonatal-infantile seizures).

**TABLE 7-1**  
*Concordance Rate for Epilepsy among Monozygotic and Dizygotic Twin Pairs*

STUDY AUTHORS NATURE OF EPILEPSY IN PROBAND	POPULATION COHORTS	PROBANDWISE CONCORDANCE RATES IN TWINS		
		MONOZYGOTIC	DIZYGOTIC	
Sillanpaa et al, 1991 (16)	Epilepsy	Finnish	0.10	0.05
Corey et al, 1991 (15)	Epilepsy	Norwegian	0.19	0.07
	Febrile seizures	Virginia	0.33	0.11
Berkovic et al, 1998 (13)	Generalized epilepsy	Australian	0.82	0.26
	Localization related		0.36	0.05
Kjeldsen et al, 2003 (17)	Generalized epilepsy	Danish	0.65	0.12
	Localization related		0.30	0.10

successful. Thus, these limitations have made association studies less popular, and have been regarded with greater skepticism than they once were. More recently there have been efforts to address these deficiencies through population stratification, use of family controls, and the use of two independent datasets of cases and controls as well as using rigorous measures of statistical significance. The results of more than 50 association studies carried out to date have either led to conflicting and nonreplicable findings or have failed to meet the requirement of biologic plausibility.

The availability of a human genome map for SNPs (30,000 of them) will accelerate the use of whole-cell linkage disequilibrium techniques to detect association between a marker and the occurrence of disease (19). Such genomewide association studies are likely to inflate the number of associations reported. Whether the marker locus actually turns out to be the disease locus is dependent on the potential confounding effects of variables such as the presence or absence of linkage disequilibrium and population stratification. Microarray technology will further strengthen and accelerate the process of understanding gene expression regulation, as well as levels and timing of expression, by allowing us to monitor mRNAs of multiple genes in parallel (20).

### GENETICS OF EEG ABNORMALITIES

Any consideration of the heritability of epilepsy is incomplete without a brief consideration of the genetics of EEG abnormalities. The same lines of evidence as for epilepsy support the inheritance of EEG abnormalities as a genetic trait. Even normal EEG patterns and variants are known to aggregate within families and co-occur in monozygotic twins. Studies have shown generalized spike wave discharges, photoparoxysmal responses, rolandic spikes, and multifocal spikes to conform to known inheritance patterns (21). However, EEG studies are complicated by problems related to sampling, because the occurrence of EEG abnormalities in a single record is influenced by many factors. Even in those with epilepsy, a single EEG record is likely to show abnormalities only 50% of the time. The association between epileptiform patterns on the EEG and the epilepsy syndromes in which they have been described are not considered to be invariable. In addition, lack of association between the presence of EEG abnormalities and clinically manifest epilepsy, as well as age-dependent penetrance of the trait, also act as confounders (10).

### ROLE FOR EPIGENETIC FACTORS?

The enormous diversity of cells and organ systems, their constituent proteins, and their functions all arise from the same genetic code. The biological explanation for this

diversity lies in understanding the process of modulation and regulation of gene expression during cell development and proliferation. The rapidly expanding field of epigenetics sheds new light on our understanding of cellular phenomena. Epigenetic processes do not affect the genetic code; however they modulate gene expression through changes in metagenetic information. These processes are stable and are also passed on during mitotic cell division. DNA methylation is one example of an epigenetic control mechanism; other examples include histone hypoacetylation, chromatin modifications, X-inactivation, and imprinting (22).

Through the addition of a methyl group to a CpG dinucleotide, the gene is effectively silenced. Thus, methylation and demethylation processes effectively function as off-on switches for gene expression. Rett syndrome, a neurodegenerative disorder with significant epileptic seizures, results from heterozygous mutations in the X-linked methyl CpG binding protein 2 (MeCP2) gene. The MeCP2 gene product functions as a transcriptional repressor by binding to methylated DNA. The genetic deregulation that follows the occurrence of mutations in the X linked MeCP2 genes has been shown to affect the expression of genes (*UBE3A* and *GABRB3*) at other locations (e.g., 15q11–q13, Angelman syndrome) through possible histone modifications (23, 24). Both Angelman and Rett syndromes share significant features of their clinical phenotype, particularly in the occurrence of epileptic seizures. The reduced expression of *GABRB3*, a GABA receptor gene, is particularly interesting given the epilepsy phenotypes encountered in both Rett and Angelman syndromes. A better understanding of epigenetic factors no doubt will unravel many of the mysteries of variability in human epilepsy. Although the entire genome has been decoded, the information by itself is likely useless without understanding of the cellular processes involved in the timing and translation of this code.

Recent research using advances in genome scanning technology have shed light in characterizing structural variations in human DNA that are ~1 Kb to ~3 Mb in size along the human genome. These copy number variations (CNV) occur at high frequencies when compared to other classes of cytogenetically detected variations. These variants, existing in a heterozygous state, lie between neutral polymorphisms and lethal mutations. Their position may directly interrupt genes or may influence neighboring gene function by virtue of a position effect. These CNVs or copy number polymorphisms (CNPs) are capable of influencing biochemical, morphologic, physiologic, and pathologic processes, thus yielding potentially new mechanisms to explain diversity in human genetic diseases. CNVs and CNPs have been used to identify genetic susceptibility loci and potential candidate genes successfully for complex genetic disorders such as schizophrenia, autism, and severe speech and language disorder (25, 26). It is only a question

of time before such an approach will yield new information on the genetically complex epilepsies.

### IDENTIFIED GENE DEFECTS IN IDIOPATHIC EPILEPSIES

Broadly these defects fall into two major categories: (1) gene defects expressed in excitatory or inhibitory ion channels (Table 7-2) and (2) non-ion channel genes. It is of interest to note that despite the involvement of many channels, the net effect achieved is an increase in the excitability of the neuronal membrane and its ability to sustain repetitive firing.

#### Mutations Affecting Ion Channel Genes

Evidence linking channel defects with specific epilepsy phenotype came with discovery of K channel mutations associated with the clinically defined syndromes of BFNC, while Na channel defects have been associated with the recently defined benign familial neonatal-infantile seizures (BFNIS). Voltage-gated potassium channels play a number of crucial roles in neuronal physiology, including regulation of resting membrane potential and action potential duration. By impairing the restoration of ionic balance after neuronal firing, potassium channel dysfunction could lead to repetitive neuronal firing and a state of heightened excitability.

In the BFNIS families, changes have been identified in the alpha2 subunit of the sodium channel (SCN2A). Sodium channels have a single pore-forming alpha subunit, and two beta subunits that modulate the gating effects. Both the mutations (L1330F and L1563V) affect a highly conserved leucine, resulting in an increased sodium current, thus reducing the rate of inactivation and increased excitability. Similarly, a mutation affecting a voltage-gated sodium channel beta subunit (associated with GEFS+ phenotype) renders ineffective the rate of channel inactivation, and thereby increases excitability by permitting greater transmembrane sodium influx. Mutations affecting the alpha 1 subunit of the sodium channel (SCN1A) have come to be established as an important gene defect underlying a wide variety of idiopathic epilepsy syndromes (severe myoclonic epilepsy (SMEI) and other borderline epileptic encephalopathies). Truncation mutations account for nearly 50%, while missense, deletions, and splice site mutations account for the remainder. The spectrum of epileptic syndromes in early life associated with SCN1A mutations appears to be ever widening, further confirming an emerging role for this ion channel as a major contributor to the polygenic model of idiopathic/cryptogenic epilepsy.

In a family with individuals affected only by juvenile myoclonic epilepsy (JME), a novel gene mutation (Ala322Asp) affecting the gene encoding for GABARA1

(alpha subunit of the GABA receptor subtype A) was identified. Voltage clamp recordings from HEK293 whole-cell lines transfected with mutant and wild-type GABA receptors show a reduction in GABA activated currents in the former. This effect is attributed to altered GABA receptor function, and not to reduced expression (27).

GABA receptor dysfunction may also be the consequence of mutations affecting other channels. Three different heterozygous mutations, a premature stop codon (M200fsX231), an atypical splicing site (del74-117), and an amino acid substitution (G715E), have been identified in the voltage-gated chloride channel gene (CLCN2), which co-segregate with other IGE traits in three families of 46 selected for the study (28). Mutations in the CLCN2 gene have been associated with common subtypes of idiopathic generalized epilepsy as well as focal epilepsy (28, 29). Whole-cell patch clamp recordings, after transfecting tsA201 cells with both mutant and wild-type genes, suggest an alteration of human CLCN2 channel function through different mechanisms. The M200fsX231 and the del 174-117 mutation abolish chloride currents, while the G715E mutation alters chloride channel gating to induce a reverse current that affects membrane polarity and electrical stability. The end result is the induction of a hyperexcitable state of GABAergic synapses at a postsynaptic level. Altered GABA-related inhibitory influences underlie the IGE phenotype, despite the differing molecular targets of gene mutations.

In addition to chloride channels, the T-type calcium channel is an obvious target channel, because it plays a critical role in the thalamocortical oscillatory network. Missense mutations in a heterozygous state were identified in a gene coding for a calcium channel (CACN1H) in the 16p13 region in a small group of individuals with absence epilepsy, suggesting a role for calcium channels in the genetic susceptibility to absence epilepsy (30). The described mutations affect highly conserved regions in the T-type calcium channel. Functional studies using site directed mutagenesis have shown a gain of function effect on calcium influx during physiologic activation, leaving the neuron vulnerable to repetitive firing (31).

Several themes appear to be emerging: one, that mutations in different genes may encode for subunits of the same channel, resulting in an epilepsy phenotype that is essentially related to the channel dysfunction in a nonspecific manner (e.g., K channel mutations in BFNC, nAChR mutations in NFLE); on the other hand, mutations affecting different channels may result in the same phenotype (GEFS+ from mutations affecting GABA<sub>A</sub> receptor or sodium channel subunits); finally, mutations may affect subunits of the same channel yet result in two entirely different phenotypes. The latter situation is illustrated by mutations in the alpha1 and gamma2 subunits of the GABA<sub>A</sub> receptor, resulting in the completely different phenotypes of GEFS+ and autosomal

**TABLE 7-2**  
***Ion Channels: Structure and Subunit Composition, Mutations and Mutagenic Effects***

ION CHANNEL	TYPE	ASSOCIATED EPILEPSY	COMPOSITION	MUTATIONS	EFFECT OF MUTATIONS ON CHANNEL FUNCTION
Nicotinic acetylcholine receptors CHRNA4/ CHRN2	Ligand gated	NFLE	Pentamers with each subunit containing 4 transmembrane domains. In the human brain there are 10 subunits that can be expressed and may combine in heteromeric or homomeric combinations to form receptors. Relatively nonselective channel	CHRNA4: α4S248F, α4L776ins3, α4S252L	Gain of function resulting in an increase in Ach receptor sensitivity in reconstitution experiments.
Gamma-aminobutyric acid, subtype A (GABRG2/ GABRA1	Ligand gated	GEFSP  ADJME	Also shares a pentameric structure with 4 transmembrane domains. Channel shows selective permeability to small anions and allows both chloride and bicarbonate.	CHRN2: β2V287L, β2V287M GABRG2 γ2K289M GABRA1 α1A322D	Mutations appear to affect the constituents around the pore. Loss of function. Mutations cause reduced amplitude of GABA-activated currents.
Sodium channel SCN1A/SCN2A SCN1B	Voltage gated	GEFSP BFNIS SMEI	Each sodium channel is formed by one pore-forming α-subunit and two α-subunits that serve to modulate channel gating kinetics. Each α-subunit is made from 4 tandem domains, each of which contains 6 transmembrane domains.	SCN1B: β1C121W SCN2A: α2L1330F, α2L1563V SCN1A: Mutations are many and often occur de novo in the gene coding for this channel.	Loss of function. Slower sodium channel inactivation.
Potassium channel KCNQ2/KCNQ3	Voltage gated	BFNC BFNC with myokymia	Each K channel is a tetramer made of 4 homologous subunits that contain 6 trans membrane domains. The 4th transmembrane domain carries amino acids that are positively charged, which effects conformational change during depolarization. The pore forming loop connects domains 5 and 6.	Multiple mutations described, 6 for KCNQ2	Loss of function. Reduction of the M current. Both KCNQ2 and KCNQ3 form heteromeric units that permits the M current K channels form the predominant inhibitory system in the neonatal period.
Chloride channel	Voltage gated	IGE	Chloride channels have two subunits, each with its own pore	3 different mutations: M200fsX231, IVS2-14del11, del 74-117 G715E	The first two mutations caused a loss of function effect, while the third modifies the voltage-dependent gating effect.

dominant juvenile myoclonic epilepsy (ADJME). It is of interest to note that *de novo* mutations in sodium channel lead to SMEI, while missense mutations in the same channel have been shown to lead to the phenotypically distinct syndrome of GEFS+.

### Mutations Affecting Non-Ion Channel Genes

It is important to point out that not all idiopathic epilepsies are turning out to be channelopathies. The identification of mutation in a G protein-coupled receptor underlying a murine audiogenic epilepsy phenotype (Frings mouse) led to a search for mutations in the human ortholog (hMASS1) (32). The gene was mapped to the 5q34 locus, which exhibits linkage to febrile seizures (FEB4). Screening for mutations in the hMASS1 gene in a family with this febrile seizure phenotype led to the identification of a nonsense mutation in one family. Although that mutation did not co-segregate with the febrile seizure phenotype in all families, it was suggested that a loss of function in this gene could lead to febrile and afebrile seizures (33). hMass1 and another gene, VLGR1, appear to be two halves of a single gene now called MASSive G protein-coupled receptor 1 gene (MGR1), which belongs to a family of genes coding for secretin-coupled receptors.

Similarly the identification of a gene mutation in the leucine-rich, glioma-inactivated 1 gene (LGI1) underlying the rare autosomal dominant partial epilepsy with auditory features (ADPEAF) appears to involve non-ion channel genes. However, the structural aspects of the proteins coded by this and other genes (VLGR1 on 5q14.1, and TNEP1 on 21q22.3) share a sevenfold repeated motif in the C terminal region that appears to define a superfamily of related proteins. These tandem repeats have been termed EPTP (34). The mechanisms through which these gene products influence epileptogenesis remain unclear at this stage. Recent studies indicate that even non-ion channel genes may carry an influence in regulating ionic currents across ion channels. Five missense mutations have been identified in unrelated individuals with JME in the EFHC1 gene (6p12-p11 region) that codes for a protein with an EF hand motif (35). This protein has been demonstrated to affect neuronal apoptosis as well as affect R-type calcium currents. It is postulated that individuals with the EFHC1 mutation could carry excess numbers of dystopic neurons that are unstable electrically, giving rise to hypersynchronous neuronal networks (36). Other highly significant associations have been described with non-ion channel genes in families with JME. These include polymorphisms in genes coding for a transcriptional regulator BRD2 (37, 38), and ME2 (malic enzyme 2), a mitochondrial enzyme (39). The functions of the BRD2 gene product remain speculative, while ME2 is involved in GABA biosynthesis/metabolism (40). Whether

these polymorphism associations are causal or merely one of the many genes involved in the generation of the complex phenotype in JME remains to be established.

The genes underlying the syndrome of X-linked infantile spasms with mental retardation can also be considered as examples of mutations in non-ion channel genes leading to a specific epilepsy syndrome. The ARX homeobox and cyclin-dependent kinase-like 5 (CDKL-5/STK-9) gene products have functional effects that are not yet well understood (41).

## GENETICS OF GENERALIZED EPILEPSIES: THE CLINICAL PHENOTYPES

A genetic basis is widely accepted for the IGEs, which include JME, childhood and juvenile absence epilepsy (CAE, JAE), epilepsy with generalized tonic-clonic seizures (GTCS), and epilepsy with grand mal on awakening. The clinical and EEG characteristics of IGEs overlap considerably. Seizure types include tonic, tonic-clonic, clonic, or myoclonic seizures that are generalized, and the interictal EEG shows bursts of synchronous generalized epileptiform patterns over both cerebral hemispheres. In each syndrome, there is an age-dependent onset of a particular seizure type, while the EEG background is often normal. Affected individuals are of normal intelligence; the neurologic examination is usually normal. While this applies to the idiopathic epilepsies with onset in later years, disorders such as SMEI and related borderline conditions beginning in early life may be associated with epileptic encephalopathy and cognitive decline. Table 7-3 summarizes the chromosomal loci and known gene defects linked to idiopathic generalized epilepsy syndromes.

### Childhood Absence Epilepsy (CAE)

There is much overlap in the clinical features between CAE and JAE, within the IGE umbrella. At present, mutations in calcium and chloride channel genes have been reported associated with the CAE phenotype (28, 31).

### Juvenile Myoclonic Epilepsy (JME)

JME appears to be a more distinct genetic phenotype in comparison to other forms of IGE (CAE, and JAE) (42). Mutations affecting both ion channel genes (CACNB4) (43) and non-ion channel genes (EFHC1, BRD2) are reported to result in a JME phenotype (35, 37, 38).

### Benign Familial Neonatal Convulsions (BFNC)

Mutations affecting the genes coding for a family of voltage-gated potassium channels (KCNQ) that are

**TABLE 7-3**

epilepsy with grand mal on awakening	Non-ion channel gene EFHC1 (JME), BRD2 (JME), ME2 (IGE)	6p12, 6p21.3
X linked infantile spasms syndrome	Non-ion channel genes Aristaless (ARX), serine-threonine kinase (STK9) gene or cyclin-dependent kinase-like 5 (CDKL5)	X linked, Xp22.13
Generalized epilepsy with febrile seizures plus (GEFS+), MIM #604233: GEFS+1, GEFS+2, GEFS+3	Sodium channel genes SCN2A (GEFS+), SCN1B (GEFS+1), SCN1A (GEFS+2)	Autosomal dominant Genetic heterogeneity Oligogenic in some families 19q13, 2q24
	GABA receptor gene GABRG2 (GEFS+3), GABARD (GEFS+)	5q31
Familial febrile seizures		Genetic heterogeneity: 8q13 (FEB1), 19p13 (FEB2), 5q14 (FEB4)
Severe myoclonic epilepsy of infancy (SMEI)	Sodium channel gene SCN1A (SMEI)	2q24, 5q31

responsible for the neuronal repolarization appear to underlie this form of epilepsy. Two loci are now recognized: one on chromosome 20q13.3 (EBN1) (44), another on chromosome 8q24 (EBN2) (45). The gene for EBN1, called KCNQ2 (46) codes for one potassium channel component, while the gene for EBN2, termed KCNQ3 (47) codes for another portion of the potassium channel. When expressed in *Xenopus* oocytes, KCNQ2 facilitates the development of potassium currents,

whereas expression of the mutant channel shows no such currents (48). The reason why a fixed genetic deficit in potassium channel structure should lead only to intermittent seizures that tend to remit over time in early life may be related to changing levels in the expression of potassium channel genes during brain development (49). It is also possible that the M-current mediated by KCNQ2/3 is less critical as GABA inhibition matures. During early life, GABA plays an excitatory role in the

immature hippocampus. Coinciding with this period, KCNQ channels seem to perform predominantly an inhibitory role. The functional switching of GABA's role from excitation to inhibition seems to interact with the KCNQ channels in an intricately time locked sequence that modulates hippocampal excitability to demonstrate an "on" and "off" effect (50, 51).

### Benign Familial Neonatal-Infantile Seizures (BFNIS)

Among the families described with benign familial neonatal convulsions, there exist families with an age of onset intermediate between the classic BFNC seizures and the BFIC (i.e., onset predominantly after 1 month). The seizures are partial onset with secondary generalization beginning between 2 to 7 months and carry a good prognosis (52). A mutation in the alpha2 subunit of the voltage-gated sodium channel (SCN2A) has been identified in such individuals in an Australian family and in a family previously described by Lewis et al (53). Thus, the association suggests yet another seizure susceptibility syndrome in early life and has been named benign familial neonatal-infantile seizures (BFNIS).

### Infantile Spasms (IS)

Infantile spasms represent a specific syndrome of generalized seizure associated with a characteristic EEG pattern of hypsarrhythmia. Although a variety of etiologies (tuberous sclerosis, inborn errors of metabolism, Down syndrome) are associated with this epilepsy syndrome, mutations in genes underlying X-linked IS and mental retardation have now been identified. These include the Aristaless homeobox gene (ARX) (54, 55) and the serine-threonine kinase (STK-9 or CKL5, cyclin-dependent kinase-like 5) gene (56), both of which are located on the short arm of chromosome X. The ARX gene defect may lead to defects in a putative transcription factor, while the STK-9/CDKL-5 gene may have a pivotal role in synaptic plasticity, thus suggesting divergent mechanisms leading to this specific epilepsy phenotype (41). The phenotypic features of the latter condition clinically overlap with a Hanefeld variant of the Rett syndrome phenotype (57, 58).

### Febrile Seizures and Related Syndromes

Table 7-3 summarizes the known gene loci and mutations associated febrile seizures and associated syndromes.

*Febrile Seizures (FS).* A genetic basis for FS is likely, based on their increased occurrence in families, though the precise mode of inheritance remains uncertain. In particular, twin studies have demonstrated a much higher risk in monozygotic than in dizygotic twins (40% vs. 7%) (13, 15).

A complex polygenic rather than simple Mendelian inheritance pattern is currently favored. Several gene loci have been identified for familial febrile seizure; however, no specific gene mutations have so far been identified.

Linkage analysis suggests that a locus on chromosome 8q (FEB1) is involved (60%) (59) with other loci (FEB2 at 19p13, and FEB4 at 5q14) identified so far. The FEB4 locus was also confirmed in nuclear families and may account for 70% of febrile seizure susceptibility. The FEB3 locus at 2q23 was reported in large Utah family, and the seizure descriptions are considered as close to GEFS+, so this may be considered more as a GEFS+ locus rather than as one linked to febrile seizures (60).

*Generalized Epilepsy with Febrile Seizures Plus (GEFS+).* Scheffer and Berkovic (61) identified an interesting pattern of FS in an Australian family. A variety of dominantly inherited epilepsy phenotypes occurred in these families, and they proposed a syndrome designated as "generalized epilepsy with FS plus" (GEFS+). The most common phenotype, termed "febrile seizures plus" (FSP), consisted of multiple FS in infancy and the continued occurrence of afebrile seizures beyond age 6 years. All seizures remit by adolescence. Other phenotypes identified in this family include FS plus absences, FS plus myoclonic seizures, and FS plus atonic seizures. The mode of inheritance in GEFS+ remains a matter of debate; in some a dominant pattern observed, in others an oligogenic effect, accounting for a wide variation in clinical phenotype.

So far only a single gene defect has been identified in each family with GEFS+ phenotype. Mutations appear to involve subunits of voltage gated sodium channels (62) and subunits of the ligand-gated GABAergic receptors (63). Both types of mutations appear to affect the functional properties of the respective channels and may serve to enhance seizure susceptibility in a nonspecific manner. An overlap is noted between the clinical features and genetic bases of GEFS+ and SMEI (see following paragraph), exemplifying the enormous complexity of genotype-phenotype correlations in the epilepsies.

*Severe Myoclonic Epilepsy of Infancy (SMEI, Dravet syndrome).* Dravet in 1982 (64) first described the clinical features of this syndrome, where seizures begin in infancy and progress to an epileptic encephalopathy with myoclonic seizures as a prominent feature. Initially the seizures are triggered by febrile events and intercurrent infections, occurring between the second month and the first year of life, after a period of normal development. Seizures are generalized clonic or hemiclonic in character, often prolonged and recurrent. Hemiclonic seizures are thought to be a distinct feature; myoclonic jerks appear later in the course of the disease, accompanied by cognitive and motor decline. Missense and truncating mutations of

**TABLE 7-4**

Benign epilepsy of childhood with central temporal spikes	?	Autosomal dominant with incomplete penetrance (EEG trait) 15q13

the SCN1A gene (coding for the alpha1 subunit for the sodium channel) have been identified in many families with SMEI (65–67). As pointed out earlier, a wide spectrum of idiopathic/cryptogenic epilepsy syndromes with both generalized and focal forms of epileptic seizures beginning in early life are being linked with mutations in the SCNA1 gene. SMEI likely represents the more severe end of this spectrum of overlapping conditions that includes both the milder variants of GEFS+ and the severe epileptic encephalopathies (68).

### Genetics of Partial Epilepsies

Most partial or focal epilepsies are assumed to not have a genetic basis. However, relatives of probands with partial epilepsy have an increased risk of epilepsy compared to the general population, suggesting a genetic influence in at least some forms of partial epilepsy. A defective gene might cause localized cortical hyperexcitability if it is expressed only in certain vulnerable neuronal regions, or if its effects are modified by local factors (69). The partial epilepsy syndromes and the chromosomal loci to which they are mapped are summarized in Table 7-4.

*Benign Epilepsy of Childhood with Central-Temporal Spikes (BECTS).* A strong genetic influence in benign rolandic epilepsy has been observed (70). The disorder appears to be inherited in an autosomal dominant manner with age-dependent penetrance, and the EEG trait is inherited similarly (71). There is an increased incidence of both focal and generalized EEG abnormalities among first-degree relatives. (Interestingly, in relatives, generalized abnormalities are even more common than focal ones.) Doose considers typical BECTS to be a special case

in a broad spectrum of clinical manifestations due to this genetic excitability defect (72). Linkage to 15q13 locus has been demonstrated in family studies (73).

*Autosomal Dominant Nocturnal Frontal Lobe Epilepsy.* This type of epilepsy (abbreviated ADNFLE) was first described in an Australian kindred of 27 affected individuals spanning six generations (74–76). ADNFLE is transmitted in an autosomal dominant fashion with incomplete penetrance. Seizures begin in mid-childhood, occurring in clusters during drowsiness or sleep. Affected individuals are of normal intelligence; they experience frequent nocturnal motor seizures (tonic or hyperkinetic), often preceded by an aura; cases are often misdiagnosed as nightmares or sleep disorders. The neurologic examination and the interictal EEG are normal; during the ictus, seizures can be shown to originate from the frontal lobes (77). There is considerable intrafamilial variability in clinical expression. Using exclusion mapping (i.e., by systematic elimination of candidate genes mapping to the same region), the disorder was assigned a chromosomal locus of 20q13.2. A missense mutation ( $\alpha$ 4S248F) in the alpha4 subunit of the nicotinic acetylcholine receptor (CHRNA4) mapped to this region in all 21 affected members of one ADNFLE family (76). However, there is allelic heterogeneity in this condition, as other families have shown different mutations in the CHRNA4 gene (78).

It appears that mutations that directly affect the ion pore can result in the epilepsy phenotype, as all of the known mutations appear to affect transmembrane domains that form the wall of the ion channel. Differences in the electrophysiologic and pharmacologic profiles among the different receptor mutations have been shown in addition to the common effect of increasing cholinergic sensitivity. In reconstitution experiments carried out in *Xenopus*

oocytes, nicotinic cholinergic receptors with mutant alpha4 subunits had faster desensitization kinetics than wild-type receptors; that is, they became rapidly unresponsive to acetylcholine stimulation (79). Reconstituted mutant receptors also show significantly reduced calcium permeability (80). These differences may account for additional specific phenotypic features, such as the occurrence of neuropsychiatric symptoms reported in  $\alpha 4776\text{ins}3$  carriers (81).

*Familial Temporal Lobe Epilepsy.* Ottman and colleagues described a single family of 11 affected individuals who presented with partial seizures and nonspecific auditory disturbances with onset during adolescence (82). This syndrome consists of the familial occurrence of mild temporal lobe seizures with age-dependent onset, with seizures originating from the mesial as well as the lateral temporal lobe. The hippocampal pathology seen in typical temporal lobe epilepsy is absent in the familial variety (83, 84). Using linkage analysis, the epilepsy susceptibility gene mapped to chromosome 10q22–24. The condition is now recognized by the phrase “autosomal dominant partial epilepsy with auditory features (ADPEAF).”

When all the 28 genes in the implicated 10q24 locus were sequenced, mutations were identified in the leucine-rich glioma-inactivated 1 gene (LGI1) (85). The implications of this finding have been discussed separately. Other autosomal dominant inheritance patterns for partial epilepsies have been identified in clinical studies of large families: autosomal dominant partial epilepsy with variable foci (83, 86), autosomal dominant rolandic epilepsy with speech dyspraxia (74), and benign familial infantile convulsions (BFIC) (87). Linkage studies have suggested associated loci; however, so far in none of these inherited syndromes has a mutation been identified.

## GENE-ENVIRONMENT INTERACTIONS

Environmental factors can strongly influence the expression and risk of developing seizures. The gene-environment connection is challenging to study, and available studies show conflicting results. Although one would intuitively suspect factors such as head trauma to dramatically increase the risk of epilepsy in individuals with a genotype of increased seizure susceptibility, family studies suggest quite the opposite for some factors (identified postnatal insults such as head trauma) (88) but are in agreement for others (alcohol-induced seizures) (89). Alcohol exposure may carry a significant relationship with genetic susceptibility to seizures, a hypothesis that merits further exploration.

Another example of this interaction is operative in the case of pregnant women. Pregnancy exposes the fetus to myriad environmental influences on early development. An increased risk of epilepsy (4–5-fold increase) has been shown in the offspring of women with a history of spontaneous abortions, and such a history may be a

marker for increased genetic susceptibility to epilepsy in the mother (90). The molecular basis of this increased susceptibility remains unclear.

In the case of febrile seizures, interesting insights have been provided at a molecular level between mutation effects on GABA<sub>A</sub> receptors and temperature effects (91). Impaired gamma2 subunit function has been strongly suspected as a factor in seizure susceptibility in patients with febrile seizures in the GEFS+ spectrum. The gamma2 receptor subunit plays a critical role in receptor trafficking, clustering, and synapse maintenance, and when mutant receptors (with the described mutations in the GEFS+ phenotype) are challenged with temperature elevation, a rapid deterioration in receptor trafficking and increased endocytosis is demonstrable, thus leading to reduced surface expression and increased vulnerability to fever induced seizures (91). The future will likely disclose many more interesting insights at the molecular level of the gene-environment interaction.

## PHARMACOGENOMICS IN EPILEPSY

With accelerated-throughput technologies that are increasingly available, the pace of identification of gene mutations has been hastened. With that, opportunities to understand the interactions of gene products and other proteins within the cell have opened up. As the intricate and complex mechanisms underlying epilepsies is unraveled, we have entered into the era of understanding the interaction between drugs and genotype. In the case of epilepsy, the developing branches of proteomics and pharmacogenomics will help us better understand the mechanisms of effectiveness of antiepileptic drugs as well as drug resistance. Variations in genotype will account for differences in drug pharmacokinetics as well as other factors that influence such differences (age, sex, race, etc.) (92).

The effect of genetic polymorphisms on drug metabolism carries with it significant implications for serum drug levels and metabolite concentrations. These in turn can affect the clinical response. Therefore, dosage scheduling by genotype may well come to be an important treatment consideration in the future. End organ targets for antiepileptic drugs may be yet another source of genetically determined pharmacoresistance. Genetic polymorphisms in drug-metabolizing enzymes CYP2C9 and in the SCN1A sodium channel receptor seem to carry significant implications for the prediction of maximal tolerated doses of phenytoin and carbamazepine in one study (93). Further studies are needed to confirm and to extend these observations.

Drug efflux transporters are another area where the relationship of pharmacoresistance to antiepileptic drugs and genotype has been explored. An association between genetic polymorphisms in the ATP-binding cassette binding member 1 (ABCB1) and the phenotype

**TABLE 7-5**  
*Risks of Epilepsy in First Degree Relatives and in Offspring*

GENETIC COUNSELING ISSUES	VARIABLES	RISK ESTIMATE APPROX %
Risk of developing epilepsy in other family members and relatives	General population risk estimates	1
	Acute symptomatic

Myoclonic	4–8	
Absence	5–9	
Risk to offspring (% of children with epilepsy by age 20)	Risk of overall epilepsy in children of probands	2–5%
	Mother with epilepsy	2.8–8.7%
	Father with epilepsy	2.4%
	Parent with IGE	3.3%
	Parent with pure absence epilepsy	9%
	Parent with partial epilepsy	4.6%
	Parent age of onset	
	Onset < 20	2.3–6%
Onset > 20	1.0–3.6%	

of drug-resistant epilepsy was suggested by Siddiqui and associates (94). The associated polymorphism is silent, and the haplotype associated with drug resistance was not clearly identified. Subsequently the findings have been replicated in one study (95) but could not be replicated in other studies with a much larger sample size (96, 97). A biologically plausible result may sometimes be a false positive finding (98). Nevertheless the hypothesis of drug resistance mediated by transporters under genetic control remains attractive and merits continued exploration.

Drug reactions are another area where genetic variation can influence the development of such reactions. Serious skin reactions to carbamazepine have been associated with a polymorphism at position 308 in the TNF alpha promoter region (99) as well as variants in HLA gene alleles such as HLA-B\*1502 (100, 101). Eventually, genotyping could be used to predict drug reactions prior to initiating treatment with drugs to avoid such serious reactions.

An improved understanding of pharmacogenetic interactions in epilepsy will eventually lead the physician in making correct choices of AEDs in treatment of seizures, improvements in drug design, prediction and avoidance of aberrant drug effects, and better strategies in dealing with pharmacoresistance.

#### GENETIC COUNSELING ISSUES IN EPILEPSY

The issues relating to genetic counseling center around addressing the heritability of epilepsy, the risk of epilepsy in family members and offspring, and the value of genetic testing in epilepsy (10). We have attempted to summarize the risk estimates in comparison to the general population risk in family relatives (sibship) and offspring (Table 7-5) based on the data from epidemiologic studies in the literature presented in (102).

At the outset, it should be clarified that epilepsy is not a single disorder, but a collection of many disorders with great a deal of variability in phenotype and causation. Therefore no single gene defect could account for the different kinds of epilepsy. The concept of the risk of developing epilepsy being influenced by single, few or many genes will need to be explained. Differences in penetrance could result in people being affected or remaining as asymptomatic carriers. The fact that common epilepsies are influenced by several genes (polygenic) and that inheritance patterns are likely to be complex and difficult to predict will need added emphasis. Finally, it must be pointed out that recurrence risks are likely to be influenced by other environmental factors.

For disorders with single gene defects, which are inherited in true Mendelian fashion, risk estimates for family members are likely straightforward. But for the non-Mendelian disorders (i.e., most common idiopathic epilepsies), estimates of risks are best expressed in terms of absolute risk (%) with a range of values as well as to provide comparison figures for the general population. It may also be possible to express this risk as a ratio rather than a percentage (1 in 25 rather than 4%). It is customary to use data from epidemiologic studies while estimating the risk. The class of relative (in relationship to the probands) should be taken into account. Sibling risks are useful in helping families with one affected child and who are at the stage of planning a pregnancy. Offspring risks are similarly based on information from epidemiologic studies. Risk estimates are influenced by a number of factors, including seizure and syndrome type, type of EEG abnormality, age of onset, parental attributes (sex and affected status), and the number of individuals with epilepsy in the family (Box 7-1).

The role of genetic testing in the routine management of common idiopathic epilepsies is limited. Affected families may undergo genetic testing through participation in numerous research studies and programs such as the gene discovery project of the Epilepsy Foundation of America. This project allows families to link up with researchers working in that area. These disorders are

relatively benign, and the complex modes of inheritance and various confounders that can influence the reliability of a result preclude routine use of genetic testing in this group. For the monogenic disorders that are rare, but where the genes and common mutations are identified, direct mutation analysis is possible in disorders such as the progressive myoclonic epilepsies (EPM1, EPM2, MERRF, and the ceroid lipofuscinoses). These are serious disorders with considerable morbidity and mortality, and genetic testing can be justified. Information gleaned can be used for appropriate genetic counseling. Molecular diagnostic tests for BFNC (KCNQ2 DNA sequencing), SMEI, and GEFS+ (SCN1A DNA sequencing), are becoming commercially available (e.g., Athena Diagnostics, <http://www.AthenaDiagnostics.com>), and the list will, no doubt, grow longer.

## SUMMARY

In summary, the modes of inheritance of epilepsy in the light of current understanding suggest diverse mechanisms and both Mendelian and non-Mendelian inheritance (complex oligogenic, polygenic). In essence, gene defects that can lead to the generation of an epilepsy phenotype display a remarkable functional diversity. The pathway from an altered genomic sequence meanders through mRNA, its stability and processing, protein translation defects, stability of the proteome, subcellular localization and expression, and, finally, to a state of electrical instability and a regional or generalized expression of seizures (Figure 7-3). Studies of other areas—for instance, regulatory molecular processes (integrins, growth factors, metabotropic glutamate receptors, GABA transporters) and mechanisms that underlying brain plasticity—will no doubt yield additional genes and their proteins linked with epilepsy. It is recognized that abnormalities of cortical development can lead to epilepsy, but the early occurrence of seizures also carries consequences for the development of neural networks in the developing brain. The genetic and epigenetic factors regulating these complex interactions will no doubt be essential for understanding the genetic-molecular aspects of epileptogenesis (12). Pathologic mutations leading to defects in the function of subcellular organelles (mitochondrial respiratory chain defects, peroxisome biogenesis defects) as well as enzymatic defects in critical metabolic pathways provide additional routes to an epileptogenesis. Ultimately, these numerous pathways seem to converge on the neuron, producing an unstable electrical state that promotes synchronized burst firing in vulnerable neuronal networks.

Thus, the state of present-day understanding of epilepsy is at a crossroads in terms of complexity. In the discussion in this chapter we have highlighted the diversity

### BOX 7-1

 Number of affected relatives  
 Role of genetic testing in epilepsy

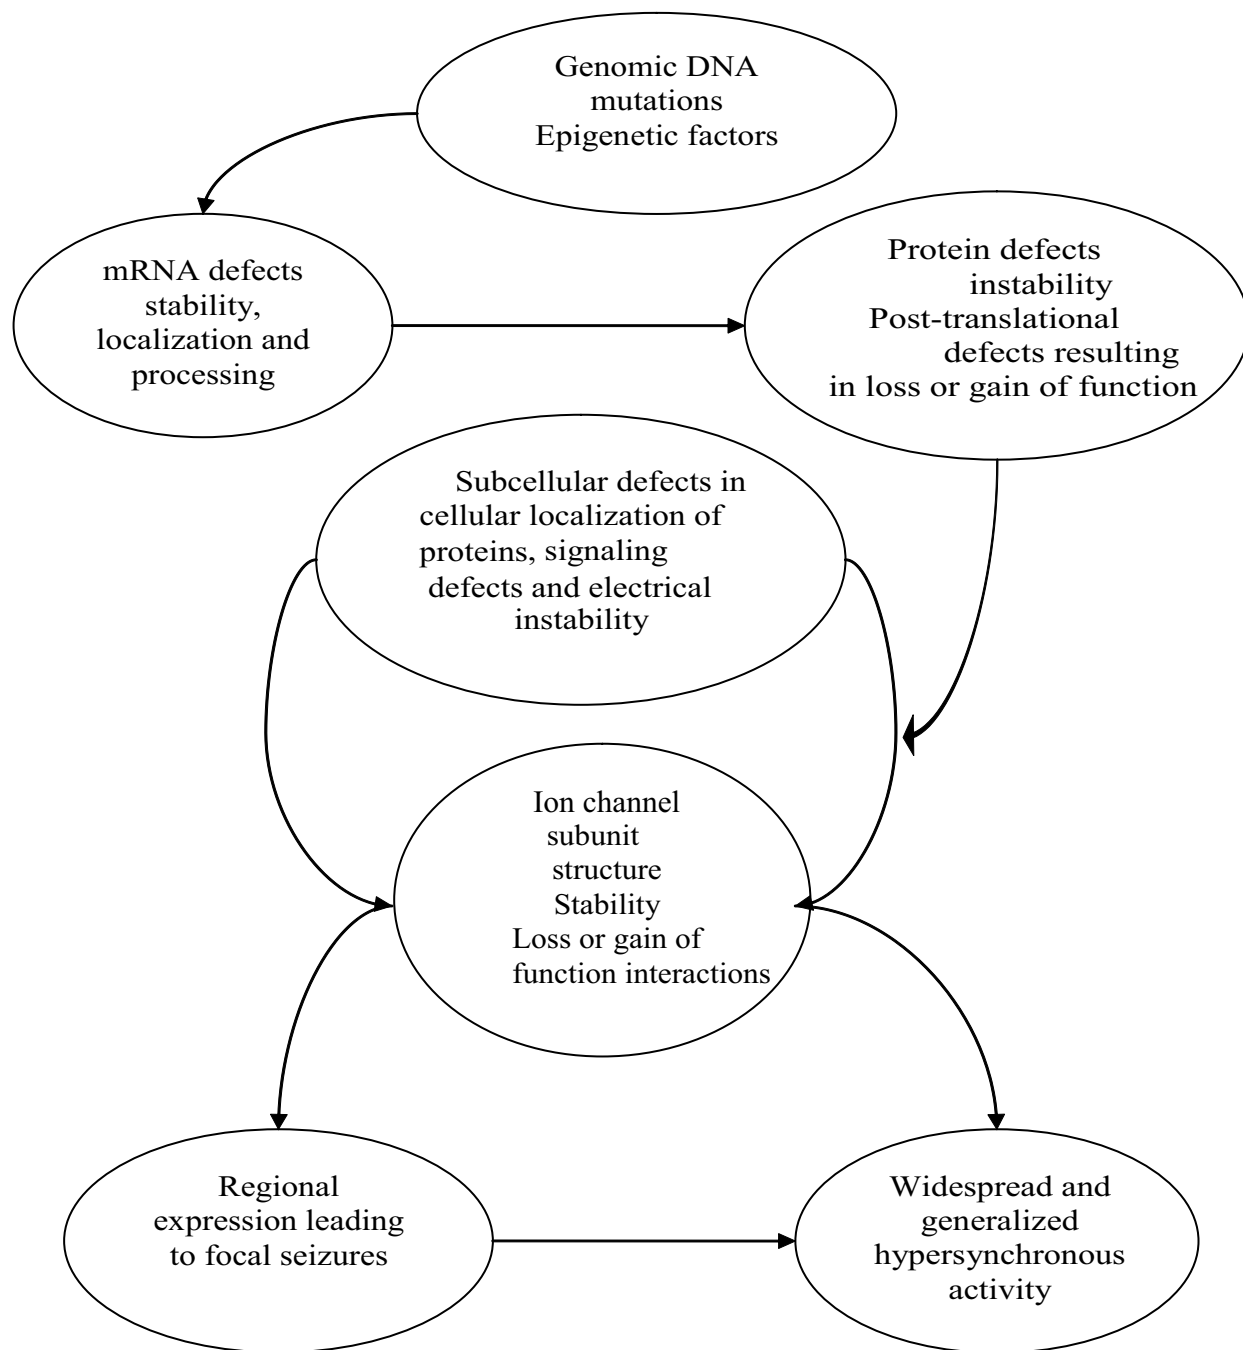

FIGURE 7-3

Genetic and epigenetic processes that can influence epileptogenesis.

of causes and mechanisms and the role of epilepsy genes in the process of epileptogenesis.

Even within the span of a decade, the list of gene defects and mutations has increased at a steady pace each year. Our understanding of the role of these genes and the proteins that they code for is in its infancy, but it underscores the many pathways to epileptogenesis. Does the practicing epileptologist and neurologist have to

know all of the numerous gene defects described? We do not think that is necessary. However, we do believe that these discoveries lay the foundation for our understanding human epilepsy and its protean presentations. From genetic defects in ion- and ligand-gated channels and signaling and regulatory molecules, chromosomal aberrations, and defects in intermediary metabolism, the multiplicity of mechanisms underlying the heterogeneity of

inherited epilepsy is truly breathtaking. For the clinician, a detailed collection of information on seizure semiology, age of onset, ethnic background, and family history remains critical in recognizing genetic contributions to the individual's epilepsy. In selected instances of single-gene defects mutation analysis will be of help in diagnosis, and even in selecting treatment, where it is or becomes commercially available. In the majority of more common epilepsy syndromes, any form of mutation analysis to determine susceptibility genes is still a long way away. When such technology becomes available, the clinical implications of the findings will have to be carefully

examined. These advances hold the promise of improving our understanding of epileptogenesis and will likely lead to methods of early detection and counseling and newer, more effective therapies for affected individuals and their family stricken by this complex disorder.

## ACKNOWLEDGMENTS

The authors are indebted to Dr. T Frewen, Dept. of Pediatrics, the Children's Hospital Western Ontario, for their support and encouragement, and Ms. J Carrier (Rathbun Library) for her help with obtaining original articles.

**CLASSIFICATION,  
EPIDEMIOLOGY, ETIOLOGY,  
AND DIAGNOSIS**

# 8

## Classification of Epilepsies in Childhood

*Douglas R. Nordli, Jr.*

### HISTORICAL BACKGROUND

Early discussions on epilepsy rarely differentiated between epilepsies in childhood and those in adult life. The history of classification of the epilepsies might be defined in three major eras: the philosophical era before the twentieth century, marked by patient observation and, to a large degree, philosophical speculation as to the nature of the disease; the era of the localizationalists and pathologists, spanning roughly the first half of the twentieth century; and the present molecular era, including neurochemistry and particularly receptor pharmacology, the physiology of excitatory and inhibitory systems, and molecular biology.

#### The Philosophical Era

In 1861 Reynolds (1) described convulsions in children by the name *eclampsia*. So-called eclamptic seizures in those days referred to seizures characteristic of the childhood age group, which encompassed febrile convulsions and convulsions due to specific systemic diseases. Although Poupert had described absence in a young girl in 1705 (2), different seizure types were not particularly related to different age groups until much later. In 1772 Tissot (3) classified epileptic seizures but made a more specific contribution that is often lost and that was further elaborated by Sachs (4) in the first

English-language pediatric neurology textbook: that is, the concept that epilepsy is composed of an ongoing predisposing condition or diathesis, but that the individual epileptic seizures, or expression of the epileptic process, is triggered by a concatenation of factors that might be considered as precipitating or triggering factors. The latter are not always recognized, and epilepsy therefore has been defined as a liability to unprovoked seizures, which is probably a procrustean attempt to exclude febrile convulsions from the epilepsy rubric.

Sachs divided childhood epilepsies into the eclamptic and the epileptic. The epileptic seizures were further divided into focal and generalized as well as lesional and idiopathic. He believed that idiopathic seizures on a heritable basis had an ultimately bad prognosis and that symptomatic seizures had an even worse prognosis. He thought that symptomatic epilepsies were the result of neonatal abnormalities, including brain hemorrhage. Freud (5) wrote about epilepsy in his text on the infantile cerebral palsies and related childhood seizures to major brain disturbances leading to the conditions included under the heading of cerebral palsy. Smith (6), in his book on diseases in children published over 100 years ago, stated that eclampsia in children was relatively benign except when severe and protracted, when it might be the cause of certain lesions, and he separated this from epilepsy occurring in older children, which he regarded as

symptomatic. Sachs, agreeing with Tissot in defining an underlying predisposition and a precipitating cause, also stated that the prognosis largely depended on the underlying cause of the epilepsy and was otherwise not inherent in the convulsions—a somewhat different conclusion than had been arrived at by Gowers (7), who studied predominantly adults and who believed that the periodicity or repetitiveness of a convulsive disorder carried within it the seeds of a progressive disorder.

### The Localizationalist and Pathologist Era

The period of the localizationalists and pathologists began with the experiments of Fritsch and Hitzig and of Ferrier and formed the basis of Hughlings Jackson's localizational endeavors, which in turn inspired the beginning of epilepsy surgery 100 years ago by Victor Horsley. The landmark activities of Penfield, Erickson, and Jasper during the past 50 years more clearly defined the nature of epileptic seizures and their localization in the nervous system. The development of electroencephalography (EEG) and, in more recent times, electroencephalography with simultaneous visualization of epileptic seizure behavior on a split-screen TV (video EEG, vEEG) has contributed to understanding epilepsy. This allowed the elaboration of the 1981 classification of epileptic seizures (8), which represented an advance made possible by objective methods of documenting seizures. The addition of other factors, such as anatomic substrate, cause, and age, based on information other than intensive monitoring, were then incorporated into the definition of individual epileptic syndromes (9).

*The Molecular and Genetic Era* Modeling of the epilepsies using various animal models; sophisticated neurophysiological, neurochemical, and pharmacological techniques; tissue slice preparations with the application of excitatory and inhibitory neurotransmitters and both extracellular and intracellular recordings; and the individual neuronal culture preparations have advanced the study of the epilepsies immensely. More recent advances in basic science research, oddly enough, could be seen as taking us back hundreds of years to the original postulates of Tissot regarding epileptogenesis. He postulated that certain factors influence the threshold for seizures, and others act in a role of acute provocation. Baraban (10) elegantly summarized the parallels in modern scientific studies: genomic research has identified factors that alter the threshold for seizures, and other factors, including glial activation, may act as the acute provocation. With these studies has come the realization of epilepsy as a system disease with an interplay of factors alluded to by students of epilepsy hundreds of years ago, the details of which are only becoming clear in the current era.

## CLASSIFICATION OF EPILEPTIC SEIZURES AND THE EPILEPSIES

### Evolution of the Classification Schemes

Classification is an ongoing process that is sequentially refined by addition of new information regarding seizures and the epilepsies. Our predecessors worked hard to lay down the foundations of our currently used classification schemes: the 1981 International League Against Epilepsy (ILAE) classification of seizures and the 1989 ILAE classification of epilepsy syndromes (8, 9). These classifications, intimately familiar to all epileptologists and many neurologists, have stood the test of time—a remarkable feat given the fact that these classifications were devised at a time when video EEG units were just starting to proliferate. Still, some of the terms are clearly outdated (e.g., “partial” is out of vogue and has been replaced by “focal”), new syndromes have been recognized in the interim, and some older syndromes have not held-up under further scrutiny. Modern genetics is challenging some of our assumptions, as in the dialectic of idiopathic versus symptomatic. Some epilepsies with strong genetic predeterminants (e.g., Dravet syndrome) do not phenotypically match the other idiopathic (*sui generis*) epilepsies. Clinical neurophysiological techniques and imaging have shown that seizures previously thought to have been “generalized” are really regional, or even triggered by focal processes. Many have recognized the need, therefore, to change the classification, but the critical question is how. What are the needs of the classification systems? Should they be practical, like a gardener's system, or scientific, like a botanist's (11)? If a scientific system is desired—one that provides insight into the underlying shared mechanisms—how is this done when we have only an incomplete knowledge of the pathogenesis of most epilepsies (12)? Some of the most thoughtful and well-informed people in the epilepsy field actively debate these issues, and we await their sage advice in the form of a newly revised ILAE classification system. Until then, the ILAE has made it clear that the only currently sanctioned classification systems are the ones from the 1980s (13). Accordingly, we will present the 1981 and 1989 classification schemes in this chapter, with modifications that incorporate the most recent published thoughts; however, the reader is encouraged to maintain an open mind and to think creatively of new ways to organize emerging information. Our predecessors never envisioned that the classification systems would remain stagnant; rather, they foresaw the need for further revisions. These will undoubtedly come forth, guided by the many exciting scientific advances in our field, and allow us to better understand and care for people with epilepsy.

### Seizure Classification

Seizures have historically been categorized as either focal or generalized (Table 8-1). Focal (or localization-related) seizures arise in specific loci in the cortex, which carry with them identifiable signatures, either subjective or observational. These may range from disorders of sensation or thought to convulsive movement of a part of the body. Originally, simple focal (partial) seizures were defined as those in which consciousness is preserved. The concept was that these arose from the six-layered

isocortex and remained localized sufficiently long to allow specific symptoms to be discerned. In contrast, complex focal (partial) seizures were defined as those in which consciousness was impaired. The implication of complex focal (partial) seizures was that they involved elaboration elements of the limbic system, thus leading to early bilateral dysfunction. The most recent work of the ILAE classification core group has moved away from the “simple” and “complex” designations. This is a welcomed change in pediatrics, because accurate determination of alteration of consciousness was often very challenging, particularly in the preverbal infant or the child with impaired ability to communicate (14)

Generalized seizures involve large volumes of brain from the outset and are usually bilateral in their initial manifestations and associated with early impairment of consciousness. They may range from absence seizures, characterized only by impaired consciousness, to generalized tonic-clonic seizures (GTCS), in which widespread convulsive activity takes place. Myoclonic seizures, tonic seizures, and clonic seizures may also occur as generalized attacks.

The latest report from the ILAE Classification Core Group has divided seizure types into those that are self-limited and status epilepticus. It further divides the self-limited seizures into those that are generalized at onset and those that are focal at onset. It does not do the same for status epilepticus. A simplified version is presented in Table 8-2 (15).

The newly suggested classification scheme for seizures is more complex than the 1981 scheme. As mentioned, the elimination of the simple and complex categories is useful in pediatrics since it is often challenging or impossible to reliably assess alteration of consciousness in preverbal children. The current scheme may still be difficult to apply to children, even for experts aided by concurrent vEEG data. Focal seizures in the immature lack declarative focal features that might otherwise point to the type of cortex generating the ictus: contralateral dystonic hand posture, ipsilateral hand automatisms, and contralateral hand and eye version rarely occur (16–18). Automatisms, when expressed, tends to be elementary and to feature simple mouthing movements or swallowing motions. Tonic postures are often nonspecific and may relate to primitive subcortical reflexes that are disinhibited during a seizure (17). Preverbal children, of course, cannot volunteer auras and cannot cooperate with testing to determine alteration of consciousness or amnesia. For all these reasons, accurately diagnosing a focal seizure in an infant, unless there is focal limb clonus, can be very difficult. Reliable differentiation of neocortical versus hippocampal seizures is probably next to impossible.

Accordingly, many different seizures in the immature would be left unclassified. This may result in a loss of valuable diagnostic and prognostic information

Modified slightly from Engel et al. (15).

and will undoubtedly thwart the refinement of further classification schemes. Classifying these seizures in semiologically descriptive terms therefore may be more useful. (See Chapter 14 on neonatal seizures for more information.)

The same difficulties apply to the propagation of seizures, even when high quality scalp EEG data is available. Most infantile seizures do not progress in the same orderly sequence that one observes in adults (19). Moreover, there is often a mismatch between the scalp EEG and clinical findings. For example, a seizure with overt focal clinical findings may be accompanied by a diffuse attenuation on EEG, suggesting that a deep ictal focus is not spreading to the scalp in an organized fashion. Differentiating between the various types of spread would not be possible for the majority of infantile seizures. For these reasons, a semiology-based scheme or a simple description of the fundamental clinical aspects of the seizures may be preferable, especially for the very young (20). Alternatively, one may add some modification to the new classification scheme to allow it to better encompass the full range of pediatric seizures. One such modification for self-limited seizures is listed in Table 8-3.

### CLASSIFICATION OF EPILEPSIES AND EPILEPTIC SYNDROMES

In the 1989 ILAE classification scheme epilepsies are classified according to seizure type and EEG findings (for example, either focal or generalized) or according to cause (that is, idiopathic, genetic, or symptomatic). They are classified by anatomic localization (for example, frontal, rolandic, occipital, or temporal lobe epilepsies). Finally, they are sometimes classified according to precipitating factors. Other factors taken into consideration are age of onset and certain diurnal influences. All of these factors (Table 8-4) are taken into account in the 1989 ILAE classification, and this is outlined in Table 8-5.

### DEFINITIONS

#### Benign Childhood Epilepsy with Centrottemporal Spikes

Benign childhood epilepsy with centrottemporal spikes is a syndrome of brief, simple, focal, hemifacial motor seizures, frequently with somatosensory symptoms, which have a tendency to evolve into GTCS (21–26). Both seizure types are often related to sleep. Onset is between 3 and 13 years of age (peak, 9–10), and recovery before ages 15 to 16. Genetic predisposition is frequent, and there is male predominance. The EEG has blunt high-voltage centrottemporal spikes, often followed by slow waves that are activated by sleep.

features brief seizures with variable manifestations, but often including some type of visual phenomena. The EEG shows occipital spikes enhanced by eye closure. The latest work from the ILAE classification commission raised some doubts about the Gastaut variant because of the paucity of recent reports.

### **Benign Neonatal Familial Convulsions**

Benign neonatal familial convulsions are rare, dominantly inherited disorders manifesting mostly on the second and third days of life, with clonic or apneic seizures and no specific EEG criteria (27). History and investigations reveal no etiological factors. Approximately 14 percent of these patients later develop epilepsy.

### **Benign Neonatal Convulsions**

Benign neonatal convulsions are very frequently repeated clonic or apneic seizures occurring around the fifth day of life. They have no known cause or concomitant metabolic disturbance (28). Interictal EEG often shows alternating sharp theta waves (theta pointu alternant). There is no recurrence of seizures, and psychomotor development is not affected.

### **Childhood Epilepsy with Occipital Paroxysms**

Two types of epilepsy have been described in this category: early-onset benign childhood occipital epilepsy (Panayiotopoulos type) and late-onset childhood occipital epilepsy (Gastaut type). In the former type, attacks are rare but may be prolonged. The seizures have pronounced autonomic features, often associated with vomiting. The affected child may be listless for a prolonged period with a pale countenance. Early reports highlighted the occipital predominance of the interictal epileptiform discharges, but later reports showed that spikes are multifocal and highly stereotyped so that they have a "cloned-like" appearance. The latter type, described by Gastaut,

### **Benign Myoclonic Epilepsy in Infancy**

Benign myoclonic epilepsy in infancy is characterized by brief bursts of generalized myoclonus that occur during the first or second year of life in otherwise normal children who often have a family history of convulsions or epilepsy (29). The EEG shows generalized spike waves occurring in brief bursts during the early stages of sleep. These attacks are easily controlled by appropriate treatment. They are not accompanied by any other types of seizures, although GTCS may occur during adolescence. The epilepsy may be accompanied by a relative delay of intellectual development and minor personality disorders.

**TABLE 8-5**  
*International Classification of Epilepsies and Epileptic Syndromes (1989)*

- 1.0 Localization-related (focal, local, focal) epilepsies and syndromes
  - 1.1 Idiopathic (with age-related onset)
  - 1.2 Symptomatic
  - 1.3 Unknown as to whether the syndrome is idiopathic or symptomatic
  
- 2.0 Generalized epilepsies and syndromes
  - 2.1 Idiopathic (with age-related onset-listed in order of age)
    - Benign neonatal familial convulsions
    - Benign neonatal convulsions
    - Benign myoclonic epilepsy in infancy
    - Childhood absence epilepsy (pyknolepsy)
    - Juvenile absence epilepsy
    - Juvenile myoclonic epilepsy (impulsive petit mal)
    - Epilepsy with grand mal (GTCS) seizures on awakening
    - Other generalized idiopathic epilepsies, if they do not belong to one of the above syndromes, can still be classified as generalized idiopathic epilepsies.
  - 2.2 Cryptogenic or symptomatic (in order of age)
    - West syndrome (infantile spasms, Blitz-Nick-Salaam Krampfe)
    - Lennox-Gastaut syndrome
    - Epilepsy with myoclonic-astatic seizures
    - Epilepsy with myoclonic absences
  - 2.3 Symptomatic
    - 2.3.1 Nonspecific etiology
      - Early myoclonic encephalopathy
    - 2.3.2 Specific syndromes
      - Epileptic seizures may complicate many disease states. Under this heading are included those diseases in which seizures are a presenting or predominant feature.
  
- 3.0 Epilepsies and syndromes undetermined whether focal or generalized
  - 3.1 With both generalized and focal seizures
    - Neonatal seizures
    - Severe myoclonic epilepsy in infancy
    - Epilepsy with continuous spike-waves during slow wave sleep
    - Acquired epileptic aphasia (Landau-Kleffner syndrome)
  - 3.2 Without unequivocal generalized or focal features
  
- 4.0 Special syndromes
  - 4.1 Situation-related syndromes (Gelegenheitsanfälle)
    - Febrile convulsions
    - Isolated seizures or isolated status epilepticus
    - Seizures occurring only when there is an acute metabolic or toxic event due to, for example, alcohol, drugs, eclampsia, nonketogenic hyperglycemia, uremia

### **Childhood Absence Epilepsy (Pyknolepsy)**

This syndrome of childhood absence epilepsy (pyknolepsy) occurs in children of school age (peak manifestation, age 6 to 7) with a strong genetic predisposition in otherwise normal children (30–34). It appears more frequently in girls than in boys and is characterized by very frequent (several to many per day) absences. The EEG reveals bilateral, synchronous symmetrical spike waves, usually three per second, on a normal background activity. GTCS often develop during adolescence. Otherwise, absences may remit or, more rarely, persist as the only seizure type.

### **Juvenile Absence Epilepsy**

The absences of this syndrome are the same as in pyknolepsy, but absences with retropulsive movements are less common (35). Age of manifestation is around puberty. Seizure frequency is lower than in pyknolepsy, with absences occurring less frequently than every day, mostly sporadically. Association with GTCS is frequent, and they precede the absence manifestations more often than in childhood absence epilepsy, often occurring on awakening. Not infrequently, the patients also have myoclonic seizures. Sex distribution is equal. The spike wave rate is often faster than 3 per second. Response to therapy is excellent.

### **Juvenile Myoclonic Epilepsy (Impulsive Petit Mal)**

Juvenile myoclonic epilepsy appears around puberty and is characterized by seizures with bilateral, single or repetitive arrhythmic, irregular myoclonic jerks, predominantly in the arms (36–40). Some patients may suddenly fall from a jerk. No disturbance of consciousness is noticeable. The disorder may be inherited, and sex distribution is equal. Often, there are GTCS and, less often, infrequent absences. The seizures usually occur shortly after awakening and are often precipitated by sleep deprivation. Interictal and ictal EEG have rapid, generalized, often irregular spike waves and polyspike waves; there is no close phase correlation between EEG spikes and jerks. Frequently, the patients are photosensitive. Response to appropriate drugs is good.

### **Epilepsy with GTCS on Awakening**

Epilepsy with GTCS on awakening is a syndrome with onset mostly in the second decade of life. The “grand mal” seizures are presumably mainly GTCS and occur exclusively or predominantly (over 90% of the time) shortly after awakening, regardless of the time of day, or in a second seizure peak in the evening period of

relaxation. If there are other seizures, they are mostly absences or myoclonic, as in juvenile myoclonic epilepsy. Seizures may be precipitated by sleep deprivation and other external factors. Genetic predisposition is relatively frequent. The EEG shows idiopathic generalized epilepsy. There is a significant correlation with photosensitivity. The most recent work of the ILAE commission has brought into question whether this is a distinct entity (15).

### **West Syndrome (Infantile Spasms, Blitz-Nick-Salaam Krampfe)**

West syndrome usually consists of a characteristic triad: infantile spasms, arrest of psychomotor development, and hypsarhythmia, although one element may be missing (41–45). Spasms may be flexor, extensor, lightning, or nods but most commonly are mixed. Onset peaks between 4 and 7 months and is always before 1 year. Boys are more commonly affected, and the prognosis is generally poor. West syndrome may be separated into two groups. The symptomatic group is characterized by the previous existence of brain damage signs (psychomotor retardation, neurologic signs, radiologic signs, or other types of seizures) or by a known cause. The smaller, idiopathic group is characterized by the absence of previous signs of brain damage and of known cause. The prognosis is dependent upon etiology and response to treatment; a subgroup of infants with no prior brain damage and good response to treatment may have an excellent prognosis with normal development and no recurrence of seizures. Patients with symptomatic etiology and incomplete response to treatment do poorly and often have mental retardation and persistent seizures.

### **Lennox-Gastaut Syndrome**

Lennox-Gastaut syndrome manifests itself in children from 1 to 8 years of age but appears mainly in preschool-age children (46–48). The most common seizure types are tonic-axial, atonic, and absence seizures, but other types such as myoclonic, GTCS, or focal are frequently associated with this syndrome. Seizure frequency is high, and status epilepticus is frequent (stuporous states with myoclonias, tonic, and atonic seizures). The EEG usually has abnormal background activity, slow spike waves of less than 3 per second, and often multifocal abnormalities. During sleep, bursts of fast rhythms (around 10 per second) appear. In general, there is mental retardation. Seizures are difficult to control, and the development is mostly unfavorable. In 60% of cases, the syndrome occurs in children suffering from a previous encephalopathy, but it is primary in other cases.

### **Epilepsy with Myoclonic-Astatic Seizures**

Manifestation begins between the ages of 7 months and 6 years, mostly from 2 to 5 years, with (except if beginning in the first year) twice as many boys affected (49, 50). There is frequently hereditary predisposition and usually a normal developmental background. The seizures are myoclonic, astatic, myoclonic-astatic, absences with clonic and tonic components, and tonic-clonic. Status epilepticus frequently occurs. Tonic seizures develop late in the course of unfavorable cases. The EEG is initially often irregular with fast spike waves or polyspike waves, often occurring in bursts so short that it is difficult to determine the repetition rate precisely. Biparietal rhythmic theta activity has also been noted. Course and outcome are variable.

### **Epilepsy with Myoclonic Absences**

The syndrome of epilepsy with myoclonic absences is clinically characterized by absences accompanied by severe bilateral rhythmical clonic jerks, often associated with a tonic contraction (51). They are always accompanied on the EEG by bilateral, synchronous, and symmetrical discharge of rhythmical spike waves at 3 per second, similar to childhood absence. These seizures occur many times a day. Awareness of the jerks may be maintained. Associated seizures are rare. Age of onset is about seven years, and there is a male preponderance. Prognosis is less favorable than in pyknolepsy because of resistance to therapy for the seizures, mental deterioration, and possible evolution to other types of epilepsy such as Lennox-Gastaut syndrome.

### **Early Myoclonic Encephalopathy and Early Infantile Epileptogenic Encephalopathy**

The principal features of early myoclonic encephalopathy are onset before 3 months of age; initially fragmentary myoclonus, then erratic focal seizures; and massive myoclonias or tonic spasms (52). The EEG is characterized by suppression-burst activity, which may vary in the awake and sleeping states. The course is severe, psychomotor development is arrested, and death may occur in the first year. Familial cases are frequent and suggest the influence of one or several congenital metabolic errors, but there is no constant genetic pattern. Early infantile epileptic encephalopathy with suppression bursts, described by Ohtahara and coworkers (52), presents in a similar fashion, but the predominant seizure type in this disorder is tonic and the EEG shows an invariant burst-suppression pattern with bursts occurring about every 3–5 seconds. It frequently evolves into a syndrome indistinguishable from West syndrome.

### **Neonatal Seizures**

Neonatal seizures differ from those of older children and adults (53). The most frequent neonatal seizures are described

as subtle because the clinical manifestations are frequently overlooked. These include tonic, horizontal deviation of the eyes with or without jerking; eyelid blinking or fluttering; sucking, smacking, or other buccal-lingual oral movements; swimming or pedaling movements; and occasionally apneic spells. Other neonatal seizures occur as tonic extension of the limbs, mimicking decerebrate or decorticate posturing. These occur particularly in premature infants. Multifocal clonic seizures characterized by clonic movements of a limb, which may migrate to other body parts or other limbs, or focal clonic seizures, which are much more localized, may occur. In the latter, the infant is usually not unconscious. Rarely, myoclonic seizures may occur, and the EEG pattern is frequently that of suppression-burst activity. The tonic seizures have a poor prognosis because they frequently accompany intraventricular hemorrhage. The myoclonic seizures also carry a poor prognosis because they are frequently a part of the early myoclonic encephalopathy syndrome.

### **Dravet Syndrome (Severe Myoclonic Epilepsy in Infancy)**

Dravet syndrome is now the preferred term for what used to be called severe myoclonic epilepsy in infants, because myoclonus is not seen in all cases (54). Characteristics include a family history of epilepsy or febrile convulsions, normal development before onset, seizures beginning during the first year of life in the form of generalized or unilateral febrile clonic seizures, secondary appearance of myoclonic jerks, and often focal seizures. EEGs show generalized spike waves and polyspike waves, and early photosensitivity and focal abnormalities occur. Psychomotor development is often delayed from the second year of life on. Ataxia, pyramidal signs, and interictal myoclonus often appear. This type of epilepsy is very resistant to many forms of treatment.

### **Epilepsy with Continuous Spike Waves During Slow Sleep**

Epilepsy with continuous spike waves during slow sleep results from the association of various seizure types, focal or generalized, occurring during sleep, and atypical absences when awake (55). Tonic seizures do not occur. The characteristic EEG pattern consists of continuous diffuse spike waves during slow-wave sleep, which occurs after the onset of seizures. Duration varies from months to years. The prognosis is guarded because of the appearance of neuropsychologic disorders despite the usually benign evolution of seizures.

### **Acquired Epileptic Aphasia (Landau-Kleffner Syndrome)**

The Landau-Kleffner syndrome is a childhood disorder associating an acquired aphasia, multifocal spikes, and

spike-and-wave discharges (56). Epileptic seizures and behavioral and psychomotor disturbances occur in two-thirds of the patients. There is verbal auditory agnosia and rapid reduction of spontaneous speech. The seizures are mostly generalized convulsive or focal motor, are rare, and remit before the age of 15 years, as do the EEG abnormalities.

### Kozhevnikov's Syndrome

Two types of Kozhevnikov's syndrome are now recognized, but only one of these two types is included among the epileptic syndromes of childhood because the other one is not specifically related to this age group (57). The first type represents a particular form of rolandic focal epilepsy in both adults and children and is related to a variable lesion of the motor cortex. Its principal features are motor focal seizures, always well localized; often late appearance of myoclonias in the same site where there are

somatomotor seizures; an EEG with normal background activity and focal paroxysmal abnormalities (spikes and slow waves); occurrence at any age in childhood and adulthood; frequently demonstrable cause (tumoral, vascular); and no progressive evolution of the syndrome (clinical, EEG, or psychological) except the evolutive character of the causal lesion. The childhood disorder Rasmussen syndrome (58), which is suspected to be of viral etiology, has onset between 2 and 10 years (peak, 6 years) with seizures that are motor focal seizures but are often associated with other types. Fragmentary motor seizures appear early in the course of the illness and are initially localized but later become erratic and diffuse and persist during sleep. A progressive motor deficit follows, and mental deterioration occurs. The EEG background activity shows asymmetric and slow diffuse delta waves, with numerous ictal and interictal discharges that are not strictly limited to the rolandic area.

## Epidemiology of Epilepsy in Children

**W. Allen Hauser**  
**P. Nina Banerjee**

**A**s a group, the convulsive disorders are among the most frequently occurring neurologic conditions in children. In the United States approximately 5% of children and adolescents experience a seizure of some type by the age of 20 (1). This proportion may be very different in other cultures—higher, for example, in Japanese and lower in Chinese or Asian Indians. The greatest proportion of these children experience convulsions only in association with a febrile illness. Only about a quarter of those experiencing seizures actually meet criteria for “epilepsy”—a condition characterized by *recurrent unprovoked seizures* (2, 3).

Despite efforts of organizations such as the International League Against Epilepsy (ILAE) to develop standardized definitions for the convulsive disorders for epidemiological uses (3), there remain differences in definitions that preclude direct comparison across studies. Population-based studies dealing specifically with children are few and suffer from difficulties with definitions and differences in methodology. Further, total-population studies of the epidemiology of the convulsive disorders or epilepsy seldom provide sufficient detail regarding the specifics of seizure type and etiology in children.

In this chapter we concentrate on studies targeted toward children while integrating data from total population studies. We focus on studies of incidence (newly

diagnosed cases), since these are more useful in the assessment of etiology and outcome than prevalence studies. In addition, there is less variation in definitions of seizures and epilepsy in incidence studies than in prevalence studies, allowing some comparison across geographic areas.

### DEFINITIONS

#### Epilepsy

Epilepsy is a condition characterized by recurrent (two or more) unprovoked seizures separated by more than 24 hours. Although epilepsy is the focus of this chapter, only a few of the cited studies here limit cases included to children with epilepsy. Rather, authors include various combinations so the other classes of convulsive disorders, so one must read papers carefully if cross-study comparisons are to be made.

#### Seizure

A seizure is the clinical manifestation of an abnormal and excessive activity of a set of cortical neurons.

#### Acute Symptomatic Seizure

Acute symptomatic seizures occur in close temporal association with a systemic or central nervous system (CNS) insult.

About 5% of children with infections of the CNS have acute symptomatic seizures at the time of infection (4). About 10% of children who suffer traumatic brain injury experience seizures early after their injury (5, 6). By age 20, 1% of all children have experienced acute symptomatic seizures (7). Inclusion of children with acute symptomatic seizures as epileptic probably doubles the reported incidence of epilepsy.

### Febrile Seizure

A febrile seizure is a convulsive episode occurring in association with an acute febrile illness. This is actually a subcategory of acute symptomatic seizure, differing only in that all children are exposed to the risk factor. Some authors place restrictions for inclusion in this category based on age or clinical symptomatology.

In the United States and in northern European countries, between 2% and 4% of all children can be expected to experience a convulsion during a febrile illness by the age of 5 years (8–10), but there is striking variation in the frequency of occurrence of febrile convulsions worldwide (11–19). The high frequency reported in Japan (9%) has been attributed to recognition of symptoms. It is hypothesized that the typical sleeping arrangement, in which children tend to sleep with or in close proximity to parents, facilitates recognition of symptoms. However, this theory may not explain all geographic difference, because similar sleeping accommodations are common in China and India as well—regions in which incidence is low. It is possible that a selective genetic predisposition for febrile convulsions and the accompanying generalized spike and wave electroencephalograph (EEG) pattern exist in Japanese. The very high frequency of febrile seizures reported in Nigeria may be related to misclassification of children suffering from cerebral malaria, who probably have parasitemia (20). These children have temperature elevation, but probably do not have febrile seizures as defined in Western countries.

Most contemporary studies segregate febrile seizures from epilepsy, but a few series have included selected cases, primarily those with “complex” features. Since such studies comprise 20% to 30% of all febrile convulsion cases, their inclusion may double the apparent incidence or prevalence of unprovoked seizures or epilepsy (21).

### Neonatal Seizures

Neonatal seizures are those that occur in the first 28 days of life. This definition, which is derived from concepts of mortality statistics, is conceivably in flux. Infants less than 32 weeks gestational age (a group with improving survivorship) are incapable of developing integrated

cerebral electrical activity. In some studies of premature infants, convulsive events occurring between birth and 44 weeks gestational age have been considered a neonatal seizure. From the standpoint of the above classification, most neonatal seizures, particularly those occurring in the first few days of life, would fall into the acute symptomatic category. Epidemiologically, there seems little unique about seizures after the first 7 days of life in full-term infants when compared with seizures identified after the first month of life.

Definitional difficulties are superimposed upon differences in risk within economic groups and geographic areas. Among full-term infants, the reported frequency of neonatal seizures ranges from slightly over 1 per 1,000 live births to 8 per 1,000 live births (22–24). The incidence is lower in developed countries than in developing countries; the incidence may be higher in infants born to mothers of low social-economic class. The frequency is higher among those with low birth weight, and may be higher in children with intracerebral hemorrhage and those who are small for gestational age. There are definite temporal trends in incidence in recent years, with a reduced frequency among full-term infants in most but not all industrialized countries (2, 25, 26). There are also differences in causes over time. Metabolic insults such as hypoglycemia and hypocalcemia were important in the 1950s and 1960s, while in most contemporary studies hypoxic-ischemic insults account for the majority of cases.

Among survivors of neonatal seizures (about 75% of the total), one-third to one-half have adverse neurologic outcomes. Approximately one-third might be expected to experience subsequent unprovoked seizures, mostly in those with neonatal seizures attributable to anoxic insults. Given that the majority of these children experiencing anoxia have associated neurologic disability, their epilepsy may be also be intractable. Children with “benign familial neonatal seizures” (27) and those experiencing “fifth day” seizures (28) have a slightly increased risk for later seizures, but their long-term prognosis in general is quite good. While most epidemiologic studies of epilepsy exclude neonatal seizures unless the patients have subsequent unprovoked seizures, their inclusion would substantially increase the reported incidence of epilepsy, particularly incidence reported in the first year of life.

### Unprovoked Seizures

Unprovoked seizures occur in the absence of an identified acute precipitant. In studies in the United States and Iceland, about 25% of newly diagnosed unprovoked seizures in children occur as a single event and never meet criteria for epilepsy (see the following paragraph) (29–31). Half of newly identified unprovoked seizures

in childhood in Japan (11) and Spain (32) were isolated events and did not recur.

## THE EPIDEMIOLOGY OF EPILEPSY

Incidence cohorts are necessary if one wishes to understand the geographic distribution, causes, and prognosis of epilepsy. A number of recent studies of the incidence have used similar methodology and definition, allowing some comparison. These studies form the basis for most of the following discussion.

### Incidence

Information about the incidence of epilepsy in children is derived from studies of total populations that provide age-specific information about incidence (29, 31, 33) and from studies limited to children. Even in studies limited to children, there are difficulties in comparisons across studies because of the inclusion of different age groups as “children,” differences in inclusion criteria, and, for the total population studies that provide age specific incidence, different age grouping.

Incidence rates have been estimated from many different populations over the past several years (11, 14, 30, 33, 35–54) and have been found to range from 35 per 100,000 in Finland (34) and Iceland (30) to 124 per 100,000 in Chile (35) (Table 9-1). Methodological differences in case ascertainment may account for some variation in rate, although the majority of studies have captured information using medical contacts. Some studies conducted in developing countries, however, have relied on door-to-door survey and may have been able to capture cases in the community who may not seek medical attention.

Most recent incidence studies of all unprovoked seizures have been conducted in developed countries (30, 55–59) (Table 9-2). The incidence of “all unprovoked seizures” should be somewhat higher than the incidence of epilepsy. An examination of the studies that have provided rates of all unprovoked seizures shows a reasonable similarity, with the exception of a study in Finland, representing the only outlier. In the most recent studies, the incidence in Tunisia (59) seems substantially higher than the incidences reported by the more recent studies in Iceland and in Sweden.

One of the more intriguing observations from longitudinal studies in children has been a reduction in the incidence of epilepsy over time. In a study in Rochester, Minnesota, incidence of epilepsy fell by about 40% between 1935 and 1975; however, this trend seems to have reversed after 1975 (31) (Table 9-3). On the other hand, among the studies that included all afebrile

seizures (60–64) (Table 9-4), a study of a British general practice reported that incidence under age 20 fell from 154 per 100,000 between 1975 to 1984 to 61 per 100,000 from 1985 to 1994 (62). The fall in the middle decades of the past century is largely unexplained, but the increase after 1975 may be related to increased survivorship of very low-birth-weight infants. Interpretation of studies reporting frequency of afebrile seizures is difficult, since there seems to be wide variation. Again, some differences in rate may be due to definition or methodology. For example, the high incidence in Ecuador is likely due to the inclusion of acute symptomatic seizures.

Some studies (12, 65, 66) have used other definitions of “epilepsy” (Table 9-5). In general, these studies seem consistent with studies from the same geographic area, taking into consideration the age structure studied. While there are a number of studies that report global incidence, there are few studies that provide data on gender, age, etiology, or seizure type. The following sections summarize results available from studies that report such data.

### Age-Specific Incidence

In all studies providing separate information regarding the incidence by detailed age groups, the incidence is highest in the first year of life. The most recent studies report incidence in the first year of life of about 100 per 100,000 children. Incidence falls after age 1 year, although the rate of the fall varies. In Canada, for example, incidence appears to be stable from ages 1 through 10 years at about 40 per 100,000, and in early adolescence incidence is similar to that reported in adult years of life (20 per 100,000) (45).

In many studies, incidence is typically provided only for 5- or 10-year age groups. In developing countries, incidence may be higher in adolescence than in early childhood, whereas in developed countries, incidence is lower in the second decade of life than in the first decade. The exception is a British study from which one can calculate age-specific incidence: the incidence seems highest in the late teenage years (65). Although this study used an unique definition of “epilepsy,” internal comparisons should be consistent, assuming that there is no bias in identification related to age group. As a result these investigators’ observations may be valid.

### Gender-specific Incidence

For most recent studies that report gender, gender-specific incidence in children is higher in males, although seldom significantly so. This seems to be true regardless of study definition. Only one Swedish study demonstrates a clearly higher incidence in females (58).

### Race

One may make broad comparisons across studies of different races, but these are unreliable because of different definitions. In one study of children that used broad definitions of epilepsy, the incidence in African-American children was higher than that in Caucasian children (67). This study did not control for socioeconomic status.

### Seizure Type

Most recent studies of epilepsy in developed countries report a slight predominance of partial seizure disorders over generalized seizure disorders. One must consider the age distribution being studied as well as seizures classified, because generalized onset seem to predominate in the first year of life, after which partial seizures seem to predominate. Some studies that seem to find exceptions to this, however, notably those from Tokyo, Japan (11), and Copparo, Italy (40), where 80% to 85% of new cases were considered generalized. Because both areas would be expected to have access to modern diagnostic techniques, the predominance is puzzling. When seizure type is reported, studies in developing countries seem to have a predominance of generalized epilepsy. Whether this represents misclassification related to limited evaluation of incidence cases remains uncertain. An excess of generalized-onset seizures may account for the higher incidence in some countries such as Chile. Studies of "all unprovoked seizures" and studies using more inclusive definitions (e.g., "all afebrile seizures") tend to report a preponderance of generalized seizures. It is likely that in children both single, nonrecurrent, unprovoked seizures and acute symptomatic seizures are predominantly generalized. This should account for the apparent difference in distribution by seizure type based upon study inclusion criteria.

### Etiology

When reported, between 60% and 80% of all new cases in children have no obvious antecedent to explain the condition. This is true even with the use of magnetic resonance imaging. A small proportion of new cases can be attributed to trauma, infection, postnatal vascular lesions, or CNS degenerative conditions. About 20% of cases are associated with neurologic handicaps presumed present from birth, mental retardation (MR), cerebral palsy (CP), or a combination thereof. Whereas most cases of MR or CP in and of themselves usually lack obvious causes, a more appropriate estimate for the proportion with identified cause may be 3%, as reported in a recent study from Sweden (68).

Familial (genetic) predisposition certainly plays a role in the risk for developing epilepsy (69–71). The offspring or sibling of a person with epilepsy has a threefold increase in risk of developing epilepsy. Although familial aggregation consistent with Mendelian inheritance is rare, there are a few childhood-onset syndromes with clear genetic patterns of inheritance. Examples of these include benign familial neonatal seizures, benign infantile epilepsy, and Baltic myoclonic epilepsy. A localization on chromosome 6 and other chromosomal localizations for juvenile-onset epilepsies remains controversial, and the mode of inheritance is not understood. A linkage for the EEG pattern (not the epilepsy) has been reported for rolandic epilepsy with central temporal spikes (72, 73).

It is important to point out factors that are *not* causal for epilepsy. Once cases of CP are accounted for, there has been no evidence of an association between adverse pre- and perinatal factors and the development of epilepsy. The concept of "birth trauma" or of "pregnancy complications" being a cause of epilepsy has not been supported in a variety of studies performed over the past 20 years (74–77). From a similar standpoint, febrile seizures are not "causal" for epilepsy. They are more likely

a marker for a preexisting susceptibility—in some cases genetic, and in other cases "structural."

### EPILEPSY SYNDROMES

Considerable emphasis has been placed on epilepsy syndromes in recent years (78). The classification to date is most useful in children, but, even in epidemiologic studies in children, a substantial proportion of cases fall into nonspecific categories (30). Syndrome classification has generally not been useful for classification in population-based studies, although its failure may occur primarily in studies of adults (79, 80). Despite limitations in these and other population-based studies, some information regarding the frequency of epilepsy syndromes is available.

Only three population-based incidence studies of all ages classified all cases according to epilepsy syndromes. The incidence of epileptic syndromes for the period between 1980 and 1984 has been investigated for the population of Rochester, Minnesota (49). In this study approximately 20% of childhood cases fell into nonspecific categories, and about one-third were considered localization-related cryptogenic epilepsies without further localization. In the other two studies (conducted in Bordeaux, France, and Iceland), data on the incidence of seizure and epilepsy syndromes were not presented separately for children (30, 80). In France, approximately 1% of the population with newly diagnosed epilepsy had juvenile myoclonic epilepsy, grand mal on awakening, or West syndrome, and 2% had pyknolepsy. The incidence of idiopathic localization-related epilepsy was 1.7 per 100,000 (7% of all cases, adults and children). These proportions correspond to those reported for studies in children alone. In the population-based, prospective study of epilepsy in Iceland, juvenile myoclonic epilepsy, West syndrome, and childhood absence epilepsy again each accounted for 1% of all newly diagnosed cases, with an incidence of 0.7 per 100,000 person years. Benign

\*Estimated from prevalence data.

rolandic epilepsy accounted for 20% of new-onset cases in children and 5% of cases in the total population, providing an incidence rate of 2.8 per 100,000 person years. In summary, most population studies show that specific syndromes are rare, with few exceptions.

### West Syndrome

The incidence of West syndrome has been evaluated in several geographic areas and seems consistent across studies (11, 30, 42, 43, 56, 57, 69, 81–90). Incidence ranges from 2 to 8 per 10,000 live births (Table 9-6). In all studies reporting gender-specific incidence, there is a male preponderance.

The clinical perception of West syndrome is that the prognosis is poor, but population-based studies in Iceland and Minnesota suggest an excellent prognosis in idiopathic cases (85). These findings underscore the need for more population-based incidence cohorts examining West syndrome.

### Lennox-Gastaut Syndrome

The incidence of Lennox-Gastaut syndrome (11, 39, 42, 56, 87, 90) is between 2 and 5 per 10,000 live births (Table 9-7), but there probably is little variation in frequency worldwide. The syndrome typically accounts for 2% to 3% of new cases of epilepsy in children. However,

RUS = recurrent unprovoked seizures; AUS = all unprovoked seizures.

in Kiel, Germany, Doose syndrome accounts for about 3 per 100,000 cases age 8 and under.

### Severe Myoclonic Epilepsy of Infancy (Dravet Syndrome)

Based upon one case identified in the National Perinatal Collaborative Project (54,000 live births), and on five cases identified from clinics in western Texas, the cumulative risk through age 7 has been suggested to be approximately 1 in 40,000 (91).

### Absence Epilepsy: Pyknolepsy and Juvenile Absence Epilepsy

Epilepsies characterized by absence seizures are separated into pyknolepsy and juvenile absence epilepsy. Although these syndromes are considered to be distinct, they are difficult to

distinguish clinically and epidemiologically. As a result, they are lumped together in most epidemiologic studies (11, 30, 40, 42, 44, 45, 49, 56, 59, 58, 87). In Sweden, Finland, and Rochester, Minnesota, absence epilepsy comprised approximately 8% of all childhood-onset epilepsy, and the incidence was about 7 per 100,000 (Table 9-8). Incidence was somewhat lower in the Faeroes and another Finnish study (less than 2 per 100,000) and highest in Copporo, Italy (15 per 100,000). Overall, there seems to be considerable consistency for this combined epilepsy syndrome category.

### Juvenile Myoclonic Epilepsy

Juvenile myoclonic epilepsy (JME) has received a considerable amount of attention and is perceived as a frequent epilepsy syndrome in children. Most of the studies reporting this syndrome in children (24, 30, 42, 44, 49, 54, 58) have been performed in Scandinavian countries (Table 9-9).

RUS = recurrent unprovoked seizures; AUS = all unprovoked seizures.

In Sweden, five children under the age of 15 had a diagnosis of JME with an incidence of 6 per 100,000. In the studies in Iceland and Rochester, Minnesota, most cases were identified between the ages of 15 and 24. If these age groups are included, the incidence under age 25 is approximately 6 per 100,000. In both Rochester and Iceland, between 5% and 10% of newly diagnosed epilepsy in children may meet criteria for this syndrome. This contrasts with the study in Bordeaux, France, in which 30% of cases were diagnosed at age 5.

### Benign Rolandic Epilepsy

Benign rolandic epilepsy is among the more common childhood epilepsy syndromes as based on studies (30, 38, 44, 49, 56, 58, 59) from Scandinavia, Italy, and other countries (Table 9-10). In Italy and Iceland this syndrome accounts for approximately 25% of incidence cases of epilepsy in children from birth through age 15 (38, 90). In Sweden the incidence in those under age 15 is 10.7 per 100,000, and this syndrome accounts for about 14% of childhood epilepsy. Benign rolandic epilepsy accounted for less than 5% of childhood-onset epilepsy in Rochester, Minnesota.

### PREVALENCE OF CHILDHOOD EPILEPSY

Tables 9-11–9-13 summarize numerous studies of the prevalence of epilepsy worldwide (11, 14, 19, 32–34, 39, 40–43, 47, 56, 61, 62, 65, 83, 84, 86, 92–124). As mentioned earlier, prevalence provides little information beyond that required for health service needs. Prevalence data are virtually useless for prognosis or etiology. Furthermore, differences in methodology and definitions frequently preclude the ability to make comparisons across studies. Nonetheless, a presentation regarding the epidemiology of epilepsy would not be complete without some discussion of prevalence.

The definitions of prevalence vary as extensively as the definitions of incidence. Prevalence rates in various studies worldwide are usually confound by a dizzying array of definitions. In Tables 9-11–9-13 we have attempted to stratify studies according to definition. When definitions are comparable, there seems little variation in the prevalence of epilepsy (12, 17, 32, 84, 103, 122), except for a moderately higher prevalence in developing countries such as Tanzania (32), Ecuador (90), Thailand (101), Zambia (102), and South Africa (99). Compared with the studies in the United States and Europe, the prevalence of epilepsy may be higher in South America (125–127), and lower in some parts of Asia.

In studies that have defined prevalence as seizures or medication in the past 5 years, estimates remain between 3 and 7 per 1,000 in developed countries and in the range of 9–22 per 1,000 in developing countries. It is hypothesized that the increased prevalence in these regions is a result of parasitic infections. In some studies, prevalence rates seem to increase with age (40, 114, 117, 120). Studies that have measured lifetime prevalence (Table 9-13) within the same population at different points in time show that prevalence of epilepsy has decreased (62).

### Prevalence by Seizure Type

Most prevalence studies find a preponderance of generalized-onset seizures. This appears to be true regardless of study site, although the proportion with partial seizures is higher in studies from developed countries.

### Etiology

When etiology is reported in incidence studies, between 60% and 80% of cases are of unknown cause. Even fewer prevalence studies report etiology in children. Epilepsy associated with neurologic handicap present from birth

				0.6		Female			

RUS = recurrent unprovoked seizures; AUS = all unprovoked seizures; AS = acute symptomatic seizures.

(e.g., MR or CP) is the most common antecedent, but few studies provide quantitative data. Several studies report the frequency of developmental delay (independent of MR) and other handicap that occurs in up to 25% of cases.

### Gender

Except for the British general practice study (62), which used broad definitions of epilepsy, there is a male excess in all studies, although it seldom reaches statistical significance. When age or gender breakdown is provided, females have a higher prevalence in the teenage years in some studies (109, 120).

### Race

Prevalence by racial subgroups can be compared in some studies in the United States. Prevalence is higher in African Americans than in Caucasians. These studies do not address whether this difference is attributable to racial or socioeconomic factors.

### Cumulative Incidence

A concept more useful than prevalence in terms of epidemiologic measurements is "cumulative incidence," which is the risk of developing a convulsive disorder through to a specific age. It is the cumulative incidence, not prevalence, that is important for comparisons of risk for epilepsy.

Cumulative incidence alone is reported from several studies (11, 31, 57, 62, 128–131) (Table 9-14) and has been reported in or may be calculated from data provided in many papers reporting incidence. If there is no mortality attributable to epilepsy (mortality is negligible in children without handicap), cumulative incidence of epilepsy and lifetime prevalence of epilepsy at age 20 should be similar. The cumulative incidence for all convulsive disorders through age 20 was slightly more than 4% in Rochester, Minnesota; that for epilepsy was slightly more than 1%; and that for all afebrile seizures was about 2%. These proportions should be similar to the lifetime prevalence for these same definitions.

## SUMMARY

Epilepsy contributes to a substantial amount of neurologic disease morbidity in children. Recent studies report incidence rates of 35 to 94 per 100,000 and, despite differences in methods and definitions, prevalence rates of 3 to 11 per 1,000, depending on children's ages. There are definite time trends, largely unexplained, that indicate that the incidence of epilepsy in certain populations is declining.

With regard to the burden of epilepsy, it seems greater in males. Developing countries also seem to have a higher burden of disease. Some of the difference between developing and developed countries may be explained by methodological differences. Other factors include misclassification of cases or cases due to parasitic infections, which account for a large proportion of additional epilepsy cases in developing countries.

More studies investigating the etiology of epilepsy are needed, since the large majority of convulsive disorders—more than 60%—have no known cause. Particularly useful would be population-based data on the natural history of untreated and treated epilepsies.

It is difficult to compare seizure type between studies, since not all studies have used the same classification system. In addition, some individuals may have more than one seizure type, and different studies may report this information differently. Regardless of variations by study, generalized-onset seizures are reported to predominate in the first year of life, but later in life partial seizures are more common, at least in developed countries.

The well-defined epilepsy syndromes are important but are less frequent than presumed, even in children. Because of the rarity of epileptic syndromes, information on etiology and classification is limited.

Although no study answers all questions and there is still much to learn, descriptive epidemiological studies of epilepsy provide insights into the frequency of the burden of epilepsy and other convulsive disorders in childhood. This information serves to assist in generating hypotheses regarding the risk factors of epilepsy. Still, more research needs to be done to further our knowledge of the etiology and prevention of epilepsy.

## An Approach to the Child with Paroxysmal Phenomena with Emphasis on Nonepileptic Disorders

*Arthur L. Premsky*  
*Amir Pshytycky*

**S**eizures are symptoms of abnormal brain function that occur due to excessive electrical discharge of cerebral neurons. Any acute or chronic insult to the brain can produce seizures. During infancy and childhood, seizures may assume many different clinical forms (1). When a child presents with what may be his first seizure, the physician is obligated to define the nature of the event and, if necessary, to search for a specific cause. The most common type of seizure in children is associated with moderate to high fever (2). These seizures rarely result in epilepsy (recurrent unprovoked seizures) or cause neurologic damage (see Chapter 19). Unless there is reason to suspect sepsis or an infection of the central nervous system (CNS), the child does not require an extensive evaluation if prior development has been normal. Even if an initial seizure occurs in the absence of fever, a search for a specific cause is often not fruitful, as many occur in patients in whom there is no detectable evidence of brain damage or systemic illness. Some of these children have family members who have been diagnosed with epilepsy. This suggests a genetic predisposition for the patient's seizure.

### EVALUATION OF THE FIRST SEIZURE

There are two populations of children whose seizures are more likely to be associated with an identifiable insult to the brain: those who have other neurologic signs or

a history of abnormal development and those who have partial seizures that arise from a specific region of the cerebral cortex. However, in infants and young children, in particular, it is not unusual for a generalized seizure to be the first sign of an acute or chronic metabolic disorder or an infection of the brain or meninges. All children who have had their first seizure, with or without fever, should be evaluated with a complete history and physical examination to determine whether prior development is suspicious, whether there are focal neurologic signs or evidence of increased intracranial pressure, and whether there is indication of other organ involvement. It is the history and physical examination, along with the age of the child at the time of the initial seizure, that determine the extent of the subsequent laboratory evaluations.

The incidence of seizures in the neonatal period is greater than at any other time of life. Most of these seizures occur during the first week of life (3). Neonatal seizures are rarely idiopathic and often have multiple etiologies (4, 5); therefore, an extensive diagnostic evaluation is required. Prognosis often depends upon etiology (6). The most common etiologies are hypoxic-ischemic encephalopathy (HIE), intracranial hemorrhage, or infection and developmental defects. The timing of these seizures may suggest the etiology. Seizures due to HIE or hypoglycemia often begin in the first day of life. Infections, congenital malformations, and other metabolic derangements usually cause seizures after 48 hours of life.

The evaluation of neonatal seizures is based upon the history and physical examination. It includes an electroencephalogram (EEG) to confirm or support seizure activity, neuroimaging, and laboratory studies aimed at identifying a treatable etiology. This includes serum chemistries: pH, electrolytes, glucose, calcium, magnesium, lactate, and pyruvate. Spinal fluid should also be obtained for routine analysis as well as lactate, pyruvate, and amino acids if seizures are repeated. If the cause of the seizures is still obscure, ancillary studies include titers for toxoplasmosis, syphilis, rubella, cytomegalovirus, and herpes simplex virus (TORCH), human immunodeficiency virus (HIV) testing, a drug screen, genetic studies, very-long-chain fatty acids, and lysosomal enzymes. Intractable seizures in a neonate can result from pyridoxine dependency (7). In this treatable autosomal recessive disorder, seizures can begin shortly after a normal birth. Seizures caused by hypoglycemia require evaluation of causes of limited sugar production or hyperinsulinism, including disorders involving organic acid, amino acid, and fatty acid metabolism.

Neuroimaging can identify intracranial hemorrhage, congenital malformations, and other brain injuries. Cranial ultrasound (US) can detect intraventricular hemorrhage and many parenchymal hemorrhages but has limitations detecting convexity hemorrhages, developmental abnormalities, and infarcts (8). Once the neonate is stable, magnetic resonance imaging (MRI) should be performed because it is superior to ultrasound and computerized tomography (CT) scans in identifying these lesions. As timing of the insult is important, the MRI should include diffusion-weighted images (9).

Older children and adolescents who are otherwise normal when they present with their first generalized seizure constitute a different situation (10). If the history is benign and the examination is normal, an EEG is the only test that is indicated. Even the EEG is helpful only in a minority of instances. A normal EEG would not exclude the diagnosis of a seizure if the history was sufficiently clear. An abnormal interictal EEG helps if the diagnosis made by history was uncertain. Many children who have had a seizure have a normal EEG in the interictal period or they show nonspecific abnormalities such as diffuse slowing. Just as the EEG does not always assist in the diagnosis of a seizure disorder, it also is not entirely reliable in predicting whether there will be further episodes (see Chapter 12); however, the initial EEG may define a focus of abnormal brain activity or occasionally show a specific pattern that has some predictive value and helps to plan the child's treatment. The history is always the most critical part of making the diagnosis of a seizure unless the episode itself is observed by the doctor. It is very important to obtain a history from adolescents in the absence of their parents. This may help to determine whether they are at risk for a sexually transmitted dis-

ease or whether they have a drug history that could have resulted in a convulsion.

The evaluation of the initial seizure should be much more extensive if the child's history or physical examination is not entirely normal. The following questions must be answered in the history: Was the event a seizure? Was the seizure focal or generalized? Is there a history of neurologic illness? Has the seizure occurred during the course of an acute or subacute systemic or neurologic illness—that is, were there prior or continuing symptoms such as fever, diarrhea, vomiting, headache, or change in level of consciousness or alterations of comprehension, speech, vision, balance, or strength? Does the child have other chronic disorders that might make his seizure more likely to be the result of structural damage to the brain, such as congenital heart disease, hypertension, sickle cell anemia, immunodeficiencies, or collagen vascular disease? A family history is also critical and should emphasize whether other members of the family have had epilepsy, febrile seizures, or other types of neurologic disorders.

The child who presents with a first seizure deserves a thorough neurologic examination and general physical examination with special attention to signs of neuroectodermal diseases, including screening with a Wood's lamp. Emphasis should be placed on whether the child has focal neurologic signs such as visual loss, weakness of one part of the body, reflex changes, or disturbances of balance or coordination that might suggest an area of brain damage that could also be the source of the seizure. Signs of elevated intracranial pressure should also be looked for (a bulging fontanel, split sutures, papilledema, slow pulse, and high blood pressure for age), as should signs of meningeal irritation (a stiff neck, Kernig's signs, Brudzinski's sign). Finally, any recent changes in the child's intellectual capacities or language should be documented. The child with a generalized seizure who has a benign history and physical examination need have little more done than a serum glucose, calcium, and magnesium, and a routine awake and asleep EEG. If the history or physical findings suggest the possibility of focal brain damage or elevated intracranial pressure, CT or MRI is indicated. The latter is more sensitive, especially if one suspects there may be migrational abnormalities that have affected the cortex (11). The CT scan is a better indicator of subependymal deposits of calcium. The ways in which a child's history and physical examination may influence the further evaluation of a child with a first seizure are outlined in Table 10-1.

At times, more sophisticated metabolic studies are indicated to define the cause of an epileptic disorder. For example, infants or children whose seizures are poorly controlled with medication should have their cerebrospinal fluid (CSF) glycine levels determined. Type II hyperglycinemia may result in an intractable

**TABLE 10-1**  
*Clinical Basis for Laboratory Investigations*

HISTORY AND PHYSICAL EXAMINATION	SEIZURE TYPE	TYPE OF EVALUATION
1. Normal	Generalized	Routine EEG; serum glucose, calcium, magnesium
2. Normal	Partial (focal)	Routine or sleep-deprived EEG; brain scan (CT or MRI); serum glucose, calcium, magnesium
3. Suggests a chronic neurologic insult not previously evaluated with focal physical findings	Generalized or partial	Routine or sleep-deprived EEG; brain imaging (CT or MRI); serum glucose, calcium, magnesium
4. Presence of mental retardation or slow development without focal signs	Generalized or partial	Routine EEG; serum glucose, calcium; serum and urine amino acids; chromosome studies, if otherwise indicated; TORCH titers, if under age 12 months. If seizure is partial, brain imaging is indicated.
5. Normal other than for presence of fever $\pm$ vomiting or diarrhea		Brain Imaging
a. Seen acutely	Generalized or partial	Lumber puncture; serum glucose, calcium, electrolytes, BUN; EEG
b. Seen some days later when well	Generalized	Fasting glucose, calcium; EEG
6. Normal other than for a clouded sensorium	Generalized or partial	Brain imaging (CT or MRI). If scan is normal, a lumbar puncture, glucose, calcium, electrolytes. If these are normal, liver chemistries including a serum ammonia, urine ketones, drug screen; EEG; AIDS testing.
7. Presence of increased ICP $\pm$ focal signs	Generalized or partial	Brain imaging with contrast enhancement (CT or MRI); calcium, electrolytes, urinalysis; lumbar puncture if scan is normal; EEG. If no cause is found, an MRI may be indicated at a later date.
8. Presence of focal signs of recent onset	Generalized or partial	Contrasted brain scan (CT or MRI); lumbar puncture if scan is normal; EEG; glucose, calcium, electrolytes. If CT scan normal, cardiac evaluation; screen for hemoglobinopathies and coagulation defects, sedimentation rate, antinuclear antibodies, serum cholesterol, triglycerides. Anticardiolipin antibodies if an infarct is seen on imaging.

Abbreviations: EEG, electroencephalogram; CT, computed tomography; MRI, magnetic resonance imaging; MRV, magnetic resonance imaging of venous sinuses and veins; TORCH, toxoplasmosis, other (congenital syphilis and viruses), rubella, cytomegalovirus, and herpes simplex virus; BUN, blood urea nitrogen; AIDS, acquired immune deficiency syndrome; ICP, increased cranial seizures causes by hypoglycemia require evaluation of the causes of limited sugar production or hyperinsulinism including disorders involving organic or fatty acids.

epilepsy, which can be diagnosed only by evaluation of glycine levels in the spinal fluid. Transport defects can affect the entry of glucose and other substrates (such as folate) (12, 13) into the spinal fluid, which can result in repeated seizures when serum levels are normal. Lactate may be more elevated in the CSF than in blood in some mitochondrial disorders. Any infant

or young child with poorly controlled seizures should also be tested for partial pyridoxine dependency after by being placed on 25–150 mg of pyridoxine daily for at least 1 month to see whether that affects seizure control. Pyridoxine dependency after infancy cannot always be diagnosed by a single intravenous injection of the vitamin during an EEG.

### DISORDERS THAT IMITATE EPILEPSY

Physicians are often asked to distinguish between many forms of epilepsy and other transient disturbances of neurologic function (Table 10-2). Nonepileptic neurologic disorders can produce recurrent, paroxysmal changes of movement, consciousness, or behavior that are similar to those exhibited by a child with epilepsy. Some disorders that mimic seizures are more likely to occur in children who have epilepsy, to be associated with epileptiform EEGs, or to be relieved by antiepileptic drugs.

This makes their differentiation from epilepsy even more difficult; however, many of these disorders are benign and do not carry the prognosis or stigma attached to many of the epilepsies. They require no treatment and disappear spontaneously. Others are best treated by medications other than antiepileptic drugs. Thus, it is extremely important to distinguish between repeated paroxysmal events that mimic a seizure and the recurrent seizures that define epilepsy. Epilepsy and the disorders that imitate it present at all ages and in many different forms. There are several excellent reviews of nonepileptic disorders

**TABLE 10-2**

based on cause (14–17). This discussion considers disorders based on their symptoms and signs and the age at which they are most likely to be confused with seizures, as well as whether they occur when the patient is awake or asleep.

## DISORDERS THAT OCCUR DURING SLEEP

### Movement Disorders (18)

*Benign Neonatal Sleep Myoclonus.* Benign neonatal sleep myoclonus is the most common quasi-epileptic disorder (19, 20). It usually occurs during sleep and begins early in infancy, often in the first weeks or months of life; however, it can be seen in older infants and even in young children. The disorder occurs during non-rapid eye movement (NREM) sleep. Rapid, forceful jerks may occur in the distal extremities, such as the hands or feet, or in the more proximal muscles, moving the entire limb or the trunk. The jerking usually recurs every 2 to 3 seconds, and episodes may last as long as 30 minutes, although most subside in 1 to 3 minutes only to recur repeatedly during the night. The movements migrate from one muscle group to another. Movements occur on both sides of the body. The involvement usually is synchronous, but it need not be. However, prolonged, repetitive involvement of the same muscles or repetitive synchronous involvement of the same muscle groups on the right and left sides of the body are more likely to be a true seizure. The movements of benign neonatal myoclonus are not stimulus sensitive, and the EEGs taken during sleep reveal that epileptiform activity is not present while the events are going on. The source of the myoclonic movements is thought to be in the brainstem. The movements stop if the child is awakened. When alert, the infant is seen to be developing normally and to have a normal neurologic examination.

Benign neonatal myoclonus is extremely disturbing to parents, but the movements rarely interfere with the infant's sleep and normally do not require treatment. If absolutely essential, the movements can generally be reduced by giving a small dose of clonazepam before bed. The prognosis for these infants is a good one. If the movements begin in early infancy, they tend to disappear in 3 to 4 months. Those few children who develop sleep myoclonus later in infancy may continue to exhibit the movements into the second year of life. There is no indication that benign neonatal myoclonus is associated with a higher incidence of epilepsy or abnormal neurologic development later in life.

*Head Banging and Other Rhythmic Parasomnias.* Repetitive episodes of head banging can occur as an infant is falling asleep and may be mistaken for a seizure because, unlike diurnal episodes of stereotyped movements, they

are not associated with emotional disturbances such as anxiety or frustration (21, 22). Other rhythmic movements of the neck and trunk, such as head rolling, body rocking, and leg banging, can occur in children during stage 2 of sleep. These movements are unassociated with EEG abnormalities and can easily be differentiated from seizures by video-EEG or polysomnographic monitoring. If the movements are violent enough to require treatment, they can usually be modified by giving clonazepam before bedtime. Periodic leg movements do not appear to quantitatively alter the quality of sleep in adults (23).

*Paroxysmal Hypnagogic Dyskinesia.* Hypnagogic paroxysmal dyskinesia or dystonia is a rare disorder in which sleep is interrupted for brief periods of time (usually less than 1 minute) several times each night by severe dystonic, ballistic, or choreic movements sometimes accompanied by screaming (21). The motor patterns are complex with bimanual/bipedal activity, rocking axial and pelvic movements, and sometimes ambulation. Prolonged attacks are believed to be epileptic and arise from the frontal lobe from areas that cannot be accessed by scalp tracings. Thus, the interictal EEG is usually normal as are many ictal EEGs, although carbamazepine often reduces the number of events. Many patients with this disorder go on to develop other forms of diurnal seizures. The disorder indicates how difficult it may be to separate epileptic from nonepileptic events (24, 25).

### Disorders of Respiration

*Apnea.* Disturbances of breathing during sleep are common in infants and children. Periods of apnea without other signs are rarely epileptic when they occur during sleep, but the abrupt cessation of respiration can sometimes be the only sign of a seizure in infants and young children (26, 27). The associated electrical abnormality is usually focal and in the temporal area; however, apnea has been described as the only manifestation of diffuse epileptiform discharges as well.

Usually disorders leading to periods of apnea during sleep are classified as central, obstructive, or mixed (28). Most premature infants and some older infants have apneic events that can be central, secondary to delayed maturation of the centers that control breathing (29), or obstructive, resulting from partial constriction of the upper airway. Polysomnography uses airflow monitors and strain gauges to relate movement of the chest and abdominal musculature to effective rhythmic inspiration and expiration. In obstructive apnea, movements of chest or abdominal musculature continue while the flow of air is markedly decreased or stopped. This is followed by a significant drop in the oxygen saturation of the blood. In central apnea, muscle movements decrease coincident with the

drop in airflow. More sophisticated measures of PCO<sub>2</sub> and transesophageal pressure may identify more subtle disorders of breathing during sleep (30, 31).

Central apnea has been reported with tumors of the brainstem or compression of the medulla or upper cord by a mass, bony deformities of the upper spine or foramen magnum (32), partial herniation of the brain, or a Chiari malformation. Metabolic or infectious disorders that damage the respiratory center in the medulla may result in loss of automatic control of respiration during sleep (Ondine's curse), producing long periods of apnea sufficient to cause further brain damage or even death.

Obstructive or mixed forms of apnea are frequently seen in young children with cranial-facial deformities that narrow the oropharynx or with adenotonsillar hypertrophy (33, 34). Aspiration may cause similar problems and is more likely to occur in infants or children with significant neurologic damage. However, gastroesophageal reflux can occur in children who are neurologically normal and produce significant repeated periods of apnea in sleep as well as in the waking child.

Studies indicate sleep-disordered breathing is sometimes associated with attention deficit disorders and learning difficulties that may improve with treatment of the sleep disorder (35).

### Behavioral Disorders

The behavioral parasomnias noted in children that are often mistaken for epileptic activity include sleepwalking (somnambulism), night terrors (pavor nocturnus), and nightmares (36, 37). The violent behaviors in non-REM sleep in older adults that can result in injury to themselves or to others are rarely seen in children (38).

**Sleepwalking.** Sleepwalking usually begins between 5 and 10 years of age and can persist into adult life (39). Approximately 15% of all children sleepwalk at least one time. Repeated episodes are much less frequent involving less than 2% of the population. Sleepwalking is often confused with automatisms seen with complex partial seizures. The cause of the disorder is not known, but there is a definite increase in the prevalence of sleepwalking in the family members of children who suffer from the problem. Sleep-disordered breathing is also a predisposing factor. Episodes of sleepwalking usually occur 1 to 3 hours after sleep begins. The child arises and walks about the room or the house in a trance and then walks back to bed. Semipurposeful behavior such as undressing and dressing may occur during the attack. The child's eyes are open and the child rarely walks into objects. The child often mumbles, but there is no purposeful speech. Sleepwalkers can sometimes be directed back to bed, but they often become agitated if

restrained. If the child is left alone, physical violence is usually not a part of the attack. The child has no memory of the event the next morning. Attacks sometimes increase with stress.

Usually no treatment is required other than providing for the safety of the child, and the disorder subsides spontaneously over a period of several years. Frequent or prolonged attacks can be treated with benzodiazepines. Polysomnography may reveal a predisposing sleep disorder. Treatment of the underlying problem may also reduce or eliminate episodes of sleepwalking (37).

**Night Terrors (Pavor Nocturnus).** Night terrors are most commonly seen in children between 5 and 10 years of age. The disorder also occurs in the first 3 hours of sleep in stages 3 or 4 of slow-wave sleep. It may be confused with complex partial seizures. The cause is not known, but there is a familial predisposition. As with sleepwalking, night terrors can be associated with disturbed sleep and a result of disordered breathing or periodic leg movements. Night terrors do not appear to be related to the presence or development of epilepsy or other neurologic or psychiatric disorders. Approximately 3% of all children have this disorder. The child often screams and then sits up. The child continues to scream and appears to be terrified. There are signs of increased sympathetic activity such as excessive sweating and dilated pupils. The attack can last up to 10 minutes, after which the child falls back to sleep. When awakened, the child has no recollection of the event.

**Nightmares.** Night terrors must be distinguished from nightmares. The latter usually occur later in the night during REM sleep. The EEG is normal. The child may be restless during the dream but usually does not scream. The child often recalls the nightmare and develops a fear of sleeping alone.

Complex partial seizures that occur during sleep are usually associated with automatisms other than walking or with episodes that can be mistaken for night terrors (41). The behaviors are usually abrupt at onset, and if there are movements, they are frequently the same in each attack. The patient may appear anxious, but screaming and sympathetic overactivity are not seen unless someone tries to interrupt the seizure. The child may be incontinent. A video-EEG is sometimes needed to make a diagnosis.

## DISORDERS THAT OCCUR WHEN AWAKE

### Simple Paroxysmal Movement Disorders

**Myoclonus.** Rapid, forceful but isolated or nonrhythmic jerks that occur when the infant or child is awake

are considered myoclonic. Whether such movements are epileptic may be a matter of semantics. Myoclonus, like other transient, paroxysmal movements, can originate in areas of brain other than the cortex (42) and can occur in the absence of paroxysmal activity in the EEG at the time the movement is seen. The physiologic processes that regulate large groups of subcortical cells, causing them to fire synchronously and repeatedly, may be similar to those seen in the recognized epilepsies involving gamma-aminobutyric acid or glycine-mediated inhibitory mechanisms that control neuronal hyperexcitability (43). However, if the patient has no other neurologic signs, a repeatedly normal EEG, and a benign course in which he fails to develop other seizure types and the movements remain static and eventually disappear, the disorder is usually considered nonepileptic.

Benign waking myoclonic patterns are usually seen in infants in the first year of life and almost always disappear spontaneously within 18 months. The jerks may be limited to head flexion, or there may be bilateral synchronous jerks of the arms (44). At times they can occur repetitively in brief clusters (45). Lombroso and Fejerman (46) described infants who had bursts of flexor or, less often, extensor movements of neck, trunk, and arms resembling those seen in infantile spasms. Their EEG tracings were always normal, and the children continued to develop normally. There was no increased incidence of epilepsy later in childhood.

*Spasmodic Torticollis.* Benign paroxysmal torticollis (BPT) of infancy is a disorder characterized by recurrent episodes of head tilt. Episodes begin within the first 12 months of life and resolve by 5 years. It presents with torticollis, with or without associated pallor, vomiting, and ataxia, settling spontaneously within hours or days. The torticollis is episodic, may occur to either side, and usually lasts between 4 hours and up to 4 days in duration. This syndrome may include two different situations: one, "periodic," which is more common, that lasts several hours or days; the other, more rare, that is short-lived and "paroxysmal," lasting only minutes and accompanied by ocular signs that are generally lacking in the periodic version (47). Typically the frequency and duration of these episodes decline as the child gets older, and by early to mid childhood they have resolved in their entirety. The etiology of BPT is not known. It has been related to an underlying vestibular disorder such as labyrinthitis or an immaturity of the central nervous system (48) and of the neurotransmitters in a given period of development. Some cases of BPT have evolved into classic migraine. BPT is considered as one of the pediatric migraine equivalent syndromes. Attacks of torticollis can also occur intermittently in the presence of gastroesophageal reflux (Sandifer's syndrome).

These episodes are usually not paroxysmal and tend to last longer (49). Inflammatory, developmental, and neoplastic disease of the cervical cord, spine, and neck also tend to produce sustained torticollis, but not a series of brief episodes. If no secondary cause can be discovered, spasmodic torticollis of infancy usually subsides in the first 3 years of life. No treatment is indicated.

*Paroxysmal Kinesogenic Dyskinesia (PKD).* Children with paroxysmal kinesogenic dyskinesia have abrupt attacks of dystonia, chorea, ballismus, and combinations of different hyperkinesias (50, 51). These episodes are triggered by movement, most commonly whole-body activity such as initiation of standing or walking, and less frequently, by focal movement or a startle. Multiple episodes less lasting less than a minute can occur each day. The EEG is normal during the episode or shows movement artifacts. Paroxysmal kinesogenic dyskinesia most commonly presents between ages 6 and 15 years, although it has been reported in the first year of life. The disorder can be familial or sporadic. It is responsive to carbamazepine and phenytoin. Sporadic cases sometimes follow such insults as hypoxia, hypoglycemia or hyperglycemia, hypocalcemia, cerebral vascular injury, multiple sclerosis, and thyrotoxicosis. Some have postulated it is a form of subcortical epilepsy (52).

*Paroxysmal Nonkinesogenic Dyskinesia (PNKD).* Paroxysmal nonkinesogenic dyskinesia usually manifests during childhood and early adolescence. Movements may involve trunk, lips, jaw, or tongue. It is rarely generalized. The movement is usually the same from one attack to another (53). The majority of cases are familial with autosomal dominant inheritance, although spontaneous cases do occur. Some cases are linked to chromosome 2q (54). Unlike PKD, the movements and abnormal postures of PNKD generally last longer, from 10 minutes to several hours, and their frequency is often as low as a few episodes per month with only few patients suffering up to three paroxysms per day. PNKD is not triggered by physical activity, but may be primed by fatigue, stress, excitement, alcohol, or caffeine. Paroxysmal nonkinesogenic dyskinesia does not respond to anticonvulsants, and limited success has been achieved with benzodiazepines.

*Paroxysmal Exercise-Induced Dyskinesia.* Paroxysmal exercise-induced dyskinesia (PED) is the rarest form of paroxysmal dyskinesias. The paroxysms are triggered by prolonged exercise, usually running or walking, and not by exposure to cold or passive joint movements. The distribution of the attacks is either focal dystonia of the foot, hemidystonia, or generalized dyskinesias, involving the legs with and additional involvement of the trunk. The frequency is daily to monthly. Duration of the episodes

is extremely variable, from seconds to hours, even in the same patient. Several drugs including antiepileptic drugs, L-DOPA, trihexyphenidyl, and acetazolamide have been reported to be of some benefit in isolated cases (55, 56).

### Other Movements

Neurologically impaired children may have many repetitive movements that can be mistaken for seizures. These include head shaking and nodding, staring, tongue thrusting, chewing movements, periodic hyperventilation, tonic postures, tics, and excessive startle reactions. Many have been treated for epilepsy unnecessarily because of these symptoms. In addition, self-stimulatory behaviors (discussed later) such as rhythmic hand shaking and body rocking are seen more often in retarded children.

*Jitteriness.* Jitteriness occurs in newborns and young infants (57). It can be so severe when a neonate is handled or is irritable or crying that it is sometimes mistaken for a clonic seizure; however, purely clonic generalized seizures are extremely rare in the neonate. Furthermore, the jittery infant is usually alert. The movements of a jittery child have more of an oscillatory quality to them than the clonic jerks seen during a seizure. The tremors seen in jitteriness either occur spontaneously or can be provoked by stimulation (58). They diminish or stop when the extremity is repositioned. However, jittery neonates are much more likely to develop seizures than the normal infant, and they often have abnormal EEGs with epileptiform transients. Jitteriness sometimes has a specific, often treatable cause. The movements are often seen in response to metabolic encephalopathies caused by hypoxia, hypoglycemia, hypocalcemia, and narcotic withdrawal. If possible, the underlying cause of jitteriness should be treated. The movements themselves usually decrease rapidly with time and require no specific therapy. If they are so severe that it is not possible to care for the baby, the baby may have to be sedated for a brief period.

*Shuddering.* Older infants and children can suffer from paroxysmal bouts of shivering during which spontaneous activity decreases and the upper extremities are adducted and flexed at the elbows or, less often, abducted and extended (59, 60). The head and knees are also frequently flexed. Aside from artifact, there are no EEG abnormalities during the attacks, and the incidence of epilepsy is no higher in these children than in the general population. Antiepileptic medications do not modify the attacks. Shuddering episodes gradually decrease in frequency and intensity in the first decade of life. Many children who have episodes of shuddering come from families in which many members have an essential tremor, and the two disorders may be related.

*Rumination.* Rumination is a stereotypical behavior beginning with repetitive contractions of the abdominal muscles, diaphragm, and tongue, and culminating in regurgitation of gastric contents into the mouth, where the material is either expectorated or rechewed and reswallowed. During a typical attack the neck is hyperextended, and there are repetitive swallowing movements and tongue thrusts. It can be one of the presentations of gastroesophageal reflux disorder (GERD) in infancy. Because episodes usually occur during or directly following infant feedings, while the infants are alert and often uncomfortable, the event is usually easily distinguished from a seizure. Rumination can occur as voluntary habitual regurgitation of stomach contents into the mouth for self-stimulation in mentally handicapped children or in infants with infant rumination syndrome. This syndrome is rare and has its onset between 3 and 8 months of age (61).

*Startle Responses.* Startle disease (hyperekplexia) is a rare familial disorder that occurs in major and minor forms in the newborn period. In the minor form the startle response is exaggerated (62–64). In the major form, the infant becomes stiff when handled. Flexor spasms (without habituation) can be elicited by repeated tapping on the infant's nasal bridge. The episodes of hypertonia may be severe, causing apnea, bradycardia, and, rarely, sudden death. Anecdotal reports suggest that forced flexion of the neck or hips interrupts the hypertonic episode. Stiffness decreases during the first year of life and disappears by 2 to 3 years of age. During the same period, the infant develops violent, repetitive jerks upon falling asleep. Many of these children have paroxysmal abnormalities in their EEGs. When they are recorded during a startle response, there are bilateral centroparietal sharp waves followed by a train of slow waves. This complex is considered to be evoked by sensory stimuli and not an epileptiform transient. Older children, juveniles, and adults suddenly stiffen and fall. This is most likely to occur when they are startled, and this is what is usually misinterpreted as an epileptic disorder. The symptoms of hyperekplexia (stiffness, jerking, and falling) respond to antiepileptic drugs such as clonazepam or valproic acid. Despite these features, the disorder is not considered a form of stimulus-sensitive epilepsy. It more likely represents a defect in inhibitory regulation of brainstem centers by the cerebrum. The disorder remains stable or improves with age. Children who have these symptoms do not develop typical seizures more frequently than the average child. Recently, one gene for this disorder has been localized to chromosome 5q33–q35 (65). Mutations that involve the gene that encodes the alpha-1 subunit of the glycine receptor result in exaggerated startle responses (66). The disorder is usually inherited as a dominant but can be recessive. Genetic analysis helps to distinguish difficult cases of hyperekplexia from epilepsy or psychogenic

disorders. It should prove most useful in those cases that were considered sporadic.

**Chorea.** Choreic movements are rapid, purposeless movements that are not repetitive or rhythmic (67). They can involve any muscles but are more prominent in the distal musculature. In most disorders, the abnormal movements are bilateral but not synchronous.

Hemichorea is limited to only one side of the body. It is seen, at times, with vascular and inflammatory disorders. In alert children, single movements such as chorea and tics can be confused with myoclonus, although, unlike myoclonic jerks, these movements almost always disappear in sleep (Table 10-3). At times, choreiform movements and multifocal myoclonic jerks are indistinguishable and must be categorized by the diseases with which they

**TABLE 10-3**  
*Tics, Chorea, and Myoclonus*

	<b>TIC</b>	<b>CHOREA</b>	<b>MYOCLONUS</b>
Common age of onset (years)	(5–10)	(5–15)	Any age
Clinical picture	Stereotyped, repetitive movements of one or more muscle groups most often located in the face, neck or upper trunk. They may be rhythmic for brief periods, but usually are irregular.	Rapid, jerky, arrhythmic movements that randomly migrate from one muscle group to another. May be unilateral. Movements tend to involve the limbs, tongue, and mouth more than other areas. Almost never synchronous.	Focal: repetitive and rhythmic jerks. Multifocal: lightning fast movements that can involve multiple muscle groups and move from one part of the body to another. May be synchronous.
Intent	Purposeless	Purposeless. Patient may consciously integrate the jerk into a willed movement	Purposeless
Voluntary inhibition	Possible for brief periods	Rare	None
Sleep	Improves markedly or disappears	Improves markedly or disappears	Slight or no improvement
Stress or startle	May worsen	No change	May worsen
Level of consciousness		Alert or obtunded	Alert or obtunded or comatose
Associated neurological problems	Compulsive behaviors, Attention deficit, learning disabilities, echolalia, coprolali	Hypotonia, mild, encephalopathic changes	Focal: none or mild encephalopathic changes Multifocal: often evidence of acute or chronic, severe diffuse brain dysfunction
EEG	Normal or background slowing unrelated to the movements	Normal slow or epileptiform but unrelated to the movements	Slow or epileptiform. Spikes can occasionally be linked to the movement.
Brain scan	Normal	Normal or hypodense areas in the corpus striatum or subthalamic region	Often normal. Acute: occasionally evidence of cerebral edema. Chronic: occasional evidence of diffuse atrophy.
Treatment	Haloperidol, clonidine, or other antipsychotics such as resperidone	Benzodiazepines, haloperidol	Antiepileptics, especially clonazepam, zonisamide

are associated. Multifocal myoclonus is more likely to occur in patients who have progressive degenerative disease of the brain or who have an acute encephalopathy. Acute chorea can occur with metabolic disorders but is more likely to be seen as the patient recovers from an encephalopathic illness. It also occurs as a sequel to beta-hemolytic streptococcal infections (Sydenham's chorea) (68) and as a result of drug ingestions or head trauma. Lupus erythematosus can be associated with unilateral or bilateral chorea, as can the antiphospholipid syndrome (69). Mass lesions or cerebrovascular accidents are more likely to produce a hemichorea. Usually this form of chorea is easily distinguished clinically from seizures. However, the EEG often fails to distinguish between diffuse chorea and multifocal myoclonus, as it is possible for both to occur in the presence of an EEG with slow background activity without epileptiform transients or with unrelated paroxysmal bursts. The presence of multifocal spikes throughout the record favors the diagnosis of myoclonus, especially when the spike is linked to the jerk. Both types of movements may respond favorably to clonazepam. Chorea may also respond to dopaminergic blockers such as haloperidol or pimozide or drugs that deplete dopamine such as tetrabenazine.

**Tics.** Tics are rarely mistaken for myoclonus. They usually involve only one or, at most, several muscle groups, and only in the most severe cases are they migratory (70, 71). The movements are usually repetitive and stereotyped. Tics occur sometime during childhood in approximately 20% of the pediatric population, but they are usually "simple" in that they are always characterized by the same movement involving only one or two muscle groups. The face and neck muscles are most commonly involved, but a simple tic can involve muscles of respiration and the extremities. Eye blinking, facial twitches, shrugging of the shoulders, head turning, sniffing, grunting, and repetitive clearing of one's throat are common forms of simple tics. In some children, simple tics may be caused or worsened by anxiety or stress. If left alone, most simple tics subside within weeks to months, although they sometimes recur for another brief period of time. The EEG is usually normal and has no epileptiform activity. Multiple types of tics or tics that involve quite complicated movements of a number of muscle groups are known as complex tics. When they are chronically associated with vocal tics, the diagnosis of Gilles de la Tourette's syndrome can be made. This is an organic brain disorder with a definite genetic component. It is inherited as an autosomal dominant with variable penetrance and variable expression. There is a much higher family incidence of simple and complex tics in relatives of these children when compared with the general population (72). Based on response to therapy, the syndrome may be the result of abnormal metabolism of dopamine in the brain. Although the disorder may

stabilize or improve slightly in adolescence or early adult life, it fluctuates in childhood and can be sufficiently severe to modify normal activity. If so, it needs to be treated. The movements usually respond to small amounts of neuroleptics such as resperidone or olanzapine or to alpha blockers such as clonidine (73). Both tics and chorea can be associated with each other and with neuropsychiatric disorders, particularly obsessive compulsive disease. When this is seen following clinically apparent streptococcal infections or with high antistreptolysin-O (ASO titers), it is known as the PANDAS syndrome (74).

### Ocular Movements

**Paroxysmal Upgaze Deviation.** Episodic upgaze is a feature of the oculogyric crisis and is usually part of a dystonic reaction to medications such as phenothiazines, carbamazepine, and lithium (75). Tonic upgaze is sometimes a transient event in neonates. Tonic upward deviation of the eyes has been observed in patients with Chédiak-Higashi disease, Rett's and Tourette's syndromes, and Wilson's disease.

**Spasmus Nutans.** Classically, spasmus nutans consists of a triad of signs: nystagmus, head nodding, and a head tilt (76). Head nodding and intermittent nystagmus are often the first abnormalities noted by the parents. The nystagmoid movements are often more pronounced in one eye than in the other and frequently lack a quick and slow component. Both symptoms can fluctuate in intensity and may come and go during the course of the day, resulting in some confusion as to whether the infant is having seizures. Infants with spasmus nutans have a somewhat higher incidence of EEG abnormalities than other children their age, but they are alert, in contact with the environment, and no more likely to develop epilepsy than the average child. The pathophysiology of spasmus nutans is not known. A small subgroup of these infants have mass lesions in the area of the optic chiasm or anterior third ventricle. A child who is diagnosed as having spasmus nutans should have an MRI scan. If the scan is normal, no further treatment is necessary. The majority of children with this disorder no longer have signs by 5 years of age; however, some may have nystagmoid eye movements that persist into adult life, and these children cannot be differentiated from those who have congenital nystagmus.

**Opsoclonus (77).** Opsoclonus-myoclonus syndrome is the presenting sign of 2% of children with neuroblastoma and ganglioneuroblastoma. The majority of patients with opsoclonus-myoclonus have a neuroblastoma. There are also reports of delayed onset opsoclonus-myoclonus syndrome and development of opsoclonus-myoclonus

syndrome in the face of recurrent disease. The presence of opsoclonus-myoclonus syndrome is typically associated with a good prognosis for treatment of the tumor and long-term survival. It is believed to be of autoimmune etiology, as supported by identification of antineural protein antibodies in patients who have the disorder (78). It is believed that the precipitation of opsoclonus-myoclonus by certain viruses, such as coxsackie, Epstein-Barr virus, mumps, and rubella, occur as a result of molecular mimicry. Patients with opsoclonus-myoclonus syndrome have responded to immunomodulatory treatments such as steroids and intravenous immunoglobulin or plasmapheresis (79). The majority of children with opsoclonus-myoclonus syndrome have multiple relapses that require prolonged treatment. Developmental sequelae are frequent (80).

### Loss of Tone or Consciousness

*Attention Deficits and Daydreaming.* Children with typical absence seizures have brief episodes in which their activity suddenly ceases and there is a brief loss of contact with the environment. Posture is maintained. Automatism can occur, but they are unusual. Normal activity is usually resumed immediately. Atypical attacks are more indicative of complex partial seizures, during which the episodes last longer, automatisms are more common, incontinence can occur, and the child may be sleepy at the end of the seizure. Few problems mimic absence or complex partial seizures. The most common is daydreaming (81).

Daydreaming is a common occurrence in children who have attention deficit disorders. They can be unaware of their immediate surroundings for a few seconds or as long as a minute. They may not react to voice or visual stimuli, but generally, they respond to touch. They may have no recollection of what transpired around them during the time their thoughts were elsewhere, but often they say they were thinking of something else at the time. Automatisms are rare, but some children have nervous habits such as picking at their nails or rubbing their hands, and these may continue while they stare ahead. The history can sometimes differentiate between daydreaming and absence seizures. Children who daydream never interrupt their own public recitations to stare ahead and lose track of time. A child who stops speaking in the middle of a sentence and has an episode of absence almost invariably has a seizure disorder. In some instances, video-EEG analysis of the spells is needed to arrive at the correct diagnosis (81).

*Drop Attacks.* One form of generalized epilepsy only involves sudden loss of tone (82). There may not be a recognizable loss of consciousness. These attacks must be

**TABLE 10-4**  
*Causes of Sudden Loss of Posture*

Generalized epilepsy
Syncope
Basilar migraine
Basilar insufficiency
Cataplexy
Compression of the upper cervical cord
Hyperventilation syndrome
Vestibular disorders
Psychogenic illness: hysteria, malingering

distinguished from other disorders that produce a similar clinical picture. Some of the causes of sudden drop attacks are listed in Table 10-4.

These episodes can occur at any age but are more likely to be confused with epilepsy in later childhood and adolescence. Many disorders in which posture is suddenly lost are much more common in elderly patients. Certainly, this is true of basilar insufficiency and the peculiar vestibular disorders that suddenly throw people to the ground. Cataplexy is also much more likely to occur in adults. Compression of the upper cervical cord that presents with sudden drop attacks is exceedingly rare at any age. Basilar insufficiency and cervical cord compression are often associated with ictal and interictal neurologic signs that point to an insult of the brainstem or the cord. Hyperventilation leading to a loss of tone and consciousness can easily be recognized by observing the attack, and the patient or family often give a history of a period of intense overbreathing preceding the loss of posture and consciousness. An adolescent hysteric has many other symptoms of an emotional disorder that help to make the diagnosis. The malingerer may not fall abruptly and when “unconscious” may resist the limbs or eyelids being moved. The ultimate diagnosis of psychogenic drop attacks may depend on recording the attack with EEG telemetry. The three diagnoses that are most often confused with recurrent postural seizures in children and adolescents are syncope, narcolepsy or cataplexy, and basilar migraine. The latter two problems are relatively rare in the pediatric population, whereas syncope is a common event at all ages.

*Syncope.* Most syncopal episodes in children are neurally mediated (83) (Table 10-5). There is reflex slowing of the heart producing a sinus bradycardia or a significant drop in systolic and, to a lesser degree, diastolic blood pressure, or both. This may be precipitated by well-defined physical events that overactivate the autonomic nervous

**TABLE 10-5**  
**Causes of Syncope**

A. Secondary to known precipitating events
1. Neurocardiogenic
a. Vasovagal
1. Fear
2. Pain
3. Unpleasant sights (situational)
b. Reflex
1. Cough
2. Micturition
3. Swallowing
4. Carotid sinus pressure
2. Decreased venous return
a. Orthostatic (with change to an erect position)
b. Soldier's syncope (standing at attention)
c. With Valsalva's maneuver
3. Hypovolemia or severe anemia
B. No clear precipitating event by history
1. Cardiac
a. Arrhythmia
b. Obstructive outflow
2. Cerebrovascular insufficiency
3. Psychogenic with or without hyperventilation
4. No known cause

system, especially the parasympathetic division. Coughing, micturition, swallowing, and carotid sinus pressure are among the more common reflex causes of neurogenic syncope. Vasovagal syncope is also neurogenic, but the physical stimuli are less well defined and include such sensations as heat, pain, and fear. The physiologic basis for neurogenic syncope is yet to be defined completely. Venous pooling may activate cardiac stretch receptors, which leads to reflex bradycardia and a drop in peripheral vascular resistance (84, 85). A second major cause of syncope in children results from decreased blood volume or decreased return of venous blood to the heart.

The majority of syncopal events that are neurogenic in origin or due to decreased blood volume or venous return can be diagnosed by clinical history even if the decrease in blood flow to the brain is sufficiently severe or prolonged to result in seizure activity shortly after the loss of consciousness (86). Most of these children faint in response to one or more limited provocations, that is, micturition, the sight of blood, or a warm, crowded environment, or, in the case of decreased venous return, assumption of upright posture or prolonged standing (87). Many patients realize they are going to faint before losing consciousness. Nausea or vague epigastric sensations are experienced by patients with either syncope or seizures (88). However, other warning signs differ. Patients suffering from syncope

are more likely to feel light-headed or dizzy than they are to complain of vertigo. Their visual sensations are also more simple than the visual auras of epileptic children. Vision begins to dim and objects lose their color, becoming gray or brown. Brief syncopal episodes are almost never followed by confusion lasting more than seconds after arousal. Drowsiness is less common after a syncopal episode than a seizure and is almost always less prolonged. After an ictal event, a deep sleep from which the patient can hardly be aroused suggests a seizure. Headache may also follow a brief syncope or a seizure, but it is usually more severe after the latter. Unfortunately, if the syncope is prolonged (lasting minutes) and is severe and the brain is deprived of oxygen for a relatively long period of time, the postictal signs of syncope and seizures may be indistinguishable, or the faint may lead to a seizure.

Of course, the most serious causes of syncope are cardiac, and they often occur without warning and produce significant brain hypoxia, which may result in a confused child after consciousness returns. Disorders of cardiac conduction, particularly the long QT syndrome, are the most common cause of this type of syncope (89, 90). Rarely, lesions of the brainstem or upper cord can cause transient cardiac arrhythmias or arrest. Because cardiogenic syncope can sometimes result in sudden death, it is this group of disorders that must be eliminated as a possible cause of fainting when children repeatedly lose consciousness. One clue to a cardiac cause for syncope is that a child faints while exercising (91). Neurogenic syncope can also occur with exercise, but the proportion of children who have cardiac conduction disorders or reduced cardiac output is greater in the group that faints during exercise than in children who faint at rest.

The physical examination may be of little help in distinguishing syncope from seizures because it is often normal in patients with either symptom, although seizures are more likely to be associated with signs of CNS injury. At the time of the event, pallor, sweating, a slow pulse, and low blood pressure are more suggestive of syncope than a seizure (86). At times, the cause of syncope can be suspected by obtaining supine blood pressure and noting its change when the child rapidly assumes the standing position. In normal children, the blood pressure remains stable ( $\pm 5$  points) or transiently increases slightly with an increase in the pulse rate of 8 to 20 beats. A drop in blood pressure of 15 or more points or a sinus bradycardia when rapidly standing confirms the history of possible orthostatic hypotension. Auscultation of the heart may also assist in the diagnosis. An irregular rhythm or a murmur may suggest that a cardiac abnormality is the cause of the faint. Provocative office tests such as carotid sinus massage and ocular pressure are not recommended and are rarely informative in children.

The laboratory evaluation of children who faint has become a complicated and argumentative issue

regardless of age (92). In the absence of a suspicious history or neurologic findings, an interictal EEG does not differentiate syncope from seizures even if there are paroxysmal transients in the tracing. Neuroimaging is almost always negative unless there are abnormalities on examination. An unexplained episode of fainting mandates an electrocardiogram (ECG). If repeated episodes of fainting have occurred with a typical history, we still obtain a routine 12-channel ECG as the initial study. Further testing may be indicated if the timing of the fainting suggests possible hypoglycemia. If there is no history of a provocative event or an aura, a more extensive cardiac evaluation is indicated if the syncope is repeated. This may include prolonged ambulatory recording of the ECG, stress testing, and possibly an echocardiogram. These are expensive and stressful tests, and their yield, even in high risk patients by history, is probably less than 20% of those tested (93).

Should children suspected of having syncope undergo tilt-table testing, and at what point should such a test be attempted? Studies in pediatric patients and young adults thought to have neurocardiogenic syncope show that they have a statistically significant increase in either bradycardia, systolic hypotension, or asystole with head-up tilting for up to 60 minutes when compared with asymptomatic controls. Drugs such as isoproterenol increase the rate of positive responses and further separate the two groups (94). However, there are still many false positives in the control group and 10% to 15% false negatives in the neurocardiogenic group. Furthermore, positive responses in another group of young adults could only be reproduced 54.5% of the time (95). It is not likely that a head-up tilt test has any more relevance to differentiating syncope from seizures than the EEG. Furthermore, tilt-table testing rarely adds useful information for patients who have a good history to suggest neurocardiogenic syncope (96). This leaves those children who have recurrent syncope without a definable cause, especially if it occurs during exercise. Most of these patients will have neurocardiogenic syncope. In this group a positive response to the head-up tilt test may establish the diagnosis and eliminate the need for further expensive tests. Hence, if a routine ECG and echocardiogram, ambulatory monitoring, and an exercise tolerance test fail to establish the diagnosis, a positive head-up tilt test might suggest appropriate therapy and allow the gradual resumption of full activity by the child. That would be particularly important for children who are interested in resuming competitive sports. A detailed study of the evaluation of syncope, irrespective of age, has been published by the American Heart Association (97).

*Narcolepsy and Cataplexy.* Children who have cataplexy suddenly drop to the ground with bilateral loss of muscle tone in response to an unexpected touch or

emotional stimulus such as laughter. The attacks are brief, and it is not clear if some patients lose consciousness during them, but that is unlikely. Most children with cataplexy also suffer from narcolepsy, a state of excessive daytime drowsiness punctuated by periods during which the patient rapidly falls asleep, frequently under unusual circumstances such as while engaged in conversation (98). This sometimes leads to confusing narcoleptic attacks with episodes of absence, or subliminal status, although the narcoleptic patient appears to be in a state of normal sleep and continues to sleep for many minutes unless aroused by an external stimulus. In addition to cataplexy and narcolepsy, the narcoleptic syndrome includes transient episodes of inability to move when awakening (sleep paralysis) and brief hallucinatory episodes on arousal, which are usually visual. The four components of the syndrome do not appear simultaneously, and some may never occur in a narcoleptic patient. Narcolepsy and cataplexy are the two that are most commonly associated. These four phenomena are consistent with features of REM sleep, in the waking state, probably as a result of yet undescribed defects in the reticular activating system.

The EEG clearly differentiates between cataplexy and narcolepsy and a tonic or absence seizure if recorded during an attack. In the interictal period, a multiple sleep latency test using the EEG can be helpful. The child is allowed to go to sleep on five different occasions during the day. If REM sleep occurs within 10 minutes of the onset of sleep on two of these occasions, the tracing is compatible with the diagnosis of narcolepsy. The HLA-DR2 haplotype has a high degree of association with the syndrome and may be helpful in making a diagnosis. Reduced hypocretin (orexin A) is found in the spinal fluid. The symptoms of narcolepsy can sometimes be ameliorated by the use of stimulant drugs such as modafinil, and cataplexy by antidepressant drugs such as fluoxetine (99) or rarely by an anti-epileptic, carbamazepine (100).

*Basilar Migraine.* The basilar variant of migraine generally begins in adolescence but may occur in children in the first years of life (101, 102). It is more common in females. Some attacks begin with sudden loss of consciousness and posture. Upon recovery, the child often experiences a severe occipital or vertex headache; however, most patients have symptoms of other abnormalities of brainstem function such as dizziness or vertigo or bilateral visual loss. Diplopia, dysarthria, and bilateral paresthesias occur less often. Frequently, there is a family history of migraine. Close relatives may have had similar attacks. Up to one-third of children with basilar migraine have paroxysmal interictal EEGs, some with occipital spike and wave complexes (103). A diagnosis must be made on clinical grounds. Many children with basilar migraine respond to antiepileptic

drugs, and others respond to agents that block the transport of calcium into the cell.

### Disorders of Respiration

*Apnea.* Sudden apneic attacks that occur when the infant is awake are even more likely to be thought of as possible seizures, especially if the infant also suddenly develops a fixed stare or begins to flail about (104). However, these kinds of attacks are exactly what one sees with some infants who have gastroesophageal reflux (105). Each of these signs—apnea, staring, and flailing—may occur alone or in combination. Of the three, episodic apnea is the most frequent sign of reflux. The problem is the result of incompetence of the upper and lower esophageal sphincters, which leads to the reflux and sometimes to the aspiration of stomach contents. This occurs most often when infants are in a flat position just after they are fed. The flailing movements are generally thought to be a response to esophageal pain resulting from the acidic refluxed stomach contents. The episodes are not associated with EEG abnormalities. Proof of reflux is often difficult to obtain, although in many infants it can be seen during a barium swallow. Lesser degrees of reflux can, at times, be diagnosed by the use of radioisotopes or the measurement of esophageal pH. The presence of reflux does not necessarily mean that the physician has found the cause of the child's symptoms unless the disorder coincides with the time of reflux. The presence of significant reflux in a symptomatic infant is sufficient reason to start therapy. Treatment usually involves positioning the baby in a more upright posture after feeding, thickening feedings, and finally, in rare instances, fundoplication (106). Video-EEG studies may be needed to prove an apneic attack is a form of epilepsy.

*Breath-Holding.* Breath-holding also involves attacks of respiratory arrest that can be mistaken for seizures, but the episodes occur in a very different setting (107). There are two forms of breath-holding spells: pallid and cyanotic. Cyanotic spells were the first to be described. They usually peak in the second or third year of life. Almost invariably, the child has been frightened or frustrated or has had a minor injury and begins to cry vigorously. Then the child suddenly stops breathing, often on inspiration. After several seconds, the child turns blue and loses consciousness. The child is often limp at this time. The period of unconsciousness is brief, usually lasting less than 1 minute, although it can be more prolonged. When the child regains consciousness, he or she is alert and frequently resumes normal activities immediately. Pallid breath-holding attacks often follow minor trauma and actually represent vasovagal

episodes. Crying is minimal or absent. The child quickly loses consciousness and is limp. The attacks last more than 1 minute and may result in a seizure caused by cerebral ischemia (108).

Both cyanotic and pallid forms of breath-holding result from reflex changes that decrease cerebral blood flow. The exact mechanism may vary from one child to another. If there is a reflex cessation of respiration in inspiration, venous return to the thorax may be decreased, resulting in a decreased cardiac output. Children with pallid spells experience changes in heart rate and rhythm and a decrease in blood pressure.

Neither type of breath-holding attack is accompanied by an epileptic EEG discharge. These attacks are not associated with an increased incidence of epileptic seizures later in life, even if generalized clonic jerks occur secondarily during the attack. The diagnosis is usually made by the history. Breath-holding attacks usually occur less than two to three times a month in susceptible children, and the episodes invariably cease by 5 to 6 years of age. Occasionally children have pallid attacks that occur several times a week or even daily. The frequency of the episodes in these children may sometimes be reduced with the use of atropine-like agents or iron supplementation, but the optimal treatment is behavioral modification directed at reducing the parents' emotional reactions to the episodes. Pallid attacks that are associated with severe bradycardia or asystole have been successfully treated with implantation of a cardiac pacemaker (109). Recently, it has been suggested that severe breath-holding spells may be inherited as an autosomal dominant trait with variable penetrance (110).

*Hyperventilation.* Hyperventilation is defined as physiologically inappropriate overbreathing (111). Acute hyperventilation is often associated with a feeling of intense anxiety or even panic. Patients may feel they are suffocating or choking during the attack. Other symptoms of acute anxiety may occur, including dry mouth, globus hystericus, chest pain, palpitations, and tachycardia. If the patient becomes severely alkalotic, he may complain of headache, tinnitus, dizziness or vertigo, tingling of the face and hands, or carpedal spasm. The patient may lose consciousness. This may be followed by a generalized seizure. The diagnosis is usually made by the history of symptoms and signs that precede the loss of consciousness. In the past, the diagnosis was assumed confirmed if (1) the attack were seen and aborted by having the patient rebreathe into a paper bag, and (2) the symptoms could be reproduced by the hyperventilation provocation test. Recently, however, studies have shown that patients' symptoms may have nothing to do with their PCO<sub>2</sub>. Hyperventilation may be a consequence and not a cause of these attacks (112).

## Perceptual Disturbances

**Hallucinations.** Hallucinatory episodes can be an aura to an ictus or less frequently or ictal event. However, hallucinatory experiences can be seen with psychoses and with extreme stress in nonpsychotic children (113). They also may result from drugs, particularly anti-epileptics (114, 115). Episodes can be visual, auditory or, less often, sensory. The history is essential to the diagnosis. An EEG taken during the event is also helpful.

**Headache and Other Pains.** Headache is often seen following a generalized motor seizure. Less frequently it occurs as an aura before a complex partial seizure (116). Ictal pain is usually unilateral; it occurs most often in the arm, and it may be the only manifestation of a seizure (117). The focus is often in the contralateral rolandic area. Headache may be the only symptom of a partial seizure, although this is extremely rare. Children who have this type of headache often have signs of cerebral injury, do not get relief from sleep, and do not have a family history of migraine (118).

Paroxysmal recurrent headaches are characteristic of migraine. When children with migraine headaches have an aura, it usually is visual. A migrainous aura is usually made up of loss of part of a visual field or of simple lines or dots that are black and white. Visual phenomena more often associated with epilepsy consist of changes in the size or shape of objects or the intrusion of colored objects. Less common migrainous auras are loss of motor, speech, or sensory function. The headaches are apt to be throbbing and are sometimes unilateral. They are often relieved by a brief period of sleep. They are frequently associated with gastrointestinal disturbances. There is a strong history of migraine in the immediate family in more than half of the patients.

Epilepsy and migraine coexist in many children. Between 3% and 7% of children with migraine have epilepsy. Most have partial seizures. Benign occipital and rolandic seizures are frequently associated with migraine (119). A large percentage of migraineurs (perhaps as high as 20%) have interictal records that are paroxysmal even though they have no seizures. Approximately 60% of children who have migraine headaches obtain significant relief with antiepileptic medication (120). Because migraine occurs in 4% to 12% of children, depending on age, and epilepsy occurs in less than 1%, the most recurrent paroxysmal headaches are likely to be migrainous, even in those children who have complex partial seizures. Furthermore, migraine headaches can be clinically defined by their associated symptoms and family history. The distinction between migraine and epilepsy is made more difficult by the fact that a migrainous aura may not be followed by headache (acephalgic

migraine). In addition, several paroxysmal events that occur in children such as recurrent episodes of abdominal pain or vomiting, vertigo, confusion, and alternating hemiplegia may be followed by migraine, not epilepsy, later in life (121).

The criteria for diagnosing an isolated headache as an ictal event should rely heavily on recording a paroxysmal change in the EEG taken at the time of the episode.

Recurrent abdominal pain (122), usually periumbilical, with or without vomiting, pallor, or an idiopathic fever, can be caused by migraine and perhaps, in rare cases, by epilepsy. Most children who have this problem do not have either disorder. Children with recurrent abdominal pain frequently see a physician to rule out epilepsy. The range of interictal paroxysmal EEGs in children with this syndrome is 7% to 76% in different series. Approximately 15% of these children do have epileptic seizures, and more than 40% have recurrent headaches. Approximately 20% have a family history of migraine. Even those children who have other epileptic seizures do not generally have isolated abdominal pain that is epileptic in origin. Children with abdominal pain usually do not respond to antiepileptic drugs, but approximately 20%, in our experience, do respond to antimigrainous drugs such as beta blockers or tricyclic antidepressants. Children with recurrent abdominal pain who do not have other seizures at the time they first present are unlikely to develop epilepsy. However, they are at greater risk for developing migraine later in life (123). In the majority, the attacks recede and are infrequent or have disappeared by the end of puberty. This is another pain syndrome in which the few cases that have been definitely diagnosed as the result of epilepsy have had EEG recordings at the time of the attack. The tracing becomes paroxysmal coincident with the onset of clinical symptoms.

## Vertigo and Ataxia

**Benign Paroxysmal Vertigo.** Sudden or repeated attacks of dysequilibrium in children are sometimes confused with epilepsy. Children with benign paroxysmal vertigo (124) have repeated attacks of vertigo lasting minutes to hours. These episodes can occur as often two or three times a week, but many children have only one attack every 2 to 3 months. The onset is sudden. During the attack, the child is often unable to walk unaided and may be nauseated. Nystagmus need not be present. There is no hearing loss or tinnitus. The child is alert, responsive, and distressed. Interictally, the examination and the EEG are normal. There is no change in the audiogram. Caloric tests of vestibular function are usually normal, but a minority of children have evidence of canal paresis indicating dysfunction of the vestibular end organ in the ear.

Many of these children have a family history of migraine, and some already have migraine headaches. They may have a directional preponderance to their nystagmus on testing. A substantial number develop migraine later in life. The association between these attacks of vertigo in childhood and migraine is so strong that some have defined benign paroxysmal vertigo as a migraine variant. No treatment is indicated. The attacks do not seem to respond to either antiepileptic or antimigrainous medicines. The disorder usually subsides by 6 to 8 years of age. The term benign paroxysmal vertigo is also used to describe positional vertigo in adults. This disorder is associated with positional nystagmus and appears to be labyrinthine in origin (125).

*Vestibulocerebellar Ataxia.* There are several forms of paroxysmal ataxia that may be mistaken for a seizure. One form is associated with nystagmus, but tests of the semicircular canals are normal. The disorder frequently responds to acetazolamide. It is an autosomal dominant disorder that has been mapped to chromosome 19p (126). In other families, similar symptoms and signs start in adult life and do not localize to chromosome 19p (127). These patients often do not respond to acetazolamide. In both disorders, the patients remain oriented and there is no other history to suggest seizures.

### Behavioral Disorders

*Stereotyped Movements.* Stereotyped movements are patterned repetitive movements that recur frequently, often many times each day, in the same form (128, 129). These movements can be seen in normal children but are much more common in children who are mentally retarded or autistic. Head banging, head rolling, and body rocking often occur when the older infant or child is awake. Head banging is often part of a temper tantrum. Head rolling and body rocking are forms of self-stimulation that seem to result in pleasurable sensations. Flapping the hands or arms is a movement that also seems to relieve anxiety. The normal infant or child may stop these repetitive movements if touched or diverted by other stimuli. None of these behaviors have any direct association with future epileptic attacks, and they occur without a significant change in the EEG (when it is technically possible to record the patient). They are more apt to occur in irritable, excessively active, or retarded children. The movements decline rapidly toward the end of the second year of life. No treatment is necessary unless they persist until the child is 30 to 36 months of age. At that time, the movements may be reduced by behavioral modification techniques. There is no specific drug that is effective in treating these disorders without producing significant sedation,

although recently it has been suggested, on the basis of a small series, that clomipramine may reduce the movements (130).

*Masturbation.* Infants who are masturbating are usually sitting with their legs held tightly together, sometimes straddling the bars of their crib or playpen, rocking back and forth (131, 132). The behavior can almost always be aborted by a distracting stimulus and usually disappears spontaneously in several months. Masturbatory movements in older children are less likely to be confused with seizure activity. They usually lay prone on a flat surface such as a rug or bed and rub their genitals back and forth against the fibers. The children are alert and usually stop on command. Furthermore, they can demonstrate the movements when requested to do so. What the parents usually mistake as the seizure is the detached look and lack of responsiveness that the children get during the period of climax. The history preceding the climax makes the diagnosis. At times, home video or EEG documentation of these events may allow the physician to determine the nature of the behavior (133).

*Acute Confusion.* Episodic confusion is not usually seen in children unless accompanied by other signs of acute disease such as fever, vomiting, or obtundation. Metabolic disorders that produce recurrent episodes of ketosis, acidosis, hypoglycemia, or hyperammonemia can also be the cause of recurrent confusional states. Children who have this problem should be screened for a metabolic disorder or drug ingestion (see Table 10-1).

Repeated attacks of confusion, usually associated with delirium, may also occur in children with migraine (134, 135). There is often no associated headache, and there is no clinical or laboratory evidence of an infection or a metabolic disturbance. There may be a history of recent trauma. The attack lasts for hours but is almost always over within a day. There is usually a family history of migraine, and the patient may have had typical migraine headaches on other occasions. Confusional migraine is much more likely to occur in adolescence than in the first decade of life. Periods of confusion can be seen with complex parietal and absence seizures without ictal motor behaviors (136). Nonconvulsive status epilepticus may present as an acute confusional state at any age and can only be diagnosed by the EEG (137).

*Panic or Fear.* Ictal fear is usually a brief event and often precedes or is accompanied by other evidence of a complex partial seizure (138). It is not related to provocation and can be overwhelming. Panic attacks can occur as an acute event during the course of a more chronic anxiety disorder or in patients who are depressed or schizophrenic, but they

can also occur in the absence of an underlying emotional disorder. Ictal fear begins in childhood.

Panic attacks last minutes to hours and are accompanied by many symptoms such as palpitations, sweating, dizziness or vertigo, and feelings of unreality or loss of control. The frequency of panic attacks increases in late adolescence and adult life. These symptoms are less prominent with ictal or preictal fear. Ictal fear is also more likely to be associated with repeated, stereotyped behaviors with each attack. Only an EEG at the time of the attack differentiates ictal fear from a nonepileptic panic attack if the history is not clear. Recent studies suggest that individuals who do not have seizures but do suffer from panic disorder may also have excessive neuronal activity in the frontotemporal region. Nonictal panic does not respond to antiepileptic drugs. The underlying disorder must be treated with psychiatric care using cognitive therapy, which can be combined with drugs to modify mood or anxiety (138, 139).

*Rage.* Rage attacks (intermittent explosive disorder) (140) are not unusual in epileptic children, especially those who have frontal or temporal lobe lesions, but they are usually not part of the ictal event. Rage is also more common in hyperactive children and in others who have conduct, mood, or personality disorders. Ictal rage is unprovoked and not focused on a particular object or individual. Interictal rage or rage reactions without seizures usually occurs in response to frustration, stress, or threatening situations. It is not the only evidence of a behavioral problem. It is often preceded by a period of whining, screaming, and crying. The anger is frequently directed at the source. The child may remember the attack. Behavior can frequently be modified during the episode. The event can rarely be recorded by EEG because of artifact. This type of rage does not respond to antiepileptic drugs, with the possible exception of carbamazepine, and is best treated by behavior modification. Propranolol, antipsychotic, antidepressant, and mood stabilizing drugs may also help.

*Pseudoseizures (Nonepileptic Seizures) (141).* Pseudoseizures are psychogenic seizures defined as episodes that resemble an epileptic seizure but are unaccompanied by EEG abnormalities (142, 143). Such episodes are felt to be the symptom of a dissociative disorder. Implicit in the definition is the idea that individuals who have pseudoseizures do not consciously produce or control them and thus are not malingerers. The definition of a pseudoseizure has always been an uncomfortable one because a number of unusual symptoms that are presumed to be epileptic can occur without an abnormality on the scalp EEG. Pseudoseizures do not respond to antiepileptic drugs. At least 20% of those who have these

nonepileptic seizures are children with true epilepsy that is often poorly controlled, which further complicates the differential diagnosis.

No particular behavior or movement before, during, or after the ictal state differentiates a seizure from a pseudoseizure. The onset of pseudoseizures often builds over minutes; the symptoms at the onset frequently suggest anxiety or a panic attack, that is, dyspnea, paresthesias, light-headedness, and palpitations; the ictal movements are often asymmetric and without rhythm, such as thrashing or flailing arm movements; the patient may scream or weep (144). There can be pelvic thrusting; unfortunately, similar movements and behaviors can be seen with seizures that arise deep in the frontal lobe. However, none of these may occur. A period of absence may still represent a psychologically determined event rather than epilepsy.

The diagnosis of pseudoseizures has been aided considerably in recent years by the development of techniques that allow the EEG to be recorded for long periods of time. EEG telemetry allows the patient's brain waves to be recorded during the episodes in question. The physician can also see and evaluate the clinical event. There are a number of clues that help distinguish seizures from pseudoseizures (Table 10-6), although none allow an absolute diagnosis. Pseudoseizures can sometimes be elicited by suggestion, usually by giving the patient a saline infusion (145). In our experience, this technique is not suitable for younger children or moderately to severely retarded patients. Photic stimulation or hyperventilation are more satisfactory techniques for these populations. Suggestion may also induce true seizures in patients who have both pseudoseizures and epilepsy.

The separation of epileptic seizures from pseudoseizures is often difficult and expensive, requiring prolonged EEG recordings and possible hospitalization. However, the distinction is extremely important because pseudoseizures can be sometimes be treated effectively as an emotional disturbance, thus avoiding inappropriate antiepileptic drug administration.

## SUMMARY

In this chapter we have presented some of the clinical conditions that can be mistaken for epilepsy or an isolated seizure in an infant, young child, or adolescent. The large number of these conditions that encompass motor function, respiration, sensory experience, and behavior, both when awake and asleep in all ages from infancy into adult life, is testimony to the variety of ways in which epilepsy can present. Many families are often perplexed by—or often ignore—unusual behaviors their

**TABLE 10-6**  
**Seizures and Pseudoseizures**

	<b>EPILEPTIC SEIZURES</b>	<b>PSEUDOSEIZURES</b>
Type of movement	Clonic jerks that are usually flexor, rhythmic, and in all involved extremities. Sudden drops to the ground.	Movements are often lateral, as well as flexor and extensor. Often out of phase in the involved limbs. Some movements have a tremor-like quality. Others are flailing. There are unusual movements such as pelvic thrusts, sudden drops to the ground
Automatisms	Simple, such as lip smacking, picking at clothes. Complex, such as dressing, undressing, walking in circles	Not usually seen or when noted, may not be stereotyped.
Consciousness	Usually out of contact with the environment	May be responsive during the attack
Language	Initial scream, groans, mumbling	Yelling and vulgar language sometimes occur
Incontinence	Frequent	Rare
Self-injury	Rare	Rare
Postictal confusion, headache, drowsiness	Frequent	Rare
Precipitating events	Can be present, specific stressful situations may increase seizure incidence	Incidence can be increased by specific stressful situations
Frequency	Usually single episodes	May occur in clusters
EEG		
Interictal	Often epileptiform transients	Often epileptiform transients
Ictal	Almost always a sudden, paroxysmal discharge, coincident with the attack	No paroxysmal changes
Elevated prolactin after ictus	Yes, but normal levels do not rule out a true seizure (146)	No
Response to antiepileptics	Usually	Rare. There may be a placebo effect.

child is experiencing and postpone seeing a physician because their notion of epilepsy involves a sudden fall to the ground with stiffening and jerking of the limbs. It is important to recognize how many experiences that

are out of the normal flow of events during the day or during sleep can be epileptic and how many nonepileptic disorders can mimic those events and confuse the physician.

## Evaluating the Child with Seizure

**Sejal V. Jain**  
**Lawrence D. Morton**

**S**eizures are time-limited paroxysmal events that result from abnormal, involuntary rhythmic neuronal discharges in the brain (1). The term *seizure* appears to arise from a notion that patients were possessed or seized by spirits in old times. Age-adjusted incidence for first diagnosis of unprovoked seizure is 61 per 100,000 person-years (2). Incidence of first nonfebrile seizure in children is 25,000 to 40,000 per year in the United States (3). Although mortality directly related to seizure is low in these children, 45% to 50% will have recurrence (4–6). Therefore it is important to evaluate patients with seizures and events that look like seizures.

Common conditions that are mistaken for seizures are gastroesophageal (GE) reflux, apneic episodes, self-stimulating behavior, breath-holding spells, migraine, attention deficit hyperactivity disorder (ADHD), and sleep disorders (see Chapter 11).

Seizures can be classified based on etiologies and types. Etiologic classification includes provoked and unprovoked seizures. Provoked seizures are defined as seizures occurring in close temporal association with an acute systemic, metabolic, or toxic insult or with an acute central nervous system (CNS) insult (7). Common causes of provoked seizures include metabolic disturbances such as hyponatremia, hypoglycemia and hyperglycemia,

hypocalcemia, and acute neurological conditions such as trauma, stroke, meningitis, and recreational drug or alcohol use or withdrawal. Unprovoked seizures can be classified based on etiologies as idiopathic (with particular clinical characteristics and specific electroencephalographic [EEG] findings), symptomatic (due to metabolic, genetic disorders or structural abnormalities), or cryptogenic (unknown etiology) (7). The term cryptogenic suggests a cause may be subsequently discovered. Classification based on seizure types is based on International League Against Epilepsy (ILAE) classification (see Chapter 9).

Epilepsy is defined as occurrence of two or more unprovoked seizures (7). It is important to note that the occurrence of multiple seizures in a 24-hour period is considered as one seizure (7).

When a patient presents with a seizure or seizure-like events, goals are to identify whether the event was a seizure or not; if it was a seizure, to identify the type of seizure based on ILAE criteria, identify the etiology of seizure, and anticipate recurrence and the need for treatment.

Identifying critical elements during the evaluation of a seizure or event that appeared seizure-like is the most important aspect of establishing the diagnosis of epilepsy. This chapter aims to recommend the initial evaluation of a patient presenting with seizure.

## PATIENT EVALUATION

### History

The following pertinent history should be elicited:

#### *Age*

Certain seizure types are age dependent. Examples are infantile spasms, febrile seizures, benign epilepsy with centrotemporal spikes (BECTS), childhood absence seizures, juvenile absence seizures, and juvenile myoclonic epilepsy. Children are most vulnerable to develop epilepsy during the first year of life (2, 8). Etiologies for status epilepticus differ based on age. During the first 2 years of life status epilepticus is more common in neurologically normal children, whereas later on it is more common in neurologically abnormal children (9).

#### *Preceding or Precipitating Events*

Knowing the events immediately before a seizure episode is very important. Parents may not perceive that premonitory symptoms or auras are part of a seizure and may not volunteer this information to the physician. Most common manifestations of aura associated with temporal lobe seizures are autonomic. These include “funny feelings,” epigastric sensations, flushing, sweating, palpitations, nausea, or dizziness.

The presence of preceding events also helps to differentiate nonepileptic events, such as crying preceding breath-holding spells and feeding preceding reflux. Loud noises and stimuli can lead to hyperekplexia, which may look like seizure.

Certain seizures are provoked by specific stimuli and are called reflex seizures. Well-known precipitating factors are visual stimuli, flickering light, thinking, praxis, reading, somatosensory and proprioceptive stimuli, eating, music, hot water, and startle (10). Other nonspecific factors are also associated with induction of seizure. In a study of 1,677 patients with epilepsy, 53% reported one and 30% reported two or more precipitating factors. Most common factors were emotional stress, sleep deprivation, fatigue, and alcohol consumption. Patients with generalized seizures were more sensitive to sleep deprivation and flickering light than patients with localization-related epilepsy (11).

#### *Timing of Event*

Epilepsies associated with awakening seizures are usually primary generalized seizure disorders such as juvenile myoclonic epilepsy and absence seizures. Sleep epilepsies include focal or secondarily generalized seizure disorders such as BECTS, Landau-Kleffner, electrical status epilepticus in sleep (ESES), and frontal lobe seizures. Temporal lobe seizures are also more common during

sleep. Complex partial seizures generalize more frequently during sleep. Seizures are more common during stage 1 and 2 sleep and least common during rapid eye movement (REM) sleep. Also nonepileptic seizures do not occur out of sleep (12, 13). Unprovoked seizures occurring out of sleep have a higher risk of recurrence and the sleep state at the time of the first seizure correlates with successive seizures (14). Patients with seizures occurring in sleep have higher chances of having an abnormal EEG (15). Knowing the child's state immediately before and after the event is extremely important and frequently diagnostic.

#### *The Event Itself*

Have the parents and family members describe a chronological account of what they witnessed. Caregivers often use diagnostic terms such as “petit mal,” drawing conclusions. Often the exact description may allow the physician to determine whether an event was a seizure or not, and if a seizure, what type. Also a majority of the time seizures are described as “shaking.” It is not reasonable to speculate that this means clonic activity because it could mean trembling associated with tonic seizure, clonic activity, or simply pelvic thrusting or bicycling motion. Witnesses should be asked to demonstrate the event if they can. A seizure may start in one part of the body and progress to the whole body with loss of consciousness. Therefore, it is important to ascertain how and where it started.

The history of forced eye closure during an event most likely suggests a nonepileptic event. The mouth is usually open during tonic seizure. Forced clenching of the mouth is associated with pseudoseizures (16). Gaze deviation can help determine focal nature of the event and help in localization.

Duration of the event may allow differentiation of seizure from status epilepticus, which is treated differently and has a different prognosis. Status epilepticus is defined as seizure or a series of seizures lasting 30 or more minutes (7). In a study of 407 children presenting with a first unprovoked seizure the authors reported that 50% had seizures lasting 5 minutes or longer, 29% 20 minutes, and 12% 30 minutes. Seizures of partial onset were more likely to be prolonged. 92% of the seizures stopped spontaneously (17). The likelihood of a seizure stopping spontaneously decreases after 5 minutes and reaches a minimum at 15 minutes. Also, the duration of subsequent seizures correlates with the length of the first episode (17). It is not uncommon, however, to overestimate or underestimate the duration of the event.

It is important to ask the patient about what they remember of the event. This may help to identify the exact duration of loss of consciousness or awareness, if any.

After the cessation of the event the patient's condition is important to know. Malingering patients will be back to baseline immediately after a dramatic motor

seizure. Others may show confusion, tiredness, sleepiness, or hemiparesis. Continued altered awareness may be due to postictal state or continued subclinical seizure.

Prior history of other paroxysmal events, similar events, other seizures, and febrile seizures is important. Recurrence risk after a second seizure increases to about 70%. High risk was seen if seizure recurred within 6 months of the first seizure (14). In patients with newly diagnosed epilepsy about 17% have seizures of more than one type (18). Such patients have lower a probability of remission of epilepsy (19). A total of 2% to 10% of patients with febrile seizures develop epilepsy. Complex febrile seizures are associated with an increased risk of subsequent development of epilepsy (4, 20).

#### *Associated Events*

Common events associated with generalized motor seizures are tongue biting, bowel or bladder incontinence, and respiratory attenuation. Tongue biting can be seen during the clonic phase of a seizure (16).

Irregular respiration and pauses in respirations are seen during clonic and tonic phases of generalized seizures. Cyanosis may be present with a seizure. Often peripheral cyanosis is not associated with central hypoxia. Malin-gering patients may not be able to demonstrate cyanosis. Respiratory involvement may also make seizures more frightening for the family, and early interventions may be needed in those at risk for prolonged convulsions.

#### *Review of Systems*

Fever, lethargy, headache, and photophobia may point toward meningitis and encephalitis as a cause of seizures. Diarrhea and vomiting leading to dehydration and electrolyte imbalance can provoke seizures. It is important to ask about diet, especially in infants and teenage females. In infants who are formula fed, if the formula is improperly mixed, there are chances of electrolyte imbalance leading to seizures. Teenage females should be asked questions regarding bulimia, "dieting" and "diet pills" if suspected. Teenagers should also be asked about recreational drug and alcohol use. History of trauma should be evaluated. Other medical conditions such as diabetes and infections should be considered. Exposure to toxins and heavy metals should be suspected in a younger child.

#### *Medication*

It is helpful to know whether the patient is taking medications that are known to decrease seizure threshold. Also, the history of hypoglycemic agents and diuretic use is helpful.

#### *Birth History*

Premature newborns who weigh less than 1.5 lb are at higher risk for brain injury leading to acute or

remote symptomatic seizures. In-utero exposure to infectious agents, recreational drugs, alcohol, and teratogenic medications can also cause structural brain abnormality. Meningitis, increased bilirubin levels, respiratory problems occurring during the postnatal period are important to know for the same reason. Maternal history of oligo-hydramnios or polyhydramnios, fetal hiccups, or episodic hammering fetal movements may suggest neurological disorders in the fetus.

#### *Developmental History*

History of language, motor or psychosocial delays, and regression and timing of regression should be evaluated. A total of 15% to 30% of patients with childhood-onset epilepsy have cerebral palsy or mental retardation and 11% to 39% of children with autistic spectrum disorders develop epilepsy (8, 21, 22). Patients with severe autism have a higher incidence of epilepsy (23). Developmental delays may be a hallmark of chromosomal disorders and associated epilepsy (24, 25). Language regression and seizures may represent Landau-Kleffner syndrome. Global regression may be seen at the onset of ESES (21) (see Chapter 26). Children with developmental delay or mental retardation have a higher risk of intractable seizure. It is likely that these disorders represent widespread underlying CNS abnormalities (19).

#### *Family History*

In a study of patients with seizures about 35% of patients reported seizures in first-degree relatives (26). Inherited epilepsies include autosomal dominant nocturnal frontal lobe epilepsy (ADNFLE), BECTS, juvenile myoclonic epilepsy (JME), generalized epilepsy with febrile seizures plus syndrome, benign familial neonatal convulsions, benign familial infantile convulsions, and other idiopathic generalized epilepsy (27).

In a study looking at risk of epilepsy in adults with seizures, cryptogenic or idiopathic epilepsy with partial onset showed a higher occurrence rate in successive generations, whereas the occurrence rate for generalized epilepsy remained the same in all generations (28). In twin studies there was concordance of occurrence of seizure in monozygotic and dizygotic twins and status epilepticus in monozygotic twins (26, 29).

#### *Physical Examination*

##### *General Examination*

Head circumference should be measured. Presence of microcephaly could be secondary to congenital infections, hypoxia or maternal diseases, and drug and toxin exposure. Cranial malformations such as lissencephaly, cortical dysplasia, and heterotropia are primary causes of microcephaly (30–32). Macrocephaly is associated with storage disorders and hydrocephalus (31).

Fundoscopy examination may show papilledema suggesting increased intracranial pressure or cherry red spot associated with storage diseases, or findings associated with neurocutaneous syndromes or congenital malformations.

The examiner should look for dysmorphic features. Microcephaly, craniosynostosis, deep-set eyes, hypertelorism, low-set ears, midface hypoplasia, depressed bridge of nose, microstomia or macrostomia, simian crease, and hand and foot abnormalities are some of the features that present in chromosomal disorders associated with seizures (24, 25). Dysmorphic features such as cleft lip and cleft palate are known to be associated with cranial dysplasia. Abnormal hair patterning may suggest abnormalities in brain development before 18 weeks. Microcephaly with abnormal hair patterning may be seen with brain abnormality rather than craniosynostosis (33).

The examination of the skin is important; a number of neurocutaneous syndromes are associated with seizures. Incontinentia pigmenti, linear nevus syndrome, hypomelanosis of Ito, tuberous sclerosis, Sturge-Weber syndrome, and neurofibromatosis are examples of these neurocutaneous syndromes (see Chapter 30). Skin examination can also reveal signs of physical abuse.

Nuchal rigidity, positive Kernig's and Brudzinski's signs suggest meningitis. Infants with open fontanel may not present with these signs but will show a bulging or tense fontanel.

Organomegaly may be seen with metabolic storage diseases.

### *Neurological Examination*

Determination of ongoing seizure should be the first step in the evaluation of a patient presenting with a history of seizure. The patient may present with altered sensorium, which could be due to ongoing seizure, postictal phenomena, or medication used. Dysarthria or visual changes may be present postictally. A hemiparesis may suggest Todd's paralysis and a partial seizure. Presence of Todd's paralysis after a first unprovoked seizure is associated with increased risk of recurrence (14).

In patients suspected of having absence seizure hyperventilate for at least 3 minutes as this may precipitate a seizure.

## **Laboratory Studies**

### *Basic Metabolic Panel*

Seizures provoked by metabolic abnormalities in an otherwise normal child are rare. Therefore, basic tests should be done based on clinical judgment per American Academy of Neurology (AAN) guidelines for evaluation of first unprovoked seizure (3).

### *Lumbar Puncture*

If there is clinical suspicion of meningitis or encephalitis, lumbar puncture should be done per AAN guidelines for evaluation of first unprovoked seizure.

### *Urine Toxicology*

Routine urinalysis is not recommended, but if there is clinical suspicion of recreational drug use, a urine drug screen should be obtained.

### *Liver Function Tests*

If there is history suggestive of a potentially degenerative, metabolic or storage disorders or there is anticipation of starting antiepilepsy drugs (AEDs), liver function tests should be performed.

### *Screening for Inherited Metabolic Disorders*

These tests may not be obtained during the initial evaluation, but are very important in seizure evaluation and management and so are mentioned here.

About 200 inherited disorders are associated with seizures (34). There are clues such as certain seizure types, characteristic EEG patterns, and specific epilepsy syndromes that point to some of these disorders. Associated symptoms of mental retardation, developmental delays, hypotonia, macrocephaly and microcephaly, and failure to thrive may also suggest the possibility of a metabolic disorder. In patients with myoclonic seizures, spasms, early-onset tonic seizures, and infantile-onset hypomotor and versive seizures, inherited metabolic disorders should be suspected (34). Other characteristics of seizures associated with inherited disorders include onset in the first month of life, usually partial seizures with migrant nature and successive appearance (35). West syndrome, early myoclonic encephalopathy, and Ohtahara syndrome are known to be associated with metabolic disorders (see Table 11-1).

EEGs showing burst suppression, hypsarhythmia, and diffuse severe depression without obvious cause demand evaluation for inherited disorders (see Table 11-2).

Serum amino acids and urine organic acids can be used as an initial screen in patients with the previously mentioned seizure types and syndromes. Cerebrospinal fluid (CSF) glucose, lactate, and amino acids are recommended for infantile seizures without clear etiology. It is important to obtain samples during the presentation of symptoms before treatment because otherwise samples may be falsely normal or difficult to interpret (36) (see Tables 11-3 and 11-4) (35–37).

Disorders of carnitine and fatty acid oxidation acutely present with a history of decreased oral intake followed by increasing lethargy, obtundation or coma, and seizures. Other features include history of recurrent hypoglycemic, hypoketotic encephalopathy, potential developmental delay, progressive lipid storage myopathy,

of more than 2:1 suggests a block in fatty acid oxidation. Urine organic acid chain length and type will help to identify the site of block. Confirmations can be obtained by specific cultured skin fibroblast tests (38).

A few cases of creatine metabolism defect and epilepsy have been reported. Associated symptoms include hypotonia, mental retardation, neurologic regression, and movement disorders. Initial tests should include serum and urine guanidinoacetic acid and creatine. Magnetic resonance (MR) spectroscopy also helps in the diagnosis (39).

**CSF metabolites.** Disorders affecting CNS energy metabolism, creatine synthesis, glucose transport, and neurotransmitter metabolism may present with hypotonia,

temperature instability, developmental delay, ptosis, dys-tonia, and tremors along with seizures. These disorders may not be detected by routine screen for inherited meta-bolic disorders. If initial metabolic screen and CSF lactate and amino acids are normal in an infant with seizure without clear etiology, profiles of CSF metabolites includ-ing biogenic amines should be considered (40).

When gamma-aminobutyric acid (GABA)-related dis-orders are suspected—that is, GABA transaminase deficiency, succinic semialdehyde dehydrogenase deficiency (SSDD), glutamate decarboxylase or GABA receptor defects—CSF GABA level should be measured. It is increased in patients with SSDD and vigabatrin treatment. SSDD can also be detected in lymphocytes and fibroblasts (41).

In nonketotic hyperglycinemia, CSF glycine is elevated. It is also elevated in patients who are receiving valproate treatment. It is decreased in defective serine synthesis (41).

Guanidinoacetate and creatine measurement can aid in diagnosis of arginine:glycine aminotransferase or guanidinoacetate methyltransferase deficiencies, and creatine transporter defect.

Measurement of tetrahydrobiopterin, neopterin, 7,8-dihydrobiopterin, homovanillic acid, 5-hydroxyin-doleacetic acid, and 3-O-methyldopa can help in diagnosis of tetrahydrobiopterin and biogenic amine metabolism.

Pyridoxine-deficient and -responsive seizures are covered in another section (see Chapter 30).

*Tests for mitochondrial disorders.* Mitochondrial disorders causing epilepsy are rare. It is possible that this rarity is due to our inability to recognize these disorders. A review by DiMauro showed that seizures are associated with MELAS (mitochondrial myopathy, encephalopathy, lactic acidosis, and strokelike episodes), MERRF (myoclonus epilepsy with ragged red fibers), pyruvate dehy-drogenase complex deficiencies, cytochrome c oxidase deficiencies, and maternally inherited Leigh's disease (42). All the patients in the review presenting with these dis-orders and seizure had symptoms such as developmental delay and eventually developed classic symptoms for the disorder. Partial seizures are more common in patients with mitochondrial encephalopathies (43).

Ammonia, serum and CSF lactate, and urine organic acid can be used as an initial screen (36). In cases of intractable seizure and developmental delays, migraine, strokelike episodes, or retinitis pigmentosa, serum testing and muscle biopsy should be considered.

### Chromosomal Studies

Chromosomal abnormalities with high association of seizures include 4p− syndrome, Miller-Dieker syn-drome, Angelman syndrome, inversion duplication 15 syndrome, terminal deletions of chromosome 1q and 1p, and ring chromosomes 14 and 20. Patients presenting with specific phenotypes and EEG abnormalities should have genetic testing done (24, 25, 44).

### EEG

EEG remains the gold standard test for evaluation of seizures, especially when an ictus is captured during the study. It can help to differentiate nonepileptic events from seizure. It can also help to identify an epileptic syndrome, because epilepsy syndromes are classified based on spe-cific patterns of abnormality on EEG. It helps to provide long-term prognosis and identify any need to do further testing. It influences the management by helping to select AEDs. Certain metabolic disorders have classic EEG pat-terns (see Table 11-2).

In a study of patients with unprovoked seizures, EEG abnormalities were associated with increased recur-rence. Abnormal EEGs were more common in patients with partial seizures than with generalized seizures (45). A study by Yoshinaga et al showed that more than 20% of seizures were classified incorrectly or missed when only history was used to identify paroxysmal events (46).

Recommendations regarding timing for the EEG testing are controversial. In a study by King et al, an EEG performed within the first 24 hours had a higher diagnostic yield (47). In a study done at Virginia Commonwealth University when EEGs were done in the emergency room in patients presenting with a seizure, 80% of patients with an abnormal EEG developed recurrence (48). EEG abnormalities are the best predictors of recurrence in neurologically normal children (3).

Hyperventilation and photic stimulation increase the yield of EEG and are recommended (49). Even though Gilbert et al showed that sleep deprivation did not increase EEG abnormalities (50), a number of other studies have shown that sleep recordings can increase the yield of EEG (3, 13, 45, 49, 51).

Thus EEG is recommended to evaluate paroxysmal events. In patients with altered consciousness and recurrent seizures, emergent EEG is recommended. Hyperventilation and sleep deprivation increase the yield of EEG. When possible, it should be obtained immediately after seizure presentation. A normal or suspicious EEG should be followed by sleep-deprived EEG.

### **Imaging**

In a study by Shinnar et al (52), only 1% of children with a first unprovoked seizure had neuroimaging abnormalities requiring acute intervention. All these children had indications for neuroimaging such as an abnormal neurological examination or prolonged seizure. The most common

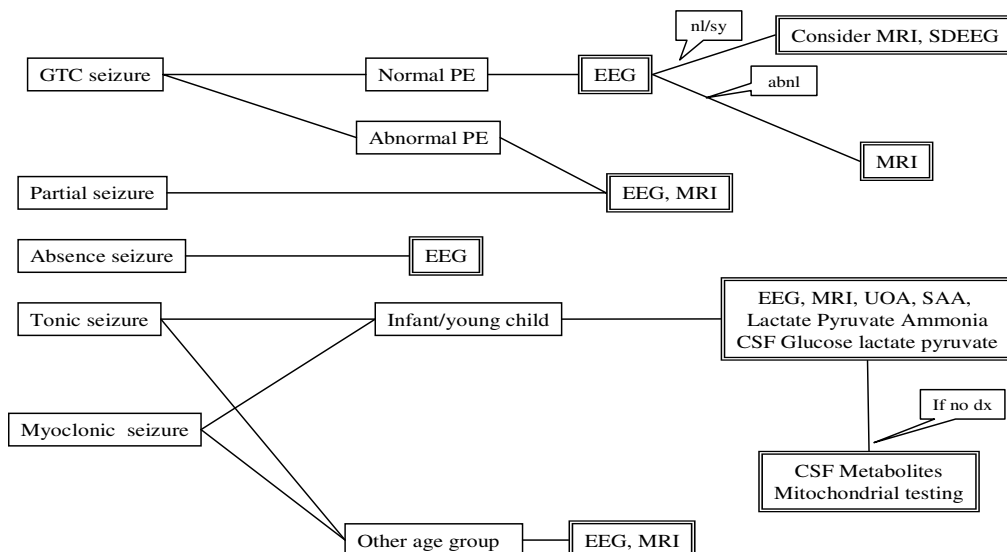

FIGURE 11-1

Recommended algorithm based on seizure types. Abbreviations: GTC, generalized tonic clonic; PE, physical examination; SDEEG, sleep-deprived EEG; UAO, urine organic acid; SAA, serum amino acid; nl/sy, normal or benign syndromic; abnl, abnormal.

Recommended algorithm for seizure evaluation. Abbreviations: CBC, complete blood count; BMP, basic metabolic panel; LP, lumbar puncture; PE, physical examination; JME, juvenile myoclonic epilepsy; BECTS, benign epilepsy with centrotemporal spikes; DD, developmental delay; MR, mental retardation; SDEEG, sleep-deprived EEG; UOA, urine organic acid; SAA, serum amino acid.

abnormalities were focal encephalomalacia and cerebral dysgenesis. Suggested risk factors for abnormal imaging were partial seizures, abnormal neurological examination, and abnormal EEG (53). In children with a brief tonic clonic seizure, normal examination, and normal EEG, 10% of imaging studies were abnormal (52).

Imaging is recommended for seizure evaluation (3). Emergent imaging studies are required in case of prolonged seizure, prolonged postictal phase, and postictal hemiparesis to rule out stroke and other structural abnormalities (3). Outside of the acute situation, Magnetic Resonance Imaging is a superior study because it can identify subtle cortical abnormalities (3, 53).

## CONCLUSION

Seizures are frightening events for the families and children in whom they occur and require precautions associated with driving, water activities, heights, and work environment. The diagnosis has immense psychosocial impact on both the family and the patient. Thus, the first seizure or similar event should be evaluated carefully to make an accurate diagnosis, the recurrence risk should be explained to the family, and appropriate treatment decisions should be made. Recommended algorithms for seizure evaluation are shown in Figures 11-1 and 11-2.

## The Use of Electroencephalography in the Diagnosis of Epilepsy in Childhood

*Douglas R. Nordli, Jr.  
Timothy A. Pedley*

**T**he electroencephalogram (EEG) is often the single most informative laboratory test in evaluating children with seizures. At the most rudimentary level, it helps in differentiating epileptic from nonepileptic behavior. Because many conditions, including breathholding spells, movement disorders, syncope, cardiac arrhythmias, sleep disorders, migraine, and various psychiatric syndromes, may mimic epilepsy, EEG findings are often essential in making an accurate diagnosis.

EEG, however, offers much more. More detailed analysis of epileptiform abnormalities assists in distinguishing focal from generalized seizures and in identifying epileptic syndromes, which are indispensable cornerstones of rational therapy. EEG aids in recognizing subclinical and nonconvulsive seizures, in documenting antiepileptic drug (AED) toxicity, and probably in selecting patients for AED withdrawal after remission of seizures. Finally, EEG is critical in evaluating patients with medically refractory seizures for focal resective and other surgical procedures.

### EEG TECHNIQUE

To record the EEG, a technician places electrodes, usually gold or silver discs, at standard locations on the scalp using collodion adhesive or a conducting paste. Potential

differences between pairs of electrodes are then amplified and the net signal from each amplifier is displayed on a monitor (digital EEG machines) or written on paper (historical EEG machines) to provide a graphic record of EEG voltage changes over time. In practice, modern EEG machines display activity from 20 or more channels (1 pair of electrodes = 1 amplifier channel) simultaneously to provide a comprehensive survey of cerebral electrical activity.

Much of the value of EEG lies in determining the spatial distribution of voltage fields on the scalp. To do this, electrodes are grouped in logical arrangements called *montages*. Montages typically allow comparisons between symmetric areas of the two hemispheres and between parasagittal and temporal areas in the same hemisphere. Most laboratories use as minimum a series of standard montages recommended by the American EEG Society (1). In addition to these, special montages may have to be designed to address issues posed by a particular patient. Creative use of rationally designed montages significantly enhances the utility of the EEG.

A technician typically records spontaneous EEG activity for approximately 30 minutes. However, the yield of positive findings is greatly increased by several activating procedures: hyperventilation, photic stimulation, and sleep. All three are useful in children with suspected seizures or epilepsy.

FIGURE 12-1

Effects of hyperventilation in a 5-year-old child. (A) EEG at onset of overbreathing effort; (B) 45 seconds later. There is a moderate buildup of generalized rhythmic slow-wave activity, maximal over the posterior head regions.

### Hyperventilation

Hyperventilation for at least 3 minutes, preferably 5 minutes if absence seizures are strongly suspected, should be performed whenever possible. Overbreathing can be achieved even with preschool children if the technician incorporates playful strategies such as blowing a pinwheel or “having a race” to see who can breathe faster. The effect of hyperventilation on EEG activity in children is usually dramatic, with high-voltage, generalized, rhythmic slow waves appearing promptly (Figure 12-1). The mechanisms underlying this age-related normal phenomenon are not known, but changes in cerebral blood flow and the neuronal metabolic milieu are probable factors. What is more important, however, is the empiric observation that a brief period of vigorous overbreathing potentially activates generalized epileptiform discharges, especially 3-Hz spike-wave activity. Sometimes focal slow-wave activity associated with structural lesions may appear or be accentuated during hyperventilation. The only responses to hyperventilation that can be unambiguously categorized as abnormal are asymmetric changes and epileptiform discharges.

### Photic Stimulation

Photic stimulation is performed using stroboscopic flashes of high-intensity white light at rates of 1 to 30 flashes per second. Stimulation is intermittent, with each frequency delivered for 10 to 20 seconds. A normal physiologic response is entrainment of EEG activity over the occipital lobes at the flash frequency (photic driving) (Figure 12-2A). In some normal children, photic stimulation produces no effect, and in others, the photic driving may be asymmetric. A photoparoxysmal response characterized by generalized bursts of irregular

spikes, spike-wave discharges, and multiple spike-wave discharges (Figure 12-2B) occurs in some patients with idiopathic generalized epilepsy. However, it also occurs in a significant percentage of normal children without seizures, presumably as an asymptomatic marker of a genetic trait. Dose and Gerken (2) propose a multifactorial mode of inheritance.

### Sleep and Sleep Deprivation

Light sleep substantially increases the percentage of EEGs showing epileptiform activity in patients with epilepsy. The occurrences of both focal and generalized discharges are increased in non-rapid-eye-movement (non-REM) sleep, but rapid eye movement (REM) sleep has a differential effect. Generalized epileptiform activity diminishes markedly or disappears altogether in REM, whereas focal spikes and sharp waves either are unaffected or actually increase in abundance (3).

Sleep deprivation also activates epileptiform activity independent of its sleep-inducing effect (4, 5). Kellaway and Frost (6) have speculated that sleep deprivation and spontaneous or sedated sleep activate abnormalities via different mechanisms.

Scheduling the EEG at the time a child normally naps facilitates sleep recordings. Older children may be partially sleep-deprived with benefit. If children do not sleep spontaneously, they may be given chloral hydrate (30–60 mg/kg) with appropriate guidelines for conscious sedation.

### Special Electrodes

Some cortical areas (mesial temporal, orbital frontal, and interhemispheric regions) are relatively inaccessible to

FIGURE 12-2

(A) Normal physiologic response is entrainment of cerebral electrical activity over the occipital regions at the frequency of light stimulation (driving response). (B) Photoparoxysmal response in another child occurring during stroboscopic light stimulation. Bursts of spikes and irregular spike-wave discharges occur during and immediately after the light stimulus. In this case, there were no clinical manifestations during the photoparoxysmal response and no clinical history of photosensitivity.

conventional recording electrodes. If one of these areas is suspected of being the epileptogenic focus, supplemental electrode placements can augment standard ones. Thus, surface placement of anterior temporal, mandibular notch, and supraorbital electrodes are useful in documenting inferior frontal and mesiobasal temporal epileptiform discharges (7).

More invasively, sphenoidal electrodes, which are fine wires inserted transcutaneously through the mandibular notch so that the tips lie near the foramen ovale at the base of the skull, are commonly used in monitoring

units evaluating patients for resective surgery (8). Nasopharyngeal electrodes, which are flexible wires that are inserted through the nose to lie in the posterior pharynx, have been widely used in the past, but subsequent studies have cast doubt on their superiority over surface locations, especially anterior and inferior temporal leads, in recording mesial temporal lobe discharges (7, 9, 10).

Invasive electrodes should not be used in children except in special circumstances. Adequate information can usually be obtained using standard scalp electrodes supplemented, as necessary, with additional special placements.

FIGURE 12-3

(A) Focal left parietal spikes (discharge is at P3 in third and fourth channels) in a 10-month-old boy with simple partial seizures involving his right arm and face. (B) Generalized 4- to 5-Hz spike-wave activity in an 18-year-old male with idiopathic generalized tonic-clonic seizures, precipitated by stimulation.

## SPECIFIC EEG FINDING

### Epileptiform Activity and Epileptogenicity

The only EEG finding that indicates a susceptibility to epileptic seizures is epileptiform activity, that is, spikes, sharp waves, or spike-wave discharges (Figure 12-3).

Although epileptiform discharges indicate an increased risk of seizures, they vary in degree of epileptogenicity, that is, the association with active epilepsy. Epileptogenicity is at least partly age-related. In adults, epileptiform discharges have a high association with seizures and occur only rarely in normal individuals. The situation is more complicated in children, largely because of the occurrence of genetic patterns that may not be associated with clinical seizures. Nonetheless, even in children, epileptiform discharges are uncommon in normal individuals, approximating perhaps 2% in the prevalence studies of Petersen and coworkers (11). From another perspective, Trojaborg (12) found that 83% of children whose EEGs contained focal spikes had seizures.

Another variable that relates to epileptogenicity is location of the discharge. The likelihood of epilepsy is highest when epileptiform discharges are multifocal or when they involve the temporal lobe: 76% and 90%, respectively (13). Risk of epilepsy is considerably lower (approximately 50%) when epileptiform activity involves the central-midtemporal (rolandic) or occipital regions (13).

All epileptiform activity decreases in abundance with age or the passage of time, and less than 10% persists indefinitely (13). In general, there is no useful correlation in individual patients between the amount of epileptiform activity in the EEG and the number and intensity of clinical seizures.

## NONSPECIFIC EEG ABNORMALITIES

Abnormalities other than epileptiform discharges are also common in the EEGs of patients with epilepsy. Nonepileptiform abnormalities are termed *nonspecific* because

FIGURE 12-4

(A) This EEG sample demonstrates continuous focal arrhythmic slow activity in the right central-parietal region (bottom three channels). (B) In contrast, this EEG sample shows excessive generalized arrhythmic slow activity. The EEG of a normal 4-year-old is shown for comparison (C).

they occur in many other conditions as well, or sometimes even in normal subjects. Examples of nonspecific abnormalities include focal or generalized slow-wave activity (Figure 12-4) or, less often, asymmetries of frequency or

voltage. Unlike epileptiform discharges, such findings do not provide support for a diagnosis of epilepsy because of their varied clinical associations and because they do not reflect an epileptogenic disturbance of neuronal function.

**FIGURE 12-5**

Hypsarhythmia in a 9.5-month-old infant with infantile spasms. There is extremely high-voltage slow-wave activity diffusely, multifocal spikes, and lack of normal organization and patterns.

Nonspecific findings are important, however, in providing general information about cerebral function. Thus, evaluation of nonspecific EEG abnormalities may help identify associated static or reversible encephalopathies, underlying focal cerebral lesions, or progressive neurologic syndromes.

## PEDIATRIC EPILEPTIC SYNDROMES

Electroencephalography is crucial for accurate classification of different forms of epilepsy. The following are brief descriptions of EEG findings in the more common epileptic syndromes encountered in childhood.

### Infantile Spasms (West Syndrome)

The EEG is always abnormal, grossly so if obtained when seizures are well established. Gibbs and Gibbs (14) identified the most characteristic pattern, hypsarhythmia, which consists of high-voltage, irregular slow waves occurring asynchronously and randomly over all head regions, intermixed with spikes and polyspikes from multiple independent loci (Figure 12-5). Variations of the pattern (modified hypsarhythmia) occur in up to 10% to 15% of children with infantile spasms (15). These other abnormalities, however, are more likely to occur in older infants or if the EEG is performed later in the course of the disorder. Like infantile spasms, hypsarhythmia is age-specific. It is usually most pronounced in slow-wave sleep and may disappear completely in REM. Ictal recordings show various patterns (16), but the most common accompaniment

to a spasm is one or more generalized, high-voltage slow or sharp-slow waves followed by abrupt voltage attenuation of background activity lasting from 1 to several seconds, the so-called electrodecremental event (Figure 12-6) (17). Type of spasm does not always correlate well with a particular EEG ictal pattern, and neither do all spasms have EEG correlates. EEG and clinical improvement usually parallel one another, but they may be dissociated.

### Childhood Absence Epilepsy

EEGs are rarely normal in untreated children with childhood absence epilepsy (formerly referred to as petit mal epilepsy), and hyperventilation is particularly effective in provoking the characteristic EEG abnormality. In fact, repeated normal EEGs in a child with lapse attacks argue strongly against a diagnosis of childhood absence epilepsy. Each absence seizure is accompanied by generalized, symmetric, stereotyped 3- to 4-Hz spike-wave activity (Figure 12-7A). Background activity is otherwise normal or near normal. Sleep produces striking effects on appearance of the epileptiform activity (Figure 12-7B). Classic features are lost, and instead epileptiform bursts are fragmented, are of shorter duration, and contain more single spikes and multiple spikes.

Spike-wave paroxysms begin abruptly, producing immediate alteration in the child's responsiveness (18). Conversely, when the 3-Hz spike-wave discharge ends, the child's behavior becomes normal at once (18). Detailed analysis of motor and cognitive effects reveals differences in their time course and evolution

FIGURE 12-6

Electrodecremental event in a 7-month-old child characterized by transient flattening of background activity (middle of figure). Such events frequently accompany the massive spasms of West syndrome.

in relation to the ictal discharge (19). Even short bursts of 3-Hz spike-wave activity produce some functional impairment that may go unrecognized clinically. Thus, childhood absence epilepsy is one instance in which follow-up EEGs are often necessary to gauge how effective treatment is; clinical reports alone may be inadequate.

### Lennox-Gastaut Syndrome

The name *Lennox-Gastaut syndrome* (childhood epileptic encephalopathy) has been applied to a heterogeneous group of children with severe seizures, mental retardation, and a characteristic EEG pattern. EEG findings are most typical between 2 and 7 years of age and are remarkably consistent despite widely different underlying causes, including progressive degenerative or metabolic disease, cerebral malformations, perinatal asphyxia, severe head injury, anoxic encephalopathy, and central nervous system infection (20).

EEGs show generalized, bisynchronous sharp- and slow-wave complexes occurring repetitively, often in extended runs, at 1.5 to 2.5 Hz (Figure 12-8). Within the same record and among patients, the sharp-slow waves vary somewhat in distribution, voltage, and repetition rate. Sleep usually activates epileptiform activity markedly; hyperventilation does so less consistently. Multifocal spikes or sharp waves also occur, especially in older children. Electrodecremental or tonic seizure patterns (Figure 12-9) lasting 2 to 4 seconds occur frequently during sleep, sometimes as often as hundreds of times per night. Clinical correlates of these nocturnal seizure discharges are minimal, most often being slight stiffening of the axial muscles. Background activity is

almost always moderately to severely abnormal because of excessive slowing and poor development of normal patterns for age.

A history of West syndrome is present in up to one-third of children with Lennox-Gastaut syndrome (21), suggesting that EEG manifestations of severe encephalopathies reflect, in part, an age-dependent continuum with particular patterns emerging from interaction of maturational and pathologic factors.

### Myoclonic-Astatic Epilepsy As Described by Doose

Myoclonic-astatic epilepsy (MAE) as described by Doose is sometimes confused with Lennox-Gastaut syndrome (21b). Children with MAE are usually normal at onset of the epilepsy. The most prominent seizure consists of a sudden drop attack, or myoclonic-astatic seizure, characterized by a combination of sudden myoclonic jerk of the arms and head followed by a brief period of atonia. This results in sudden falls with the potential for injury. This is often accompanied by a brief bursts of generalized spike or repeated spike-wave activity followed by a diffuse profound attenuation (Figure 12-10). Nocturnal tonic seizures may be seen in some individuals, but more common are clonic-tonic-clonic seizures of intermediate duration (“moyen-mal”). Absence seizures can also occur, and sometimes children develop absence or myoclonic status epilepticus. The interictal EEG may show runs of rhythmic parasagittal slowing (Figure 12-11) and brief generalized spike-wave discharges. These discharges may appear as single spike-wave discharges or as doublets or triplets, so that it may be hard to determine the

FIGURE 12-7

(A) Stereotyped 3-Hz spike-wave activity in a 4-year-old child with childhood absence epilepsy. The bottom channel records a test tone (T) to which the child has been trained to respond by pressing a button (R). During the generalized spike-wave activity, the child's ability to respond is impaired (absence attack). Normal responsiveness returns immediately upon cessation of the discharge. (B) EEG from same child showing alteration in spike-wave morphology during sleep. The epileptiform activity has become fragmented and contains multiple spikes (polyspikes). The well-formed 3-Hz spike-wave complexes seen during wakefulness no longer occur. Such changes, although varying in degree, are typical of generalized epileptiform abnormalities.

repetition rate accurately. When discernible, repetition rates may be slow (i.e., below 3 Hz) or fast (i.e., above 3 Hz) (Figure 12-12).

### Benign Focal Epilepsy with Central-Midtemporal Spikes

The syndrome of benign focal epilepsy with central-midtemporal spikes, which is also referred to as central-temporal epilepsy, sylvian seizures, and rolandic epilepsy,

is an idiopathic localization-related epilepsy with highly characteristic EEG and clinical features (22–24).

EEG findings are distinctive and diagnostic. Focal di- or triphasic sharp waves of almost invariant morphology occur in the central and midtemporal regions (Figure 12-13). Epileptiform discharges are usually of high voltage ( $>100 \mu\text{V}$ ), tend to occur in clusters, and activate dramatically during sleep, when they may seem almost continuous. Discharges may be unilateral in a single EEG, but they are almost always bilaterally present with prolonged or repeated recordings. Lateralization

**FIGURE 12-8**

Generalized sharp- and slow-wave complexes (slow spike-and-wave discharges) occurring repetitively at about 2 Hz in a child with Lennox-Gastaut syndrome.

may switch in serial tracings (22, 23). Generalized spikes and spike-wave activity occasionally occur, usually during sleep (23, 25, 26), and “benign” occipital spikes or multifocal spikes may coexist, especially in younger patients (22, 25).

There is no correlation between EEG findings and seizure occurrence or frequency. As a rule, EEG abnormalities are much more impressive than clinical

cal seizure activity. Indeed, when central-midtemporal spikes are recorded in children without seizures who have EEGs for other reasons, only about half eventually develop typical seizures (13). Furthermore, in symptomatic children, EEG abnormalities persist long after seizures cease. Thus, EEG does not provide assistance in making decisions about when or how long to treat.

**FIGURE 12-9**

Tonic seizure during sleep in a child with severe mental retardation and uncontrolled tonic, atonic, and atypical absence seizures. The EEG correlate is an electrodecremental event. Sometimes a low voltage 16- to 25-Hz rhythmic discharge (tonic seizure pattern) occurs during this type of clinical event.

FIGURE 12-10

This patient with myoclonic-astatic epilepsy had a head drop accompanied by a diffuse spike-wave discharge with after-going attenuation.

Genetic studies indicate that the EEG trait is controlled by an autosomal dominant gene with age-dependent penetrance (27, 28).

### Benign Focal Epilepsy with Occipital Spikes

Gastaut (29) has described another form of idiopathic localization-related epilepsy in children, in which visual symptoms—either amblyopia or hallucinations—are a common early feature of ictal events. The EEG shows stereotyped, high-voltage (200–300  $\mu$ V) sharp-wave discharges over one or both occipital regions. Epileptiform activity is attenuated by eye opening and is activated by sleep. Discharge morphology resembles that of central-midtemporal spikes. Background activity is normal. This electroclinical entity is more heterogeneous than benign focal epilepsy with central-midtemporal spikes. Nonetheless, outcome is usually benign in a typical case, with complete resolution of clinical and EEG findings in most children by 18 years of age. Like central-midtemporal spikes, occipital spikes do not correlate with clinical seizure activity or prognosis, and they often persist after seizures cease. Generalized spike-wave discharges and central-midtemporal spikes may coexist.

A more common benign epilepsy has been described by Panayiotopoulos (29b). Affected children are usually younger than those described by Gastaut and have few clinical attacks. Seizures are, however, often prolonged and have prominent autonomic features. Children characteristically vomit and become listless during the seizures (autonomic status epilepticus). Early descriptions highlighted the importance of stereotyped occipital spikes, but Panayiotopoulos has subsequently showed that “cloned-like” or highly stereotyped interictal epileptiform discharges may be seen in multiple different locations. Spikes may be most prominent in the occipital regions in younger individuals, but they “migrate” to more anterior locations in older individuals (Figure 12-14).

### Dravet Syndrome (Severe Myoclonic Epilepsy in Infancy)

Dravet syndrome manifests in the first year of life, often with febrile convulsions (29c). These may be hemic convulsions and are often prolonged. Later, myoclonic seizures, atypical absences, and focal seizures develop. Not all seizure types are seen in each individual child. The interictal EEG may initially be normal. Some infants will show

FIGURE 12-11

Children with MAE may have prominent runs of rhythmic biparietal slowing.

photoparoxysmal responses. Usually within one year of onset, the EEG becomes abnormal with background slowing and the appearance of interictal epileptiform discharges. In our experience, these are often most marked in the posterior derivations, and later multifocal spikes and generalized spike-wave discharges are commonly seen. Myoclonic jerks are often accompanied by generalized spike or polyspike-wave discharges. Focal seizures correlate with focal ictal patterns.

### Juvenile Myoclonic Epilepsy

Janz and Christian (30) described juvenile myoclonic epilepsy (JME) or “impulsive petit mal” as a subtype of idiopathic generalized epilepsy. Interictal EEGs show generalized 4- to 6-Hz “atypical” spike-wave activity, short bursts of polyspikes, and polyspike-wave discharges (Figure 12-15). An incrementing run of 10- to 16-Hz polyspikes, maximal over the frontal-central areas, followed by a generalized burst of spikes or spike-wave activity accompanies bilateral myoclonic jerks (30, 31). If absence seizures occur, the EEG shows 3.5- to 4-Hz generalized spike-wave paroxysms. Photoparoxysmal responses are common in JME, occurring in approximately one-third of patients (32).

### Acquired Epileptic Aphasia

Acquired epileptic aphasia, which is also known as the Landau-Kleffner syndrome, is not primarily an epileptic disorder, although epileptiform activity is part of the diagnostic criteria. Seizures occur in approximately 70 percent of cases but usually are infrequent. EEGs show abundant high-voltage epileptiform activity, which may be temporal, bitemporal, or generalized. Considerable slow activity accompanies epileptiform discharges. In the early stages, EEG abnormalities may occur only during sleep, and throughout the illness slow-wave sleep produces marked activation, sometimes with almost continuous generalized spike-wave activity. Review of the original case (33) and subsequent cases (34–37) of acquired epileptic aphasia does not support any single EEG feature or combination of features as being distinctive of this syndrome. AED treatment does not clearly alter the natural evolution of EEG abnormalities, clinical findings, or outcome.

### Epilepsia Partialis Continua

Epilepsia partialis continua manifests as several different subtypes, but one variant—Rasmussen syndrome—occurs primarily in children as a reasonably distinct entity (38).

FIGURE 12-12

The interictal epileptiform discharges in MAE are often brief generalized discharges with an irregular repetition rate.

EEG findings are variable, and their topography is often difficult to characterize precisely (38, 39). Most often, interictal EEGs show excessive arrhythmic or rhythmic delta activity that is usually bilateral but accentuated over a large area contralateral to the partial seizures. Epileptiform discharges are rarely well localized and often

sporadic, especially early in the illness. As the disease progresses, more abundant pleomorphic spikes and sharp waves appear over an extensive area or bilaterally. It is usually difficult to recognize distinct ictal discharges with scalp recordings; in any event, correlation of EEG changes with muscle jerks is always poor to nonexistent.

FIGURE 12-13

Stereotyped di- and triphasic sharp wave discharges occur independently in the central regions bilaterally in this child with partial seizures (benign rolandic epilepsy).

FIGURE 12-14

Highly stereotyped interictal epileptiform discharges are seen in patients with Panayiotopoulos Syndrome.

### NEONATAL EEG

EEGs of neonates pose special problems in interpretation. From 26 to 40 weeks of gestation, there are explosive maturational changes in the brain that result in rapid changes in neuronal orientation, alignment, and layering accompanied by substantial dendritic development, extensive synaptogenesis, glial proliferation, and onset of myelination. These biological developments underlie rapid

and predictable sequences of EEG changes that are sufficiently consistent as to allow accurate determination of conceptional age in healthy newborns to within 2 weeks.

EEGs in newborns are sufficiently different from those of older children and adults that one must take considerable caution not to overinterpret the significance of certain normal or inconsistent findings, all of which may be only transiently present. Thus, isolated spikes, or sharp transients, are common normal components of the

FIGURE 12-15

Generalized multiple spike-wave (polyspike-wave) discharge followed by a single spike-wave complex in a child with juvenile myoclonic epilepsy.

**FIGURE 12-16**

Severely abnormal EEG in a 2-week-old newborn born at 33 weeks gestational age. EEG activity is depressed and poorly differentiated bilaterally, with intermittent low-voltage activity and random sharp transients punctuated by higher-voltage mixed-frequency burst activity. Note the positive sharp transients occurring at Cz (channels 10–11 and 13–14) (*middle portion of figure*). Such positive rolandic discharges have a high correlation with periventricular leukomalacia.

newborn's EEG, and their significance depends on their location and abundance and the infant's state and conceptional age. Tharp (40), Lombroso (41), and Hrachovy and coworkers (42) give complete discussions of neonatal EEG interpretation.

Just as there are special considerations that relate generally to EEG interpretation in the newborn, some cautionary notes are indicated about using EEG in diagnosing and treating newborns with seizures. EEG background activity characterized in terms of expected developmental features provides important information about the extent to which cortical physiology is normally maintained or disturbed (Figure 12-16). Background activity often deteriorates transiently following a seizure because of associated hypoxia or other metabolic stresses. Interictal background activity, therefore, is extremely variable, reflecting the severity of any encephalopathy underlying or associated with seizures and the timing of the EEG in relation to seizure activity. In some infants, specific patterns or evolution of findings on repeated EEGs provide helpful and reliable prognostic information. When EEG background activity is used to help predict long-term neurologic outcome, interpretation should be based on interictal tracings to avoid problems related to revers-

ible postictal abnormalities. Identifying and visually quantifying spikes is important, but in newborns these results are less an indication of specific susceptibility to seizures (epileptogenicity) than a measure of the underlying encephalopathy. In general, one should be extremely conservative in using interictal spikes or sharp waves to diagnose neonatal seizures.

To establish that an observed behavior is an epileptic seizure, one must record an associated ictal discharge. This can be done using conventional EEG recording if the technician makes copious and temporally accurate notations on the tracing. Better still, however, are simultaneous EEG, polygraphic, and video recordings, which provide objective documentation of the relationship among EEG activity, other physiologic variables, and behavior. Kellaway and colleagues at Baylor College of Medicine have exploited this methodology creatively to identify epileptic and nonepileptic paroxysmal behaviors and to propose a new classification of neonatal seizures (43–45). Such data indicate that one must be cautious in inferring an epileptic basis for all paroxysmal clinical events and that concurrent EEG recordings are usually necessary to distinguish epileptic seizures from similar phenomena caused by different mechanisms (43, 46).

FIGURE 12-17

EEG of a newborn with a postconceptional age of 36.5 weeks demonstrating onset of a repetitive sharp-wave discharge from the left occipital region (A). Forty-five seconds later the discharge involves the entire left hemisphere and is associated with staring (B). Simultaneously, there is a buildup of spiking in the right temporal area that evolves independently from the seizure pattern on the left (B, C). The baby's eyes remain open, and there are occasional irregular body movements (C). Just over 2 minutes after the seizure begins, clinical and EEG seizure activity subside, and EEG background is severely depressed bilaterally (D).

Focal or multifocal clonic seizures, focal tonic seizures, some generalized myoclonic seizures, and ictal apnea are consistently associated with EEG ictal patterns. In contrast, staring, ocular movements, excessive salivation, and various autonomic phenomena occurring in isolation, such as changes in heart rate and blood pressure, may be accompanied by EEG discharges but often are not. Motor automatisms, including various oral-buccal-lingual movements; progression movements such as stepping, pedaling, or swimming; and complex asynchronous motor activities such as thrashing and writhing are not consistently accompanied by EEG seizure patterns. Generalized tonic seizures in the newborn also have no EEG correlate. These latter events presumably arise either from nondetectable (at the scalp) epileptic mechanisms or, more likely, from nonepileptic dysfunction of motor systems at subcortical and brainstem levels (release phenomena) (43).

Ictal discharges are almost always focal or multifocal in newborns, with variable spread to ipsilateral regions and the contralateral hemisphere (Figure 12-17). Repetitive rapid spiking is unusual at this age, especially in premature babies, and most seizure patterns consist of rhythmic sequences at almost any frequency or slowly repetitive (0.5–2 Hz) sharp waves. Seizures may occur simultaneously in the same hemisphere or in different hemispheres and progress independently.

## LONG-TERM MONITORING

It is often desirable to record EEG activity for longer periods than conventional EEG recordings allow, so as to increase the likelihood of detecting epileptiform activity or capturing intermittent behavioral events. Two methods of long-term monitoring are now widely available; they have greatly improved diagnostic accuracy and reliability of seizure classification. Both have value in providing continuous recordings through one or more complete wake-sleep cycles and in documenting ictal episodes. Each has additional specific advantages and disadvantages (47–49). Which method one selects depends on the question posed by a particular patient. Gummit (50) has provided a useful overview.

### Ambulatory Monitoring

Multichannel cassette records allow relatively inexpensive continuous EEG recording in the outpatient setting. In terms of EEG information alone, ambulatory cassette recordings are only slightly less accurate in yield of epileptiform abnormalities than recordings made in intensive monitoring units (51). For this purpose, both methods are substantially more useful than routine EEG. Ambulatory EEG is often especially helpful in the pediatric setting, where the young child is often

more comfortable in his familiar and unrestricted home environment (52). Limitations include the relatively limited coverage of cortical areas and the absence of video documentation. Thus, ambulatory cassette recordings are inadequate for detailed localization of epileptogenic foci, and very discrete foci may be missed. Furthermore, negative ambulatory EEG recordings are not usually helpful when the question is one of nonepileptic paroxysmal events. Here the video image of the child is frequently indispensable in recognizing and definitively characterizing the event.

Most makers of ambulatory EEG equipment have also converted to digital technology. This technique has all of the advantages of digital technology (described subsequently), allows more channels to be recorded, and offers automated computerized detection of interictal and ictal discharges. These technical advantages have greatly expanded the role of ambulatory monitoring.

### **Intensive Closed Circuit Television–Video EEG Monitoring**

Closed circuit television (CCTV)–Video EEG monitoring in a specialty equipped inpatient unit is the procedure of choice to document pseudoseizures, establish precise electrical–clinical correlations, and localize epileptogenic foci for resective surgery. Emphasis in intensive monitoring units usually is on behavioral events, not interictal activity.

Demonstrating that an electrical seizure discharge accompanies undiagnosed disturbances in behavior is unequivocal proof of an epileptic mechanism. Unfortunately, the converse is not true without qualifications. Various physiologic and technical considerations conspire to obscure some ictal discharges and thus lead potentially to false negative results. When the epileptogenic focus lies deep to the surface and the ictal discharge remains localized to this area, scalp recordings may be negative. For example, epileptiform discharges confined to mesiobasal limbic structures may go undetected at the scalp. This means that simple partial seizures manifesting as autonomic, cognitive, affective, or special sensory changes (auras) have EEG correlates in only approximately 15 percent of cases (53). As another confounding variable, consider epileptogenic foci whose physical geometry is such that electrical activity is not ideally oriented for detection by scalp electrodes. Discharges arising from orbital frontal or mesial parasagittal areas may not result in long current loops (dipoles) whose vectors are orthogonal to the surface, the optimal orientation for scalp detection of electrical events. Finally, seizures may be associated with sufficient muscle activity that high-voltage noncerebral electrical activity [electromyography (EMG), movement artifact] prevents detection of low-voltage EEG changes. This is frequently the case with frontal lobe seizures, in

which early onset of movement makes it difficult to determine whether EEG change has occurred. In the absence of an unambiguous ictal discharge, postictal slowing is usually indicative of a preceding epileptic event if similar changes are not seen in the preseizure record.

To enhance detection of ictal discharges, especially their earliest manifestations, and to provide a comprehensive analysis of the epileptogenic region, most laboratories supplement usual EEG recording sites with additional placements, including extratemporal electrodes, nasopharyngeal and sphenoidal electrodes, and supraorbital electrodes. Because of the many additional recording sites, it is not unusual for monitoring units to record simultaneously from 32, 64, or even more channels. The need for many recording channels is even more urgent when intracranial electrodes are used. These may be depth probes, subdural strips, or subdural grids, each containing multiple recording contacts. Intracranial electrodes are required in patients being evaluated for resective surgery when extensive surface (including sphenoidal) recordings do not provide definitive localization of the epileptogenic zone (54–57) or when other clinical data conflict with EEG findings (58).

A variety of ictal patterns may be seen in children. For the most part, these are similar to those encountered in adults. Focal ictal discharges are often characterized by sustained runs of rhythmic delta or theta-alpha activity that evolve in frequency and voltage. Generalized convulsive seizures may be characterized by runs of diffuse rhythmic fast activity during tonic phases or runs of spike-wave discharges during clonic phases. Some patterns, however, are peculiar to children. Examples of these are runs of rhythmic positive sharp waves in some infantile focal seizures and electrodecremental events (Figure 12-6) during infantile spasms. Seizures in infants and young children usually are focal and secondarily generalize less often than in adolescents and adults. Bilaterally synchronous generalized ictal discharges occur only very rarely in infants less than 13 months old (59).

### **MAGNETOENCEPHALOGRAPHY**

Magnetoencephalography (MEG) detects and measures magnetic activity of the cortex using superconductive quantum interference devices (SQUIDs). Neuronal aggregates that are current sources of brain electrical activity also generate magnetic fields. Models depicting the head as a homogeneously conducting sphere demonstrate that measurements of magnetic fields can provide three-dimensional localization of a neuronal source. MEG differs from EEG in ways that are potentially very useful. For example, MEG is more accurate than EEG in localizing dipoles of neuronal activity oriented parallel to the surface. Furthermore, MEG is relatively unaffected by overlying tissue and bone,

which significantly attenuate volume conduction of electrical potentials between cortex and scalp. Finally, MEG appears to arise solely from intracellular currents in active neurons (60, 61). Thus, for some current sources, MEG may offer greater spatial resolution than EEG.

Several investigators have used MEG to map epileptogenic foci, and results have compared favorably with EEG localization (61–64). Applications are currently limited by the complex technology required to detect the extraordinarily weak magnetic fields of the brain. Until now, most investigators have used only a single SQUID, which is then moved from place to place on the head. Multichannel recording is clearly feasible, however, and reports are appearing of recording devices with 20 or more channels. There is promise, therefore, of using MEG as a complement to EEG to improve source localization in studying epileptiform activity in people with epilepsy.

Digital technology has quickly changed how EEG signals are collected and stored in many laboratories across the country. One difference is that digital signals are not contaminated by sources of noise encountered with analog technologies. The EEG signal is electronically stored and may be reviewed in any desired montage, sensitivity, or filter setting. The digital format also allows for quantitative methods of EEG analysis, including Fourier (spectral cross-correlation) and cross-spectral analysis. In addition, interpolation techniques may be applied to estimate the electric potentials at intermediate scalp positions from known values at each electrode position. Topographic or spatial maps are another way of displaying EEG data that differs from the conventional display by producing maps of electrical potentials that loosely resemble images seen with MR or CT. Finally, source dipole localization has been proposed as a method to find the intracranial sources generating scalp potentials. Most of these techniques are still research tools and have not yet come into common clinical practice.

## CONCLUSIONS

In this chapter we have indicated the role of EEG in evaluating children with known or suspected seizures. EEG is an important, perhaps *the* most important, adjunct to history and examination. But, as with any laboratory test, care and judgment must be used in relating EEG findings to other clinical data. Indeed, the full potential of EEG can be realized only when interpretations are placed in the full clinical context.

EEG interpretation in infants and children is complicated by two important considerations. First, many normal potentials are high-voltage, occur paroxysmally, and have spiky waveforms. Unusual benign variants are common. Thus, EEGs of children are easy to overinterpret or misinterpret. The second issue is that the developing brain has unique neuroanatomic, biochemical, and neurophysiologic features. The various EEG abnormalities in childhood epilepsy and their clinical expression result from the interaction of developmental features with genetic or acquired pathology.

The EEG examination should always be framed to answer a particular question. There is no evidence that routine follow-up EEGs every 6 or 12 months serve any useful purpose. Dialog between the clinician and laboratory is essential, especially if special recording circumstances are necessary to obtain maximal information. Questions that the EEG may help answer include:

1. Does the child have epilepsy?
2. Are seizures of localized or generalized onset?
3. Does the child fit a specific electroclinical syndrome?
4. Is clinical deterioration the result of unrecognized seizures, a progressive neurological syndrome, or drug toxicity?
5. Is the child a candidate for surgery?
6. Can AEDs be safely withdrawn?

## Basics of Neuroimaging in Pediatric Epilepsy

*James M. Johnston*  
*Matthew D. Smyth*  
*Robert C. McKinstry*

**N**euroimaging, especially magnetic resonance imaging (MRI), has become a critical tool in the evaluation of the child with epilepsy. The introduction and ongoing refinement of MRI have allowed noninvasive visualization of the many substrates of epileptogenesis. Identification of mesial temporal sclerosis, neoplasms, vascular malformations, and subtle cortical dysplasias converts some cases of heretofore “nonlesional” to “lesional” epilepsy, and thus amenable to surgical intervention and improved outcomes.

Imaging is an essential component of a multidisciplinary evaluation of children with epilepsy. Because imaging is only one of many evaluation tools available to help locate epileptogenic foci, imaging results need to be interpreted in the context of the medical history, physical exam, electroencephalogram (EEG), neuropsychologic testing, and, where indicated, invasive intracranial electrophysiologic monitoring. In this chapter we aim to provide a general overview of the many imaging modalities available to the clinician in furthering our understanding of the pathophysiology of epilepsy. We also briefly review newer technologies aimed at noninvasively localizing epileptogenic cortex.

### SEDATION

Movement significantly decreases the resolution and quality of most advanced imaging techniques, especially MRI, making adequate sedation for uncooperative children quite important. Neonates often do not require sedation if they are fed immediately before arrival, kept warm, and provided with ear plugs during the study. Some institutions have installed audiovisual systems in their MR scanners, with subsequent reductions in sedation, motion artifact, and room time. However, most children under 7 years of age will require some form of sedation. When sedation is needed, most institutional protocols call on the expertise of nurse anesthetists, hospitalists, or anesthesiologists to ensure safe and effective sedation.

### IMAGING MODALITIES

#### Head Sonography

Fetal ultrasound is a screening tool that has an established role in the diagnosis of cerebral malformations, congenital anomalies, and complex syndromes. In the postnatal period, ultrasound is often the initial study in a diagnostic workup for seizure activity. It has the benefits of being noninvasive and avoiding radiation exposure.

Neonatal head ultrasound's primary role has traditionally been in the evaluation of the preterm newborn for diagnosis of parenchymal hemorrhage, germinal matrix hemorrhage, and hydrocephalus. Ultrasound may detect changes of hypoxic ischemic injury, vascular anomalies, or brain malformations.

### Computed Tomography

Computed tomography (CT) is most helpful in the identification of intracranial hemorrhage, major vascular malformations, and ventriculomegaly. The sensitivity of CT is approximately 30% in the detection of many of the causes of epilepsy (1–5). Given these limitations, as well as the risks of radiation exposure in infants and young children, CT has been replaced by MRI in the elective workup of childhood epilepsy.

In cases of recording in order to localize epileptic foci with electrode grids, CT may also be used to obtain images of electrodes in situ that can later be fused onto preoperative MR images with standard software. This technique allows the use of neuronavigation to guide operative resection of epileptogenic lesions (6).

### Magnetic Resonance Imaging

*Technical Considerations.* The continued development of MRI has improved our ability to visualize the most common causes of epilepsy. Routine sequences should include high-resolution T2-weighted, fluid attenuation inversion recovery (FLAIR), T2\*-weighted gradient echo, 3D high resolution T1W gradient echo, and diffusion-weighted imaging. Imaging after administration of gadolinium contrast agents helps differentiate neoplasia from dysplasia and should be done whenever a structural abnormality is present.

The advent of high-resolution, multichannel coils and higher field strength ( $\geq 3$  Tesla) has enhanced signal-to-noise ratio and reduced scan times. Phased-array coil imaging has improved cortical lesion detection by 64% compared with standard 1.5-T coils (7). As phased-array technology is adapted for 3-T systems, signal-to-noise ratio and resolution should improve even more (8). Research with 7-T multichannel array technology promises visualization of cortical abnormalities of less than 100  $\mu\text{m}$  in the near future, prompting some authorities to predict an era of “in vivo histology” (9).

#### Overview of Myelination in the Normal Brain

Any interpretation of magnetic resonance imaging of the developing brain must take into account the dynamic process of myelination and changes in water content, with corresponding signal intensity changes on T1- and T2-weighted imaging. In most basic terms, T1 and T2 relaxation

times become shorter as maturation progresses, as a result of increased myelin and decreased water content in imaged tissue. Myelination begins in the dorsal brainstem and cerebellum as early as the fifth fetal month, then involves the pyramidal and somatosensory radiations, and progresses later to the subcortical white matter of the prefrontal and anterior temporal regions over the first two years of life (10). Thus, white-matter maturation is evaluated best with T1-weighted images until 6 to 8 months of age, after which T2-weighted images become more sensitive to white-matter changes.

### Quantitative MR Techniques

Detailed manual segmentation of specific brain regions and structures such as hippocampus and amygdala has permitted a more quantitative formulation of standardized growth trajectories and better understanding of both normal and abnormal development (8). For example, mesial temporal sclerosis (MTS) has been studied using quantitative techniques that have excellent sensitivity and specificity for detecting hippocampal asymmetry (11). Quantitative studies of regional brain volume also have found decreases in cerebral and cerebellar size in children with epilepsy (12).

Surface-based and volume-based representations of cortex provide population-averaged “architectonic” maps to permit truer comparisons of functional or structural data between individuals or research cohorts (13). For example, construction of a surface-based atlas has permitted the identification of cortical folding abnormalities in Williams syndrome (14).

### Cortical Malformations

A wide spectrum of cortical malformations, due to genetic or environmental insults, can cause pediatric epilepsy. These can be classified in terms of disruption of neuronal production, differentiation, and migration. The most common malformations are well visualized on MRI, especially with the use of high resolution 3-T and modern phased-array technology. The examples that follow illustrate the types of abnormalities that can be identified. For a more extensive review of this topic, see the references by Barkovich and by Raybaud et al (15, 16).

### Transmantle Dysplasias

Transmantle dysplasias are disorders of neuronal and glial differentiation with or without abnormal migration. Histologically, these abnormalities contain dysplastic glioneuronal elements that increase signal on T2/FLAIR imaging depending on the child's age and state of myelination of the brain. In many ways these dysplasias represent a one pole of a spectrum that blends into low-grade neoplasia. As a result, it can be difficult to differentiate the two based on imaging alone.

FIGURE 13-1

Cortical dysplasia. Coronal high-resolution T2W image demonstrates extensive abnormal signal hyperintensity in the right inferomedial temporal lobe (within the circle). The cortex has elevated signal, as does the subcortical white matter. The junction between the gray matter and the white matter is indistinct.

Focal cortical dysplasias of Taylor are the most common of the transmantle dysplasias. Histologically, they are characterized by abnormal dendritic arborization, disorganized neurons, and large dysmorphic astrocytes called “balloon cells.” The poorly differentiated glioneuronal cells span the cerebral mantle, with blurring of the gray–white junction. These lesions are best visualized as high signal on T2 and FLAIR images. Classically they have a triangular shape with the apex pointed at the superolateral margin of the ventricle and the base on the cortical surface (Figure 13-1). Imaging after contrast administration helps differentiate this entity from a neoplasm.

Hemimegalencephaly is a highly epileptogenic transmantle dysplasia. It is characterized by an enlarged hemisphere and ipsilateral ventricle, with tilting of the corpus callosum and septum pellucidum towards the involved side (Figure 13-2). There is variable loss of gray–white matter differentiation throughout the abnormal hemisphere. Typically, the white matter has increased T1 and decreased T2 signal, thought to represent hypercellularity or an advanced myelination (17).

In pathologic specimens these hamartomas were described as “candle dripping” (Figure 13-3). Over time, because of increasing myelination and calcification, they are most easily identified on T1-weighted images and variably enhance with contrast. *Cortical*

FIGURE 13-2

Hemimegalencephaly. Horizontal T2W image reveals the extensive transmantle dysplasia of left hemimegalencephaly. The right hemisphere is normal. On the left the cortical ribbon is thickened (long white arrow) relative to the normal cortex (white arrow head), the gray-white junction is indistinct, and the left ventricle is dysmorphic and enlarged.

*hamartomas* (tubers) are characterized histologically by a dense gliosis, disordered myelination, and bizarre giant cells similar to those seen in cortical dysplasia. Sometimes calcified, the MR appearance of tubers changes with advancing age and myelination. In neonates, tubers appear as T1-hyperintense, T2-hypointense to surrounding white matter. With myelination, the lesions slowly become isointense, then T2/FLAIR hyperintense in older infants. Approximately 5–10% of children with TSC will develop a subependymal giant cell astrocytoma. Typically found near the foramen of Monro, these lesions can acutely become symptomatic when they enlarge and obstruct flow of CSF at the foramen. On MRI, they have increased T1 and decreased T2 signal and enhance homogeneously after contrast administration. Degeneration into diffuse astrocytoma is rare but should be suspected when associated with increased T2 signal in the surrounding white matter.

FIGURE 13-3

Tuberous sclerosis. Horizontal T2W image demonstrates three classic features of tuberous sclerosis. The black arrow indicates an area of subcortical flame-like hyperintensity typical of a cortical tuber. The arrow heads illustrate the T2-hypointense subependymal nodules, which are likely calcified. The white arrow identifies an intraventricular heterogeneous mass with bowing of the septum pellucidum due to a subependymal giant cell astrocytoma.

*Disorders of Migration.* Heterotopias are characterized by groups of neurons in abnormal locations. Unlike the transmantle dysplasias described in the preceding paragraphs, signal characteristics are identical to normal cortex, without T2/FLAIR abnormality. However, the advent of increasingly sensitive MR techniques has allowed visualization of more subtle structural abnormalities.

Nodular heterotopias are either isolated or diffuse clumping of gray matter adjacent to the ventricular wall (subependymal) (Figure 13-4, black arrow) or between the ventricle and cortical mantle (subcortical). The nodules may be unilateral or bilateral and vary greatly in size, and are often associated with commissural agenesis, polymicrogyria, or schizencephaly.

Band heterotopias, also known as laminar heterotopias, are characterized by a duplication of the cortical gray matter extending below and then away from normal cortex. Typically they are bilateral and symmetrical, and they occur almost exclusively in females.

FIGURE 13-4

Periventricular nodular heterotopia and pachygyria. Horizontal T1W image from a child with extensive periventricular nodular heterotopia (black arrow) and bilateral posterior parieto-occipital pachygyria. Note the thickened, broadened, and flattened appearance to the pachygyria relative to normal cortex.

Polymicrogyria (or microgyria) is a disorder of cortical sulcation and lamination with loss of intermediate cortical layers and fusion of the molecular layer. On MRI, the sylvian fissure extends posteriorly beyond its normal confines at the temporoparietal junction, and the remainder of the brain has an “overfolded” appearance (Figure 13-5, white arrows) as compared with normal cortex (Figure 13-5, black arrow). The peri-insular cortex is typically the most severely affected, and variable atrophy of the hemisphere is usually apparent. Often there is increased T2/FLAIR signal in the periventricular and subcortical white matter, suggestive of dysmyelination.

Schizencephaly or split brain refers to the presence of a pia-lined cleft extending from the cortical surface to the ventricle (Figure 13-5, black arrow head). Subclassified as fluid filled (“open-lip”) or collapsed (“closed-lip”), it is often associated with adjacent polymicrogyria (Figure 13-5, white arrows), septal agenesis, partial agenesis of the corpus callosum, and cortical heterotopias. This malformation should be differentiated from encephaloclastic porencephaly, in which the cleft is lined with white matter.

Lissencephaly (agyria-pachygyria complex) is a series of brain abnormalities with decreased sulcal and gyral

FIGURE 13-5

Polymicrogyria and schizencephaly. Parasagittal T1W image and horizontal T2W image from a child with extensive malformation of cortical development. The white arrows show cobblestone irregularity of the frontal lobe cortex with numerous small gyri compared with the normal cortex (black arrow). The black arrow head points to a closed lip schizencephalic cleft, which is lined by polymicrogyria. The dimple in the lateral wall of the left lateral ventricle is the site of the pial-ependymal seam.

development. “Agyria” refers to an absence of gyri (complete lissencephaly), while “pachygyria” refers to areas of broad, flat gyri (incomplete lissencephaly). Both are characterized by thickened cortex, and result from abnormal neuronal migration (Figure 13-4, white arrow).

### Neoplasms

Dysembryoplastic neuroepithelial tumors (DNET or DNT) are benign glioneuronal neoplasms of the cortex associated with partial complex epilepsy, usually without neurologic deficit. Accounting for nearly 20% of the pathology found in pediatric cases of surgically treated epilepsy (18), approximately 60% of these tumors are located in the temporal lobe with 30% in the frontal lobe and the remainder distributed in other brain regions. Imaging findings on MR include decreased T1, increased T2/FLAIR signal without surrounding edema, and enhancement in approximately one-third of cases. Most have cystic or microcystic components and are well demarcated from the surrounding brain parenchyma (Figure 13-6, black arrow).

Gangliogliomas and gangliocytomas are relatively rare. These mixed glioneuronal tumors account for 3% of pediatric brain tumors and usually are seen in

older children and young adults with long histories of partial seizures, occasionally with focal neurologic deficits (19). Gangliogliomas are most commonly located in the neocortex and temporal lobe, though they have been described near the hypothalamus and third ventricle. Lesions may be solid or cystic, with or without mural nodule. Solid portions of the tumor demonstrate increased T2 signal with variable enhancement, and calcification is occasionally present (Figure 13-7). Differential diagnosis includes astrocytoma, oligodendroglioma, and DNET. Surgical resection of these tumors usually cures the patient’s seizures.

Oligodendrogliomas, though relatively rare (1% of all pediatric brain tumors), commonly cause seizures when they are present. These are most commonly found in the frontal and temporal lobes and are frequently cystic and calcified on CT. MR appearance is nonspecific: They are commonly isointense to surrounding brain on T1 and T2, with areas of T1 hyperintensity (related to calcification) and variable enhancement (Figure 13-8).

Hypothalamic hamartomas are rare, congenital malformations located in the region of the tuber cinereum of the hypothalamus. Clinically, these are associated with precocious puberty, epilepsy, developmental delay, and

**FIGURE 13-6**

Dysembryoplastic neuroepithelial tumor (DNET). Horizontal post-contrast T1W image of a child with a DNET. The lesion is based in the cortical and subcortical region of the posterior insula on the left. The lesion has minimal mass effect and a cystlike appearance medially with a posterolateral nodule that follows gray matter signal (black arrow).

gelastic seizures as well as other types of partial and generalized seizures, including atypical absence and drop attacks (20). Lesions usually are isointense to gray matter on T1 and iso/hyper intense on T2 sequences without enhancement. Large hamartomas (up to 4 cm) may have cystic components extending into the sella or even middle cranial fossa.

### *Vascular Malformations*

Cavernous angioma (or cavernoma) has been associated with epilepsy in children and is frequently associated with a benign venous malformation. Histologically, cavernomas are characterized by sinusoidal vascular spaces with dilated capillary beds filled with blood and breakdown products of varying age. MRI shows a lobulated center (“popcorn”) with high T1, T2, and FLAIR signal surrounded by a rim of T2 hypointensity related to hemosiderin and ferritin breakdown products. The rim, related to intermittent small hemorrhages, is best visualized with T2\*-weighted gradient echo sequences. Some cavernomas have surrounding gliosis and increased T2 signal (21).

**FIGURE 13-7**

Ganglioglioma. Horizontal post-contrast T1W image of a left posteromedial temporal lobe mass. The cystlike lesion with an enhancing mural nodule is a classic appearance for ganglioglioma.

Sturge-Weber (encephalotrigeminal angiomatosis) is a sporadic disorder characterized by angiomatosis involving the eye, face (facial nevus flammeus, or port-wine stain), and/or leptomeninges. Intracranially, there is a disorganized angiomatosis of the leptomeninges involving the capillaries, venous channels, and arteries, with characteristic “matting” and fibrosis. There is also typically diffuse calcification of the underlying cortex, most commonly in the temporo-parieto-occipital region secondary to ischemia. Typical findings on MR include weblike enhancement of the subarachnoid space, corresponding to the matted vasculature of the pial angioma (Figure 13-9). Calcification of the underlying cortex is best visualized on CT or MR T2-weighted images and is usually unilateral. The ipsilateral choroid plexus may also be enlarged (22), and may be correlated with the extent of pial angiomatosis (23).

Arteriovenous malformations (AVM) are abnormal, often friable connections between cerebral arteries and veins without intervening capillaries. Thought to be congenital, AVMs may grow over time, resulting in hypoperfusion and the development of aneurysms, and can cause seizures, neurologic deficits, headache, hydrocephalus, or hemorrhage (24). CT is most sensitive in the detection of hemorrhage that presents acutely. CT angiography with 3D reconstructions can help delineate feeding artery and draining vein anatomy (25) (Figure 13-10, long white

FIGURE 13-8

Oligodendroglioma. Horizontal CT, T2W, and post-contrast T1W images from a right frontal lobe mass. The hyperdensity on the CT peripherally indicates calcification, a common feature of oligodendroglioma. The heterogeneous T2W signal with enhancement are nonspecific but common features in this neoplasm.

arrow). Imaging findings on MR include flow voids on T2 spin echo sequences and low intensity T2\* signal in areas of old hemorrhage.

### *Mesial Temporal Sclerosis*

The term *mesial temporal sclerosis* (MTS) refers to hippocampal atrophy, with or without damage to surrounding structures in the mesial temporal lobe. Clinically, MTS is synonymous with temporal lobe epilepsy (TLE) or epilepsy with partial complex seizures. Typically, MTS involves lateral temporal neocortex as well as extratemporal structures, especially the frontal lobe. Histopathologically, hippocampal sclerosis refers to a small, firm hippocampus with neuronal loss in CA1 and CA3, as well as sclerosis in all sectors. As mentioned above, pathologic changes may be discerned in other mesial structures, including the amygdala, fornix, and mammillary body. MTS may be associated with other developmental abnormalities of the brain, especially porencephaly (26, 27). A current area of active investigation includes better delineating the relationship of MTS to complex febrile seizures of childhood as well as status epilepticus.

The classic imaging findings in mesial temporal sclerosis are hippocampal atrophy, increased T2 signal, and loss or distortion of adjacent white matter (Figure 13-11, right image). In addition, quantitative methods have been developed by several groups with excellent results (11, 28). Both automatic and manual segmentation techniques have been applied to high-resolution T1 images in an

FIGURE 13-9

Sturge-Weber. Horizontal post contrast T1W image demonstrates diffuse, bilateral leptomeningeal enhancement and atrophy of the right hemisphere typical of encephalotrigeminal angiomatosis. The surface of the cortical gyri are enhancing. Bilateral involvement is present in this example, but unilateral involvement is the more typical presentation.

FIGURE 13-10

Arteriovenous malformation. Cerebral angiography (left) of a temporoparietal arteriovenous malformation (AVM). The long white arrow points to a tangle of vessels in the nidus of the AVM. BOLD functional MRI was performed (right) to determine whether the AVM involved eloquent cortex. The circle encloses the AVM. The crossing lines localize activation along the precentral gyrus. The graph confirms that the activation is synchronized with the finger-tapping task paradigm.

oblique coronal plane, perpendicular to the long axes of the hippocampi (Figure 13-11, left image). Volumetric analysis of hippocampi in normal children can provide normative data used for diagnosing hippocampal sclerosis (29). Hippocampal volume has been correlated with prognosis for seizure freedom and neuropathologic findings after surgical resection (30, 31).

#### *Rasmussen's Encephalitis*

The term *Rasmussen's encephalitis* describes a syndrome of partial-onset seizures and progressive neurologic

deficits that commence between 14 months and 14 years of age. Fluctuating deficits follow seizures, lengthen, and then become permanent in more than half of affected children. Partial and generalized seizures often evolve over time, and progressive deterioration of neurologic status with hemiparesis, focal neurologic deficits, and dementia characterize the most severe cases. Histopathologically, the affected brain shows diffuse lymphocytic infiltration and perivascular cuffing, consistent with chronic viral encephalitis (32). MRI features have been correlated with quantitative histopathology, showing higher numbers of

**FIGURE 13-11**

Mesial temporal sclerosis. Coronal inversion recovery T1W and high resolution T2W images of left hippocampal sclerosis. The black arrows localize a small, T2-hyperintense left hippocampus. The internal architecture of the left hippocampus is indistinct as well.

T cells and reactive astrocytes in the earlier, acute inflammatory stage of the disease (33). Classic imaging findings include progressive brain atrophy, edema of the cortical ribbon with increased T2 and FLAIR signal, and relative enlargement of the ipsilateral ventricle.

### Diffusion Tensor Imaging

Diffusion tensor imaging (DTI) has emerged as a powerful tool in the analysis of brain development and myelination of axons, and in visualization of the fine detail of white matter organization in children. Diffusion MR imaging, acquired using single-shot spin echo echo-planar pulse sequence using Stejskal-Tanner pulsed diffusion gradients, is sensitive to the subvoxel movement of water in brain tissue. Signal intensity in DTI is inversely related to the magnitude of water diffusion (hyperintense = decreased movement of water) (10).

The apparent diffusion coefficient (ADC) is a quantitative measure of water diffusion along a given applied gradient. Water diffuses more freely in the direction of white matter bundles structural elements such as the myelin sheath, axolemma, and neurofilaments. The term *fractional anisotropy* (FA) refers to the degree of asymmetric water diffusion (e.g., greater along a fiber tract as opposed to between fiber tracts) within a given location (voxel). Thus, by measuring ADC along multiple diffusion-encoding directions it is possible to obtain information about rate, magnitude, and directionality of water

diffusion. This information is then translated into images depicting white matter tract location and directionality.

During normal brain development, there is a general decrease in water diffusivity and increase in anisotropy associated with myelination and tract development. In general, these changes follow both a temporal and spatial sequence that parallels that of myelination noted previously.

Diffusion tensor imaging has proven useful in the study of epilepsy. In MTS, increased diffusivity and decreased fractional anisotropy are present in the epileptogenic zone (34–36). Combining DTI with statistical parametric mapping (SPM) or zonally magnified oblique multi-slice echo planar imaging (ZOOM-EPI) acquisition, some investigators have suggested that increased diffusivity may be an early marker of mesial temporal lobe epilepsy (MTLE), even when the MRI is normal (37, 38). Recent work demonstrates more widespread bilateral changes, including increased diffusivity throughout the ipsilateral hippocampus and mesial temporal lobe, decreased anisotropy in posterior ipsilateral extratemporal regions, as well as decreased anisotropy in the contralateral hippocampus, ipsilateral thalamus (39), and bilateral limbic system (40), suggesting multiple abnormalities over the course of an “epileptogenic network” (41, 42).

Diffusion tensor imaging has also been applied to extratemporal epilepsy with good results. DTI with SPM has demonstrated either reduced anisotropy or increased diffusivity in brain surrounding cortical malformations (43, 44). Paradoxically, dysplastic gray

matter demonstrates increased anisotropy in some reports (45). Among children with tuberous sclerosis, DTI studies have identified abnormalities in cortical tubers and in associated white matter lesions (46). Asymmetries in temporal anisotropy have been associated with atypical language lateralization (47). Fractional anisotropy in frontotemporal regions has been correlated with interictal psychosis (48). Generalized decreased fractional anisotropy in injured brain regions may be useful in predicting epileptogenesis in patients with traumatic brain injuries (49). Diffusion tensor imaging tractography is sensitive enough to detect both axonal fragmentation and delayed myelin degradation in patients undergoing corpus callosum (50). In combination with functional MRI and MR spectroscopy, DTI provides a noninvasive window on the functional, microstructural, and biochemical characteristics of epileptogenic tissue (51).

DTI has also been utilized for both preoperative and intraoperative applications in the surgical treatment of intractable epilepsy (52). Preoperative DTI visualization of the optic pathways may also be useful for predicting visual field defects after resection of the temporal lobe (53).

Diffusion spectroscopic imaging (DSI) and tractography uses probabilistic map calculation algorithms to better visualize small tracts, as well as the white matter organization outside large tracts, with a spatial resolution of 8 mm<sup>3</sup> (Figure 13-12). Increased resolution of this approach has the potential to allow better definition of the microanatomy of seizures.

**FIGURE 13-12**

Diffusion tensor tractography. Diffusion tensor tractography (DTT) of bilateral corticospinal tracts in a 3-year old child. (Figure courtesy of Joshua Shimony, Mallinckrodt Institute of Radiology, Washington University School of Medicine.)

### Proton MR Spectroscopic Imaging

Proton magnetic resonance spectroscopy (MRS) is a technique for the assessment of chemical composition and cellular metabolism of the brain *in vivo*. The most commonly used nuclei are <sup>1</sup>H and <sup>31</sup>P. Magnetic resonance spectroscopy provides a qualitative and quantitative depiction of metabolites present in brain tissue. In clinical applications <sup>1</sup>H-MRS is more commonly used because of its better spatial resolution. The most common metabolites imaged are N-acetyl aspartate (NAA), choline (Cho), glutamate/glutamine (Glx), lactate/lipid (Lac), myo-inositol (mI), and creatine/phosphocreatine (Cr/PCr). In general terms, NAA is a marker of neuronal health, and its concentration probably reflects neuronal density. Cho is thought to be a marker of cell membrane turnover and thus glial health or myelin turnover. Lactate is a marker of anaerobic glycolysis, whereas creatine is a marker of high-energy metabolism. Myo-inositol is an osmolyte and marker of glial health. Glutamate is elevated in ischemia and excitotoxic injury. <sup>31</sup>P-MRS is useful in the imaging of phosphate-containing compounds such as adenosine triphosphate (ATP), phosphodiesterases, phosphocreatine, and inorganic phosphate. It is also useful in determining tissue acidity/pH (54).

MR spectroscopy has a role in the differentiation of high-grade tumors, in which choline is typically elevated relative to NAA and Cr, as compared to metabolic disorders, ischemia, and glial scarring. Other MR spectroscopy applications include metabolic disorders, stroke, hypoxia and monitoring gene therapy; however, this discussion focuses on its application in the study and localization of epileptogenic cortex.

Studies of children with intractable epilepsy have shown a significantly decreased NAA/(Cho+Cr) ratio (55–59), on the order of 19% in the involved temporal lobe compared with normal controls (56). Postictal <sup>1</sup>H-MRS of hippocampi has also shown increased NAA/(Cho+Cr) and lipid/lactate levels if performed within 7–24 hours following a seizure. When the findings were unilateral, they always corresponded to the affected side and were somewhat helpful in the localization of extratemporal foci (60–62). Although ipsilateral apparent diffusion coefficient (ADC) but not NAA/(Cr+Cho) correlated with disease duration, neither ADC nor NAA/(Cr+Cho) correlated with hippocampal volume. Hence these three variables appear to capture different but complementary aspects of hippocampal pathology (35).

Spectroscopy has emerged as a means of locating epileptogenic cortex in children with otherwise normal MRI and hippocampal volumetry (63) and in children with complex febrile convulsions (64). When combined with amygdalo-hippocampal volumetry, the accuracy of <sup>1</sup>H spectroscopic imaging (MRSI) maps approaches that of the EEG for lateralizing epileptogenic temporal cortex (65).

Quantitative  $^1\text{H}$ -MRS has also proven useful in detecting metabolic changes in hippocampi in children with asymptomatic localization-related epilepsy and infrequent seizures (66). Some children with juvenile myoclonic epilepsy have reduced frontal lobe concentrations of NAA (67). In tuberous sclerosis, researchers have found significantly lower NAA/Cr and NAA/(Cho+Cr) in cortical tubers than in normal brain (68).

In summary, proton MR spectroscopy holds great promise for improving our understanding of the metabolic dysfunction that accompanies or predisposes to epilepsy. Future applications will likely allow observation of transport and metabolism of macromolecules in the brain, combination with functional MRI, and assessment of the short-term effects of CNS-targeted pharmacologic interventions (69).

## Functional Neuroimaging

### *Positron Emission Tomography*

Functional neuroimaging provides information complementary to structural MR imaging in the diagnosis of epilepsy. Positron emission tomography (PET) allows visualization of brain glucose metabolism with the use of positron-emitting ligands such as 2-deoxy-2- $^{18}\text{F}$ fluoro-D-glucose (FDG). Other ligands more specific to epilepsy have been developed, including  $^{11}\text{C}$ flumazenil (FMZ), which binds to GABA<sub>A</sub> receptors (70), and alpha- $^{21}\text{C}$ methyl-L-tryptophan (AMT), which measures tryptophan metabolism (71). Research continues regarding the use of radiolabeled ligands to opioid, histamine H1, monoamine oxidase type B enzyme, N-methyl-D-aspartate, peripheral-type benzodiazepine, and serotonin 1A receptors.

Baseline glucose metabolism varies significantly as a function of age, with low values in infants, increasing to a maximum between 4 and 12 years, slowly declining during adolescence (72). Quantitative analysis by statistical parametric mapping (SPM) and statistical probabilistic anatomical mapping improves diagnostic performance (45).

PET has proven useful in the evaluation of many disorders associated with partial-onset seizures. These include infantile spasms, Rasmussen's syndrome (73), as well as partial epilepsies without MRI abnormality (74). Interictal FDG PET imaging of patients with medically refractory temporal lobe epilepsy shows glucose hypometabolism of the involved temporal lobe in about 85% of cases (75). It is important to note that if unrecognized epileptic discharges occur during a PET scan that is thought to be interictal, hypermetabolism may be occurring in the affected cortex. When this occurs, it may lead to false lateralization to the normal side, which appears to be relatively hypometabolic in this setting. Furthermore, the degree of hypometabolism is related to seizure duration and is thus likely to be less sensitive in younger children than in adolescents or adults (76).

PET seems to be most useful in the localization of hypometabolic epileptogenic areas that appear to be normal by MRI (74, 75, 77–82). When areas of hypometabolism are found, they can guide the placement of intracranial electrodes used to further hone in on the epileptogenic region. In children with frontal lobe epilepsy, PET sensitivity of 92% and specificity of 62.5% have been reported (75). Though it is less commonly used than functional magnetic resonance imaging (fMRI), PET may also be useful in functional brain mapping to identify speech and sensory/motor areas (77).

PET has also proven useful in furthering our understanding of certain epileptic syndromes. Heterogeneous metabolic patterns have been correlated with subtypes of Lennox-Gastaut syndrome (82–85). Bilateral abnormalities have been demonstrated in hemimegalencephaly (86). Finally, some authors propose that PET may provide a sensitive measure of the extent of involvement and correlate with clinical course in Sturge-Weber disease (73, 87).

### *Single-Photon Emission Computed Tomography (SPECT)*

Single-photon emission computed tomography (SPECT) noninvasively measures changes in cerebral blood flow (CBF) associated with epileptic discharge. The agents (iodinated radiotracers or technetium-99m methyl cysteinate dimer) that are used in these studies quickly cross the blood-brain barrier and “imprint” the local brain parenchyma, providing a snapshot of CBF. The injection can occur either during seizure activity (ictal), in which case it is associated with an increase in CBF in discharging cortex; just after an event (postictal), when CBF is decreased; or at baseline (interictal) (88–89).

In addition to being aware of the occurrence of seizure activity when SPECT is obtained, SPECT imaging in children must be interpreted with an understanding of the changes in cerebral metabolism and CBF that accompany growth and development. At birth, there is high baseline CBF in the thalamus, central white matter, and cerebellar vermis. By age 3 months, the striatum and occipitoparietal frontal and cerebellar cortex all become relatively hypometabolic. At 12 months of age, the infant brain is very similar to the adult one, but then between 2 and 6 years of age it doubles adult values, finally decreasing to adult levels by age 15 (90).

In adults with temporal lobe epilepsy, ictal and postictal SPECT have sensitivities of 97% and 75%, respectively (91). In extratemporal epilepsy the sensitivity of SPECT is less than 50%, though it may be improved to 80% when subtraction ictal SPECT is coregistered to MRI in the so-called SISCOM (89, 92). Interictal SPECT is most useful as a baseline that can be compared with perictal images, and it has a reported sensitivity of 67% (93). SPECT has also been found to be useful in classification

of absence seizures associated with localization-related epilepsies (94).

In pediatric patients, the role of SPECT is less well established. Among children who had a favorable surgical outcome, there was approximately a 70% correlation between areas of increased ictal perfusion and areas of cortical resection, suggesting that SPECT can help optimize the placement of intracranial electrodes (95). However, in a recent meta-analysis, data regarding the use of SPECT failed to support the use of SPECT in extra-temporal epilepsy in children, although ictal combined with immediately post-ictal SPECT scanning might improve results (91). In practical terms, however, performing true peri-ictal SPECT with the subtraction techniques like this requires a highly significant institutional commitment for radioactive tracer acquisition, tracer storage, coordination of peri-ictal injection, and prompt scanning of patients (92).

### Functional MRI (fMRI)

Functional MRI allows visualization of active brain regions based on changes in CBF and oxygen metabolism. The most common contrast mechanism used in fMRI is blood oxygenation level-dependent (BOLD). Since neuronal activity drives cerebral metabolism and CBF, fMRI acts as a surrogate marker of cortical activation. Though originally applied to study the localization of movement, language, and memory, fMRI has been applied for the study of epilepsy as well.

Practically speaking, task-related fMRI has been very useful in older children and adults, but can be difficult to impossible to perform in younger children. The most common applications of fMRI include lateralization of language and memory function as well as localization of epileptic phenomena (96). Among many helpful roles, fMRI can help localize eloquent cortex prior to epilepsy surgery (Figure 13-10), help guide the placement of subdural electrode grids, influence the extent of resection, especially in cases of subcortical abnormalities, and

generally contribute positively to outcome (97). Recent work shows that fMRI imaging of the amygdala during the fearful face task plus Roland's Hometown Walking Task highly increases the reliability of lateralization in patients with MTLE (98).

Functional MRI data complement EEG data in the elucidating the pathophysiology of epilepsy (99). In approximately 68% of patients with focal epilepsy, BOLD signal and EEG data correlate significantly (100, 101). Atypical language lateralization identified with fMRI has been correlated with duration of epilepsy in pediatric patients (102).

### Magnetoencephalography and Magnetic Source Imaging

Magnetoencephalography (MEG) and magnetic source imaging (MSI) are additional noninvasive techniques for localizing epileptogenic cortex. Highly sensitive magnetometers detect faint magnetic fields associated with current flow at postsynaptic membranes of neurons. These data are processed and then superimposed on anatomic MR images to produce MSI (103). Because there is no distortion of magnetic signals by the scalp or skull, MEG has the potential to surpass EEG in the localization of epileptic discharges (104), but this potential has yet to be realized. Compared with invasive monitoring, attempts at localization with MEG have a lower yield in classic temporal lobe epilepsy (105).

Applications for MEG are expanding, with studies describing its use in preoperative evaluation, subdural electrode grid placement, and identification of the central sulcus and somatosensory cortex using evoked somatosensory fields. However, MEG mapping of language, primary motor areas, and memory has been inconsistent. As equipment and mathematical processing of data have improved, MEG is being investigated as a means of reducing the need for invasive subdural electrode monitoring (106–110). MEG may have a role in the localization of epileptogenic tubers in children with TSC (111, 112).

## Neonatal Seizures

*Eli M. Mizrahi*

**T**he first four weeks of life are one of the greatest periods of seizure hazard during childhood. The occurrence of seizures within this neonatal period is associated with significant morbidity and mortality. These seizures are often difficult to recognize clinically and treat effectively and can represent significant diagnostic and management challenges. In addition, despite their clinical importance, there are a number of unresolved issues concerning aspects of pathophysiology, mechanisms of comorbidity, and therapeutic strategies; these issues can complicate the care of affected infants.

Reported incidence rates of neonatal seizures range from 1.5 to 5.5 per 1,000 neonates (1–7). Most have onset within the first week of life with a slow accumulation of incidence over the ensuing three weeks (5). Seizure occurrence may vary with risk factors such as degree of illness, possible etiology, and—according to several investigators—birth weight (5). Scher and colleagues (8, 9) reported that seizures occurred in 3.9% of neonates of less than 30 weeks' conceptional age and 1.5% in neonates older than 30 weeks. Similarly, Kohelet and colleagues (10) found an overall incidence of seizures in a cohort of very low-birth-weight infants to be 5.6/1,000, higher than most reported incidence in full-term infants.

The International League Against Epilepsy (ILAE) has used the terms “acute reactive” or “symptomatic” to

classify most neonatal seizures, implying an immediate cause of these events. However, the ILAE has also designated some so-called unprovoked neonatal seizures as the basis of epileptic syndromes. Two are relatively benign and two considered catastrophic (11–13). The benign syndromes are discussed in this chapter and include benign neonatal convulsions and benign familial neonatal convulsions. Two catastrophic syndromes are referred to below, but discussed in more detail in Chapter 15: early myoclonic encephalopathy (EME) and early infantile epileptic encephalopathy (EIEE). Acute reactive or symptomatic seizures are the most frequent; neonatal epileptic syndromes are rare.

### CLINICAL FEATURES

Neonatal seizures have clinical features that are unique compared to those of infants and children. Neonatal seizures may be fragmented; be disorganized; exhibit unusual patterns of spread; and may appear in various limbs simultaneously but asynchronously. These features are, for the most part, based on mechanisms of epileptogenesis in the immature. Other differences are based on the relative importance of nonepileptic mechanisms of “seizure” generation in this age group.

Neonatal seizures are classified by various methods: clinical features; the relation between clinical seizures and electrical seizure activity on the electroencephalogram (EEG); seizure pathophysiology; and epileptic syndromes. Each classification can be clinically useful. There have been a number of classification systems proposed over the years (14–20). Early classification schemes focused on the differences between neonatal seizures and those of older children; neonatal seizures were reported to be clonic or tonic, not tonic-clonic, and when the seizures were focal, there were characterized as unifocal or multifocal (14). Later classifications included myoclonus (15).

Early investigators also identified clinical events that had less of a traditional organization of motor

activity (14, 21, 22). Such seizures were initially characterized as “anarchic” (14) and then later as “subtle” (16) or “minimal” (18). These descriptions included oral-buccal-lingual movements such as sucking and chewing; movements of progression, such as bicycling of the legs and swimming movements of the arms; and random eye movements. While these events were initially considered to be epileptic in origin, others later suggested that they were exaggerated reflex behaviors and referred to them as “brainstem release phenomena” or “motor automatisms” (20).

Tables 14-1 and 14-2 list the clinical characteristics of neonatal seizures according to a current classification scheme (23). This scheme can be applied through clinical observation of the neonate. The basic classifica-

**TABLE 14-1**  
*Clinical Characteristics, Classification, and Presumed Pathophysiology of Neonatal Seizures*

CLASSIFICATION	CHARACTERIZATION	PATHOPHYSIOLOGY
<b>Focal clonic</b>	Repetitive, rhythmic contractions of muscle groups of the limbs, face, or trunk May be unifocal or multifocal May occur synchronously or asynchronously in muscle groups on one side of the body May occur simultaneously, but asynchronously on both sides Cannot be suppressed by restraint or repositioning	Epileptic
<b>Focal tonic</b>	Sustained posturing of single limbs Sustained asymmetrical posturing of the trunk Sustained eye deviation Cannot be provoked by stimulation or suppressed by restraint	Epileptic
<b>Generalized tonic</b>	Sustained symmetrical posturing of limbs, trunk, and neck May be flexor, extensor, or mixed flexor/extensor May be provoked or intensified by stimulation May be suppressed by restraint or repositioning	Presumed nonepileptic
<b>Myoclonic</b>	Random, single, rapid contractions of muscle groups of the limbs, face, or trunk Typically not repetitive or may recur at a slow rate May be generalized, focal, or fragmentary May be provoked by stimulation	May be epileptic or nonepileptic
<b>Spasms</b>	May be flexor, extensor, or mixed flexor/extensor May occur in clusters Cannot be provoked by stimulation or suppressed by restraint	Epileptic
<b>Motor Automatisms</b>		
<b>Ocular signs</b>	Random and roving eye movements or nystagmus (distinct from tonic eye deviation) May be provoked or intensified by tactile stimulation	Presumed nonepileptic
<b>Oral-buccal-lingual movements</b>	Sucking, chewing, tongue protrusions May be provoked or intensified by stimulation	Presumed nonepileptic
<b>Progression movements</b>	Rowing or swimming movements Pedaling or bicycling movements of the legs May be provoked or intensified by stimulation May be suppressed by restraint or repositioning	Presumed nonepileptic

**TABLE 14-2**  
*Classification of Neonatal Seizures with Electroclinical Correlation*

**CLINICAL SEIZURES WITH A CONSISTENT ELECTROCORTICAL SIGNATURE (PATHOPHYSIOLOGY: EPILEPTIC)**

Focal clonic

- Unifocal
- Multifocal
- Hemiconvulsive
- Axial

Focal tonic

- Asymmetrical truncal posturing
- Limb posturing
- Sustained eye deviation

Myoclonic

- Generalized
- Focal

Spasms

- Flexor
- Extensor
- Mixed extensor/flexor

**CLINICAL SEIZURES WITHOUT A CONSISTENT ELECTROCORTICAL SIGNATURE (PATHOPHYSIOLOGY: PRESUMED NONEPILEPTIC)**

Myoclonic

- Generalized
- Focal
- Fragmentary

Generalized tonic

- Flexor
- Extensor
- Mixed extensor/flexor

Motor automatisms

- Oral-buccal-lingual movements
- Ocular signs (aside from sustained eye deviation)
- Progression movements
- Complex purposeless movements

**ELECTRICAL SEIZURES WITHOUT CLINICAL SEIZURE ACTIVITY**

From Mizrahi and Kellaway, 1998 (23).

tion includes seizures characterized as focal clonic, focal tonic, myoclonic, spasms, generalized tonic and motor automatisms (also referred to as “subtle seizures”). Paroxysmal changes in autonomic nervous system measurements have also been reported to be manifestations of seizures, such as alterations in heart rate, respiration, and blood pressure as well as flushing, salivation, and pupillary dilation (19, 24, 25). However, any of these findings occurring as isolated epileptic events are rare, and when they do occur, they do so most consistently in association with other clinical manifestations of seizures (20).

Other classification systems are based upon the temporal relation of clinical events to the occurrence of electrical seizure activity on EEG. An “electroclinical” seizure occurs when the clinical event overlaps in time with electrographic seizure activity. A seizure is referred to as “clinical only” when it occurs in the absence of any EEG seizure activity. A seizure is referred to as electrographic “only” if the electrical seizure occurs without any coincident clinical seizure activity (26).

Seizures may also be classified according to their pathophysiology: epileptic or nonepileptic in character (20). Some seizures may be confidently classified as “epileptic” in nature just by their clinical appearance: focal clonic, focal tonic, some types of myoclonic seizures, and spasms (Table 14-1). These seizure types can be recognized and characterized at the bedside by the visible features of the spontaneous event. In addition, during the event, the clinician can attempt to suppress the motor behavior by holding the affected limb; a continuation of rhythmic muscle contractions indicates the epileptic basis of the event. When EEG is available, these events occur in close association with EEG seizure activity, and the clinical event cannot be provoked by stimulation nor suppressed by restraint of the infant. When EEG is utilized, seizures characterized as electrical-only seizures are also considered, by definition, epileptic in origin.

Other behaviors, previously referred to as “subtle” seizures, are best considered as nonepileptic in origin (4, 20) including some types of myoclonic events, generalized tonic posturing, and motor automatisms such as oral-buccal-lingual movements, movements of progression, and some ocular signs (Table 14-1). These events occur in the absence of electrical seizure activity but, more importantly, have clinical characteristics similar to reflex behaviors. These clinical events can be provoked by stimulation of the infant. Both the provoked and spontaneous events can be suppressed by restraint or by repositioning the infant during the event. In addition, the clinical events may increase in intensity with the increase in the repetition rate of stimulation (temporal summation) or the number of sites of simultaneous stimulation (spatial summation). The response can spread to regions of the body distant from the site of stimulation.

## CLINICAL NEUROPHYSIOLOGY

### Electroencephalography

The application of the EEG in the evaluation of a newborn suspected of seizures differs from its application to older children and adults in terms of the significance of interictal focal abnormalities and the interpretation of the background activity.

*Interictal EEG Findings.* Although focal sharp waves may be present interictally in the neonatal EEG, they are not considered epileptiform. Some focal sharp waves are normal features of the neonatal EEG, such as frontal sharp transients and some temporal sharp waves (those that occur randomly, are low or moderate in voltage, and present in transitional or light sleep) (27). Other focal sharp waves are abnormal. They are persistent, excessively numerous, and high in amplitude; they are present in wakefulness and sleep; and they have complex morphology. Persistent focal sharp waves may suggest focal injury. When multifocal, such sharp waves may suggest diffuse dysfunction. There may also be focal spikes. These may suggest focal injury, such as localized stroke, or may have uncertain diagnostic significance (28). Despite the interpretation of some interictal focal sharp waves or spikes as abnormal, in the neonate they are not usually considered direct evidence or confirmation that an individual has had or will have electrographic seizures.

The background EEG activity can provide information concerning degree of associated central nervous system (CNS) dysfunction, potential risk for seizures, and prognosis. The degree of abnormality of the interictal background activity may suggest the extent and type of CNS dysfunction associated with seizures. The nature of the interictal background activity may also indicate the potential risk the individual infants have in experiencing a seizure (29). Infants with initial normal background activity are less likely to eventually experience electrographic seizures than those with persistent diffuse background abnormalities. In addition, the extent, degree, evolution, and rate of resolution (if any) of background EEG abnormalities can suggest prognosis. An EEG with normal background activity recording within the first 24 hours of life may suggest a good outcome (30), while EEG background activity with abnormal features that persist or resolve slowly suggest a poorer outcome (28).

*Ictal EEG Findings.* Although not clearly defined, it appears that electrical seizure activity in neonates is rare before 34–35 weeks. When recorded, the manifestations of electrical seizures have wide-ranging features (27, 31). Frequency, voltage, and morphology of the seizure discharges may change within an individual seizure, between

seizures in an individual infant or among infants. The minimum duration has been designated to be 10 seconds (32), but the duration discharges can vary widely. Electrical events are typically focal and well circumscribed. They frequently arise from the central or centro-temporal region of one hemisphere and less commonly in the occipital, frontal, or midline central regions. Although seizures may arise focally and remain confined to that region, they may also spread to other regions. This spread may appear as a gradual widening of the focal area, by an abrupt change from a small regional focus to involvement of the entire hemisphere (as in a hemiconvulsive seizure) or by migration of the electrical seizure from one area of a hemisphere to another or from one hemisphere to another (23, 27).

There are some relatively unique ictal neonatal patterns that are typically associated with severe encephalopathies and accompanying abnormal background EEG. *Seizure discharges of the depressed brain* are typically low in voltage, long in duration, and highly localized (4). They may be unifocal or multifocal and show little tendency to spread or modulate; typically are not associated with clinical seizures; and occur when the EEG background is depressed and undifferentiated. Their presence suggest a poor prognosis. *Alpha seizure activity* is characterized by a sudden appearance of paroxysmal, rhythmic activity of the alpha frequency (8–12 Hz) typically in the temporal or central region and may evolve from the more typical seizure discharges or may appear *de novo* (33–35). Like seizure discharges of the depressed brain, alpha seizure discharges usually are not accompanied by clinical events and usually indicate the presence of a severe encephalopathy and poor prognosis.

### Video-EEG Monitoring

Video-EEG monitoring has proved to be a powerful tool in diagnosis and management of neonatal seizures and as well as in clinical research (20, 36–38). It is now becoming more available at many centers for routine use and more widely employed in neonatal intensive care units (39). Correlation of EEG with video can be very helpful in seizure characterization and classification, although attended EEG can also provide important clinical information, when preformed by a well-trained electroneurodiagnostic technologist who can carefully observe an infant's behavior and characterize the events.

### Computer-Assisted EEG Analysis of Neonatal Seizures

Computer-assisted analysis of EEG has been applied to detect and quantify electrical seizure activity in neonates. Such programs have been developed and may provide reliable data, particularly if the recordings are

attended by a trained electroneurodiagnostic technician (ENDT) (40, 41). Amplitude integrated EEG (aEEG) or cerebral function monitors (CFM) have experienced a renewed interest (42–44). However, these techniques are limited in terms of their ability to provide data from all brain regions, low resolution, compressed time frame, and reliance on nonexpert health care professionals. One recent study reports that, using CFMs, up to 50% of neonatal seizures were misclassified or unrecognized (45). Shellhaas et al (46) examined 851 electrographic neonatal seizures detected in 125 conventional, full-array EEG recordings. A one-channel EEG (C3 → C4) was digitally created to simulate the contemporary use of single-channel EEGs for seizure detection by CFMs. Although 78% of the seizures were visible in the single-EEG channel, the seizures were briefer and lower in amplitude, and less than half were diagnosed by aEEG based on the C3 → C4 channel. On the other hand, advocates suggest that the ability to monitor specific brain regions with aEEG for long periods may balance the restricted localization and other limitations (47).

## ETIOLOGY

Neonatal seizures are typically a correlate of CNS disease. In clinical practice, these seizures prompt a detailed evaluation for etiology. If the etiology is identified, etiologic-specific therapy is initiated. There is a wide range of potential causes of neonatal seizures, and this, in association with the susceptibility of the immature brain to injury, may account for the high incidence of acute neonatal seizures. The list of potential etiologies is extensive (23); however, most can be broadly categorized as hypoxia-ischemia, metabolic disturbances, CNS or systemic infections, and structural brain lesions. Table 14-3 (23) lists the most frequently identified etiologies of neonatal seizures.

### Symptomatic Neonatal Seizures

Hypoxic-ischemic encephalopathy (HIE) is often cited as the most frequent cause of neonatal seizures. The diagnosis may be difficult to establish, because diagnostic criteria have not been uniformly accepted. In addition, some proposed criteria have been so restrictive that infants with encephalopathy may not meet all of them but still carry the diagnosis of “suspected HIE.” At other centers, clinical practice is directed towards identification of measures of asphyxia that have predictive value in the occurrence of long-term sequelae (48). This strategy has resulted in less restrictive criteria for HIE. Both approaches, however, include the tabulation of delivery room Apgar scores, blood gases, requirement for resuscitation, recognition of

**TABLE 14-3**  
*Most Frequently Occurring Etiologies of Neonatal Seizures*

Hypoxia-ischemia

Congenital abnormalities of the brain
Neurodegenerative disorders
Inborn errors of metabolism
Benign neonatal convulsions
Benign familial neonatal convulsions
Drug withdrawal or intoxication

Main categories are listed in relative order of frequency (subcategories listed alphabetically). “Unknown” etiology is not listed, although encountered in approximately 10% of cases (although some in this category may be benign neonatal convulsions). From Mizrahi and Kellaway, 1998 (23).

clinical aspects of encephalopathy including seizures, and confirmation of multisystem involvement. There is also an emerging discussion of the use of computer-assisted analysis of EEG, including aEEG, to aid in the staging of the severity of HIE (49), although this is still considered investigational.

Associated metabolic disturbances range from electrolyte imbalances to inborn errors of metabolism. This category is important because of its potentially treatable

disorders such as hypocalcemia, hypomagnesemia, and hypoglycemia. Inborn errors of metabolism are much less frequent and include aminoacidurias, urea cycle defects, or organic acidurias. Other rare causes of medically refractory neonatal seizures that are potentially treatable include pyridoxine and biotinidase deficiency.

Bacterial and viral agents are associated with seizures to such an extent that almost all neonates with new-onset seizures are investigated for such infection. Some viral infections, such as herpes simplex encephalitis, may be treated empirically at clinical presentation prior to confirmation of the diagnosis. In addition, prenatal toxoplasmosis, rubella, cytomegalovirus, herpes simplex, or other (so-called TORCH) infections can be risk factors for neonatal seizures.

Associated structural brain lesions include both acquired and congenital conditions, such as stroke or hemorrhage and developmental anomalies of the brain. Congenital brain malformations may range from highly localized focal dysplasias to catastrophic defects such as holoprosencephaly and lissencephaly.

### Neonatal Epileptic Syndromes

In its Classification of Epilepsies and Epileptic Syndromes, the ILAE has designated only four syndromes in the neonatal period (11): benign neonatal convulsions, benign neonatal familial convulsions, early myoclonic encephalopathy, and early infantile epileptic encephalopathy.

These have been reviewed recently (50). The first two are associated with a relatively good prognosis and are discussed here, while the others suggest a poor outcome, have been included among the catastrophic pediatric epilepsy syndromes (51) and are discussed elsewhere in this volume (Chapter 15) and compared in Table 14-4 (12, 52, 53).

**Benign Neonatal Convulsions.** The syndrome of benign neonatal convulsions (BNC) has also been referred to as “benign idiopathic neonatal convulsions,” because of the lack of an identifiable etiology (54), and “fifth day fits” because of the timing of onset (55), and has been recently extensively reviewed by Plouin and Anderson (56). The features of this syndrome are normal interictal neonate; focal clonic seizures or, rarely, focal tonic seizures; no family history of neonatal seizures; full-term gestational age; and a history of an uncomplicated, normal pregnancy, labor, and delivery. Seizure onset is usually between the fourth and sixth day after birth. The seizures are typically brief (1 to 3 minutes), although, rarely, the seizures can be prolonged. The seizure disorder is self-limited in that seizures may recur only during a 24- to 48-hour period after onset, although this period on rare occasion may also be prolonged. The clinical seizures are usually unifocal clonic and may be associated with apnea. A critical feature for diagnosis is that no etiology for the seizures can be identified. In the past this disorder has been associated with a finding of rotavirus in stool but not in cerebro-

**TABLE 14-4**  
**Comparison of Early Myoclonic Encephalopathy (EME) and Early Infantile Epileptic Encephalopathy (EIEE).**

	EME	EIEE
Age of onset	Neonatal period	Within first 3 months
Neurologic status at onset	Abnormal at birth or at seizure onset	Always abnormal even prior to seizure onset
Characteristic seizure type	Erratic or fragmentary myoclonus	Tonic spasm
Additional seizure types	Massive myoclonus, simple partial seizures, hemiconvulsions, infantile spasms (tonic)	Focal motor seizures, generalized seizures
Background EEG	Suppression-burst	Suppression-burst
Etiology	Cryptogenic, inborn errors of metabolism, familial	Cerebral dysgenesis, anoxia, cryptogenic
Natural course	Progressive impairment	Static impairment
Incidence of death	Very high, occurring in infancy	High, occurring in infancy, childhood, or adolescence
Status of survivors	Vegetative state	Severe mental retardation, quadriplegic, and bedridden
Long-term seizure evolution	Infantile spasms	West syndrome, Lennox-Gastaut

Based on data from Aicardi, 1997 (52), and Ohtahara et al, 1992 (53). Reprinted from Mizrahi and Clancy, 2000 (12).

spinal fluid (CSF) (57) and with acute zinc deficiency in CSF (25); these findings are now considered of doubtful etiologic relevance.

The ictal EEG is characterized by focal, rhythmic, recurrent sharp wave or spike activity that is closely correlated with the clinical seizures. The background EEG is typically normal, although it has also been reported that in up to 60% of neonates with this syndrome the interictal EEG pattern referred to as “*theta pointu alternant*” may be present (58). The background activity is discontinuous and nonreactive. The bursts include rhythmic (4 to 7 Hz) theta activity, which may be mixed with sharp waves that alternate between hemispheres. Although in this disorder this pattern has not been considered diagnostic for BNC (56). The *theta pointu alternant* EEG pattern may persist for up to 2 weeks after the clinical syndrome resolves.

This syndrome is a diagnosis of exclusion, since the initial clinical presentation may resemble infants with symptomatic focal clonic seizures. Thus, a thorough evaluation for an etiology is conducted in order to identify a potentially treatable cause of seizures, even though the diagnosis of benign neonatal convulsions may be considered at the onset (56). Treatment is controversial, although most frequently the seizures are treated with phenobarbital. Because the seizures tend to be brief and infrequent, it has been argued that antiepileptic drug (AED) therapy may not be needed. If AEDs are used, they are typically discontinued once the seizures subside. The prognosis is considered to be generally good. However, one group of investigators has found either transient or persistent psychomotor delays in affected infants (55). Plouin (59) found neurodevelopmental deficits at 2 years of age in 50% of those with this syndrome and a slightly higher incidence of postneonatal epilepsy (0.5% of those patients) than in the general population.

**Benign Neonatal Familial Convulsions.** This syndrome is characterized by early-onset focal clonic or focal tonic seizures in a neonate with a family history of neonatal seizures and with no other neurological findings (60–62). There is an autosomal dominant pattern of inheritance with incomplete penetrance with two known chromosomal loci: one on chromosome 20q13 (63) and one on chromosome 8q (64–66). Genes responsible for this disorder are potassium channel genes, referred to as KCNQ2 for the chromosome 20q gene (67, 68) and KCNQ3 for the chromosome 8q gene (66).

The clinical seizures are best characterized as focal clonic or focal tonic. Seizure onset is between the first few days and one week of life (69), although there have been reports of onset as late as the second month of life. These various ages of onset may be developmentally determined, since infants who are born prematurely with this disorder will have seizure onset at an older chronological age than the infants born at term. The seizures may

be brief but can recur up to 2–3 months of age, when they will remit spontaneously. The interictal EEG is typically normal, although *theta pointu alternant* pattern has also been reported. While the outcome is generally good, there is a higher incidence of seizures in affected infants later in life; ranging from 11% to 16% (58, 70). Phenobarbital therapy is often used with success, although some investigators use valproate as an alternative (59).

## TREATMENT

With seizure onset, basic principles of medical management are initially applied to establish and maintain airway patency and access the circulatory system. Some seizures, as well as the use of some AEDs, may be associated with changes in respiration, heart rate, and blood pressure, and the anticipation and potential treatment of these associated conditions are critical to the overall care of neonates with seizures.

Following clinical stabilization, the assessment of seizure etiology and the initiation of the first phase of AED treatment are typically undertaken concurrently. Etiologic-specific therapy, if appropriate, is directed to treat the underlying cause of seizures and potentially limit associated brain injury. In addition, some seizures may not be controlled effectively with AEDs unless the underlying cause is treated—in particular, seizures associated with metabolic disturbances such as hypocalcemia, hypomagnesemia, and hypoglycemia. Additional etiologic-specific therapies include appropriate antiviral agents, antibiotics, treatments for some in-born errors of metabolism, and, in rare instances, surgery (71).

### Initiation of AED Therapy

The decision to initiate AED therapy is based upon seizure type and seizure frequency and severity. Ideally, only seizures of epileptic origin should be treated with AEDs. These include electroclinical seizures when clinical seizures are witnessed during EEG recording. When clinical observation alone is the basis for management, focal clonic seizures and focal tonic seizures are the seizure types most clearly characterized as epileptic in origin. Clinical events considered nonepileptic in origin are generalized tonic and motor automatisms (those provoked by stimulation and suppressed by restraint) and are typically not treated with AEDs. Electrical seizures without clinical events are also treated with AEDs.

An important, although unresolved issue, is whether all neonates with seizures of epileptic origin should be treated with AEDs, since some are brief, infrequent, and self-limited, presenting only as reaction to an acute CNS insult. It has been argued that these brief, reactive events

many not warrant AEDs, with potential risks of acute and chronic AED therapy perhaps outweighing the potential risks of the seizures themselves. On the other hand, epileptic seizures that are long in duration, frequent, and not self-limited are treated acutely and aggressively with AEDs. The management of seizures with features that fall between these two extremes represent more of a clinical challenge. In clinical practice, almost all neonatal epileptic seizures within this intermediate category receive AEDs.

### Acute AED Therapy

First-line AEDs that are most frequently used and their dosing schedules are listed in Table 14-5 (23, 72–74), although comprehensive clinical trials have not established the most effective regimen (75). The most established strategy is acute treatment with an AED that can be subsequently given as maintenance therapy; most often this is phenobarbital, and less frequently phenytoin or fosphenytoin.

Phenobarbital is given as a loading dose followed by additional boluses titrated to response until the maximum tolerated dose, or serum level in the high therapeutic range, is reached. Boylan and colleagues prospectively assessed the efficacy of phenobarbital utilizing video-EEG monitoring (38) and found that only 4 of 14 infants responded, while the remainder experienced a reduction in electroclinical seizures but an increase in electrical seizures.

After phenobarbital, phenytoin is the AED most often used as a first-line AED, now typically initiated with fosphenytoin because of reports of reduced adverse effects with acute administration (76). Phenytoin administration is increased to maximum tolerated dose or high therapeutic serum levels, and then a maintenance dose is established. Painter and colleagues (77) compared the effectiveness of acute administration of phenobarbital and phenytoin in seizure control and found no significant

difference between the two medications. However, neither proved as efficacious as generally believed.

Another strategy for initial AED treatment is acute administration of repeated doses of short-acting benzodiazepines (lorazepam or midazolam) until seizures are controlled. Chronic AED therapy or maintenance doses are avoided if seizures do not recur.

Control of both the clinical and electrical seizures is ideal but often difficult to achieve or, on occasion, unattainable. Typically, the initial response of electroclinical seizures to acute AED therapy is characterized by control of the clinical seizures with the persistence of the electrical seizure activity, referred to as “uncoupling” (20). While additional dosing may eventually control the electrical seizures (78) there are instances in which the EEG seizures cannot be controlled despite increasing doses of the initial AED and addition of other AEDs.

In current practice, if no EEG is available and the clinician relies only on observation, acute AED therapy is given until clinical seizures are controlled. The first AED is given to serum levels in the high therapeutic range or maximum tolerated dose followed by the second. Benzodiazepines are also given as needed. If EEG is utilized, the same AED strategy is followed. The AEDs are given to achieve high therapeutic serum levels even if electrical seizure discharges persist, since most are often resistant to further AED therapy. A second AED may be added to high serum levels, but if electrical seizures continue unabated, additional drugs are typically not given, beyond a second maintenance AED and dosing of benzodiazepines, in order to avoid adverse effects without significant benefit.

The pharmacology of phenobarbital and phenytoin in the neonate is discussed elsewhere in detail (Chapters 48 and 49). However, there it is important to emphasize that some pathologic conditions can alter the availability of active drug given at standard doses in sick neonates (79–82).

**TABLE 14-5**  
*Dosages of First-Line and Second-Line AEDs in the Treatment of Neonatal Seizures*

DRUG	DOSE		AVERAGE THERAPEUTIC RANGE	APPARENT HALF-LIFE
	LOADING	MAINTENANCE		
Diazepam	0.25 mg/IV (bolus) 0.5 mg/kg (rectal)	May be repeated 1–2 times		31–54 h
Lorazepam	0.05 mg/kg (IV) (over 2–5 min)	May be repeated		31–54 h
Phenobarbital	20 mg/kg IV (up to 40 mg)	3–4 mg/kg in 2 doses	20–40 µg/L	100 h after day 5–7
Phenytoin	20 mg/kg IV (over 30–45 min)	3–4 mg/kg in 2–4 doses	15–25 µg/L	100 h (40–200)

\*Based on Fenichel, 1990 (72); Aicardi, 1994 (73); Volpe, 2001 (74). Table originally from Mizrahi and Kellaway, 1998 (23).

Phenobarbital is a weak acid and is protein bound. Infants with acidosis may have less active AED available, and those with hypoalbuminemia may have greater unbound or active drug available. Both conditions may be found in sick neonates. In addition, the drug is eliminated by the liver and kidney. Infants with impaired hepatic or renal function, such as those with hypoxic ischemic encephalopathy, may have a reduced rate of drug elimination and thus a potential for toxicity with standard dosing. In preterm infants, the half-life of phenobarbital is longer than in term infants, and in term infants it is reduced with chronologic age in the first month of life. Thus, in preterm infants there is a potential for higher serum levels with standard doses, and with that the potential for toxicity. With increasing age, there is the potential for established doses to result in lower serum levels over time, creating the potential for breakthrough seizures with no other change in the infant's clinical condition (74, 83–85).

Important pharmacologic characteristics of phenytoin require individualization of dosing after initiation of therapy. These include nonlinear pharmacokinetics; a variable rate of hepatic metabolism; a decrease in elimination rates during the first weeks of life; and a variable bioavailability of the drug with various generic preparations (86, 87). After initial dosing, there is a redistribution of the AED with a relative drop in brain concentrations after the first dose, which may result in breakthrough seizures with established doses.

### Alternative and Adjuvant AED Therapy

Alternative or adjuvant AEDs fall into two categories: those administered in attempts to control otherwise medically refractory seizures and those used for control of acute seizures. The latter holds the most promise. Agents in both classes have been utilized either intravenously or orally with variable success. Those given intravenously and primarily as alternatives to acute therapy include: clonazepam (88), lidocaine (89), midazolam (90) and paraldehyde (not available in the United States) (91). One recent study reported success with continuous midazolam infusion in the treatment of otherwise uncontrolled neonatal seizures (92), although infants experienced treatment-related hypotension that was medically managed. Midazolam is given first as a 0.15 mg/kg bolus followed by initial continuous infusion of 1 µg/kg/min, titrated by 0.5 to 1 µg/kg/min increments to termination of clinical or electrical seizures or a maximal dose of 18 µg/kg/min. Lidocaine is another medication that has been the topic of renewed interest. Boylan and colleagues (93) reported limited success with lidocaine in refractory neonatal seizures. Others (94) reported that during the use of lidocaine (initial loading dose of 2 mg/kg over 10 minutes followed by a continuous infusion of 6 mg/kg per

hour), 4.8% of infants experienced a cardiac arrhythmia (all responding to lidocaine discontinuation).

Other agents have been given orally to control medically refractory seizures after acute AEDs have failed include carbamazepine (95), primidone (96), valproate (97), vigabatrin (98), and lamotrigine (99). The success of this latter group of AEDs is difficult to assess, since they have been used in conjunction with other AEDs and well into the course of the seizure disorder.

### Chronic AED Therapy

After acute seizures have been controlled, maintenance therapy is typically initiated. However, there are no well-defined criteria for maintenance AED treatment. When chronic therapy is considered, either phenobarbital or phenytoin is given in maintenance doses of 3 to 5 mg/kg/day and serum levels are monitored. There are also no well-established criteria for discontinuation of maintenance AED therapy. Reported schedules range from 1 week up to 12 months after the last seizure, although a currently utilized and successful schedule is to withdraw AEDs 2 weeks after the infant's last seizure (72). At some centers, an EEG is also performed at the end of this 2-week period to be certain there are no subclinical electrical seizures.

### Potential Adverse Effect of AED Therapy

There has been much concern about the potential adverse effects of AEDs on the developing brain. These have included alteration in cell growth and energy substrate utilization, although the applicability of these findings to humans has been called into question. There have been few studies of clinically significant adverse effects of acute AED therapy. However, vigorous acute AED administration can result in CNS depression, hypotension, bradycardia, and respiratory depression. Any of these clinical events represent risk for secondary CNS hypoxia or ischemia. More recently, Ikonomidou and colleagues (100) assessed the effect of phenytoin, phenobarbital, diazepam, clonazepam, vigabatrin, and valproate on apoptotic neurodegeneration in the developing rat brain in plasma concentrations relevant for seizure control in humans. The basis of their study was the consideration that AEDs' mechanisms of action are also those essential for the endogenous neuroprotective system crucial for neuronal survival during development. Thus, they suggested that these vital mechanisms would be blocked by AEDs and have an adverse effect on development. However, it is unclear whether these results can be extrapolated to the human. In addition, recent data from the same group show that another AED, topiramate, lacks the toxicity seen with some of the other drugs mentioned above (101).

## PROGNOSIS

In general, the long-term outcome of neonates with seizures is predominantly determined by the etiology underlying seizure onset, although the relative contribution, if any, of adverse effects of seizures and of AEDs on the developing brain has not been definitively determined.

Early investigators suggested that, even though the immature brain was more likely to develop seizures in response to injury than the more mature brain, either the immature brain was more resistant to seizure-induced injury or any seizure-related alterations were either transient or not clinically significant. More recent data suggests otherwise: Seizures in early life may result in permanent anatomical and functional alterations and enhanced epileptogenicity (102–105). A number of mechanisms of seizure-induced injury have been investigated, including direct neuronal injury; the so-called “double-hit” mechanism of enhanced vulnerability to a second injury after seizures; aberrant cell growth or reorganization of circuitry (104, 106); or the interference of fiber tracts projections during development (102, 107).

Recent findings indicate that seizures in immature animals do not, in the immediate postseizure period, result in significant alterations of learning, memory, or activity levels. However, animals exposed to seizures early in life have demonstrated impairments and alterations in learning and behavior later in life in comparison to those exposed to seizures when mature (108–110). Adverse effects of seizures are more apparent when animals exposed to prolonged seizures early in life are then exposed to seizures when mature (111, 112). Holmes and colleagues (102, 113) indicate that prolonged seizures in immature animals result in minimal behavioral consequences when the animals are studied later in life and are associated with minimal morphological changes. However, such early-onset seizures result in changes in the brain that make it more vulnerable to the development of cognitive impairment when animals are exposed to post-neonatal seizure.

Clinical studies describe the outcome of infants with neonatal seizures in terms of survival, neurological disability, developmental delay, and postneonatal epilepsy. Ortibus and colleagues (114) reported that 28% of those with neonatal seizures died, 22% of survivors were neurologically normal at an average of 17 months of age, 14% had mild abnormalities, and 36% had severe abnormalities. In a prospective study of full-term infants 2 years following neonatal seizures, Mizrahi and colleagues (115) found that 28% died, and in survivors 42.7% had abnormal neurological examinations, 55.2% had Bayley Developmental Assessment of Mental Development Index less than 80, 49.6% had a Bayley Developmental Assessment of Psychomotor Developmental Index less than 80, and 26% had postneonatal epilepsy (115). Brunquell and

colleagues (116) found that 30% of those with neonatal seizures died and 59% of survivors had abnormal neurological examinations, 40% were mentally retarded, 43% had cerebral palsy, and 21% had postneonatal epilepsy after a follow-up to a mean of 3.5 years. Most recently, Tekgul et al (117), describing a selected population, found that 7% of neonates who had experienced seizures died and, of the survivors, 28% had a poor outcome.

Ellenberg and colleagues (118) studied postneonatal epilepsy in more detail. Postneonatal epilepsy occurred in approximately 20% of survivors of neonatal seizures studied; nearly two thirds of post-neonatal seizures occurred within the first 6 months of life (118). Similar rates of postneonatal epilepsy were found by Scher and colleagues (8), 17–30%; Ortibus and colleagues (114), 28%; Bye and colleagues (36), 21%; Mizrahi and colleagues (115), 26%; Brunquell et al (116), 21%; and, most recently Da Silva et al (119), 22% at 12-month follow-up and 33.8% within 48 months. Clancy and Legido (120) found a much higher (56%) rate of postneonatal epilepsy in a population skewed toward severe brain injury.

Some clinical factors that may influence outcome may include seizure duration or severity and seizure type. Some infants who experience brief and infrequent seizures may have relatively good long-term outcomes, while those with prolonged seizures may not do as well. Easily controlled seizures or self-limited seizures may be the result of transient or more benign CNS disorders, whereas medically refractory neonatal seizures may be the result of more sustained, refractory, or more severe brain disorders. On the other hand, a relationship has been shown in infants with perinatal asphyxia between a greater amount of electrographic seizure activity and subsequent relative increased mortality and morbidity (121). Other investigators, utilizing proton magnetic resonance spectroscopy in neonates, found an association between seizure severity and impaired cerebral metabolism measured (122).

However, the dominant variable that predicts neurodevelopmental outcome may be the underlying cause of the seizures rather than the presence, duration or degree of brain involvement of the seizures themselves. Mizrahi and Kellaway (23) analyzed a number of clinical studies indicating that normal outcomes occurred with increasing frequency in association with the following etiologies: HIE, infection, hemorrhage, hypoglycemia and hypocalcemia. In discussing prognosis, Volpe emphasized the clinical factors of gestational age and etiology on outcome and found that mortality increased with the greater degree of prematurity and that specific etiologies were associated with varying degrees of developmental delay. Most recently, Tekgul et al (117) suggested that seizure etiology and background EEG patterns—themselves markers of the degree and distribution of brain injury—remain powerful prognostic factors.

It has been suggested that clinical seizure type may also predict outcome (20), also most likely as a reflection of etiology or the degree of associated brain dysfunction at the onset of seizures. Focal clonic and focal tonic seizures were associated with a relatively good outcome, primarily because these seizure types are typically associated with relatively confined, nondiffuse brain injury and significant spared CNS function. Generalized tonic posturing and motor automatisms were associated with a poor outcome, since they are associated with diffuse CNS dysfunction. Recently Brunquell and colleagues (116) demonstrated similar findings in long-term studies.

In multivariate analyses, predictors of outcome have included features of the interictal EEG from one or serial recordings, the ictal EEG, the neurological examination at the time of seizures, the character or duration of the seizures, etiology, findings on neuroimaging, conceptional age, and birth weight. Multiple rather than single factors appear to be most accurate in predicting outcome. Ortibus and colleagues (114) found that the predicted

outcome is less reliable when based solely on EEG variables from a single recording obtained at seizure onset than when based on a combination of imaging findings and clinical and EEG data. Pisani and colleagues (123) also considered several different independent variables and found the character of the EEG background activity is predictive of developmental outcome. However, in these studies all variables related to a single factor—the degree of brain injury at the time of seizure occurrence—and this, in turn, is related to etiology.

## Severe Encephalopathic Epilepsy in Early Infancy

*Shunsuke Ohtahara  
Yasuko Yamatogi*

**F**rom the neonatal to the early infantile periods, seizures are relatively rare, compared with other periods of childhood, because of the structural and biochemical immaturity of the brain, which may regulate the seizure susceptibility or threshold. Only a few epileptic syndromes have their onset during these periods, and most of them are severe epilepsies (1). Peculiar representatives are early-infantile epileptic encephalopathy with suppression bursts or Ohtahara syndrome (OS) (2) and early myoclonic encephalopathy (EME) (2, 3). Both syndromes are classified as symptomatic generalized epilepsies with nonspecific etiology according to the present international classification (1), and are designated as epileptic encephalopathies in a newly proposed diagnostic scheme of International League Against Epilepsy (ILAE) classification (4). They could be inclusively called “early infantile epileptic syndromes with suppression-burst” or “severe neonatal epilepsies with suppression-burst pattern” (3) because of shared common characteristics: very early onset with frequent minor seizures and suppression-burst (S-B) pattern on the electroencephalogram (EEG).

### EARLY-INFANTILE EPILEPTIC ENCEPHALOPATHY WITH SUPPRESSION BURSTS OR OHTAHARA SYNDROME

Ohtahara syndrome was first described by Ohtahara and coworkers in 1976 (5) as the earliest form of an age-dependent epileptic encephalopathy, and it is characterized by frequent tonic spasms of early onset within the first few months of life and a S-B EEG pattern (6–8). Its evolutionary change with age is specific (2, 3, 6, 9–12). The seizures are refractory to medications and the prognosis for neurological development is very poor.

The age-dependent epileptic encephalopathy includes OS, West syndrome (WS), and Lennox-Gastaut syndrome (LGS). Although each of these syndromes is an independent electroclinical entity with its own special features, they have the following common characteristics (5–9, 12, 13):

1. Onset during a specific period of life
2. Peculiar types of frequent, minor generalized seizures
3. Severe and continuous massive epileptic EEG abnormality

4. Heterogeneous cause
5. Frequent association with mental defect
6. Therapy resistance and grave prognosis

Furthermore, transition is often observed over time among patients with these syndromes. A considerable number of OS cases evolve into West syndrome and from West to Lennox-Gastaut syndrome in their clinical course (9–12). Because of these common characteristics and mutual transition with age, the inclusive term *age-dependent epileptic encephalopathy* has been applied to this group of syndromes (7, 13). “Epileptic encephalopathy” was applied to them according to the following four characteristics: (1) the presence of serious underlying disorders, (2) extremely frequent seizures, (3) continuously and diffusely appearing marked epileptic abnormality on EEG, and (4) mental deterioration often manifesting with the persistence of seizures.

As the electroclinical features specific to each syndrome appear on the basis of many causes commonly observed in the three syndromes, the age factor should be considered as the determinant for the manifestation of their individual characteristics. These syndromes, therefore, may be the age-specific epileptic reaction, at a special developmental stage, to various nonspecific exogenous brain insults.

### Epidemiology

Several dozens of cases of OS have been reported, but its incidence is rare compared with those of West and Lennox-Gastaut syndromes. An epidemiological study on childhood epilepsy carried out in Okayama, Japan, in 1980, detected one case of OS (0.04%) and four cases of EME (0.17%) among 2,378 epileptic children younger than 10 years of age (14). Compared to the 40 cases (1.68%) of WS observed in the same study, the prevalence of OS and EME is low. Similarly, Kramer et al (15) described one case of OS (0.2%) and 40 cases of WS (9.1%) in a cohort of 440 consecutive children with epilepsy under 15 years of age in Tel Aviv, Israel. Thus, the relative prevalences of OS and EME to WS may be 1:40 or less and 1:10 or less, respectively.

No obvious sex difference has been observed in either syndrome.

### Clinical Manifestations

The onset of seizures is very early and is confined to the first 2 or 3 months after birth, mainly the first month. The main seizure type is tonic spasms with or without clustering. The duration of each tonic spasm is up to 10 seconds. One cluster consists of 10 to 40 spasms, at intervals of 5 to 15 seconds. These epileptic spasms occur not only in waking states but also during sleep states in most cases. Daily seizure frequency is very high, ranging from 100 to 300 isolated spasms or 10 to 20 series in those with

clustering spasms. In addition to tonic spasms, partial seizures such as erratic focal motor seizures and hemiconvulsions are observed in about one-third of the cases. In contrast to EME, myoclonic seizures or myoclonia are rarely observed (2, 6).

### EEG Findings

The most characteristic feature is the S-B pattern, which is persistently observed regardless of the circadian cycle (Figure 15-1). This is a diagnostically most important and indispensable finding. The S-B pattern is characterized by high-voltage bursts alternating with nearly flat patterns at an approximately regular rate. Bursts of 1 to 3 seconds' duration comprise 150 to 350  $\mu$ V high-voltage slow waves intermixed with multifocal spikes. Duration of the suppression phase is 3 to 5 seconds. The burst-burst interval, measured from onset to onset of the bursts, ranges from 5 to 10 seconds. Presumably reflecting the underlying organic brain lesion, some asymmetry in S-B occurs in about two-thirds of cases, but no remarkable asynchrony is found except for the case of Aicardi syndrome (16).

The ictal EEG of tonic spasms shows principally a desynchronization with or without evident, sometimes remarkable, initial rapid activity (6, 11). A low-voltage fast activity is also often observed. Tonic spasms appear concomitant with bursts. Partial seizures usually originate in some fixed foci and are followed by tonic spasms in series, or sometimes they follow them.

### Other Investigations

Brain imaging such as computed tomography (CT) and magnetic resonance imaging (MRI) reveal structural abnormalities, notably asymmetric lesions even at the early stage of seizure onset in most cases. Progressive brain atrophy is often suspected with seizure persistence, particularly in infancy. No abnormalities are found in routine laboratory examinations of blood, urine, cerebrospinal fluid, bone marrow, and liver functions, or in metabolic studies including amino acids, lysosomal enzymes, pyruvate and lactate, and organic acids, or in immunological and virological examinations.

### Etiology

Although the causes of OS are heterogeneous, obvious brain lesions including brain malformations are often found. Porencephaly, Aicardi syndrome (3, 16), hemimegalencephaly (17–19), olivary-dentate dysplasia (20, 21), lissencephaly, linear sebaceous nevus (22), Leigh encephalopathy (23), and subacute diffuse encephalopathy (3) have all been associated with the syndrome. In a few cases no cause has been identified, and these are labeled cryptogenic (3). But cryptogenic cases may have undetectable

FIGURE 15-1

Interictal EEG (Ohtahara syndrome). Two-month-old boy. High-voltage bursts and almost flat suppressions alternately repeat continuously and consistently throughout the waking (upper) and sleeping (lower) states. The horizontal calibration mark, 1 second; the vertical one, 50  $\mu$ V.

microdysgenesis or migrational disorders that cause the progressive atrophy during follow-up (6). Postmortem pathologic examination has sometimes disclosed significant abnormalities in cases with no evident abnormalities on neuroimaging (18). Metabolic disorder was not reported except in rare cases of cytochrome c oxidase deficiency or Leigh encephalopathy (3).

### Treatment and Prognosis

Seizures are intractable. Natural or synthetic adrenocorticotropic hormone (ACTH) therapy is partially effective in only a few cases (6). Clobazam, acetazolamide, vitamin B<sub>6</sub>, valproate, vigabatrin, and zonisamide are recommended to be tried (6). Successful resection of focal cortical dysplasia is reported (24, 25). Although seizures possibly subside by school age in about half of the cases, developmental and life prognoses are very poor. All those who survive are severely handicapped, both mentally and physically. Mortality is high, especially in the early stage of the disease (6).

## EARLY MYOCLONIC ENCEPHALOPATHY

Early myoclonic encephalopathy is a rare epileptic syndrome of very early onset with frequent myoclonias and partial seizures, and S-B in the EEG. It was first described by Aicardi and Goutières (26) in 1978.

### Clinical Manifestations

The onset of seizures is in the first 3 months of life, mostly during the neonatal period. The cardinal seizures are myoclonias, which are mostly fragmentary. Frequent erratic partial seizures, massive myoclonias, and tonic spasms are also seen. Among these types of seizures, fragmentary myoclonias are the essential symptom in EME and the initial seizure type in most cases (2–3, 26). They may occur within the first several hours of life or perhaps even prenatally (27).

Such myoclonias are characterized by only a slight twitching of the distal ends of the extremities, eyelids, and corners of the mouth, and are sometimes too subtle to be detected without careful observation. The frequency of these myoclonias varies greatly from several times a day to several dozen times a minute. The ictal EEG usually shows no consistent change with myoclonia, although some myoclonias coincidentally occur with bursts (2, 28). This suggests that myoclonias in EME are mainly of a nonepileptic type.

Throughout the course of the syndrome, the main seizure types are partial seizures; those include complex partial seizures with eye deviation or autonomic symptoms such as apnea and facial flushing, clonic seizures

of various parts of the body, and asymmetric tonic posturing with or without generalization. Partial seizures simultaneously associated with erratic myoclonias are particularly characteristic of this syndrome (2, 3, 29). Partial seizures have a tendency to cluster in the early stage. They are seen during both waking and sleep states. The frequency of partial seizures is remarkably high, ranging from 7 to 8 times to 30 to 100 times a day, but decreases with age.

Tonic spasms are also often observed, but massive myoclonias and tonic spasms are not necessarily observed in all cases. Cases with tonic spasms are considered WS when tonic spasms appear at 3 to 4 months of age. The period of WS is, however, transient, and the EME state recurs and persists for a long period thereafter (28, 30). Tonic spasms are usually seen during both waking and sleeping states and appear either in series or in isolation. Tonic spasms in series sometime appear following a partial seizure, but a partial seizure may appear just after tonic spasms in other occasions or infants.

### EEG Findings

Interictal EEG of EME is also characterized by a S-B pattern with bursts lasting 1 to 5 seconds and nearly flat periods of 3 to 10 seconds. This pattern becomes more distinct during sleep and more pronounced as sleep deepens (28, 29) (Figure 15–2).

The S-B pattern tends to be replaced by atypical hypsarrhythmia or by multifocal paroxysms after 3 to 5 months of age. In most cases, however, the appearance of atypical hypsarrhythmia is transient, lasting up to 2 years 6 months of age at the latest (28, 30), after which the S-B pattern returns again and persists for a long period thereafter (28, 30). In addition to the S-B pattern, multifocal spikes persist throughout the clinical course. The location of spike foci varies in every case and is not consistent in a given patient.

With the ictal EEG of partial seizures, various patterns of focal onset, such as fast activity, alpha or theta patterns, rhythmic sharp waves, and irregular spike waves, are observed, usually from two or more sites with migration in each individual case (2, 28–31). Ictal EEG of tonic spasms shows desynchronization, which appears concomitant with bursts. Myoclonic seizures also occur during bursts (31, 32).

### Other Investigations

Neuroimaging is often normal at the onset, but progressive cortical and periventricular atrophies are observed in some cases (2–3, 29). Abnormalities are often detected from 3 to 10 months of age, that is, 3 to 8 months after the onset. Diffuse cortical atrophy is noted

FIGURE 15-2

Interictal EEG (early myoclonic encephalopathy). Six-month-old girl. Multifocal spikes are noted frequently in the disorganized background activity in the waking record (upper), but suppression-burst pattern is apparent in the sleeping record (lower).

in all, with associated ventricular dilatation in some cases, but focal abnormalities are exceptional.

### Etiology

The most striking feature of this disorder is the high incidence of familial cases as found in 4 of 12 families in the series of Aicardi and Ohtahara (3) and 2 of 8 families in the series of Dalla Bernardina et al (29). This suggests the etiologic participation of some kinds of genetic and congenital metabolic errors in many cases. Nonketotic hyperglycinemia (32–34), propionic acidemia, methylmalonic acidemia, and D-glyceric acidemia, carbamyl-phosphate synthetase deficiency (34), pyridoxine-dependency, molybdenum cofactor deficiency, Menkes disease (3, 35), and Zellweger syndrome (36) have been reported to be associated with EME. In many cases; however, the cause remains unknown.

### Treatment and Prognoses

None of the conventional antiepileptic drugs, ACTH, corticosteroids, or pyridoxine has been effective, excepting pyridoxine-dependency (3). Both partial seizures and myoclonias, however, decrease gradually with age. EME has an extremely poor prognosis including a high mortality, with death usually occurring before 2 years of age. Survivors have persistent partial seizures and progressive psychomotor deterioration to a vegetative state (3, 29).

### DEVELOPMENTAL ASPECTS

Compared to EME, the remarkable characteristic of OS is its age-dependent evolutionary change. It develops from OS to WS in middle infancy, particularly during 3 to 6 months of age, in many cases, and further from WS to LGS in early childhood, at 1 to 3 years of age, in some cases (12, 30).

The EEG also evolves from the S-B pattern to hypsarrhythmia in many cases at around 3 to 6 months of age, and further from hypsarrhythmia to diffuse slow spike-waves in some cases at around 1 year of age (9,12). Some cases evolve further to the severe epilepsy with multiple independent spike foci (37).

Concerning the changing process of S-B pattern in OS, its transition to hypsarrhythmia starts with a gradual increase in the amplitude of the suppression phase. Disappearance of the S-B pattern in waking precedes that in sleep, and S-B remains in the sleeping EEG even after the waking EEG has already transformed to hypsarrhythmia. In the course of evolution from hypsarrhythmia to diffuse slow spike-waves, the change in the waking EEG is followed by the change in the sleep EEG. Thus, the evolution from a S-B pattern to hypsarrhythmia and further to diffuse slow spike-waves

proceeds in a close relation with the waking and sleeping cycle (2, 9, 12, 30). The timing of transition among the three epileptic syndromes and EEG patterns is specific; evolving syndromes and EEG patterns appear at characteristic ages.

EME, however, manifests no fundamental change in the electroclinical feature throughout its course, except for the EEG change from suppression-burst or burst-suppression pattern to a disorganized pattern with frequent multifocal spikes that occur within several months of life (3, 26, 29) and transient manifestation of WS and hypsarrhythmia in some cases (28, 30).

### DIFFERENTIAL DIAGNOSIS

#### Differential Diagnosis between OS and WS

The age of onset of the two syndromes is different: OS appears from the neonatal to early infantile periods and WS in middle infancy. Although the main seizure type is tonic spasms in both syndromes, tonic spasms in OS appear not only while awake but also during sleep, and not only in clusters. Partial seizures also occur in some OS cases but are rare in WS. Most cases with OS have severe cortical pathology, often displaying asymmetric lesions on neuroimaging.

The EEG discriminates the S-B pattern in OS from hypsarrhythmia in WS. The S-B pattern differs from the periodic type of hypsarrhythmia in which periodicity becomes evident only during sleep.

Seizures are more intractable in OS, and ACTH therapy is usually not effective. Furthermore, children with OS have less favorable prognoses than those with WS.

#### Differential Diagnosis between EME and OS

As EME and OS have common clinical and electrical characteristics such as early onset within a few months of life and the S-B pattern on EEG, differentiation may be difficult (28, 30). The main seizure type is tonic spasms, and myoclonias are rarely seen in OS. In contrast, myoclonias, especially erratic myoclonias, and frequent partial seizures predominate in EME (28, 30).

Electroencephalographically, the S-B pattern is a common feature of both syndromes, but its relation to the circadian cycle and age of its appearance and disappearance differ considerably. The S-B pattern in OS is characterized by consistent appearance during both waking and sleeping states, whereas in EME it is enhanced by sleep and often not manifest in the waking state. Concerning the duration of appearance, the S-B pattern appears at the beginning of the disease and disappears within the first 6 months of life in OS, whereas in EME, it becomes distinct at 1 to 5 months of age

in some cases and characteristically persists for a long period (28, 30).

The evolution of the EEG abnormalities during the clinical course is a characteristic feature of OS: from the S-B pattern to hypsarrhythmia in many cases and further from hypsarrhythmia to diffuse slow spike-waves in some cases (2, 11, 12, 30). In EME, the S-B pattern persists for a long time, although atypical hypsarrhythmia appears transiently in some cases. Therefore, the age-related evolutionary pattern differs considerably between OS and EME (30).

Regarding epileptic syndromes, OS shows a characteristic evolution as the earliest form of the age-dependent

epileptic encephalopathy, whereas EME has no specific evolution with age (28, 30).

Etiologically, OS is usually based on evident organic brain lesions including brain malformations. Neuroimaging demonstrates abnormal findings even at the early stage. No familial cases have been reported in OS. In contrast, the frequent incidence of familial cases suggests some undetermined inborn metabolic disorders as the cause in many cases of EME.

The differences between OS and EME indicate that they are independent electroclinical entities (30). Efficiency of the developmental study should be stressed to clearly delineate both syndromes.

## Severe Encephalopathic Epilepsy in Infants: Infantile Spasms (West Syndrome)

*Richard A. Hrachovy  
James D. Frost Jr.*

### INTRODUCTION AND DEFINITION

Infantile spasms (West syndrome) is a unique disorder that is peculiar to infancy and early childhood. More than 75 different names have been applied to the disorder (1), including massive spasms, flexion spasms, jackknife seizures, infantile myoclonic seizures, and the like, and they have been recognized as an epileptic phenomenon since they were first described by William West in 1841 (2). Approximately 100 years later, Gibbs and Gibbs (3) described the interictal electroencephalogram (EEG) pattern, hypsarrhythmia, which was noted to occur in a large number of patients with infantile spasms. Most patients with infantile spasms have some degree of mental and developmental retardation. In 1958, the first therapeutic breakthrough was reported by Sorel and Dusaucy-Bauloye (4), who observed improvement in EEGs and amelioration of spasms in patients treated with adrenocorticotrophic hormone (ACTH).

A considerable amount of literature pertaining to this disorder has accumulated over the past several decades. However, classifications and clinical descriptions of the seizures, based largely on routine bedside observations, have been highly variable, and this lack of uniformity has led to considerable confusion and controversy. Our understanding of the clinical manifestations of this disorder was greatly increased by the development of

long-term polygraphic-video monitoring techniques in the 1970s (5). These techniques also provided objective means of evaluating the acute effects of therapy on seizure frequency and the EEG. The introduction of computed tomography (CT), magnetic resonance imaging (MRI), and positron emission tomography (PET) scanning in the 1970s and 1980s greatly increased our understanding of associated brain abnormalities seen in these patients. Such information has not only been helpful in the classification of patients (symptomatic versus cryptogenic) but has also aided our understanding of the possible pathophysiological mechanism(s) underlying this condition.

In this chapter, we briefly describe the clinical and EEG features of infantile spasms and review some of the more controversial and as yet unresolved issues, including therapy and pathophysiology.

### EPIDEMIOLOGY

Although the reported incidence of infantile spasms has ranged from 0.05 to 0.60 per 1,000 live births, the average incidence of this disorder is approximately 0.31 per 1,000 live births (1 in 3,225 live births) (1, 6). Spasm onset is usually within the first 4 to 8 months of life with a peak at 6 months. Most cases occur before 3 years of age. Although several studies have reported that infantile

spasms occur more commonly in males, there is no clear evidence of a preponderance of one sex over the other (1).

The information concerning the familial occurrence of infantile spasms is limited. The percentage of patients who have a family member with infantile spasms has ranged from none to 7% (7–9). The percentage of cases having a positive family history for any type of epilepsy has ranged from none to 33% (7, 10–14). A major problem with most of these studies is that the authors do not provide comparable data for normal subjects.

## CLINICAL MANIFESTATIONS

### Description of Spasms

The motor spasm typically consists of a brief, bilaterally symmetrical contraction of the muscles of the neck, trunk, and extremities. This muscle activity is typically characterized by an initial phasic contraction lasting less than 2 seconds, which may be followed by a less intense, but more sustained, tonic contraction lasting up to 10 seconds in duration. The exact character of the seizure depends on whether the flexor or extensor muscles are predominantly affected and on the distribution of the muscle groups involved (5, 15). The position of the body (e.g., supine versus sitting) usually influences the type of spasm. The intensity of the spasm may vary from a massive contraction of all flexor muscles, resulting in a jack-knife at the waist, to a minimal contraction of muscles such as the abdominal recti.

Three main types of motor spasm have been identified: flexor, extensor, and mixed flexor-extensor. In our polygraphic-video monitoring experience, mixed spasms were the most frequent (approximately 42%), followed by flexor spasms (approximately 34%), and extensor spasms were the least common (approximately 25%). Asymmetrical spasms were rare (less than 1%). Periods of attenuated responsiveness, which have been termed *arrest phenomena*, may occur following a motor spasm or may occur independently. Most infants with this disorder have more than one type of spasm (15, 16).

A variety of clinical phenomena have been reported to occur in association with the motor spasms. These include autonomic changes (heart rate alterations, cyanosis, pallor, sweating, and flushing), respiratory rate changes, vocalizations (crying, laughter, and grunting sounds), hiccups, smiling, grimacing, tongue and mouth movements, and ocular events (eye deviation, nystagmus, eye opening or closing, pupillary dilation, and tearing).

Monitoring studies have shown that there is little variation in the number of spasms recorded from the same patient in consecutive 24-hour monitoring periods; however, there is a marked variation in spasm frequency

when patients are monitored at 2-week intervals (17). The number of spasms recorded during 24-hour periods has ranged from a handful to several hundred in different patients (15, 16).

Approximately the same number of spasms occurs during the day as at night; however, the spasms rarely occur when the infant is actually asleep (less than 3%) (18–20). Instead, they frequently occur immediately upon, or soon after, arousal (10, 12, 15, 16, 21, 22). The spasms are not precipitated by feeding or photic stimulation but may occasionally be elicited by tactile stimulation or unexpected loud noises, although this is uncommon (15).

Although spasms may occur in an isolated fashion, they frequently occur in clusters, with clusters being reported in 47% to 84% of cases (13, 15, 16, 20, 23). In the series reported by Kellaway et al (15), the number of spasms per cluster varied from 2 to 138. Succession rates of up to 15 spasms per minute were recorded, and the intensity of the motor spasms within a cluster would usually wax and then wane.

### Spontaneous Remission

The phenomenon of spontaneous remission of infantile spasms is poorly understood. Published data concerning the duration of this disorder have been infrequent and imprecise. In 1973, Jeavons and coworkers (24) reported that 28% of patients were free of spasms by 1 year of age, 49% before age 2, 65% before age 3, and 74% by age 4. Unfortunately, some of their patients had been treated with steroids, and EEG findings were not presented. To further investigate spontaneous remission in this disorder, we retrospectively studied 44 patients who had not been treated with hormonal drugs (25). Our results indicated that spontaneous remission of spasms and disappearance of the hypsarrhythmic EEG pattern can begin within 1 month of the onset of this disorder and that 25% of patients with infantile spasms experience spontaneous remission within 1 year.

Spontaneous remission in two consecutively identified patients with infantile spasms being evaluated for possible admission to a trial of ACTH therapy is illustrated in Figures 16-1 and 16-2. This phenomenon must always be remembered when interpreting results of any therapeutic trial in this disorder and must also be considered in discussing possible pathophysiological mechanisms underlying infantile spasms.

### Coupling of Spasms with Other Seizures

The coexistence of partial seizures and spasms in patients with infantile spasms has been recognized for many years (10, 12, 14, 26–28). Partial seizures may appear before the onset of spasms, concurrently with spasms, or after

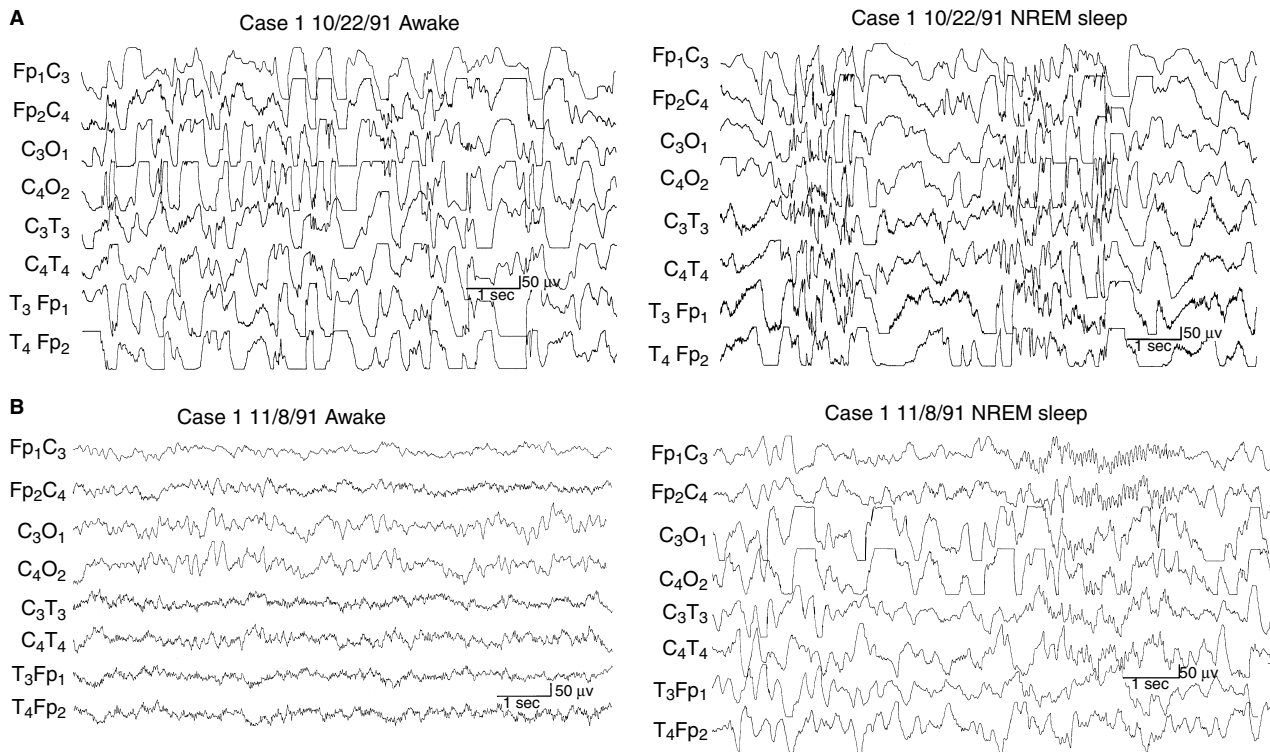

FIGURE 16-1

Spontaneous remission in a 7-month-old girl with cryptogenic infantile spasms. ACTH was not initiated in this patient because of a concurrent infection. Representative samples of the awake and NREM-sleep EEG selected from 18-channel-24-hour polygraphic-video monitoring records. (A) Recording at the time of diagnosis shows hypsarrhythmia. Spasms were recorded. (B) Repeat study 3 weeks later showing normal activity awake and during NREM sleep. Awake sample shown was taken with the patient's eyes open (eyes-closed recording revealed a well-defined occipital rhythm of 5–5.5 Hz). No spasms were recorded during the 24-hour monitoring study.

spasms have ceased, either spontaneously or following treatment. Recently, there has been increased interest in the observation that in some patients with infantile spasms focal electrical seizure discharges (FS) may be tightly coupled with spasms. Our group first described this association in 1984 (29), and since that time several additional reports of this phenomenon in small groups of patients have appeared (30–35). Although this is an interesting phenomenon, its significance remains uncertain. These observations have been used by some investigators to support the hypothesis that infantile spasms occur as a result of an interaction between a primary cortical generator and subcortical structures (see subsequent section). To further investigate the significance of the temporal coupling of FS and spasms, we analyzed the video-EEG studies performed on 96 consecutive patients newly diagnosed with infantile spasms and hypsarrhythmic EEGs (36). Ten of these patients also demonstrated FS; however, in only five patients was there an apparent coupling of FS with spasms. More importantly, in only three patients (3% of the entire population) was the observed coupling

statistically significant. Three different couplings were documented: FS could precede a cluster of spasms, could occur during a cluster of spasms, or could follow a cluster of spasms. FS always arose independently from various sites in a given patient, and in some patients coupling of spasms and FS always occurred on arousal from sleep.

Our conclusion from this study is that coupling of FS and spasms at the time of diagnosis of infantile spasms occurs only rarely. We believe there are several possible explanations for this coupling phenomenon. In some instances, apparent coupling may best be explained by random coincidence. A second possibility is that FS may facilitate or induce the appearance of spasms (or vice versa), as has been the major explanation suggested by others. Finally, the coupling of spasms and FS may result from the effect of some "critical factor" that simultaneously affects the seizure thresholds of the neuronal systems involved in the generation of both seizure types. This final hypothesis assumes that in the presence of the critical factor, the seizure thresholds for FS and epileptic spasms are concurrently altered, resulting in the simultaneous or

FIGURE 16-2

Spontaneous remission in a 5-month-old boy with symptomatic infantile spasms. The parents refused to give permission for treatment. Representative samples of the awake and NREM-sleep EEG selected from 18-channel 24-hour polygraphic-video monitoring records. (A) Recording at the time of initial diagnosis shows hypsarrhythmia. Spasms were recorded. (B) Repeat study 3 weeks later, showing normal background for age. NREM-sleep sample shows right temporal spikes. Left temporal spikes (not shown) were also present in the sleep tracing. No spasms were recorded during the 24-hour monitoring study.

near simultaneous occurrence of both seizure types. In some of our patients the critical factor appeared to be the arousal mechanism, a known potent activator of spasms and other seizures.

Tonic seizures may also be coupled with spasms, and these two seizure types may be difficult to differentiate because the clinical and EEG features are very similar. The major distinguishing features between the two are that tonic seizures usually are more prolonged and lack the intense initial phasic component seen with most spasms. An interesting observation is that tonic seizures may rarely immediately precede a cluster of spasms. A review of video-EEG monitoring studies of 57 consecutive patients with infantile spasms revealed coupling of tonic seizures with spasms in three (5%) cases (personal observations). Because of the similarities between tonic seizures and spasms, it is likely that these two seizure types are

generated by a similar mechanism and arise from the same region of the brain, possibly the brainstem.

## ELECTROENCEPHALOGRAPHIC FEATURES

### Interictal Patterns

The interictal pattern most commonly associated with infantile spasms is hypsarrhythmia (Fig 16-3), which was originally defined by Gibbs and Gibbs (3) as follows:

. . . random high voltage slow waves and spikes. These spikes vary from moment to moment, both in duration and in location. At times they appear to be focal, and a few seconds later they seem to originate from multiple foci. Occasionally the spike discharge becomes generalized, but it never appears as a rhythmically

FIGURE 16-3

Hypsarrhythmia. Digital recording from a 6-month-old male.

repetitive and highly organized pattern that could be confused with a discharge of the petit mal or petit mal variant type. The abnormality is almost continuous, and in most cases it shows as clearly in the waking as in the sleeping record.

This prototypic pattern is usually seen in the early stages of the disorder and most often in younger infants (younger than 1 year of age). The pattern has been reported in 7% to 75% of patients with infantile spasms (10, 12, 37–41). In addition, variations or modifications of this pattern may be seen in many patients. In 1984, we identified five variations of the originally described pattern after reviewing the 24-hour EEG-video monitoring studies in 67 infants with infantile spasms (29). These variations include hypsarrhythmia with a consistent focus of abnormal discharge, hypsarrhythmia with increased interhemispheric synchronization, hypsarrhythmia comprising primarily high-voltage, slow-wave activity with very little spike or sharp wave

activity, asymmetrical or unilateral hypsarrhythmia, and hypsarrhythmia with episodes of generalized, regional, or localized voltage attenuation, which, in its maximal expression, is referred to as the “suppression-burst variant.” These variations were subsequently confirmed by Alva-Moncayo et al (37) in 100 cases.

In addition to demonstrating these basic variations, 24-hour EEG-video monitoring studies have shown that hypsarrhythmia is a highly dynamic pattern, with transient alterations in the pattern occurring throughout the day. The hypsarrhythmic activity tends to be most pronounced and to persist to the latest age in slow-wave (non-rapid-eye movement [NREM]) sleep. During NREM sleep there is a tendency for grouping of the multifocal spike and sharp wave discharges resulting in a quasi-periodic appearance of the background activity (29, 42, 43). Also during NREM sleep, attenuation episodes frequently occur. The hypsarrhythmic pattern is least evident or completely absent during REM sleep, when the background activity may

**FIGURE 16-4**

Digital recording from a 6-month old male showing ictal EEG change associated with infantile spasms. Note the period of voltage attenuation associated with superimposed fast activity.

appear normal (42). Transient disappearance or reduction of the hypsarrhythmic activity is usually seen on arousal from sleep; this normalization may last from a few seconds to many minutes. In addition, there is usually a reduction or disappearance of the hypsarrhythmic pattern during a cluster of spasms, with the pattern returning immediately following cessation of the spasms (15).

Although hypsarrhythmia or one of its variants is most commonly seen in patients with infantile spasms, several other interictal patterns may occur (1, 26). These include diffuse slowing of the background activity, focal slowing, focal or multifocal spikes and sharp waves, generalized slow-spike-and-slow-wave activity, focal depression, paroxysmal slow or fast bursts, or continuous spindling. These patterns may occur in isolation or in various combinations. In a

small number of infants, the background activity may appear normal.

### Ictal Patterns

A variety of ictal EEG patterns have been identified (15). These include generalized slow-wave transients, sharp-and-slow-wave transients, and attenuation episodes, occurring alone or with superimposed faster frequencies. These patterns occur singly or in various combinations. However, the most common ictal EEG change is a generalized slow-wave transient, followed by an abrupt attenuation of background activity in all regions (Fig 16-4). The duration of the ictal EEG event may range from less than 1 second to more than 1 minute, with the longer episodes being associated with arrest phenomena. Also, episodes of generalized voltage attenuation may occur in

the absence of clinical spasms. These observations have been confirmed by many authors (16, 33, 44–55). There is no close correlation between the character of the ictal EEG event and the type of spasm, with the exception that an asymmetric ictal pattern usually correlates with focal or lateralized brain lesions (47, 56).

### PATHOPHYSIOLOGY

The pathophysiological mechanism underlying infantile spasms is not known, and a suitable animal model exhibiting the major clinical and electroencephalographic features of this disorder has yet to be developed. At present, it is not even known whether the disorder occurs in any species other than humans. For those interested in a thorough discussion of the proposed pathophysiological mechanisms underlying this disorder, it is suggested that the reader review our recently published study on this topic (1). Here, we will provide only a brief overview of some of the hypotheses that have been proposed.

Considerable evidence implicates the brainstem as the area in which epileptic spasms and the hypsarrhythmic EEG pattern originate (42, 57–61). We previously described a pathophysiological model of infantile spasms, based on our long-term polygraphic-video monitoring experience (42, 62), which suggested that dysfunction of certain monoaminergic or cholinergic regions of the brainstem involved in the control of sleep cycling may be responsible for the generation of the spasms and the EEG changes seen in this disorder (62). According to this model, the clinical spasms would result from phasic interference of descending brainstem pathways that control spinal reflex activity, whereas the hypsarrhythmic EEG pattern, and perhaps the cognitive dysfunction seen in these patients, would result from activity occurring in ascending pathways projecting from these brainstem regions to the cerebral cortex. Various other investigators have also suggested that dysfunction of monoaminergic neurotransmitter systems may be responsible for the generation of epileptic spasms (63–68). It has also been reported that corticosteroids (65) and ACTH (69) suppress central serotonergic activity, a finding consistent with this brainstem hypothesis. However, this model did not exclude the possibility that these critical brainstem region(s) might be affected by distant sites, because the brainstem sleep system receives input from many other areas (62). Several years later, Chugani and coworkers (60, 70) expanded our hypothesis. Primarily on the basis of PET scan studies, these authors suggested that the brainstem dysfunction causing infantile spasms was produced by an abnormal functional interaction between the brainstem (raphe nuclei) and a focal or diffuse cortical abnormality. According to this hypothesis, the cortical

abnormality exerts a noxious influence over the brainstem from where the discharges spread caudally and rostrally to produce spasms and the hypsarrhythmic EEG pattern. The association of partial seizures with infantile spasms (described previously) was further evidence used to support the hypothesis that a primary cortical generator interacts with subcortical structures, resulting in infantile spasms. This model provides for the observation that a subset of infantile spasms patients with localized lesions in the cortex may have cessation of seizures and improved EEGs after resection of focal cortical lesions (70–73). A similar model proposing that spasms arise from subcortical structures was provided by Dulac et al (74). This group hypothesized that the epileptic spasms result from a functional deafferentation of subcortical structures such as the basal ganglia caused by abnormal cortical activity, but the hypsarrhythmic EEG pattern directly reflects the cortical dysfunction. A cortical-subcortical interaction was also postulated by Avanzini et al (75) and Lado and Moshe (76).

Another major hypothesis is that infantile spasms is the result of a defect in the immunological system (62, 77, 78). Supportive evidence for this hypothesis includes the presence of antibodies to extracts of normal brain tissue in the sera of patients with infantile spasms (79, 80), the presence of increased numbers of activated B cells and T cells in the peripheral blood of patients with infantile spasms (81), and abnormal leukocyte antigen studies in patients with infantile spasms compared with control subjects (82–84). Although these findings indicate abnormal immune function in patients with infantile spasms, there is no direct evidence that an immunologic defect causes this disorder.

Another hypothesis is that corticotropin-releasing hormone (CRH) may play a mechanistic role in infantile spasms (85–87). According to this model, stress or injury during early infancy results in the release of excess amounts of CRH, which in the presence of an abundance of CRH receptors, produces epileptogenic alterations in the brainstem pathways that result in spasms. The therapeutic benefit of corticosteroids and ACTH in this disorder would be secondary to the suppression of CRH synthesis by these hormones. However, although injection of CRH into the brains of infant rodents does produce seizures, the ictal behaviors and EEG features are not typical of those seen in the human condition (88). In addition, CRH levels are not elevated in the cerebrospinal fluid (CSF) of patients with infantile spasms (86). Furthermore, treatment of patients with infantile spasms with a competitive antagonist of CRH did not alter spasm frequency or significantly change the EEG pattern (89).

Several additional pathophysiological mechanisms underlying this disorder have also been proposed. It has been suggested that infantile spasm results from a failure or delay of normal developmental processes (90). This theory is based largely on the assumption that ACTH and

corticosteroids accelerate certain normal developmental processes in immature animals (91–95).

Also, several biochemical and metabolic disturbances have been reported in patients with infantile spasms. These include dysfunction of metabolic pathways for neuropeptides, pyridoxine, and amino acids, such as aspartate, glutamate, and gamma-aminobutyric acid (1).

Finally, there are 13 genetically based conditions associated with infantile spasms (1), some of which involve the same region of the X chromosome. For example, Aicardi syndrome has been associated with X chromosome abnormalities near Xp22 (96). Patients with incontinentia pigmenti type I have abnormalities in the same region, with evidence of X/autosomal translocation at Xp11 (97). Patients with X-linked infantile spasms have mutations involving the ARX gene located on the X chromosome at Xp22 (98–102) and the CDKL5 (STK9) gene (103–109). Pyruvate dehydrogenase complex deficiency, a metabolic defect associated with infantile spasms, has been localized to Xp22.1–Xp22.2, a region similar to that associated with X-linked infantile

spasms (110). These findings suggest that defects in the involved region of the X chromosome and products of the involved gene (or genes) may play a role in the pathophysiology of this disorder (1, 101, 111).

Recently, we proposed a new model concerning the pathophysiology of this disorder based on developmental desynchronization (112). According to this model, infantile spasms results from a particular temporal desynchronization of two or more developmental processes, resulting in a specific disturbance of brain function. As shown in Figure 16-5, the developmental desynchronization could be produced by (1) a mutation or inherited abnormality affecting the primary genes governing ontogenesis, (2) a mutation or inherited abnormality affecting the genes specifying transcription factors (or other genetic modulators), or (3) an injurious external environmental factor affecting the maturational processes of brain tissues, neurochemical systems, or both. Each mechanism (or combination of mechanisms) could be manifested at different locations and at different points of development. As a

Developmental desynchronization model of infantile spasms pathogenesis showing schematically the interaction of developmental processes controlled by primary genes (e.g., neurogenesis, myelination, synaptogenesis, apoptosis, neurotransmitter systems) (horizontal lines) with regulatory gene effects (vertical lines from bottom) and environmental factors (vertical lines from top). Vertical dashed lines indicate hypothetical maximal extent of desynchronization consistent with normal function at 6 months. Reprinted from J.D. Frost, Jr. and R.A. Hrachovy, Pathogenesis of infantile spasms: A model based on developmental desynchronization, *J. Clin Neurophysiol.* 22:25–36, Figure 1, page 28; copyright 2005, with kind permission from Wolters Kluwer/Lippincott Williams & Wilkins.

result, at least one developmental process would lag behind other processes, resulting in a loss of integration of brain function. This model would allow for the observation that multiple, seemingly unrelated, conditions and insults occurring at different points of development (prenatal, perinatal, or postnatal) could result in the same functional deficit. Also, this hypothetical model would be consistent with the response of patients with infantile spasms to a diverse group of therapeutic agents with different modes of action. All agents would not be effective in all patients because of the different fundamental impairments responsible for the common functional deficit resulting in spasms. Also, the phenomenon of spontaneous remission could result from internal control mechanisms detecting the developmental desynchronization that caused spasms and responding to it by the activation or modulation of other gene regulatory systems.

## DIAGNOSTIC EVALUATION AND TREATMENT

### Diagnostic Evaluation

The diagnosis of infantile spasms is suggested on the basis of a good clinical history. Thorough general physical and neurological examinations must be performed. This should include a careful ophthalmic evaluation and close examination of the skin using a Wood's lamp to rule out such conditions as tuberous sclerosis. A routine EEG, recorded with the infant awake and asleep, is then obtained, which helps confirm the diagnosis. If the routine EEG does not reveal hypsarrhythmia and if the typical ictal EEG patterns (described previously) or spasms are not recorded, a prolonged video-EEG monitoring study should be performed to establish the presence of the disorder. Neuroimaging studies, preferably MRI, should be obtained to search for structural brain abnormalities. If ACTH or corticosteroids are to be started, the neuroimaging studies should be obtained before institution of such therapy, because these agents produce enlargement of CSF spaces that cannot be easily distinguished from preexisting cerebral atrophy. Routine laboratory studies including complete blood count with differential, renal panel with electrolytes and glucose, liver panel, serum calcium, magnesium, and phosphorus, and urinalysis should be obtained in all cases before institution of therapy. If an associated etiology is not identified on the basis of the previous information, a metabolic workup including serum lactate and pyruvate, plasma ammonia, urine organic acids, serum and urine amino acids, and serum biotinidase should be obtained. Chromosomal analysis should be performed. The CSF should be evaluated for cell count, glucose, protein, viral and bacterial culture, lactate and pyruvate, and amino acids.

### Associated Etiological and Clinical Factors

In approximately 40% of patients, no associated etiological factor can be clearly identified. In the other 60%, various prenatal, perinatal, and postnatal factors have been implicated. In our recent review of the more than 400 published reports concerning etiology (1) more than 200 associated conditions were identified. These include such prenatal conditions as cerebral dysgenesis (e.g., lissencephaly), intrauterine infection, hypoxia-ischemia, prematurity, and genetic disorders (e.g., tuberous sclerosis), perinatal conditions such as traumatic delivery and hypoxia-ischemia, and postnatal conditions such as inborn errors of metabolism (e.g., nonketotic hyperglycinemia), head injury, central nervous system (CNS) infection, hypoxia-ischemia, and intracranial hemorrhage.

Approximately 80% of patients with infantile spasms show some degree of mental and developmental retardation, and approximately the same percentage of patients have neurologic deficits (1).

Diffuse and focal abnormalities on MRI and CT scans may be seen in (70–80%) of cases. In addition, MRI may also reveal evidence of delayed myelination (113–115). PET reportedly detects focal or diffuse hypometabolic changes in up to 97% of patients with infantile spasms (116). However, these changes do not necessarily persist over time, suggesting that cortical hypometabolism in some patients with infantile spasms does not represent a structural lesion, but only a functional change (115, 117, 118).

### Immunization

During the last several decades, there has been a major disagreement as to whether immunization is an etiological factor for infantile spasms. This is an important issue, not only from a medical standpoint but also from a legal point of view, as evidenced by the large number of lawsuits against manufacturers of vaccines. Of the various vaccines that have been reported to be associated with infantile spasms, the one most frequently implicated is the diphtheria-pertussis-tetanus (DPT) vaccine. The pertussis agent has generated the most concern, and a number of publications have reported its apparent relationship to the development of infantile spasms (119–125). The major problem in determining whether there is a causal relationship between DPT immunization and infantile spasms is that the vaccine is given at the same age as the usual onset of infantile spasms. Therefore, if a large population were studied, an association between infantile spasms and DPT immunization would be expected on the basis of coincidence alone. Few studies have approached this problem in a manner amenable to statistical analysis; however, those that have done so have demonstrated that the apparent association between DPT immunization and infantile spasms is coincidental and that no causal relationship exists (126–129).

### Patient Classification

In the past, the classification of infantile spasm patients was variable and inconsistent (1, 26). Currently, patients are best classified on the basis of medical history, developmental history, neurologic examination, and neuroimaging studies (MRI, CT, and perhaps PET). Based on these criteria, patients can be divided into two main groups: cryptogenic or symptomatic. Those with no abnormality on neurologic examination, no known associated etiological factor, normal development before onset of the spasms, and normal neuroimaging studies are categorized as cryptogenic. Currently, approximately 20% of patients with infantile spasms are classified as cryptogenic (1), with the remaining 80% classified as symptomatic. This classification scheme can be helpful in the management of these patients because patients in the cryptogenic category have the best prognosis for spasm control and long-term developmental outcome (see following discussion).

### Differential Diagnosis

The diagnosis of infantile spasms is often delayed for weeks or months because parents, and even physicians, do not recognize the motor phenomena as seizures. Colic, Moro reflexes, and startle responses are diagnoses frequently made by pediatricians. Parents also may confuse infantile spasms with hypnagogic jerks occurring during sleep, head banging, transient flexor-extensor posturing of trunk and extremities of nonepileptic origin, and other types of myoclonic activity.

Infants with benign myoclonic epilepsy in infancy (BMEI) may have repetitive jerks, but the seizures are much briefer than spasms, and the EEG during the seizures reveals 3-Hz spike-and-wave or polyspike-and-wave activity. The background EEG activity is usually normal. These myoclonic seizures are treated with standard anticonvulsants, and the long-term prognosis in these patients is favorable. Another type of myoclonic movement that has been reported to be confused with infantile spasms is so-called benign myoclonus of early infancy (130). Infants with this disorder reportedly have tonic and myoclonic movements involving either the axial or limb musculature, which, like infantile spasms, may occur in clusters. The age at onset of this disorder (3 to 8.5 months) coincides with the age at onset of infantile spasms. In none of the reported cases did these movements persist beyond the age of 2 years. Unlike patients with infantile spasm, infants with benign myoclonus of early infancy have normal development, normal neurologic examinations, and normal EEGs. The motor movements are not accompanied by EEG changes, thus suggesting a nonepileptiform basis for the events. Patients with severe myoclonic epilepsy in infancy (SMEI), a disorder that may be confused with infantile spasms, usually have a family history of seizures and the disorder often begins

following a prolonged febrile seizure. Unilateral clonic seizures, generalized tonic-clonic seizures, and myoclonic seizures, but not epileptic spasms, typically occur in these patients. The EEG reveals generalized spike-and-wave or polyspike-and-wave activity (131–133). The seizures are typically refractory to anticonvulsants and mental retardation and neurological deficits are common. Epilepsy with myoclonic-astatic seizures (EMAS) may also be confused with infantile spasms. However, these patients experience brief myoclonic seizures, not epileptic spasms. The EEG typically shows spike-and-wave or polyspike-and-wave activity (134). Most patients are developmentally normal before onset of this disorder, which tends to be at a later age (7 months to 10 years) than infantile spasms.

### Related Syndromes

Three different epilepsy syndromes—early myoclonic encephalopathy (EME), early infantile myoclonic epilepsy (EIEE) and Lennox-Gastaut syndrome—may be difficult to differentiate from infantile spasms. They may share a common pathophysiological basis, with each disorder being expressed at a different age. A comparison of the important ictal and interictal features of these disorders, as well as the other myoclonic epilepsies described previously, is provided in Table 16-1.

Ohtahara (135) proposed that the syndrome of infantile spasms, suppression-burst activity in the EEG, and developmental retardation, when seen in the first few months of life, represents a disorder different from that seen in older infants, and he termed this disorder early infantile epileptic encephalopathy (EIEE). This disorder, which has been reported by many authors (133, 136–143), has a high mortality rate. The major reported difference between EIEE and infantile spasms is that the suppression-burst pattern seen with EIEE is continuous during wakefulness and sleep, whereas infantile spasms are associated with hypsarrhythmia. However, as discussed previously, a suppression-burst variant of hypsarrhythmia may be seen in patients with infantile spasms. Without knowing the age and clinical history of the patient, it is not possible to differentiate between these two suppression-burst patterns. Another reported difference between EIEE and infantile spasms is that in infantile spasms the spasms occur almost entirely while the patient is awake, whereas the spasms associated with EIEE reportedly occur both during wakefulness and sleep (138, 142).

A similar syndrome, early myoclonic encephalopathy (EME), has an onset within the first few weeks of life (132, 133, 144). This syndrome differs from EIEE and infantile spasms chiefly by the main type of clinical seizure observed. EME patients reportedly have fragmentary myoclonus, whereas patients with infantile spasms and EIEE have epileptic spasms. However, EME patients reportedly begin to experience epileptic spasms as they grow older. Also, the EEG in EME shows a suppression-burst pattern, but it is

reportedly less persistent than the suppression-burst pattern seen in EIEE. The various etiologies associated with these three disorders overlap, although EME has been reported to be associated primarily with metabolic disorders, whereas EIEE is more likely to be associated with structural brain abnormalities (133, 137, 142, 144–146).

It is usually not difficult to differentiate Lennox-Gastaut syndrome from infantile spasms in the infant younger than 1 year of age. However, in older patients, the myoclonic, brief tonic and atonic seizures seen in the patient with Lennox-Gastaut syndrome may be confused with infantile spasms, particularly on the basis of clinical description alone.

The fact that these syndromes transition from one to the other also complicates the issue. For example, an average of 71% of patients with EIEE transition to infantile spasms. Some of these patients then transition to Lennox-Gastaut syndrome. Some cases of EME reportedly transition to EIEE, and some cases of EIEE may evolve directly to Lennox-Gastaut (1, 136, 138, 147). In addition, an average of 17% of patients with infantile spasms will evolve to Lennox-Gastaut syndrome. If these disorders do share a common pathophysiological mechanism, with the stage of brain maturation being the only factor affecting the appearance of each disorder, it is difficult to explain why the following evolution is not seen in all or most patients: EME → EIEE → infantile spasms → Lennox-Gastaut syndrome. From this brief discussion, it is clear that much additional work is needed to clarify the relationship of these disorders.

Differentiation of infantile spasms from nonepileptic events, other types of myoclonic activity, and the three syndromes just described frequently requires that video-EEG monitoring studies be performed to capture the questionable episodes and thus provide a definitive diagnosis.

## TREATMENT

No aspect of this disorder has created as much confusion and controversy as the area of therapy. During the past four decades, numerous studies on the treatment of infantile spasms have been published; however, the results of these studies are so diverse that no consensus exists, and no true “standard of care” has been established. In this section, we briefly review the prevailing attitudes and opinions on the treatment of this disorder and make recommendations for the most appropriate therapy based on the best available data.

### Medical Therapy

Since 1958, when Sorel and Dusaucy-Bauloye (4) reported that treatment of patients with infantile spasms using ACTH resulted in cessation or amelioration of spasms and

disappearance of the hypsarrhythmic EEG pattern, many reports have appeared on the treatment of this disorder with ACTH and corticosteroids and more traditional anti-convulsants (1, 148, 149). To date, most of these studies have been plagued with methodological shortcomings that hamper interpretation and comparison of results. Some of the problems encountered are the following:

1. The natural history of the disorder is not completely understood—particularly the phenomenon of spontaneous remission. As noted previously, we reported in a retrospective study (25) that spontaneous remission could begin within 1 month of onset of the disorder, and within 12 months of onset, one quarter of patients had disappearance of the hypsarrhythmic pattern and cessation of spasms. More recently, Appleton et al. (150) performed a comparative trial of vigabatrin and placebo and reported that 2 of 20 patients (10%) responded to placebo. In addition, there are several case reports documenting the spontaneous remission of infantile spasms (1, 151–153).
2. There have been marked variations in dosages of medications used and durations of treatment.
3. Usually, an objective method of determining treatment response (video-EEG monitoring) has not been used. Instead, most studies have relied on parental observation to determine spasm frequency, which, as we have shown in previous studies, is unreliable. As shown in Figure 16-6, parents often underestimate spasm frequency to such an extent that they might

FIGURE 16-6

Spasm frequency after institution of ACTH or prednisone therapy: comparison of parents' estimates with results of 24-hour polygraphic-video monitoring. The coefficient of determination ( $r^2$ ) between the parents' and video monitoring counts was 0.26. The 24-hour monitoring studies were performed 2 to 4 weeks after institution of ACTH or prednisone therapy. Patients who failed to respond to ACTH were treated with prednisone and vice versa. Sixteen patients eventually responded to hormonal therapy.

report that no spasms occurred in a child who, in fact, is experiencing many spasms per day. In 8 of 24 patients, parents reported complete cessation of spasms during ACTH or prednisone therapy; however, in 3 of these patients, the presence of spasms was documented by long-term polygraphic-video monitoring. Conversely, parents may report that spasms did occur in a child who, in reality, does not have spasms. These discrepancies are probably related to the fact that spasms often occur in clusters shortly after arousal from sleep; they occur relatively equally during the nighttime and daytime; they are relatively brief in duration and may be subtle in appearance, and they are easily confused with other types of infant behavior (see previous discussion).

4. In most studies, response to therapy has been defined in a graded fashion. However, there is no reliable evidence that spasms respond to any form of therapy in such a manner. Our long-term monitoring of patients with infantile spasms treated with ACTH and prednisone indicates that the response to therapy is an all-or-none phenomenon—complete control or no control (154–157). This point is emphasized in the Guidelines to Antiepileptic Drug Trials in Children (Commission, 1994 [158]).
5. Almost all reported studies were inadequately powered because of small study populations and so do not provide meaningful statistical data.
6. Few well-controlled, prospective studies have been performed. Most studies have been case reports or retrospective studies that are uncontrolled and unblinded (1, 26, 148, 149). In our initial analysis of the various therapeutic agents used to treat this disorder, we categorized 214 treatment studies into six different groups (1) (Table 16-2). The most rigorously designed studies are listed in the first column of the table. The remaining studies meeting progressively less stringent criteria are listed in the remaining columns. Only six studies (150, 156, 157, 159–161) were prospective, using blinded and randomized protocols. Furthermore, only eight studies (154–157, 159, 162, 163) used serial 24-hour video-EEG monitoring to determine response to therapy objectively. Of the 15 agents shown in the table, 8 have never been evaluated using prospective, blinded, and randomized protocols, or with 24-hour EEG/video monitoring.

In addition, Table 16-2 lists the response rates to the various agents used to treat these patients. The dosages and durations of treatment, side effects, formulations, proposed mechanisms of action, and response characteristics of each of these agents may be found in our review of the topic (1). Between 2003 and 2006, more than 30 additional studies reporting the effectiveness of various

treatment modalities have been published. Review of these studies reveals that almost all of these studies suffer from the same methodological shortcomings described previously, with the exception of two randomized, controlled studies (164, 165).

Because of these methodological problems, several opinions have been published regarding the treatment of infantile spasms. After their review of the subject, Hancock and Osborne (148) concluded that no single treatment could be proven to be more efficacious than any other in terms of long-term psychomotor development or subsequent epilepsy rates. Vigabatrin may be more efficacious than placebo, and ACTH may be more efficacious than low doses of prednisone in stopping spasms. Vigabatrin may be more efficacious than hydrocortisone in stopping spasms in the group of patients with tuberous sclerosis. However, they found no treatment to be more efficacious than any other with regard to reduction in number of spasms, relapse rates, or resolution of hypsarrhythmia. Mackay et al (149) published a best practice parameter for the treatment of infantile spasms for the American Academy of Neurology and the Child Neurology Society. This group concluded that ACTH is probably effective in the short-term treatment of infantile spasms, but the evidence was insufficient to recommend the optimal dosage or duration of treatment. Vigabatrin is possibly effective in the short-term treatment of infantile spasms and possibly effective in children with tuberous sclerosis. However, there was insufficient evidence to recommend any other treatment for this disorder. Also, there was insufficient evidence to conclude that successful treatment of infantile spasms improves long-term prognosis.

On the basis of our analysis of the available data, we believe that it is reasonable to conclude that:

1. All agents listed in Table 16-2 have shown some efficacy in the treatment of infantile spasms.
2. As concerns treatment of this disorder with corticosteroids and ACTH, most investigators believe ACTH to be more effective.
3. There is no convincing evidence that higher doses of ACTH are more effective than lower doses of the drug.
4. Vigabatrin appears to be particularly effective in stopping the spasms in patients with tuberous sclerosis.
5. Response to any form of therapy usually occurs relatively quickly (within 1–2 weeks).
6. About 25% to 33% of patients will relapse after initial response to an agent.
7. There are no factors (e.g., treatment lag or patient classification) that can definitely be used to predict response to therapy.

### Surgical Therapy

Over the decades, several anecdotal reports have appeared reporting the beneficial effects of the surgical removal of anatomical lesions such as tumors and cysts (11, 72, 166–170). In recent years, there has been a greater emphasis on the surgical treatment of infantile spasms in patients with focal abnormalities on EEG, CT, MRI, or PET. In one of the largest series, Chugani and coworkers (171) reported that 9 of 23 patients with either focal or lateralized hypometabolism (18 patients) or focal hypermetabolism (5 patients) on PET also had focal abnormalities on MRI, CT, or both. All 23 patients had focal EEG findings that matched focal areas of abnormality on PET; 15 patients underwent focal cortical resection and 8 underwent hemispherectomy. At an average follow-up of 28 months, 14 (64%) were reported to be seizure-free. Others (172, 173) have reported similar results. The most common pathological finding of the resected tissue was cortical dysplasia.

There are several problems in interpreting the results of these surgical studies.

1. Not all of the patients identified in these reports actually had infantile spasms at the time of surgery. Many of the patients had a prior history of infantile spasms, but at the time of surgery were actually experiencing other seizure types (e.g., partial seizures).
2. The time required for cessation of infantile spasms following surgical treatment is usually not provided. In most instances, it is not possible to determine whether spasms stopped immediately following surgery or weeks to months later. This point is extremely important when one considers the phenomenon of spontaneous remission.
3. Most patients who were treated surgically continued to receive medical therapy after surgical resections were performed.
4. In most cases, video-EEG monitoring was not used to document the presence of spasms immediately before surgery or the cessation of spasms following surgery.

The problem in determining the effect of surgical treatment on spasm frequency can be further demonstrated by comparing studies of the long-term outcome in a group of patients with surgically treated infantile spasms and in a group of patients who failed to respond to hormonal therapy but were not treated surgically. Of the 17 patients reportedly experiencing infantile spasms at the time of surgery in Chugani's series (171), 10 (59%) were reportedly seizure free at follow-up. In a study of 26 patients who failed to respond to hor-

monal therapy but were not treated surgically (174), 12 (46%) were seizure free at follow-up. Therefore, it is difficult to determine whether cessation of spasms in all of the surgically treated patients was secondary to the surgical procedure itself or to some other factor (i.e., spontaneous remission). Of equal importance is the question whether surgical treatment of patients with infantile spasms affects long-term development. Although some authors report that patients with infantile spasm treated surgically show some improvement in developmental skills following surgery (171), the degree of improvement is difficult to assess because of the limited developmental information provided and the lack of control subjects.

Despite these shortcomings, focal cortical resection and hemispherectomy may contribute significantly to the treatment of a select group of patients with infantile spasms with focal cortical abnormalities who have failed medical treatment.

### Recommended Treatment Approach

Based on critical analysis of the data (1, 148, 149), no single drug demonstrates superior efficacy, and several different treatment modalities appear to exert an effect on this disorder. Also, as indicated previously, focal cortical resection or hemispherectomy may benefit a small number of patients who have failed medical therapy. Because it is not possible to predict which patient will respond to a particular medical treatment or surgical approach, the following systematic approach is recommended (Fig 16-7). The primary goal is to obtain a therapeutic response (cessation of spasms and EEG improvement) as soon as possible and to avoid prolonged treatment with ineffective drugs. If the patient fails to respond to one modality, it should be immediately stopped, and another agent immediately initiated. The specific implementation guidelines for each modality are shown in Table 16-3.

As discussed previously, prolonged video-EEG monitoring is the best method to use to determine if a response to treatment has occurred. However, if long-term video-EEG monitoring is not available, or if such monitoring is not reimbursed by third-party payors, the physician will have to rely on the observations of parents and the results of routine EEG studies to evaluate treatment response. In this situation, if the caregiver has not observed spasms during close observation for at least five consecutive days, and if a repeat EEG, including a sleep recording, reveals disappearance of the hypsarrhythmic pattern, it can be assumed that a response has occurred. If a relapse occurs, the treatment protocol should be restarted, beginning with the agent that previously produced a response.

### COURSE AND PROGNOSIS

Unique to medical treatment of infantile spasms has been the belief that treatment with various modalities not only improves the EEG and stops the spasms but also improves

the outlook for mental and motor development. However, there is no conclusive evidence that such treatment alters the developmental or mental outcome in these patients. This is because the designs of most studies concerned with long-term outcome do not permit definitive

**TABLE 16-3**  
**Therapeutic Modalities with Demonstrated Efficacy in Infantile Spasms**  
**and Suggested Parameters for Implementation**

THERAPY	INITIAL DOSE	MAXIMUM MAINTENANCE DOSE	MINIMUM DURATION OF THERAPY	MAXIMUM DURATION OF THERAPY IF NO RESPONSE	CONTINUE THERAPY IF RESPONSE OCCURS?
ACTH	20 u/day	30 u/day	2 weeks (plus 1 week taper)	6 weeks (plus 1 week taper)	No
Corticosteroid (prednisone)	2 mg/kg/day	2 mg/kg/day	2 weeks (plus 1 week taper)	6 weeks (plus 1 week taper)	No
Vigabatrin <sup>a</sup>	50 mg/kg/day	200 mg/kg/day	N/A <sup>b</sup>	8 weeks	Yes <sup>c</sup>
Nitrazepam <sup>a</sup>	1 mg/kg/day	10 mg/kg/day	N/A <sup>b</sup>	12 weeks	Yes <sup>c</sup>
Valproate	40 mg/kg/day	100 mg/kg/day	N/A <sup>b</sup>	8 weeks	Yes <sup>c</sup>
Pyridoxine (vitamin B <sub>6</sub> )	100 mg/day or 20 mg/kg/day	400 mg/day or 50 mg/kg/day	1 week	2 weeks	Yes <sup>c</sup>
Topiramate	12 mg/kg/day	24 mg/kg/day	N/A <sup>b</sup>	8 weeks	Yes <sup>c</sup>
Zonisamide	3 mg/kg/day	13 mg/kg/day	N/A <sup>b</sup>	6 weeks	Yes <sup>c</sup>
Immunoglobulin	100–400 mg/kg/day × 1–5 days	400 mg/kg/day × 5 days every 6 weeks	5 days	8 weeks	Yes, up to 6 months
TRH	0.05–0.5 mg/kg/day	1.0 mg/kg/day	2 weeks	4 weeks	No
Surgery	N/A <sup>b</sup>	N/A <sup>b</sup>	N/A <sup>b</sup>	N/A <sup>b</sup>	N/A <sup>b</sup>

<sup>a</sup>These drugs are not approved for general use in the United States.  
<sup>b</sup>N/A = Not applicable to this form of therapy.  
<sup>c</sup>An attempt at discontinuation is suggested after several months.

conclusions to be reached. Past studies of long-term prognosis have typically been retrospective, and older studies did not use such diagnostic tests as CT and MRI scans to aid in classifying patients as symptomatic or cryptogenic. Various treatment protocols have been used, and many patients were treated with multiple agents. No placebo-treated groups were included for analysis, and times for follow-up were not standardized. Also, in most studies, standardized tests of developmental and mental status were not utilized (1, 148, 149).

In our review of long-term outcome, we analyzed 67 studies (1). We included studies (minimum of 25 patients per study) for which populations were not preselected. The average duration of follow-up was 31 months in 52 studies that provided data concerning length of follow-up. Only 16% of the patients in these studies had normal

development at follow-up, and approximately 47% continued to experience seizures. Symptomatic patients experienced a higher rate of seizure occurrence (54%) compared to cryptogenic patients (23%). The most common seizures observed were tonic, generalized tonic-clonic, and simple partial seizures. Lennox-Gastaut syndrome developed in an average of 17% of patients. Abnormal EEG findings were seen in 61% of patients and 44% had persistent neurologic deficits. The average mortality rate was 12% (mortality has declined slightly over the decades, and this is probably related to better medical care).

Many factors have been reported to be predictive of a good outcome. In our analysis, the most favorable predictive factor was classification into the cryptogenic category. The percentage of cryptogenic patients with normal development (51%) was significantly higher than that of

symptomatic patients (6%). Each of the criteria defining the cryptogenic category (normal neuroimaging, normal development before onset of spasms, and absence of associated etiological factors) may also be good prognostic indicators, but additional information is needed to confirm these observations. A sustained response to therapy

(no relapse) and the absence of other seizure types are also factors predicting a favorable outcome. The evidence that other factors frequently mentioned in the literature (e.g., a classic hypsarrhythmic pattern, older age at onset, and short treatment lag) are associated with a good outcome is less convincing.

## Myoclonic Epilepsies in Infancy and Early Childhood

*Pierre Genton*

**I**t is still common to use the concept of “myoclonic epilepsy” as a diagnosis in epilepsy, although the past decades have led to the individualization of numerous and highly different epileptic syndromes in this category. More important, perhaps, is the fact that myoclonias can be found in the most benign and in the most severe forms of epilepsy, particularly in young children. The clinician’s job is to provide patient and family with the best possible treatment, and with a prognosis; diagnosis of a “myoclonic” epilepsy may help narrow the range of possible diagnoses and may also help avoid the risk of using inappropriate therapies. Indeed, myoclonias and myoclonic seizures are (with absences) those that are most likely to be aggravated by a whole range of anticonvulsants (1).

In this paper, we shall review some of the best-established early childhood epilepsy syndromes associated with the word “myoclonic,” and this review is based on recent reference textbooks on this subject (2, 3). However, we must acknowledge from the very start that many individual cases fall between the lines that separate syndromes and that diagnoses may remain tentative in some patients until a long-term follow-up has enabled the clinician to confirm (or change) the initial diagnosis.

The traits of the three major myoclonic epilepsy syndromes found in infants and young children and treated

in this chapter have been summarized in Table 17-1; we have included “differential diagnoses.” Indeed, many patients with myoclonias and myoclonic seizures cannot be diagnosed as having one of the typical syndromes. Several points should be made in this respect:

- Lennox-Gastaut syndrome (LGS) is not typically a myoclonic epilepsy. Myoclonic jerks and seizures have been reported, historically, in some patients who would still be categorized as LGS, whereas most others would now be considered to have Dravet syndrome or Doose syndrome. Important clinical and neurophysiological differences exist between these entities, as shown by a recent neurophysiological study of myoclonic jerks comparing patients with LGS and patients with Doose syndrome: this work underlines the difference between truly generalized myoclonus (as in Doose syndrome) and secondary bilateral synchrony (as in LGS) (4).
- Although epilepsy with myoclonic absences is a well-defined syndrome (5), there are, particularly among the cases with early-onset typical absences before the age of 2 or 3 years, many cases with prominent, nonrhythmic or stereotyped myoclonias. There are also typical childhood absence epilepsy cases with marked myoclonic (eyelid, perioral) features.

**TABLE 17-1**  
*Distinctive Features of the Main Types of Myoclonic Epilepsies Occurring in Younger Children*

<b>SYNDROME</b>	<b>AGE AT ONSET</b>	<b>SEIZURE TYPES</b>	<b>ASSOCIATED CONDITIONS/ ETIOLOGY</b>	<b>EEG FEATURES</b>	<b>PROGNOSIS/ OUTCOME</b>
Benign myoclonic epilepsy in infancy	4 m–3 y (later onset uncommon)	Bilateral jerks; spontaneous or reflex	Idiopathic	Normal background; fast, irregular SW associated with bilateral myoclonic jerks	Excellent in most; self-limited condition; treatment may not be necessary
Severe myoclonic epilepsy in infancy (Dravet syndrome)	3 m–2 y	Febrile, convulsive, unilateral, sleep-related; falsely generalized; myoclonic, atypical absence, polymorphous seizures	Progressive mental decline; Na channelopathy in most	Normal background at onset, progressive deterioration; polymorphic interictal and ictal changes	Poor to very severe; mental handicap; high risk of SUDEP; sensitivity to fever may persist; most severe seizures sleep-related
Myoclonic-astatic epilepsy (Doose syndrome)	1–4 y	Myoclonic; astatic; myoclonic-astatic; absence status; GTCS	Idiopathic; progressive mental deterioration in some; ion channel disorder demonstrated in some	Normal background with some theta slowing; bilateral SW, atypical absences and absence states, polymorphous changes during sleep that may include tonic discharges	Excellent to poor; self-limited in some with offset in childhood; chronic in others, with severe seizure and cognitive handicap
<b>DIFFERENTIAL DIAGNOSIS</b>					
Lennox-Gastaut syndrome	2–7 y	Tonic, absence, astatic; very rarely myoclonic	Multiple etiologies; no genetic factors	Slow spike-waves; fast activities in sleep	Poor to very severe
Myoclonic absences	1–10 y	Typical absences with rhythmic myoclonias	Usually idiopathic	3-Hz spike-waves with axial hypertonias	Not necessarily poor in all
Early onset absences	6 m–3 y	Typical absences with myoclonus, GTCS	Heterogenous	Typical absences, various interictal changes	Highly variable
Specific conditions with myoclonus	All ages	Various presentations	Various metabolic and genetic disorders	Abnormal background, specific features according to etiology	Usually poor, depending on etiology

However, such cases should be discussed with the absence epilepsy syndromes.

- Numerous specific, metabolic, and/or genetically determined conditions are associated with epileptic seizures and with myoclonias. Such conditions are beyond the scope of this chapter and are dealt with in other chapters of this volume.

## BENIGN MYOCLONIC EPILEPSY IN INFANCY

### Introduction and Definition

Benign myoclonic epilepsy in infancy (BMEI) was individualized among the early-onset myoclonic epilepsies nearly 30 years ago (6). BMEI stands out as the earliest form of idiopathic generalized epilepsy (7, 8). It is easily recognizable, with solid clinical and electroencephalogram (EEG) features. Extensive experience with this syndrome has led to the description of clinical variants, which share its excellent overall prognosis. Its diagnostic criteria can be summarized as follows:

- Onset in a normal infant aged 4 months to 3 years
- Bilateral myoclonic jerks, isolated or in brief series, occurring spontaneously or, less commonly, after unexpected sensory stimulations
- Myoclonic jerks always associated with fast, generalized, irregular spike-wave or polyspike-wave discharges
- EEG showing normal background and few interictal changes
- Favorable neurological and cognitive outcome in most with or without treatment, although some patients may experience infrequent generalized tonic-clonic seizures (GTCS), or rarely other forms of epilepsy, later in life

### Epidemiology

In our experience, BMEI is uncommon, and boys clearly outnumber girls (M/F ratio close to 2). BMEI represents less than 1% of all epilepsies and less than 2% of all idiopathic generalized epilepsies (9). This was confirmed by other studies, BMEI representing around 2% of all epilepsies with onset in the first 3 years of life (10), or 1–2% of all epilepsies with onset in the first year of life (11, 12).

### Clinical Manifestations

Myoclonic jerks begin usually between the ages of 4 months and 3 years. At the onset, the clinical manifestations are usually rare (seen less often than once/day) and barely noticeable. After some weeks or months, they become more frequent and more obvious. They involve

prominently the upper limbs, with a sudden upward extension, but are usually generalized and may be associated with a head drop and a quick upward rolling of the eyes. They may cause falls, drops of objects, or crying. If a short cluster occurs, it does not last more than 2–3 seconds. Sudden brief vocalization (13), or longer myoclonic attacks lasting up to 5 seconds (14), have also been reported, but are uncommon. There are usually no specific triggering factors, and attacks occur unexpectedly (although a slight increase of occurrence may be noted during drowsiness in some children).

A significant clinical variant, now accepted as *reflex* BMEI (15, 16), is characterized by the triggering of myoclonic jerks by sudden tactile or acoustic stimuli. Its prognosis does not differ from the usual type, and it may even be more benign. Some authors have also stressed the possibility of a later age at onset, but such patients still experience the self-limited course of the usual type of BMEI, and there is apparently no overlap with juvenile myoclonic epilepsy (JME) (17).

There are no significant associated features. Cognitive development and behavior remain normal, but some patients may experience various problems in this respect. A recent study showed that attention deficit or slightly below normal IQ can be found in single cases (18), but the significance of such findings is disputable (9).

### EEG Features

As an idiopathic type of generalized epilepsy, BMEI is not associated with global changes of the waking or sleeping EEG (Figure 17-1). The interictal EEG is normal, with the exception of rare generalized discharges not associated with myoclonias, especially during sleep. Most importantly, all myoclonias occur in association with EEG discharges. The EEG may remain fully normal if no myoclonic attacks are recorded, and long-term waking video-EEGs should be obtained until the ictal event is well documented. Sleep EEGs are useful in terms of differential diagnosis, because most other syndromes that may be suspected in the early diagnostic phases will be associated with significant global EEG changes during sleep or at awakening. However, drowsiness may in some cases increase the incidence of jerks, and it is recommended that a daytime sleep recording (easy to obtain in infants or very young children) be added to the clinical workup of these patients.

The typical EEG feature is a brief discharge of irregular, often fast spike-waves or polyspike-waves, that is very often associated with myoclonic jerks (Figure 9-1). This discharge can predominate anteriorly. Myoclonic jerks occur as an isolated event, or in very brief rhythmic or near-rhythmic clusters of 2–4 jerks, and may be associated with brief loss of tone in axial muscles (neck). There is no EEG or polygraphic particularity in

FIGURE 17-1

Benign myoclonic epilepsy in infancy (BMEI). Two-year old female infant with onset before age 1 of myoclonic jerks, who remained untreated until this polygraphic-EEG evaluation at age 2, showing waking and drowsiness. Note the correlation between generalized, irregular spike wave discharges on the EEG and myoclonic jerks shown on the deltoid EMG leads.

the reflex forms, or in patients with slightly later onset, after infancy. The jerks may begin at the eyelids, but they predominate clinically in the arms in most patients (15). A photoparoxysmal response following intermittent light stimulation (ILS) may be found in ca. 10% of patients, sometimes inducing myoclonic jerks (9, 17, 19). Focal changes, mostly in the form of frontal or temporal spike-waves, can be found transiently in rare cases, often only in sleep recordings (9, 19).

### Pathophysiology

There is no significant personal history in patients with BMEI, which has all the characteristics of idiopathic epilepsy. The only significant history is the occurrence of simple febrile seizures, which precede (or coexist with) BMEI in up to 26% of cases (9). The main physiopathological discussions surrounding BMEI concern the genetic context. Indeed, family histories of epilepsy (mostly of idiopathic forms) and/or febrile seizures are present in up to 44% of cases. There is no report of familial cases of BMEI, but this condition may occur in association with other forms of epilepsy in some families. One patient had a sibling with myoclonic-astatic epilepsy (20), but other family histories have not been reported in detail. There is, at present, no data to formally link BMEI with other

myoclonic epilepsies or to a larger grouping of idiopathic epilepsies. Nor is there data to exclude such linkage.

### Diagnostic Evaluation and Differential Diagnosis

The diagnosis of BMEI should immediately come to mind when myoclonic jerks occur in an infant who is progressing normally. The only major differential diagnosis in this age class is with benign infantile spasms (21), a comparatively frequent, likewise benign condition in which the clinical manifestations occur in clusters and in which the EEG remains normal. A familial infantile myoclonic epilepsy was reported in a large kindred, with benign outcome and autosomal recessive inheritance and clinical and EEG characteristics that differ from both BMEI and SMEI (22). These patients had often long-lasting myoclonic attacks preceding GTCS, the GTCS were the initial seizure type in most, and seizures tended to persist into adulthood. Febrile myoclonus is clearly a different entity (23). The diagnosis of SMEI and of myoclonic-astatic epilepsy, which may be confused with BMEI at their very early stages, will be discussed subsequently.

The diagnosis of BMEI can be easily confirmed by video-EEG monitoring, coupled with clinical monitoring. Video documentation of the attacks by the family may be of help at the first consultation and should be requested whenever possible. The frequency of myoclonic jerks is usually such that video-EEG monitoring, coupled with polygraphic recording of the jerks by surface EMG, is productive (Figure 9-1). However, several hours of recording, or repeated recordings, may be necessary in some cases. In the absence of clear video-polygraphic data, or in the presence of atypical findings, the diagnosis and prognosis should remain open; long-term follow-up is necessary to bring about a better established diagnosis in such patients. Neuroimaging procedures are seldom performed and do not reveal significant findings (9). Cognitive and behavioral assessment may be useful for the management of cases with problems in these areas.

### Treatment

Myoclonic jerks are easily controlled by valproate (VPA) (9). Untreated patients continue to experience myoclonic attacks, and this may contribute to difficulties in terms of psychomotor development and behavior. Thus the classically recommended attitude is to treat patients with VPA and discontinue treatment after several years of seizure freedom.

In their review of the current literature, Dravet and Bureau (9) have stressed the major efficacy of VPA in BMEI. Out of 87 patients treated in monotherapy, 73/82 became seizure free on VPA, 2/2 on phenobarbital (PB), 2/2 on clonazepam (CZP). Addition of PB, CZP,

or clobazam (CLB) resulted in seizure freedom in half of those who had not responded to VPA. Overall, 94% of the patients become seizure free on therapy. Resistance to VPA may be overcome using high initial doses (30 to 40 mg/kg) (13). There are also patients with a very benign course who remained untreated, and the necessity of drug treatment may be discussed in individual cases.

### Course and Prognosis

BMEI is a self-limited condition, with an active period lasting seldom more than a few years, and spontaneous remission during childhood. Myoclonic jerks disappear after a period of active epilepsy that may be shortened by anticonvulsant treatment; intellectual development progresses normally, and the EEG normalizes. However, this rule does not apply to all patients. The overall outcome may depend on an early diagnosis and treatment. Persistence of myoclonic attacks may lead to impaired psychomotor development and behavioral disturbances (9, 24). The cases with reflex triggering of myoclonic jerks appear to be more benign than average among BMEI patients, and often do not necessitate treatment.

No other seizure types are usually seen in the course of BMEI, except simple febrile seizures, and afebrile GTCS: the latter occur very late, usually during adolescence, and are often ascribed to drug withdrawal at that age. VPA may still be withdrawn without recurrence of GTCS in some, but has to be maintained in others, for example, because of persisting photosensitivity. Photosensitivity can indeed appear after the cessation of myoclonic jerks and persist into adulthood (13, 25, 26). Some patients may present with other seizure types: two patients had typical absences at age 10 and 11 years, after several years of seizure freedom off VPA (14). A multicentric study reported that, among 34 BMEI cases diagnosed between 1981 and 2002, there were two who later developed JME (27), but such findings need confirmation.

The cognitive outcome is favorable (9). In patients with long-term follow-up, 81.6% are normal, while 14.47% have mild retardation and attend a specialized school, none being institutionalized. Associated conditions may account for some of these unfavorable courses; one of our patients had Down syndrome. In other cases, the myoclonic seizures had remained untreated for many years. Mangano et al. (18) reported the cognitive and behavioral outcome in seven patients. Five were normal, one had a slight and one a moderate mental retardation, and all but one also had attention deficit disorder. The pathogenesis of such unfavorable outcomes is probably multifactorial. In addition to the existence of co-pathologies, it appears that treatment delay (in patients with frequent attacks), familial anxiety, and inappropriate educational attitudes, as well

as a putative underlying biological factor, may contribute to a less than fully benign prognosis in some patients.

## SEVERE MYOCLONIC EPILEPSY IN INFANCY (DRAVET SYNDROME)

### Introduction and Definition

Severe myoclonic epilepsy in infancy (SMEI) was described in the late 1970s (28) as a condition with severe epilepsy and progressive mental impairment, distinct from Lennox-Gastaut syndrome. It was included among the undetermined (as to whether focal or generalized) epilepsies in the 1989 International League Against Epilepsy (ILAE) classification (7) and ranked among the epileptic encephalopathies by the more recent classification scheme proposal (8). Following the increasing description of less typical forms, in which myoclonic jerks seem to play a lesser part, the eponym “Dravet syndrome” is now widely accepted, which puts less emphasis on its myoclonic components.

SMEI has gained a major importance in recent years as a result of the realization that it is a fairly common syndrome, with many cases reported from all continents, and that many cases are related to a specific abnormality of sodium channel receptors (29). SMEI is nowadays considered an archetypical form of an ion channel disorder-related epilepsy.

Although it is fairly easy to diagnose after a certain duration of follow-up, SMEI still poses multiple diagnostic and therapeutic problems. Its diagnostic criteria can be summarized as follows:

- Onset in a normal infant aged 3 months to 2 years
- Repeated simple febrile seizures, becoming progressively longer and afebrile, unilateral, sleep-related, and increasing in duration
- Occurrence of myoclonias, both bilateral and erratic, in the second year of life or thereafter
- Progressive occurrence of multiple seizure types, including falsely generalized seizures, various forms of status epilepticus, atypical absences, myoclonic seizures, and focal seizures, with increased incidence during febrile episodes
- Progressive mental decline after the second-third year of life
- EEG normal at onset, with progressive deterioration of background, frequent and early photosensitivity, and multiple interictal and ictal abnormal patterns
- Poor prognosis, with progressive mental decline during the first years and a fairly stable residual state with marked to severe mental impairment, persisting seizures, and high mortality

## Epidemiology

In spite of its major rank among epileptic encephalopathies, SMEI remains uncommon, but far from rare, and increasing numbers of cases are diagnosed nowadays. The incidence was estimated at less than 1 per 40,000 (30). Among epilepsies with onset in the first year of life, SMEI represents 3% (11) or 5% (31). Among epilepsies with onset in the first three years of life, the prevalence has been estimated at 6.1% (29) or 7% (10). Males are more often affected, with a sex ratio of 2 (30, 31).

## Clinical Manifestations

SMEI is characterized by a stereotyped clinical course, beginning with simple convulsive febrile seizures, which become frequent and predominantly nocturnal, increase in duration, and are progressively associated with afebrile events, multiple seizure types, myoclonias, and mental decline as well as neurological symptoms and behavioral disturbances.

The first febrile seizures may not be particularly disturbing. In most cases they are associated with intercurrent ear, nose, and throat (ENT) infections, or they follow vaccinations, but Japanese authors have stressed that they can also be triggered by hot baths producing a rise in body temperature (32). Early characteristic features occur in some patients, with long febrile seizures, or clusters (33), or afebrile seizures in 28 to 48% of cases (29). Febrile seizures tend to recur within weeks, and the first afebrile seizures occur within 2 to 14 months (33). The diagnosis of SMEI becomes more apparent when other seizure types appear, and when cognitive problems start manifesting, between 1 and 4 years of age.

There are several types of convulsive seizures in SMEI (29), which can all last 30 minutes or more, or recur after short interruptions:

- GTCS are uncommon, usually short, with a tonic phase often already intermixed with clonias.
- Hemiclonic seizures are seen in the very young, before age 3.
- “Falsely generalized” seizures are complicated, with discrepancies between the EEG onset (which may precede the clinical phenomena) and offset (EEG discharges persisting after the clinical offset). They consist in bilateral, asymmetric, asynchronous tonic contraction and clonias, leading to variable postures during the seizure, and each component may transiently predominate on one side or one one limb. They last up to 2–3 minutes.
- “Unstable” seizures are characterized by shifting EEG predominance, while their clinical appearance resembles the falsely generalized seizures.

Myoclonias appear after age 1 year, usually before age 5. Generalized myoclonic jerks, sometimes with falls, may be prominent upon awakening, disappear during sleep, and be provoked by intermittent light stimulation in the EEG laboratory. Fragmentary, asynchronous myoclonias are also seen (in up to 85% of the patients) in association with the former or, very often, as interictal manifestations, involving the limbs or facial muscles.

Atypical absences, often associated with increased myoclonias, may appear at any age during childhood and are found in 40 to >90% of patients. The clouding of consciousness is incomplete, with some staring and slowing. The EEG correlates range from 3-Hz spike-wave discharges to diffuse slowing interspersed with multifocal spike-waves. Eyelid myoclonias and head drops may also occur during absences. They can culminate in states of obtundation, which occur in close to 50% of SMEI patients, and are characterized by fluctuating contact, slowing, and erratic myoclonias (Figure 9-2). Convulsive seizures may trigger, accompany, or terminate such states, which may last hours to days. The EEG shows diffuse slowing with focal and generalized spikes and spike-waves.

Focal seizures occur early in the course of SMEI, as simple motor seizures or as complex focal seizures with autonomic symptoms, often as soon as 4 months after the first febrile events. They may follow a myoclonic seizure. Complex focal seizures are with drooling, pallor, automatism, and erratic myoclonias. Simple motor focal seizures are usually versive, or clonic, limited to one side or one limb. The EEG changes are clearly focal, originating in the occipital, temporal, or frontal region.

Tonic seizures are extremely uncommon but have been reported by several authors (29).

Motor milestones are normal at the beginning, with walking at the normal age, but unsteady gait is often noticed. Slight ataxia is noted in 60%, and mild pyramidal signs in 20%, during early childhood. Language also starts at the normal age but progresses slowly. Cognitive delay occurs often in the second year of life, sometimes only later. The children often become hyperkinetic. Twenty patients aged 11 months to 16 years 7 months were investigated with neuropsychological tests (34): motor, linguistic, and visual abilities were strikingly affected. Children with an initial high frequency of convulsive seizures showed earlier cognitive slowing. The number and duration of convulsive seizures correlated with the degree of mental deterioration. Better development correlated with milder epilepsy. In children with marked photosensitivity, self-stimulation (using light sources or geometric patterns) may become prominent (35).

## EEG Features

The EEG changes found in SMEI (Figure 17-2) are highly polymorphic and not specific. At the onset the EEG is normal and may remain so after repeated, simple febrile

FIGURE 17-2

Dravet syndrome (severe myoclonic epilepsy in infancy, SMEI). This child had a typical history, with early-onset simple febrile seizures. This plate illustrates one of the multiple aspects of clinical manifestations of SMEI. During a state of obtundation, the patient has both segmental, asynchronous, and diffuse myoclonias, as shown on the polygraphic EMG leads. The EEG shows global slowing, and predominantly multifocal sharp waves.

seizures. Later, the background activity is variable, partly in relation to the delay since the last convulsive seizure, showing diffuse slowing in the wake of major seizures. Sharp activities consist in spikes, spike-waves, and polyspike-waves, often predominating over the frontal and central areas, together with multifocal slow activities. Brief generalized discharges are associated with massive jerks, but there are no evident EEG correlates, or only focal spikes, in association with erratic or segmental myoclonias. Sleep patterns are conserved unless sleep-related seizures are frequent. Photoparoxysmal responses can be elicited by intermittent photic stimulation or by geometric patterns, but this EEG laboratory finding is not always correlated with clinical photosensitivity.

The ictal patterns are also highly variable and depend on the seizure type. Some have been summarized in the previous section. The multifocal aspect of changes, both slow and sharp, is highlighted by the recording of a state of obtundation (Figure 17-2).

The EEG changes progress during childhood, with diffuse, but moderate overall slowing, while the sharp changes tend to decrease over time.

### Pathophysiology

The genetic context in which SMEI occurs has been stressed repeatedly, with a family history of febrile

seizures in up to 71% of cases (34). A new light was shed on the nosology of SMEI after the description of the GEFS+ syndrome (generalized epilepsy with febrile seizures “plus”) (36). Proband with SMEI may belong to GEFS+ families, with other members having more benign phenotypes (such as simple febrile seizures, febrile seizures+, but also myoclonic-astatic epilepsy or focal epilepsy) (37). Indeed, although familial occurrence of SMEI remains rare (29), two GEFS+ families, each with two siblings with SMEI, have been reported (38). SMEI was thus related to a group of epilepsies with sensitivity to fever.

The next step in the discovery of pathophysiological mechanisms underlying SMEI occurred in 2001, when mutations in the SCN1A sodium-channel gene were found in all seven SMEI probands studied by Claes et al (39). These mutations occurred *de novo*, and were confirmed by numerous other studies. Mutations are predominantly frameshift and nonsense, but missense and other types have been reported. Most mutations were confirmed to occur *de novo*, but some, all missense, were inherited (40, 41). SCN1A mutations were thus found in most, but not all, patients with SMEI, with a lesser prevalence in borderline or atypical cases (29). Among 11 mutation-negative patients with typical or atypical SMEI, a recent study found that three had microdeletions in the SCN1A gene (42). Other candidate genes, including those implied in some families with GEFS+, were consistently negative, with one exception: a patient with a GABRG2 gene mutation was reported by Harkin et al. (43).

Genotype-phenotype correlations were extensively studied (29). There is a higher frequency of truncating mutations in the patients with SMEI. Some authors emphasize the localization of missense mutations and found that those situated around the pore-forming region and around the voltage-sensor region were more likely to produce the more severe phenotypes (44). Most mutations result in loss of function of the SCN1A channel (45), while others can lead to increased function (46). In spite of marked and rapid progress in the understanding of the cellular mechanisms producing SMEI, there is thus still ample room for further research.

### Diagnostic Evaluation and Differential Diagnosis

The diagnosis of SMEI can be suspected on clinical grounds in a context of repeated febrile seizures with a progressive tendency to occur at lower temperatures, to last longer, and to have an apparently unilateral or shifting aspect. It will be confirmed during follow-up, with the onset of myoclonias and multiple seizure types, and of progressive mental alteration. Waking and sleeping polygraphic video-EEG recordings are useful, because the children progressively fulfill the diagnostic criteria of

SMEI. Molecular biology can, nowadays, help characterize a defect in sodium channel receptors in most cases, and positive findings in this field may constitute a diagnostic criterion in the future.

CT scan and MRI are usually normal, or show slight diffuse atrophy, without hippocampal sclerosis, a strange fact given the occurrence of numerous prolonged febrile seizures in these patients (29). However, recent works have shown some significant findings. Ictal single-photon emission computed tomography (SPECT) may show lateralized or bilateral hypoperfusion (47, 48), and interictal positron emission tomography (PET) may show lateralized cortical hypometabolism (49). Contrary to previous studies, unilateral or bilateral hippocampal sclerosis was found in 10 of 14 patients at various stages of SMEI (50), and 6 of these 10 patients had an initially normal MRI. The real incidence and significance of acquired, progressive lesions in SMEI thus remain to be defined. A high-resolution MRI is thus recommended, whenever possible, at the early stages of this condition.

Many differential diagnoses are usually discussed before a consensus can be reached on the diagnosis of SMEI. Simple febrile seizures and BMEI can be easily eliminated after some follow-up. Lennox-Gastaut syndrome (LGS) may begin in infancy, but usually in children with brain lesions, who present with another type of symptomatic epilepsy, such as infantile spasms; moreover, the EEG is much more specific in the LGS, showing fast discharges during sleep, with or without overt tonic seizures. Myoclonic-astatic epilepsy (discussed subsequently) may be more difficult to differentiate in the first or second year of life. Major differential diagnoses are represented by the following:

- Some metabolic disorders, such as mitochondrial encephalomyopathies or neuronal ceroid lipofuscinosis, resemble SMEI; one patient with a condition mimicking SMEI had biological signs of mitochondrial dysfunction (51).
- Severe cryptogenic frontal lobe epilepsy with onset in infancy may be discussed in some patients also but is not associated with the polymorphic association of seizures or the alternating character of unilateral seizures seen in SMEI.
- Recurrent febrile seizures may raise the possibility of SMEI, which remains unlikely if seizure types and febrile threshold do not change over time. Recurrent febrile seizures can occur in a context of GEFS+ and may also be associated with Na channel functional defects.

A major diagnostic problem is raised by the existence of atypical, or « borderline » cases of SMEI, that only partially fulfill the diagnostic criteria, but share the

same overall prognosis. Among such atypical features: the absence of prominent myoclonus, which, if all other criteria are present, will not change the practical management and the outcome (12, 31, 48); a clinical picture with predominant refractory GTCS or unilateral clonic or tonic-clonic seizures, onset in infancy, and an evolution similar to SMEI (52). In both cases, recent molecular studies have shown that an SCN1A gene mutation could be demonstrated in patients with borderline SMEI (53) or with only refractory GTCS seizures (41). Thus the borders of SMEI remain controversial, and the actual weight of molecular biology in its diagnosis has yet to be established.

### Treatment

SMEI is characterized by marked drug resistance, and there is no report of full seizure control over a long period with any single drug or drug combination. In spite of this, a rational approach of pharmacological management can be proposed in SMEI.

Some anticonvulsants have a clearly deleterious effect, which has been noted by clinicians and has not received satisfactory explanations. Lamotrigine was shown to aggravate at least 80% of SMEI patients, at any stage of the condition (54). The same phenomenon has been noted for carbamazepine (55), and both drugs (with the likely addition of oxcarbazepine, which is closely related to CBZ) should not be used in SMEI.

Most other anticonvulsants have been used with some benefit in SMEI. Phenobarbital (PB), VPA, and benzodiazepines may decrease the frequency and duration of convulsive seizures. Phenytoin (PHT) can be useful in critical situations. Zonisamide is a potent antimyoclonic agent and has been used with success (56). Other drugs merit special attention:

- Bromides brought major improvement of convulsive seizures in 8 of 22 patients with SMEI, but did not influence absences or myoclonias (57).
- Topiramate caused a 50–100%, long-term reduction in convulsive seizures (up to 36 months) in 23 patients out of 27 in our experience (Villeneuve, personal communication), and good results have been published by other groups (58, 59).
- Felbamate, in our experience, also proved efficient in several patients with SMEI, reducing all seizure types; there is, however, no published study to confirm this interesting effect in SMEI.
- Stiripentol was efficient in association with VPA and CLB on convulsive seizures in SMEI (60). In this randomized, placebo-controlled, add-on trial, 15 of 21 children (71%) had more than 50% reduction in seizure frequency (nine were seizure free), compared to 1 of 20 (not seizure free) under placebo (5%).

The ketogenic diet is also an option: Of seventeen patients, seven achieved a 75–100%, and two a 50–74% seizure reduction (61). Seizures remained well controlled for more than one year. Steroids may be used in case of repeated status but do not have long-term efficacy. In some patients, immunoglobulins gave satisfactory results (Dravet, personal communication). In case of convulsive status, intravenous benzodiazepines, clonazepam, and midazolam can be used (62), in association with chloral hydrate or barbiturates.

### Course and Prognosis

SMEI stands out as a particularly severe epilepsy, with a very poor overall prognosis, confirmed by all published studies. Seizures tend to persist, all patients have cognitive dysfunction, and mortality is high, especially when patients reach adolescence and adulthood (30). The diagnosis of SMEI is comparatively easy in adults, because it is based on a fairly typical clinical evolution. A recent assessment of 14 adult patients with SMEI showed that predominantly nocturnal convulsive seizures persisted and that all patients were mentally disabled and had various degrees of neurological dysfunction (63).

Seizures are drug-resistant at all ages but tend to become less frequent in early adolescence, persisting as nocturnal convulsive attacks, often triggered by intercurrent febrile conditions. In the Tokyo cohort (30), one patient has been seizure free for more than one year, 20 (51%) had weekly seizures, 14 (36%) monthly seizures, 3 (8%) one seizure in 1 to 6 months, and 3 (7%) one seizure in 6 months to 1 year. Febrile status still happens during adolescence, but febrile episodes are less frequent than in young children.

Neurological impairment may appear insidiously during childhood, with poor coordination, tremor, or slight action myoclonus (64). Some patients may necessitate wheelchairs as a result of ataxia, spastic paresis, and kyphoscoliosis. The cognitive outcome is poor, but deficits tend to stabilize in older children. Among the patients followed at our institution (30), all those aged more than 10 years needed institutional care, and half had an IQ below 50. Behavior tended to become less hyperkinetic and rather marked by slowness and perseverations.

Mortality is a major problem in SMEI at any age. Among 128 patients who died in a department of child neurology, there were 4 of 8 patients with SMEI, including three during status epilepticus (65). The experience from our center notes that by 1992, 15.9% of our patients had died during follow-up, with the following causes (30): sudden unexpected death in epilepsy (SUDEP) (2 cases, aged 7 and 13 years), drowning (3 cases, aged 4, 10 and 14 years), status epilepticus during respiratory infection (1 case, age 3 years 3 months), accident (1 case, age 15 years), malignant measles under steroids (1 case, age 3 years

4 months), unknown (1 case). Over the past 15 years, several adolescent and adult patients have died in their sleep, with indirect evidence of seizures in some. We now recommend that adolescent and adult patients with SMEI sleep without soft cushions, and we also recommend that febrile episodes be treated as early as possible.

## MYOCLONIC-ASTATIC EPILEPSY (DOOSE SYNDROME)

### Introduction and Definition

Myoclonic-astatic epilepsy (MAE) is one of the few epileptic syndromes named after a particular seizure type (66), but it is also known under the name of Doose syndrome, a tribute to the German author who first described “centroencephalic myoclonic-astatic petit mal” (67), without, however, separating it clearly from Lennox-Gastaut syndrome (LGS), which had been characterized in the same period, or from SMEI, which was described later. It was classified among the cryptogenic or symptomatic generalized epilepsies (7), but rightly moved to the idiopathic forms in the 2001 proposal (8). Recent studies have stressed the relationship between MAE and other idiopathic epilepsies, including the GEFS+ syndrome. There are still debates about the precise syndromic classification of patients diagnosed with MAE, “cryptogenic” LGS, and some cases with BMEI or SMEI.

The diagnostic criteria of MAE can be summarized in the following manner:

- Onset in a normal child, between age 1 and 5 years
- Absence of structural brain anomalies
- Strong genetic context, with high incidence of idiopathic epilepsy in the family
- Myoclonic-astatic seizures resulting in drops and falls, associated with multiple generalized seizure types: myoclonic, atonic, absence, GTC, less commonly tonic seizures, as well as nonconvulsive status epilepticus
- Variable response to medication, with high efficacy of the valproate + lamotrigine combination
- Possible progressive cognitive impairment in some patients
- Variable prognosis for epilepsy and cognition, ranging from excellent to poor

### Epidemiology

The sex ratio is strongly in favor of males (2.7–3:1) (68). Incidence data vary according to the precise definition used, but overall MAE represents 1–2% of all childhood epilepsies (69), or 2.2% of children with seizure

onset between age 1 and 10 years in a hospital-based study (70).

### Clinical Manifestations

MAE occurs in neurologically normal young children. Seizure onset is between 18 and 60 months, and 94% of the children start their seizures before age 5 years. Onset in children older than 7 has not been reported. MAE may be preceded by (or associated with) simple febrile seizures in 11 to 28% of children in the usual age range (age 17 to 40 months) (70, 71), or 90% if MAE occurs in GEFS+ families (72).

The first seizures are usually generalized tonic-clonic, and soon after, they become myoclonic. They increase in frequency over a few months (73). Up to one-third of the patients can experience within 1–3 months a “stormy” evolution with multiple convulsive seizures per day, episodes of nonconvulsive status, or multiple daily falls due to myoclonic-astatic seizures (68). Such patients do not necessarily have a worse outcome than do those with a more gradual onset.

The characteristic presentation of MAE is as a multiple seizure disorder. Myoclonic and myoclonic-astatic seizures are present in all, as are generalized jerks occurring isolated or in clusters of 2 to 3. A prominent feature consists of sudden falls that may be related to myoclonic jerks or to atonias, usually to the characteristic combination of both. This can be documented by polygraphic video-EEG recording (74). Injuries are common. Minor episodes are limited to head drops.

The following are other seizure types that may occur in MAE (68, 70, 71):

- GTCS are found in 75–95% of patients and may occur during waking, but mostly during sleep after the first months.
- Pure atonic seizures were documented in 11 of 30 patients and associated with sudden falls and immediate recovery (74).
- Atypical absences are found in 62–89% of patients, often associated with lowered muscle tone.
- Stupor, or nonconvulsive status, has been reported in up to 95% of patients. Such episodes may occur upon awakening from sleep or from a nap and last up to one hour or more, or occur as true status, lasting up to several days, often longer in children with unfavorable outcome. Discrete, arrhythmic myoclonias of the face and extremities usually accompany these episodes (Figure 17-3).
- Tonic seizures may occur during sleep.

### EEG Features

At first appearance of seizures, the EEG (Figure 17-3) has a normal background and may show brief bursts of 2–3 Hz generalized spike-wave or polyspike-wave discharges,

FIGURE 17-3

Doose syndrome (myoclonic-astatic epilepsy, MAE). A typical aspect of the EEG in a patient with MAE. Both segments: generalized or diffuse EEG changes with irregular spike waves. Right segment: a myoclonic-astatic episode, with myoclonias and atonia (as shown on the polygraphic EMG leads).

which increase during sleep. The presence of a regular, rhythmic theta activity at 4–7 Hz predominating over the vertex and central areas is considered fairly specific of MAE, but it is not present in all patients and may become less prominent during follow-up. Myoclonic and myoclonic-astatic seizures are characterized by a single generalized (poly)spike-wave complex or by a cluster of sharp elements at 3–4 Hz lasting 2–6 seconds (74). Closer analysis of myoclonic seizures with back-averaging techniques have demonstrated the generalized nature of the ictal phenomenon, with a 2–4 ms latency between sides, which contrasts with the findings in Lennox-Gastaut syndrome, in which the interside latency is much higher and in favor of bilateral synchrony (4). Atonias correlate with a 200–400-ms silent period on the EMG and polyspike discharges on the EEG (73, 74). Tonic seizures are characterized by 10–15 Hz polyspike discharges.

Stuporous states are associated with mixed, slow and sharp activities, and when they are accompanied by prominent myoclonias, these can be associated, using back-averaging techniques, with cortical events (75).

### Pathophysiology

The “idiopathic” character of the Doose syndrome is based on the lack of acquired pathology and on the presence of significant genetic backgrounds. Very rarely, MAE

can coexist with brain lesions, as recently shown in a patient with Sturge-Weber syndrome, in whom MAE developed and kept its peculiar pharmacological sensitivity (76). Although the “generalized” nature of MAE remains uncontroversial, magnetoencephalographic findings have pointed to a frontal, premotor generation of myoclonic-astatic attacks (77).

Most studies pointed to a high incidence of positive family histories of epilepsy, found in 15–32% of cases (70, 71). Recent studies have stressed the existence of MAE patients in large GEFS+ pedigrees (36, 37, 72). However, none of the known three genes associated with GEFS+ was found to be mutated in a series of sporadic MAE cases (78), and only three out of 20 patients with sporadic MAE demonstrated SCN1A mutations (79). Other genetic factors may play a major part, and the precise genetic etiology or etiologies of MAE is (are) thus still unknown.

### Diagnostic Evaluation and Differential Diagnosis

The diagnosis of MAE can be suspected from the onset but, in most cases, requires a certain amount and duration of follow-up with clinical and EEG monitoring before it can be accepted as likely; as with other epileptic syndromes that lack a clear biological marker, it will never be definitive and can change during the course of the condition. The clinical evaluation ascertains normal development prior to the onset of epilepsy, a family history of idiopathic epilepsy, onset in early childhood, absence of brain pathology, multiple seizure types, as well as fairly characteristic EEG changes awake and asleep; pharmacological sensitivity (discussed subsequently) may also constitute a major diagnostic criterion. Diagnosis of MAE may remain tentative over a prolonged period, especially if atypical features are present in the patient’s history or clinical presentation.

Thus, various diagnoses may be considered during the early phases of MAE: BMEI (discussed earlier in this chapter), which may belong to the same spectrum of “idiopathic myoclonic epilepsies,” has a different, simpler presentation, but a cryptogenic form of Lennox-Gastaut syndrome may pose difficult problems, as several major clinical features overlap with those of MAE (70). A precise neurophysiological assessment of myoclonic jerks may help differentiate the truly “generalized” features of MAE from those of LGS, which are more likely to be associated with secondary bilateral synchrony (4). Other forms of “encephalopathic” early childhood epilepsies can be diagnosed in this context:

- Atypical benign partial epilepsy (80), or the syndrome of continuous spike-waves during slow-wave sleep (81), may also occur in normal children who present with multiple seizure types, including drop

attacks, but the EEG is different, showing focal and diffuse spike-wave discharges with major activation during sleep.

- The late infantile form of ceroid lipofuscinosis, or other specific progressive disorders, may resemble MAE at the onset, especially if there is a “stormy” onset of MAE, or during periods of worsening, but clinical and EEG traits (e.g., visual impairment, single-flash responses on ILS, and rapid cognitive decline) quickly change the diagnostic context.

### Treatment

In recent years the treatment of MAE has changed for the better, but it remains difficult, and the multiplicity of therapeutic proposals is a clear witness to this unsatisfactory situation. Valproate (VPA) is still considered the drug of first choice, as it may be effective against the multiple seizure types. Ethosuximide (ESM) can be considered to treat prominent absences and myoclonic attacks. When the initial phase of MAE is “explosive,” phenobarbital (PB) may be a reasonable option, as it has proven efficacy in convulsive attacks, but its use should not be continued beyond this initial stage (68). Steroids can help in the management of periods with multiple astatic seizures and frequent prolonged episodes of nonconvulsive status in MAE (73). Others have reported a positive effect of high-dose intravenous gamma-globulins (82) or intravenous lidocaine (83) in the treatment of minor motor status in MAE. The ketogenic diet may also be proposed in the most severe cases (84, 85).

Conversely, such drugs as carbamazepine (CBZ) and vigabatrin (VGB), and probably phenytoin, oxcarbazepine, tiagabine, gabapentin, or pregabalin, should be used with utmost care in MAE, as in other myoclonic epilepsies, as they may be responsible for paradoxical aggravation of seizures, resulting at times in myoclonic status (75, 86).

Newer anticonvulsants may help control MAE. Lamotrigine (LTG) has achieved a major role in the treatment regimen of patients with MAE (87), especially in association with VPA: This synergic combination, recommended in focal epilepsies (88), may have found a major application in MAE. Other newer anticonvulsants such as zonisamide, topiramate, and levetiracetam (LEV) may also be appropriate. However, a case of MAE with paradoxical aggravation (leading to myoclonic status) has been reported with LEV monotherapy (89). Topiramate may have some lasting beneficial effect on seizure control in some patients (90). Felbamate has been used with positive effect in selected cases (91).

### Course and Prognosis

MAE stands out as a syndrome with a very variable, difficult-to-predict outcome that ranges from benign (with total remission without sequelae) to very poor

(with severe persisting epilepsy and mental impairment). MAE appears to follow a natural course that cannot be accurately predicted on the basis of its characteristics at onset. In spite of frequent seizures and initial apparent resistance to drugs, the condition is self-limited in many patients, with abatement of seizures after an active period of 1–3 years and good cognitive evolution. The proportion of “favorable” cases with total remission of epilepsy has apparently grown in recent years, from around 50% to up to 68% (70, 71, 84). Some patients may experience infrequent, easy-to-control GTCS, while myoclonic-astatic seizures remit in 89% (84). Behavioral problems occur in some patients. The cognitive outcome was considered poor in 18% and was mostly associated with persisting minor motor states (84). Various factors of poor outcome have been proposed: repeated prolonged episodes of nonconvulsive status and positive family histories (71); occurrence of numerous falls, of atypical

absences, and of frequent GTCS (17); frequent minor motor attacks and presence of a family history of epilepsy (84). The occurrence of tonic seizures during sleep is often but not always associated with a poorer prognosis (70, 92). In patients with long-term EEG recordings that include nocturnal sleep, they occur in only one-third of patients with favorable outcome but up to 95% of those with poor outcome (70).

For all practical purposes, there are no solid hints at severity or benignity at the onset of the condition, no matter how “stormy” it is. Clinicians in charge of such patients should closely follow the evolution, use adequate drug regimens that avoid toxicity and paradoxical aggravation, and apply less common treatment procedures, together with educational support, when seizures become disabling and cognitive development deteriorates. If the epilepsy has not markedly abated three years after the onset, a poor prognosis is likely.

## Partial Epilepsies in Infancy

*Kazuyoshi Watanabe*

**P**artial epilepsies had been considered infrequent in infancy (1–3), but this may be because partial seizure manifestations in infants are subtle and often difficult to identify unless they show definite focal motor phenomena. It is often difficult to distinguish partial from generalized seizures on the basis of clinical observations and interictal encephalograms (EEGs) (4). In a previous study of seizures in the first year of life (2), partial seizures comprised only 12%, whereas infantile spasms accounted for 41% and generalized motor seizures for 35%. Generalized motor seizures, however, may represent partial seizures that are secondarily generalized. Generalized tonic-clonic seizures are very rare in infants, if present, and ictal EEGs of such seizures usually display partial seizure patterns evolving to secondarily generalized tonic-clonic seizures (5, 6). In another study, partial epilepsy comprised 12%, whereas West syndrome represented 69% of the cases (7). Later studies of epilepsies in the first years of life revealed an increased incidence of partial epilepsies, although West syndrome remained the most common syndrome: 17–36% for partial epilepsies vs. 39–48% for West syndrome (8–10). Recent studies have reported a higher incidence of partial epilepsies in the first 2 years of life: 43% for partial epilepsies vs. 28% for infantile spasms at a tertiary center (11), and 60% vs. 35% in the first 2 years of life in a regional

general hospital (12). This increased incidence is probably due to an increased recognition of partial seizures with or without secondary generalization in infants.

The prognosis of partial epilepsy in infancy had been considered poor, and benign partial epilepsy was reported to be extremely rare or nonexistent in infancy (13, 14). Complex partial seizures of infancy were reported to be medically intractable and often associated with mental handicap, necessitating aggressive treatment (15). However, Watanabe et al (16) first reported the presence of partial epilepsy in infancy with complex partial seizures in 1987, and, subsequently, of benign partial epilepsy with secondarily generalized seizures (17).

This chapter reviews symptomatic, cryptogenic, and idiopathic benign partial epilepsies and related syndromes in the first 2 years of life, excluding neonatal seizures.

### ICTAL CLINICAL MANIFESTATIONS

The repertoire of ictal manifestation of epilepsy in infants is limited. Seizures often begin with a change in facial expression or behavior, but the most striking feature is an arrest or marked reduction of behavioral motor activity, which was formerly called a hypomotor seizure (18). Some authors consider seizures complex partial if nonconvulsive ictal phenomena are associated with disturbance of contact

or unresponsiveness and focal or nongeneralized paroxysmal EEG discharges (15, 19), but others avoid the term because of difficulty in determining impairment of consciousness (18). The most ordinary sequence of infantile complex partial seizures consists mainly of motion arrest, decreased responsiveness, staring or blank eyes, or simple gestural automatisms followed by mild convulsive movements and subsequent alimentary automatisms (16, 19). Convulsive movements consist of eye deviation or head rotation; mild clonic movements involving face, eyelids, or limbs; and increased limb tone. These tonic or clonic movements are qualitatively not as intense as those in generalized tonic-clonic seizures. They are more frequent in younger children and may be widespread, covering a wide area of the body, often leading to an erroneous diagnosis of generalized tonic-clonic seizures. Constant focal or unilateral motor seizures are characteristic of symptomatic partial epilepsy. Symmetric motor phenomena of the limbs and head nodding are characteristic of seizures in younger children with temporal lobe seizures (20). Bilaterally synchronous motor seizures (21), or bilateral tonic stiffening and extension of all limbs with or without evolution to a bilateral asymmetric clonic phase, tonic seizures with a sustained fencer posture, epileptic spasms in cluster, or brief loss of muscle tone on one side of the body may also be seen in infants (18). Automatisms consist of simple head, arm, or leg movements, and alimentary automatisms such as chewing, lip and tongue smacking, swallowing, or licking one's lips (19). Alimentary automatisms are the most common form, and no complex, semipurposive gestural automatisms are present in infants. Eye deviation or head rotation occurs early in the attack, whereas oral automatisms occur later, or postictally. Some authors feel these subtle limb or oral movements difficult to distinguish from background behavior (18). Autonomic changes such as flushing, mydriasis, pallor, cyanosis, apnea, or tachypnea may be seen (22). All focal motor seizures and most versive seizures are associated with focal EEG seizure patterns in the contralateral hemisphere. Generalized motor seizures display focal EEG discharges in 37%, while hypomotor seizures do so in 70% (23). Hypomotor seizures originate from temporal, temporoparietal, or parietooccipital regions. Seizures with localized or bilateral clonic, tonic, or atonic motor phenomena arise predominantly from frontal, frontocentral, central, or frontoparietal areas. Temporal or temporoparietal foci are associated with diminution of behavioral activity, whereas frontal or central foci are associated with localized or generalized motor phenomena (18). Frontal lobe seizures are often initiated by psychomotor arrest followed either by limb hypertonia or tonic posturing and complex global motor behavior, or by simple gestural automatisms and eyelid myoclonias (24). Hypermotor seizures and complex motor automatisms are not seen in young children with frontal lobe seizures (25). Rolandic seizures often

begin by uni- or bilateral hypertonia of the limbs, followed by uni- or more frequently bilateral clonic activity. Eye opening or psychomotor arrest mainly occur at the onset of temporal lobe seizures, during which oroalimentary automatisms are observed, often associated with eyelid myoclonias (24). Younger children with temporal lobe seizures show convulsive movements more often than older children (19, 26). The first clinical signs of occipital seizures frequently consist of eye deviation, or more rarely eye opening, frequently followed by oculoclonias and eyelid myoclonias (24, 27). Ictal smile, flush, head nod, and behavioral changes are typical in infants and young children with posterior cortex seizures (28). Focal clonic activity, predominantly unilateral spasms, focal tonic activity, ictal nystagmus, and postictal paresis are good lateralizing signs occurring contralateral to the hemisphere of seizure onset, whereas tonic eye deviation is not a good lateralizing sign (29). The duration of complex partial seizures, timed from the first clinical or EEG change until the end of paroxysmal discharges, excluding postictal polymorphous delta waves, ranges from 40 to 250 seconds in infants, longer than that of older children, ranging from 10 to 110 seconds (19). Partial seizures may evolve into secondarily generalized tonic-clonic seizures. In such cases, initial partial seizures last 5–33 seconds, and the following generalized tonic-clonic seizures 40–120 sec (17). Convulsive movements may be extensive, but secondary generalization is infrequent in symptomatic partial epilepsies (19, 25, 28). In contrast, secondarily generalized seizures are more frequent in idiopathic benign partial epilepsy (11). *Epilepsia partialis continua* may occur in hemimegalencephaly or focal cortical dysplasia (30, 31). Epileptic spasms are usually considered a seizure manifestation of generalized epilepsy, but they may be seen in partial epilepsy if it is defined by localized ictal EEG or localized lesion on neuroimaging with seizure-free surgical outcome (18, 23). Epileptic spasms are often the initial manifestation or seen transiently during the course of symptomatic partial epilepsy due to focal cortical dysplasia (25, 27, 32–34). About one-third of infants with partial epilepsies beginning in the first 2 years of life presented initially with infantile spasms (12).

### EEG FEATURES

In infants with partial epilepsies, interictal EEGs demonstrate paroxysmal discharges infrequently (19). In idiopathic benign partial epilepsy in infancy with complex partial seizures or secondarily generalized seizures, interictal EEGs are normal and do not show paroxysmal discharges, although small vertex spikes with larger bell-shaped slow waves are seen in benign partial epilepsy with vertex spikes and waves during sleep (35). Paroxysmal discharges may be absent even in symptomatic partial

epilepsies in infancy. In symptomatic partial epilepsies, interictal background EEG rhythms are usually slow and poorly organized, and regional posterior frequencies are not observed (15). Sleep EEGs display abnormal organization, often without stage II features, and persistent voltage and frequency asymmetry may be observed. Interictal EEGs often show paroxysmal discharges such as spikes, spike and waves, and sharp waves that may be unilateral, bilateral, or multifocal (36).

Ictal EEGs usually display focal discharges of low-voltage fast waves or rhythmic or repetitive sharp alpha or theta waves of increasing amplitude and decreasing frequency, which are followed by theta and delta waves mixed with spikes or sharp waves with gradual or rapid spread to other regions (16, 19). In secondarily generalized seizures, ictal EEGs show focal discharges of low-voltage fast waves or rhythmic or repetitive sharp waves or spikes of increasing amplitude and decreasing frequency, which transmit to the contralateral and adjacent regions, then to all areas. These waves or spikes resemble epileptic recruiting rhythm, which then become mixed with slow waves of decreasing frequency, giving rise to spike, polyspike, or sharp- and slow-wave complexes. Bilateral synchrony of these discharges and associated clonic seizures is poorer in comparison with those observed in older children and adults (17).

## IDIOPATHIC PARTIAL EPILEPSIES

### Benign Partial Epilepsy in Infancy with Complex Partial Seizures

This syndrome is characterized by complex partial seizures (CPS) occurring in clusters, age at onset mostly during the first year of life, a family history of benign infantile seizures in many cases, normal development prior to onset, no underlying disorders or neurological abnormalities, normal cranial computed tomography (CT) and magnetic resonance imaging (MRI) findings, normal interictal EEGs, excellent response to drug treatment, and normal developmental outcome (11, 16, 37–40). Seizures occur mostly during wakefulness in clusters 1–10 times a day for 1–3 days. They may recur within a few months even on drug treatment. The most frequent site of origin of ictal discharges is the temporal area, but other foci or even dual foci can be seen. We previously proposed to combine this syndrome with benign partial epilepsy with secondarily generalized seizures, described subsequently, and call them benign partial epilepsy in infancy (17). But CPS may be misdiagnosed as generalized tonic-clonic seizures because of concomitant convulsive movements (19). The unique characteristics of this syndrome with CPS as the sole type of seizures should be emphasized, because it may be difficult to diagnose it unless we know its presence. It is

important to recognize this subtype, because it may be too subtle or atypical to diagnose it as an epileptic seizure. In fact, gastroesophageal reflux disease was initially thought to be the etiology of symptoms in a substantial number of patients, delaying referral to the pediatric neurologist by as much as 3 months (11).

### Benign Partial Epilepsy in Infancy with Secondarily Generalized Seizures (SGS)

The main clinical features are similar to those of the aforementioned subtype with CPS in regard to family history, age of onset, neurodevelopmental normality, absence of underlying disorders, and normal interictal EEGs (17). This subtype presents only with SGS. Seizures occur more frequently during wakefulness than during sleep, but more frequently during sleep than in the subtype with CPS. Partial seizures lasting 5–35 seconds, manifested by motion arrest with staring or blank eyes during wakefulness, or opening of eyes with staring during sleep, are followed by generalized tonic-clonic seizures of 40–150 seconds' duration. Seizures occur in clusters 2–5 times a day for 1–3 days. They may recur within a few months after treatment, but they can be easily controlled with an adjustment of the dosage. The site of initial paroxysmal discharges is usually in the central, occipital, or parietal area (38). Different foci (occipital and central) were disclosed at the onset and recurrence in an infant (17). SGS are easily mistaken for primarily generalized seizures, because it is not always easy to recognize the presence of preceding partial seizures. For their accurate diagnosis, the initial partial seizure manifestation should be specially sought, or an ictal EEG recording should be done.

### Diagnosis and Long-Term Follow-up of Benign Partial Epilepsy in Infancy

It is not always easy to make an accurate diagnosis of benign partial epilepsy in infancy (BPEI) at the onset of seizures (41), as the diagnostic criteria include seizure freedom and normal developmental outcome. A positive family history of similar disorders is helpful, but it is absent in many cases. Okumura et al (42) defined *possible BPEI* as partial epilepsy with CPS and/or SGS meeting the aforementioned criteria excluding outcome items, and made the final diagnosis of *definite BPEI* at age 5 years, when there was no seizure beyond age 2 years and normal psychomotor development beyond 5 years. *Definite BPEI* accounted for 76% of the patients diagnosed as having *possible BPEI* at the first presentation and 90% of those who met the conditions on reevaluation at age 2 years. Thus, recognition of BPEI is possible, to some extent, at the first presentation, and reevaluation at age 2 years is useful for a more precise diagnosis. A recent long-term follow-up study revealed that most of patients with *possible BPEI*

at age 2 years and almost all of the patients who met the criteria of *definite BPEI* at age 5 years did not have seizure recurrence or mental problems beyond 8 years of age (43). Thus, the diagnosis of BPEI can be made reliably at age 5 years. During the follow-up period in this study, 9% of patients with definite BPEI at age 8 years or older had convulsions with mild gastroenteritis at age 18–22 months after an antiepileptic drug (AED) was discontinued. In view of the long interval between the two types of seizures and the different age of onset of two syndromes, it is reasonable to consider that these patients had two different syndromes rather than a relapse of BPEI. Another 9% of the patients developed paroxysmal kinesigenic choreoathetosis (PKC) at age 6–8 years. The association of PKC with benign infantile convulsions has been recently recognized (see the following section). No patients developed other types of idiopathic epilepsy.

### Benign Infantile Convulsions/Seizures

The presence of infantile convulsions with benign outcome was first described by Fukuyama in 1963 (44), who defined them as having the following features: onset before 2 years of age; generalized, symmetrical convulsion, mainly tonic-clonic, lasting 1–2 minutes; no family history of epilepsy; no remarkable past history; normal psychomotor development; no etiology; (EEG normal); and benign course. This type of infantile convulsions has been the subject of many subsequent studies in Japan and has been called benign infantile convulsions (BIC) (38). As generalized, symmetrical convulsions are one of the criteria of BIC, none of the studies considered BIC partial seizures. We pointed out, however, that ictal EEGs of such patients usually display partial seizures evolving to secondarily generalized tonic-clonic seizures (5). Tsurui et al (45) made a similar observation in patients with BIC meeting the criteria of Fukuyama except for a family history. The absence of a family history of epilepsy was another criterion of BIC described by Fukuyama, but a family history of benign convulsions was often elicited in BIC (38). Vigeveno et al (46) reported an autosomal dominant disorder, benign infantile familial convulsions (BIFC), characterized by a family history of benign seizures in infancy and secondarily generalized partial seizures confirmed by ictal EEG recordings. The site of origin of ictal discharges was in the parieto-occipital area. Since the description by Vigeveno et al (46), there have been reports on BFIC from many different parts of the world (47, 48). This syndrome corresponds to the familial type of BIC described by Fukuyama (44) and to benign partial epilepsy with SGS described by Watanabe et al (17). Later reports recognized the presence of simple or complex partial seizures without secondarily generalization in a number of patients (49–51). These cases may correspond to BPEI with CPS described by Watanabe et al (16).

BFIC show an autosomal dominant mode of inheritance. So far, three loci for BFIC have been mapped on chromosomes 19q12–q13.11 (52), 2q24 (53), and 16p12–q12 (51, 54). The last region is the same locus as that for familial infantile convulsions and paroxysmal choreoathetosis (49). Recently, Striano et al (55) have reported a pedigree with BFIC in which genetic analysis revealed a novel SCN2A gene mutation on chromosome 2q24. Mutations in the same gene has been identified in families affected by benign familial neonatal-infantile seizures (BFNIS) (56, 57), suggesting these two benign familial seizures may share the same genetic abnormality. Both share many clinical features except for the age of onset.

### Benign Familial Neonatal-Infantile Seizures

This is an autosomal dominant benign seizure disorder, presenting in early infancy, in which mutations of SCN2A gene have been detected (56, 57). The age of onset ranges from day 2 to 7 months (mean, 11.2 weeks). Seizures are characterized by secondarily generalized partial seizures; neonatal seizures were not seen in all families. The frequency of seizures varied; some individuals had only a few attacks without treatment, whereas others had clusters of many per day. Febrile seizures were rare. All cases remitted by 12 months. Ictal recordings showed a focal onset in the posterior quadrants.

### Benign Familial Infantile Convulsions and Paroxysmal Choreoathetosis

The association of paroxysmal choreoathetosis with BFIC was first reported by Szepetowski et al (49) and subsequently described by several authors (58–63). This disorder is inherited as an autosomal dominant trait and linked to chromosome 16p12–q12. The clinical expression is variable, and affected individuals may display infantile seizures, paroxysmal dyskinesia, or both. The paroxysmal dyskinesia starts at age 5–28 years and occurs spontaneously at rest or is induced by sudden movements, anxiety, or prolonged exercise. Some patients exhibited recurrence of epileptic seizures at a much later age (59). Two families with this disorder in which one of the members developed temporal lobe seizures in adolescence and adulthood, respectively, were reported (64, 65). Carbamazepine is usually effective against dyskinesia, although the condition may not be so disabling as to make individuals seek medical advice.

### Benign Familial Infantile Convulsions and Familial Hemiplegic Migraine

Vanmolkot et al (66) reported novel missense mutations in the ATP1A2 Na<sup>+</sup>, K<sup>+</sup>-ATPase pump gene on chromosome 1q23 in two families with familial hemiplegic

migraine (FHM). The M731T mutation was found in a family with pure FHM, whereas the R689Q mutation was identified in a family in which FHM and benign familial infantile convulsions (BFIC) partially cosegregate. In this family, all available affected family members with FHM, BFIC, or both carry the ATP1A2 mutation. Like FHM linked to 19p13, FHM linked to 1q23 also involves dysfunction of ion transport, and epilepsy is part of its phenotypic spectrum.

### **Benign Partial Epilepsy in Infancy and Early Childhood with Vertex Spikes and Waves During Sleep**

This syndrome is a form of benign partial epilepsy in infancy characterized by the presence of typical focal interictal EEG abnormalities in the vertex regions only during sleep (35, 67). Spikes and waves have a particular morphology consisting of a low-voltage fast spike followed by a higher-voltage bell-shaped slow wave, appearing isolated or grouped in short sequences with spread from vertex to central regions. A family history of febrile or afebrile benign seizures is relatively common (30–50%). The age of onset ranges from 13 to 30 months with a peak between 16 and 20 months, but an earlier onset before age 1 year was reported later (68). Seizures occur infrequently, varying from one episode to three to four per year, mostly in wakefulness, and are characterized by staring and motion arrest, followed by stiffening of the arms, cyanosis, and loss of consciousness, lasting 1–5 minutes. They never occurred in clusters or in the form of status (67). Seizure remission occurred between 2 years 3 months and 3 years 7 months, whereas spike and waves remitted between 3 and 5 years. Antiepileptic treatment is considered unnecessary because of low seizure frequency and short duration (69).

### **Benign Convulsions with Mild Gastroenteritis**

Benign convulsions with mild gastroenteritis (CwG) are situation-related seizures associated with gastroenteritis. They were first described by Morooka in Japan (70) and have been studied by many Japanese and a few Taiwanese investigators (71) but rarely reported from other countries (72–74). Uemura et al (71) studied clinical features of this disorder in 114 episodes of 105 patients. CwG are defined as having the following features: seizures associated with gastroenteritis without signs of dehydration or electrolyte derangement; the body temperature less than 38°C before and after the seizures; patients with bacterial or aseptic meningitis, encephalitis/encephalopathy associated with viral infection, or a history of epilepsy are excluded. The age of onset ranged from 8 to 52 months (average 21.1 months). A family history of febrile or afebrile seizures is infrequent (7%, 6% respectively). A

pair of identical twins had CwG on the same day (75). Sakai et al (76) reported a family with CwG and BIC. Only 5% had febrile seizures on occasions unrelated to CwG. Seizures occurred in clusters in 75% of the episodes, presented as generalized convulsions in 87% of patients and complex partial seizures in 13%, and lasted from 30 seconds to 3 minutes. They were induced by pain and/or crying in 43% of episodes, although no patients had convulsions associated with crying on any occasions before and after the episode of CwG. These seizures were clearly different from breath-holding spells. In patients with multiple seizures, the interval between the first and last seizure was 0.5–48 hours (mean 8.6 hours), and seizures ceased within 6 hours in 59% of episodes. None of the patients developed epilepsy, and all patients exhibited normal psychomotor development. Interictal EEGs are normal. Ictal EEGs were recorded in a few cases and showed complex partial seizures evolving to secondarily generalized tonic-clonic seizures (75, 77, 78). The site of origin of ictal discharges was occipital in 5, parietal in one, and centroparietotemporal in one of 7 episodes recorded from 5 patients. One of the patients showed three different foci in three episodes (77). Rotavirus is the most common etiologic agent of gastroenteritis, but other viruses, such as small round structured virus, may also be responsible (79, 80). It is not always easy to distinguish patients with CwG from those with encephalitis/encephalopathy. Hongou et al (81) reported a patient with rotavirus encephalitis mimicking CwG who showed slowing of the background EEG.

### **Treatment of Benign Partial Epilepsies and Other Benign Infantile Seizure Disorders**

Although benign partial epilepsies and other benign infantile seizures have a tendency to spontaneous remission, the seizures often occur in clusters, and the benignity of the condition can not usually be ascertained at the very beginning of the disease, so an AED may be administered for a certain period. However, there is no consensus as to the choice of an AED and the period of administration. Various AEDs have been tried, but the efficacy of each drug is difficult to assess because of the tendency toward spontaneous remission. Breakthrough seizure rates while on AED treatment were 11–37% and highest in the population where phenobarbital was mainly used (11). Recently, a once-daily dose of 5 mg/kg of carbamazepine has been reported to be highly effective for the treatment of benign infantile convulsions (82) or convulsions with mild gastroenteritis (83). In contrast, diazepam is generally ineffective against clusters of seizures in benign infantile convulsions or convulsions with mild gastroenteritis (82, 84). Phenobarbital is considered effective against convulsions with mild gastroenteritis if used in a large dose, but its effect is not usually satisfactory (84).

Lidocaine in drip infusion or in the form of skin tape is reported to be more effective against CwG than diazepam or phenobarbital (85). For the treatment of BIC, it is recommended to administer the aforementioned dose of carbamazepine as quickly as possible, orally or through a nasogastric tube if oral administration is not possible. For BPEI, we previously recommended to administer an AED for one year or until the child reaches 3 years of age, as no seizures occurred after this age (38). But a shorter treatment period may be feasible in view of the short period of seizure persistence in BPEI (average 3 months, range 0–12 months) (39). Nelson et al (11) suggested weaning from AED 6 months after seizure onset in BPEI.

## SYMPTOMATIC AND CRYPTOGENIC PARTIAL EPILEPSIES IN INFANCY

### Etiology

Etiologies of symptomatic partial epilepsies in infants include focal cortical dysplasia (FCD), pachygyria, polymicrogyria, low-grade dysplastic changes, heterotopic gray matter, schizencephaly, Sturge-Weber syndrome, tuberous sclerosis, hemimegalencephaly, with or without various neurocutaneous syndromes, dysembryoplastic neuroepithelial tumor, ganglioglioma, gangliocytoma, glialneuronal hamartoma, perinatal/postnatal insult, and hippocampal sclerosis with or without cortical dysplasia (18, 86–89). FCD is one of the most frequent causes of symptomatic partial epilepsy in infancy (27). Diffuse or bilateral cortical dysplasia is more often associated with generalized epilepsy, but not infrequently associated with partial epilepsies (90). Inborn errors of metabolism or chromosomal disorders may also induce partial seizures (91–93). Neonatal hypoglycemia may cause posterior cerebral lesions and symptomatic epilepsy, most frequently occipital lobe epilepsy (94). The syndrome of celiac disease, epilepsy, and cerebral calcifications is a rare clinical condition characterized by occipital seizures (95).

### Surgical Treatment

The prognosis of symptomatic or cryptogenic partial epilepsies of patients with onset under age 3 years is less favorable than for patients with onset at 3 years or more (96). The probability of seizure control steadily increased until 15 years of treatment, but the cumulative probability of seizure control was small after 5 years of treatment. But epilepsy surgery should be considered in infants with refractory partial epilepsy as early as possible, because partial seizures in early infancy may be catastrophic and associated with poor long-term outcome. Repeated uncontrolled partial seizures in the first months of life may result in cognitive deterioration (97). Cortical resection or

hemispherectomy can produce cessation or a dramatic reduction of seizures for highly selected infants with severe, intractable epilepsy and developmental delay (98). Identification of infants for surgery is often challenging, because seizure semiology may yield few clues to the partial nature of the epilepsy in infants. The interictal EEG is often nonlocalizing, and ictal EEG may not be helpful. Neuroimaging with high-resolution MRI, interictal and ictal single-photon emission computed tomography (SPECT), and interictal positron emission tomography (PET) plays an important role in identifying an epileptic lesion. In infants as well as older patients, the location of a potentially resectable epileptogenic zone must be defined by convergence of results from video-EEG, anatomic and functional neuroimaging, and clinical examination (98). Diagnosis of focal cortical dysplasia may be especially difficult during infancy, when myelination is incomplete and MRI does not reveal the abnormality. Sometimes neuroimaging abnormalities are evident only in early life or for a limited period (99–101).

Seizure-free outcome has been reported to be about 50–80% in infants who had cortical resection or hemispherectomy for catastrophic partial epilepsy due to FCD, infantile spasms with focal or hemispheric lesions, Sturge-Weber syndrome, ganglioglioma, or hemimegalencephaly (88, 98, 102–108). Catch-up developmental progress may be expected after surgery in some infants (98). A better developmental outcome is associated with early surgical intervention (109). The presence of a discrete lesion on preoperative neuroimaging correlated with a favorable surgical outcome (88). Seizure outcomes after surgery were less favorable in infants with FCD than for Sturge-Weber syndrome or low-grade glioma, and patients with hemispherectomies had a better outcome than those with focal cortical resections (105–107).

### Epilepsy with Periodic Spasms

This is a peculiar type of partial epilepsy in infants and children, characterized by an initial focal clinical manifestation or ictal focal discharges followed by a series of bilateral and asymmetrical spasms in periodic sequence (110). The interictal EEG showed focal or multifocal epileptiform discharges but never hypsarrhythmia. The ictal EEG demonstrated a slow wave with superimposed fast rhythm at 15–25 Hz. This disorder is resistant to treatment and is found only in patients affected by a brain disease consisting of a fixed or progressive encephalopathy.

### Partial Epilepsy with Transient West Syndrome

Partial seizures may be combined with epileptic spasms in patients with West syndrome (111–119). In contrast to epilepsy with periodic spasms, the interictal EEG shows

hyparrhythmia. Epilepsy with such combinations often starts with partial epilepsy in the neonatal period or early infancy and evolves into West syndrome, and it often will end up again in partial epilepsy, although it may evolve into Lennox-Gastaut syndrome (120).

### Malignant Epilepsy with Migrating Partial Seizures in Infancy

This syndrome was first described by Coppola et al (121) and subsequently reported by several authors (122–126) and is characterized by onset between 1 day and 7 months of frequent or nearly continuous multifocal partial seizures, intractability to conventional AEDs, lack of identifiable etiology, and progressive decline in psychomotor function. Interictal EEGs show diffuse slowing of the background activity with multifocal epileptiform discharges, which may be rare in the early stage of the disorder. Ictal EEGs display paroxysmal discharges occurring in various regions in consecutive seizures in a given patient. They start in one region and progressively involve the adjacent areas. The area of ictal onset shifts from one region to another and from one hemisphere to the other, with occasional overlapping of consecutive seizures. The migratory feature of ictal discharges is not pathognomonic of the disorder and may be seen in BPEI with complex partial seizures (37). Most conventional AEDs have failed to control seizures, although bromides have been reported to be effective (122). The prognosis, although poor, is not uniformly grim as previously reported (126).

### Symptomatic Partial Epilepsy with Subcortical Lesions

*Gelastic Seizures due to Hypothalamic Hamartoma:* Early-onset gelastic seizures, in association with hypothalamic

hamartoma and occasionally precocious puberty, are a rare but well-recognized epileptic syndrome (127, 128). Gelastic seizures most commonly begin in infancy, even in the neonatal period, and are brief, frequent, and mechanical in nature (127). Seizures may either evolve toward a catastrophic encephalopathy or be transiently severe and progressively settle down. Intermediate situations also exist, as well as cases presenting with a mild epilepsy (129). Cognitive deterioration occurs, and severe behavior problems are frequent. The interictal EEG shows focal frontal or temporal spikes or generalized spike-waves. The ictal EEG demonstrates generalized fast rhythmic activity, generalized suppression of background activity, or both, sometimes preceded by single or multiple generalized spike-waves (127, 130). The variable expression of the epileptic syndrome renders difficult any dogmatic position on early surgery, but recent data suggest that a surgical solution must be sought early (129).

*Hemifacial Seizures of Cerebellar Origin.* Harvey et al (131) reported a 6-month old infant with daily episodes of left hemifacial contraction, head and eye deviation to the right, nystagmoid jerks to the right, autonomic dysfunction, and retained consciousness. The episodes began on day 1 of life and were unresponsive to antiepileptic medication. Interictal and ictal scalp recordings were unremarkable. MRI revealed a mass in the left cerebellar hemisphere and middle cerebellar peduncle. Ictal SPECT revealed focal hyperperfusion in the region of the cerebellar mass. Ictal EEG recordings with implanted cerebellar electrodes demonstrated focal seizure discharges in the region of the mass. Resection of the mass resulted in remission of seizures, and histopathology revealed a ganglioglioma. They concluded that this patient constituted a rare but important clinicopathological syndrome of infancy characterized by epileptic seizures of cerebellar origin.

## Febrile Seizures

**Shlomo Shinnar**  
**Tracy A. Glauser**

**T**he International League Against Epilepsy (ILAE) defined a febrile seizure as “a seizure in association with a febrile illness in the absence of a CNS infection or acute electrolyte imbalance in children older than 1 month of age without prior afebrile seizures” (1). The temperature associated with the febrile illness must be greater than 38.4°C, although the temperature may not be evident until after the seizure. Prior epidemiological studies have used either one month (2–8) or 3 months (9,10) as the youngest age of occurrence, while no specific upper age limit was employed. Febrile seizures have a peak incidence at about 18 months of age, are most common between 6 months and 5 years of age, and onset above age 7 is rare, although it does occur. The child may be neurologically normal or abnormal.

Febrile seizures can be classified as either simple or complex. A simple febrile seizure is isolated, brief, and generalized. Conversely, a complex febrile seizure is focal, multiple (more than one seizure during the febrile illness), or prolonged, lasting either more than 10 (2–6, 11) or 15 (9–11) minutes. The child’s prior neurological condition is not used as part of the classification criteria (1, 12).

### EPIDEMIOLOGY

Febrile seizures are the most common form of childhood seizures, affecting between 2% and 4% of children in the United States and Western Europe (4, 8, 9, 13–15), 9% to 10% of children in Japan (16), and up to 14% of children in Guam (17). The peak incidence of febrile seizures is at approximately 18 months of age.

Most febrile seizures are simple. In a study of 428 children with a first febrile seizure (11), at least one complex feature was noted in 35% of children, including focality (16%), multiple seizures (14%), and prolonged duration (>10 minutes, 13%). Five percent of the total group experienced a seizure lasting more than 30 minutes (i.e., febrile status epilepticus) (11). Despite febrile status epilepticus representing only 5% of febrile seizures, it accounts for approximately one quarter of all episodes of childhood status epilepticus (18–23), and more than two thirds of status epilepticus cases in the second year of life (23). The majority of febrile seizures do not occur at the onset of the fever. In the study of Berg et al, only 21% of the children experienced seizures either prior to or within one hour of the onset of fever; 57% had a seizure after 1 to

24 hours of fever, and 22% experienced their febrile seizure more than 24 hours after the onset of fever (5, 6).

### Risk Factors for First Febrile Seizure

Two studies (24, 25) have examined risk factors associated with experiencing a febrile seizure (Table 19-1). In a 1993 case control population-based study, four factors were associated with an increased risk of febrile seizures: (1) a first- or second-degree relative with a history of febrile seizures, (2) a neonatal nursery stay of >30 days, (3) developmental delay, or (4) attendance at day care. There was a 28% chance of experiencing at least one febrile seizure for children with two of these factors (24). A second case control study examined the issue of which children with a febrile illness were most likely to experience a febrile seizure, using febrile controls matched for age, site of routine pediatric care, and date of visit (25). Significant independent risk factors, on a multivariable analysis, were the peak temperature and a history of febrile seizures in a first- or higher-degree relative. Gastroenteritis as the underlying illness appeared to have a significant inverse (i.e., protective) association with febrile seizures.

### Risk Factors for Recurrent Febrile Seizures

Overall, approximately one-third of children with a first febrile seizure will experience a recurrence; 10% will have three or more febrile seizures (4–10, 14, 26–29). An assessment of various factors potentially associated with the recurrence of febrile seizures is shown in Table 19-2. The most consistent risk factors reported are a family history of febrile seizures and onset of first febrile seizure at <18 months of age (4–7, 9, 10, 14, 26–29). This relationship is not due to a greater tendency to experience seizures with each specific illness, but rather to the longer period during which a child with a younger age of

onset will be in the age group at risk for febrile seizures (27, 28, 30).

Two other definite risk factors for recurrence of febrile seizures are peak temperature (3–5, 27, 28, 31) and the duration of the fever prior to the seizure (3, 4). In general, the higher the peak temperature, the lower the chance of recurrence. In one study, those with peak temperatures of 101°F (38.3°C) had a 42% recurrence risk at one year, compared with 29% for those with peak temperature of 103°F (39.4°C) and only 12% for those with a peak temperature  $\geq$  105°F (40.6°C) (3, 4). Note that the risk factor is the peak temperature during the illness, not the temperature at the time of the seizure or at the time of presentation to the emergency department. The other risk factor related to the acute illness is duration of recognized fever, with a shorter duration of recognized fever associated with a higher risk of recurrence. The recurrence risk at one year was 46% for those with a febrile seizure within an hour of recognized onset of fever, compared with 25% for those with prior fever lasting 1 to 24 hours, and 15% for those having more than 24 hours of recognized fever prior to the febrile seizure.

Children with multiple risk factors have the highest risk of recurrence (3, 27). A child with two or more risk factors has a greater than 30% recurrence risk at 2 years; a child with three or more risk factors has a greater than 60% recurrence risk (3). In contrast, the 2-year recurrence risk is less than 15% for a child with no risk factors (e.g., older than 18 months with no family history of febrile seizures, who experiences a first febrile seizure associated with a peak temperature > 40°C [104°F] after a

recognized fever of more than one hour) (3, 27). A recurrent febrile seizure is also more likely to be prolonged if the initial febrile seizure was prolonged (11, 27).

The relationship between a family history of unprovoked seizures or epilepsy and the overall risk of febrile seizure recurrence appears to be doubtful. Some studies report a modest increase in the risk of febrile seizure recurrence in children with a family history of unprovoked seizures, but a large study in Rochester, Minnesota, found no difference in recurrence risk between children with a family history of epilepsy (25%) and those with no such family history (23%) (4). Other studies have found equivocal results (5, 6, 27, 28).

The presence of a neurodevelopmental abnormality in the child, or a history of complex febrile seizures, have not been shown to be significantly associated with an increased risk of subsequent febrile seizures (4-7, 9, 11, 27, 28). Ethnicity and sex have also not been associated with a clear increased risk of recurrent febrile seizures.

### Risk Factors for Subsequent Epilepsy

The risk factors for developing epilepsy after febrile seizures are summarized in Table 19-3. Following a single simple febrile seizure, the risk of developing epilepsy is not substantially different from the risk in the general population (2, 3, 9, 13, 32, 33).

Data from five large cohorts of children with febrile seizures indicate that 2% to 10% of children who have febrile seizures will subsequently develop epilepsy (2, 3, 9, 13, 32, 33). In each of these five large studies, the occurrence of a family history of epilepsy and the occurrence of a complex febrile seizure were associated

with an increased risk of subsequent epilepsy (2, 3, 9, 13, 32, 33). The occurrence of multiple febrile seizures was associated with a slight, but statistically significant, increased risk of subsequent epilepsy in two studies (2, 33). One study found that children with a febrile seizure that occurred within one hour of a recognized fever (i.e., at onset) had a higher risk for subsequent epilepsy than those children with a febrile seizure associated with longer fever duration (33). Two studies have found that very prolonged febrile seizures (i.e., febrile status epilepticus) were associated with an increased risk of subsequent epilepsy above that of a complex febrile seizure that was less prolonged (2, 33).

The number of complex features in a febrile seizure may possibly affect the risk of recurrence. Although one study found that patients with two complex features (e.g., prolonged and focal) had further increased risk of subsequent epilepsy (2), another study did not detect this association (33). A family history of febrile seizures, age at first febrile seizure, and the height of fever at first seizure are not associated with a differential risk of developing epilepsy (2, 3, 9, 32, 33). The only common risk factor for both recurrent febrile seizures and for subsequent epilepsy was duration of fever prior to the febrile seizure (5, 6, 33); this may be a marker for overall seizure susceptibility.

In general, the types of epilepsy that occur in children with prior febrile seizures are varied and are not very different from those that occur in children without such a history (2, 34-36). Febrile seizures can also be the initial manifestation of specific epilepsy syndromes, such as severe myoclonic epilepsy of infancy (37).

It is controversial whether febrile seizures are simply an age-specific marker of future seizure susceptibility or have a causal relationship with the subsequent epilepsy (38, 39). Two factors support the former, and not the latter, interpretation. There is not an increased incidence of epilepsy in populations with a high cumulative incidence of febrile seizures (e.g., 10% in Tokyo, Japan) (16). Secondly, no evidence exists that treatment of febrile seizures alters the risk of subsequent epilepsy (5, 40-43). However, newer data suggest that, while in most cases the link is not causal, there is a causal link between very prolonged febrile seizures, or febrile status epilepticus, and subsequent hippocampal injury, mesial temporal sclerosis, and temporal lobe epilepsy (44, 45).

### MORBIDITY AND MORTALITY

The morbidity and mortality associated with febrile seizures are extremely low. Multiple studies have demonstrated no evidence of permanent motor deficits following febrile seizures or febrile status epilepticus (8-10, 19, 21, 22, 46-49). No reports of acute deterioration of cognitive abilities have been noted following febrile seizures,

**TABLE 19-3**

even in series limited to status epilepticus (21, 22, 47, 48, 50–52). Three large studies have shown that cognitive abilities and school performance of children with febrile seizures were similar to those of controls (46, 47, 50, 53). Even prolonged febrile seizures do not appear to be associated with adverse cognitive outcomes (47, 48, 50, 52).

No deaths were reported from the National Collaborative Perinatal Project (9, 10) or the British cohort study (8, 46, 47). The mortality of febrile status epilepticus in recent series is extremely low (19–22, 47–49, 51).

## GENETICS

Genetic influences are evident in multiple studies. A positive family history of febrile seizures is a definite risk factor for both a first febrile seizure (24, 25) and recurrent febrile seizures (4–7, 9, 27, 28). Tsuboi reported a febrile seizure concordance rate of 56% in monozygotic and 14% in dizygotic twins in a study of 32 twin pairs and 673 sibship cases (54). Correlation of clinical symptoms, including age of onset and degree of fever, was larger in the twin pairs than in the sibship cases. A separate data set from Rochester, Minnesota, demonstrated similar results (55). Most likely, all children have some increased susceptibility to seizures from fever at the specific age window. Genetic influences are therefore likely to account for some, but not all, of the cases.

Overall, there appears to be a multifactorial mode of inheritance for febrile convulsions, but there may be a subset of children with an autosomal dominant mode of inheritance (55–57). To date, no definitive gene or locus for febrile seizure has been established. Some cases of febrile seizures in large families have been linked to genes on chromosomes 8 and 19 (56–58). A discussion of the relationship of febrile seizures and specific syndromes such as GEFS+ is found in Chapter (20).

## INITIAL EVALUATION

Meningitis, encephalitis, serious electrolyte imbalance, and other acute neurological illnesses must be excluded in order to make the diagnosis of a febrile seizure. A detailed history and physical and neurological examinations are essential and can eliminate many of those neurological conditions. Routine serum electrolytes, calcium, phosphorus, magnesium, complete blood count (CBC), and blood glucose are of limited value in the evaluation of a child above 6 months of age with a febrile seizure in the absence of a suspicious history (e.g., vomiting, diarrhea) or physical findings (14, 59–62).

The most common evaluation issue is whether a lumbar puncture is necessary to exclude meningitis. The

incidence of meningitis in children who present with an apparent febrile seizure is between 2% and 5% (14, 60–67). In each of these series, the majority had identifiable risk factors. In one series, four features were noted in children with meningitis: a visit for medical care within the previous 48 hours; seizures on arrival to the emergency room; focal seizure; or suspicious findings on physical or neurological examination (63). In the absence of risk factors, other authors have found a low yield for routine lumbar puncture (14, 64, 65, 67).

The American Academy of Pediatrics issued guidelines for the neurodiagnostic evaluation of a child with a simple febrile seizure between 6 months and 5 years of age (14). A lumbar puncture should be strongly considered in infants less than 12 months of age. Children between 12 and 18 months of age need careful assessment, because the signs of meningitis may be subtle. In the absence of suspicious findings on history or examination, a lumbar puncture is not necessary in children above 18 months of age. A lumbar puncture is still recommended in children with a first complex febrile seizure, as well as in any child with persistent lethargy. It should also be strongly considered in a child who has already received prior antibiotic therapy. A recent practice parameter of the American Academy of Neurology also recommends that a lumbar puncture be done in children with status epilepticus and fever (68). Any CSF pleocytosis is of concern, because, even in children with febrile status epilepticus, more than 4 or 5 white blood cells (WBCs) per mm<sup>3</sup> are very uncommon (69).

Skull X-rays are of no value. Computed tomography (CT) scans are also of limited benefit in this clinical setting and are used when there is concern about increased intracranial pressure or when trauma is suspected. Magnetic resonance imaging (MRI) scans are not indicated in children with a simple febrile seizure (14). It is unclear whether or not an MRI study is indicated in the evaluation of a child with a prolonged or focal febrile seizure (39, 70). Recent data do indicate that a number of children with prolonged febrile seizures will have acute changes in the hippocampus seen on MRIs done within a few days of the episode (44, 45, 70), but at this point such imaging has not yet become routine practice.

Electroencephalograms (EEG) are of limited value in the evaluation of the child with febrile seizures (14, 71–74). EEGs are more likely to be abnormal in older children, children with preexisting neurodevelopmental abnormalities, children with a family history of febrile seizures, or children with a complex febrile seizure (36, 71, 73, 75–78). Even if present, the clinical significance of these EEG abnormalities is unclear. There is no evidence so far that EEG abnormalities help predict either recurrence of febrile seizures or the development of subsequent epilepsy (14, 36, 71, 73, 75–79), though

preliminary data from an ongoing study suggest a high rate of significant EEG abnormalities in children with very prolonged febrile seizures (80).

### PATHOPHYSIOLOGY

In general, febrile seizures appear to be an age-specific occurrence, where increased susceptibility to seizures is induced by fever. However, the detailed pathophysiology remains unclear. Decades ago, the key factor was thought to be the rate of rise of the fever (81); recent data suggest that the key factor is the actual peak temperature (25, 82). Gastroenteritis is associated with a lower incidence of febrile seizures (25), whereas herpesvirus-6 infections have had a high reported association with febrile seizures (83–85).

Animal models of febrile seizures also show an age-dependent effect (86–89). In addition, *in vitro* preparations show induction of epileptiform activity by temperature elevation in hippocampal slices in young rats (90). Recent animal data from Baram and colleagues suggest that prolonged febrile seizures may lead to long-lasting changes in the hippocampal circuits. In a rat model of prolonged febrile seizures, cytoskeletal changes in neurons were evident within 24 hours and persisted for several weeks without leading to cell loss (91). However, altered functional properties of these injured neurons were evident (92, 93). Nevertheless, even in this model, which has produced convincing data for functional changes, a seizure duration of 20 minutes or more was required. Seizures lasting 10 minutes or less were not associated with any anatomic or functional changes.

As may be the case in humans, animals with pre-existing neurological abnormalities are more susceptible to seizures and to their consequences. Young rats with neuronal migration disorders appear more susceptible to hyperthermia-induced seizures (87) and are also more susceptible to hippocampal damage. Interestingly, in this model, hippocampal damage occurs with hyperthermia even in the absence of seizures. The availability of animal models provides a new means of studying the pathophysiology of febrile seizures and their consequences.

### FEBRILE SEIZURES AND MESIAL TEMPORAL SCLEROSIS

It remains controversial whether prolonged febrile seizures cause mesial temporal sclerosis (MTS) (39, 52). Retrospective studies (from tertiary epilepsy centers) report that many adults with intractable mesial temporal lobe epilepsy had a history of prolonged or atypical febrile seizures in childhood (94–100). However, both population-based studies and prospective studies of children

with febrile seizures have failed to find this association (2, 8, 9, 13, 33, 38, 47).

In those studies that reported an association between prolonged febrile seizures and MTS, the duration of the febrile seizures was extremely prolonged. Maher and McLachlan (101) reported on a large family with a high rate of both febrile convulsions and temporal lobe epilepsy. The mean duration of the febrile seizures in those who subsequently developed temporal lobe epilepsy was 100 minutes. Van Landingham et al (70) reported that few children with very prolonged (mean of >90 minutes) focal febrile seizures had acute changes on an MRI, which, in some cases, was followed by later chronic changes (70). However, these MRI changes only occurred in a small minority of patients. Furthermore, all cases of MTS in this study occurred in patients who had focal seizures, some of whom also had focal lesions, which raises the question of preexisting focal pathology.

Overall, febrile seizures are not likely to account for the majority of cases of MTS. Febrile seizures lasting more than 90 minutes are very rare and are uncommon even in series of febrile status epilepticus (9, 11, 15, 21, 22, 33, 47, 48, 50, 51, 70, 102). Very prolonged febrile seizures are also usually focal (70, 102). In cases of febrile status epilepticus, imaging abnormalities are relatively uncommon (70). MTS can also be found in many patients who have no prior history of febrile seizures (103–108). Recent clinico-pathological studies have also provided evidence for multiple etiologies for MTS, as well as the frequent presence of dual pathology, such as subtle migration defects (105–108).

More recent studies do suggest that prolonged febrile seizures can cause acute hippocampal injury in 20–30% of cases and that these may lead to hippocampal volume loss and MTS (44, 45, 109). An ongoing multicenter study currently in progress should eventually provide the answers to the relationship between prolonged febrile seizures and subsequent MTS and temporal lobe epilepsy (109).

## TREATMENT

### Overview

Two distinct approaches to the treatment of febrile seizures have developed based on the perceived immediate and long-term risks of febrile seizures. One approach is based on the old idea that febrile seizures are harmful and may lead to the development of epilepsy; this approach is aimed at preventing febrile seizures by using either intermittent or chronic treatment with medications (72, 110, 111). The second approach is based on the epidemiological data that febrile seizures are benign; the only concern focuses on aborting febrile seizures to prevent status epilepticus.

## Stopping a Febrile Seizure

### *In Hospital*

Ongoing seizure upon arrival in the emergency department is an indication for initiating therapy. Intravenous diazepam is effective in most cases (20, 112). Rectal diazepam or diazepam gel would also be appropriate for use in a prehospital setting, such as an ambulance, and in cases where intravenous access is difficult (20, 113–115). Other benzodiazepines, such as lorazepam, may also be effective but have not been adequately studied (20, 112). If the seizure continues after an adequate dose of a benzodiazepine, a full status epilepticus treatment protocol should be initiated (20, 112).

### *At Home*

The majority of febrile seizures are brief, lasting less than 10 minutes, and no intervention is necessary. Rectal diazepam or diazepam gel has been shown to be effective in terminating febrile seizures and is the therapy of choice for intervention outside the hospital (113–115). It should be used with caution, and only by reliable caregivers who have been trained in its use. Families with children at high risk for, or with a history of, prolonged or multiple febrile seizures (11), and those who live far from medical care, are excellent candidates to have rectal diazepam or diazepam gel readily available in their homes. For many families, the availability of a rectal diazepam formulation will relieve anxiety, even after a single febrile seizure, even though they will most likely never have to use it (116–118).

## Preventing a Febrile Seizure

### *Intermittent Medications at Time of Fever*

*Antipyretics.* Despite the logical assumption that aggressive treatment with antipyretic medication would reduce the risk of having a febrile seizure, and the finding of case control studies that the risk of a febrile seizure is directly related to the height of the fever (25, 82), there is little evidence to suggest that antipyretics reduce the risk of a recurrent febrile seizure (66, 119). It should be recalled that the children in whom the febrile seizure occurs at the onset of the fever have the highest risk of recurrent febrile seizures (5, 6). Any recommendations for antipyretic therapy should take into account its limitations and avoid creating undue anxiety and guilt in the parents.

*Benzodiazepines.* Diazepam, given orally or rectally at the time of onset of a febrile illness, has demonstrated a statistically significant, yet clinically modest, ability to reduce the probability of a febrile seizure (26, 120–124). In one large, randomized trial comparing placebo with oral diazepam (0.33 mg/kg/dose every 8 hours with fever), 22% of the diazepam-treated group

had seizure recurrence by 36 months, compared with 31% of the placebo-treated group (124). One must weigh this modest reduction in seizure recurrence with the side effects of sedating children every time they have a febrile illness.

*Barbiturates.* Intermittent therapy with phenobarbital at the onset of fever is ineffective in reducing the risk of recurrent febrile seizures (125, 126). Surprisingly, it is still fairly widely used for this purpose (72, 110, 111).

### *Daily Medications*

*Barbiturates.* Phenobarbital, given daily at doses that achieve a serum concentration of 15 µg/mL or higher, has been shown to be effective in reducing the risk of recurrent febrile seizures in several well-controlled trials (119, 122, 123, 127–130). However, in these studies, a substantial portion of the children had adverse effects, primarily hyperactivity, which required discontinuation of therapy (131–133). More recent studies have cast some doubt on the efficacy of the drug and, more importantly, have raised concerns about potential long-term adverse effects on cognition and behavior (131, 134). Chronic phenobarbital therapy is rarely indicated, as the risks seem to outweigh the benefits in most cases.

*Valproate.* Daily treatment with valproic acid is effective in reducing the risk of recurrent febrile seizures in both human and animal studies (89, 123, 129, 130). However, it is very rarely used, because children considered most often for prophylaxis (young and/or neurologically abnormal) are also the ones at highest risk for fatal idiosyncratic hepatotoxicity (135, 136).

*Other AEDs.* Despite evidence of effectiveness when used in intermittent therapy, there is no experience with chronic use of benzodiazepines for treatment of febrile seizures. Even if effective, benzodiazepines' toxicity and adverse effect profile would likely preclude their widespread use in this setting. Phenytoin and carbamazepine are ineffective in preventing recurrent febrile seizures in humans and in animal models of hyperthermia-induced seizures (89, 127, 128, 137). There are no published data on the efficacy of the newer AEDs, such as gabapentin, lamotrigine, topiramate, tiagabine, or vigabatrin, in the treatment of febrile seizures.

## Preventing Epilepsy

There is no evidence that preventing febrile seizures will reduce the risk of subsequent epilepsy. One rationale for starting chronic antiepilepsy therapy in children with febrile seizures was to prevent the development of future epilepsy (72, 110, 111). In three studies comparing

placebo with treatment (either with daily phenobarbital or with diazepam administered at the onset of fever), treatment significantly and substantially reduced the risk of febrile seizure recurrence, but the risk of later developing epilepsy was no lower in the treated groups than in the controls (26, 40–43, 126). No difference in the occurrence of epilepsy, or in school performance or other cognitive outcomes, was seen between the treated group and control group in two of these studies with more than 10 years of follow-up (40, 41).

### Therapy Recommendations

A recent practice parameter by the American Academy of Pediatrics suggests that the best treatment for simple febrile seizures is reassurance of the parents regarding their benign though frightening nature (138). The authors wholeheartedly agree that treatment is only rarely indicated for a simple febrile seizure. In fact, no treatment is needed in most children with complex febrile seizures. Because the data suggest that only prolonged febrile seizures are associated with hippocampal injury and may be causally linked to subsequent epilepsy (39, 44), a rational goal of therapy would be to prevent very prolonged febrile seizures. When treatment is indicated, particularly in those at risk for prolonged or multiple febrile seizures (11) or those who live far away from medical care, rectal diazepam or diazepam gel used at the time of seizure as an abortive agent would seem the most logical choice (20, 112–115). Daily medications or benzodiazepines at the time of fever are rarely used in the management of febrile seizures.

### Counseling and Education

Counseling and education will be the sole treatment for the majority of children with febrile seizures. Education is key to empowering the parents, who have just experienced a very frightening and traumatic event (139). Many parents, even of children with a simple febrile seizure,

are afraid that their child could have died (140). Parents need to be reassured that the child will not die during a seizure and that keeping the child safe during the seizure is generally the only action that needs to be taken.

The basic facts about febrile seizures should be presented to the family. The amount of information and the level of content will depend largely on the medical sophistication of the parents and their ability to attend to the information given to them at that particular time. The parents' perception of their child's disorder will be an important factor in their later coping and will ultimately impact on their perception of quality of life (139).

Parents will usually be interested in information that will help them manage the illness or specific problems; lengthy explanations are usually not helpful. Information should be provided about how to manage further seizures should they occur. This should include what to do during a seizure, when it may be necessary to call the physician, and when the child should be taken to the emergency department.

In those cases where rectal diazepam or diazepam gel is being recommended for the next seizure, explicit instructions regarding its use should be given. As it is difficult to absorb all this information in an emergency department setting, it is usually advisable to see the family again a few weeks later to review the information and answer any additional questions they may have.

### CONCLUSION

Febrile seizures are the most common of childhood seizures and are usually benign. There is accumulating evidence that prolonged febrile seizures lasting more than 30 minutes may have long-term consequences. An understanding of the natural history and prognosis will enable the physician to reassure the families and provide appropriate counseling and management while avoiding unnecessary diagnostic and therapeutic interventions.

## Generalized Epilepsy with Febrile Seizures Plus (GEFS+)

*Douglas R. Nordli, Jr.  
John M. Pellock*

**G**eneralized epilepsy with febrile seizures plus (GEFS+) was defined by Scheffer and colleagues in 1997 and was based upon a very careful and extensive examination of large families with multiple affected individuals (1). Family members had febrile seizures alone (FS); febrile seizures “plus,” meaning febrile seizures beyond the typical age limit of 6 years, or a history of febrile seizures along with afebrile generalized seizures; or afebrile seizures. Early descriptions of the afebrile seizures in these individuals highlighted generalized seizures including absence, convulsions, myoclonus, and atonic seizures. Later descriptions included a richer variety of seizures and epilepsy syndromes. Perhaps the most startling revelation was the fact that some families contained children with severe epilepsies, including myoclonic-astatic epilepsy (MAE) as described by Doose, Dravet syndrome, temporal lobe epilepsy, and infantile spasms. It was quickly recognized that this was a very important contribution to our understanding of the genetic contributions to epilepsy. Some characteristics appeared to be inherited in an autosomal dominant fashion, but the extremely broad clinical spectrum of affected individuals in some families strongly suggested polygenic contributions. These genetic influences may involve complex interactions among susceptibility genes, modifier genes, and the environment.

### EPIDEMIOLOGY

The discovery of GEFS+ postdates many of the classic and extensive epidemiological studies of childhood epilepsy. The original patients were described in large family kindreds, which are undoubtedly quite rare. GEFS+ more commonly presents in small families, or perhaps with spontaneous mutations where the genetic contributions are probably not appreciated by the physicians caring for the patients, unless the individual presents with a severe phenotype, such as Dravet syndrome, and undergoes SCN1A testing. These facts, coupled with the large and diverse clinical spectrum of the disorder, make it difficult to establish the precise incidence and prevalence. It is nevertheless clear that families with GEFS+ have been confirmed in many different regions of the world with diverse racial backgrounds and that the phenomenon is not isolated to a restricted gene pool. There is no clear gender preponderance.

### CLINICAL MANIFESTATIONS

The clinical manifestation of GEFS+ are diverse (1, 2). The commonest phenotype is typical febrile seizures, defined as convulsions in the setting of fever (above 38°C) in children between the ages of 3 months and 6 years. The

second most common phenotype is febrile seizures plus, which indicates that febrile seizures continued beyond 6 years of age or that there were afebrile convulsions in addition to the febrile seizures. The least common phenotype was isolated afebrile convulsions in childhood. Generalized seizure types seen include absence, atonic, and myoclonic seizures. Focal seizures arising from the temporal or frontal regions have also been reported (3).

Two of the most severe phenotypes reported in families with GEFS+ include MAE, as described by Doose and colleagues, and Dravet syndrome. About one third of children with myoclonic-astatic epilepsy have a history of febrile seizures. Boys are more commonly affected. Myoclonic-astatic seizures are the commonest manifestation, but myoclonic, atonic, absence, and generalized clonic-tonic-clonic seizures are also observed. Tonic seizures may be present, particularly during the night, and nonconvulsive status epilepticus is also seen. Generalized spike-wave discharges are common, as are rhythmic bursts of biparietal theta activity. Many patients will go into remission with several years of onset, but the outcome is variable, and some patients will be left with substantial cognitive disabilities (4).

Children with Dravet syndrome typically present in the first year of life with febrile hemiclonic seizures or generalized convulsions (5). Children then develop a variety of afebrile seizures including absence, atonic, myoclonic, or focal seizures. The electroencephalogram (EEG) may initially show focal spikes in the posterior derivations, but later, generalized spike-wave discharges develop in most individuals, and a photoparoxysmal response may be seen in some.

### EEG FEATURES

EEG backgrounds are usually normal. Interictal features appear to vary according to the clinical phenotype. Those individuals with febrile seizures alone often have normal EEGs (1). Those with febrile seizures and generalized afebrile seizures may have generalized spike-wave discharges. Patients with the MAE or Dravet phenotype have the corresponding EEG features. Patients with focal seizures may have focal spikes, or focal slowing (3).

### PATHOPHYSIOLOGY

The pathophysiology of GEFS+ has been well studied. Mutations involving three different genes have been shown to be relevant, but these genes alone cannot explain the large phenotypic variety seen in the families of affected individuals. It is likely that other genes yet to be discovered, the environment, or both play additional roles in determining the phenotype. It has been speculated

that a fuller knowledge of these interactions may illuminate important pathophysiological mechanisms in other forms of epilepsy.

These genes involved in GEFS+ encode the gamma-aminobutyric acid A (GABA<sub>A</sub>) receptor and the neuronal sodium channel. The gene encoding the alpha1 subunit of the sodium channel, SCN1A, is the most frequently mutated in GEFS+. This subunit has four domains, which create the pore of the channel, a voltage sensor, and an anchor to the axonal membrane. Missense mutations are found at many different loci and may cause gain of function, loss of function, or no discernable change in the channel properties (6–8). Mutations of the beta subunit, SCN1B, have also been found, but these are less common (9). The mutations effect an extracellular portion of the protein that is important in altering properties of the channel. Finally, mutations of the gene that encodes the GABA<sub>A</sub> receptor are reported in GEFS+. These mutations involve the gamma2 subunit, GABRG2, and the delta subunit, GABRD (10, 11). These mutations are the most rare in GEFS+ but may be of particular importance because of their association with idiopathic generalized epilepsies.

### DIAGNOSTIC EVALUATION AND DIFFERENTIAL DIAGNOSIS

Patients with febrile seizures are common, and as many as 15–20% of all patients with epilepsy have had febrile seizures. The main features suggesting GEFS+ are a positive family history, the persistence of seizures beyond 6 years of age, and the coexistence of other, afebrile seizures (see Table 20-1). The evolution to severe forms of epilepsy

**TABLE 20-1**  
*Features of GEFS+*

Positive Family History
Febrile Seizures +
Starting earlier than typical febrile seizures (before 6 months)
Continuing longer than usual (above age 6 years)
Generalized Epilepsy (from early to mid-childhood)
Brief nonfebrile generalized convulsions
Absences
Myoclonic jerks
Tonic seizures
Focal Seizures
May be seen, mostly of frontal or temporal origin
Severe Epilepsies (May Be Associated)
Dravet syndrome
Myoclonic-astatic epilepsy
West syndrome

is most likely to be phenotypically consistent with Dravet syndrome or MAE. Genetic testing for SCN1A gene mutations (targeted at identification of individuals with the severe or Dravet phenotype) is now commercially available in the United States.

## TREATMENT

The large amount of emerging information regarding the pathogenesis of the seizures in GEFS+ should ultimately direct the development of rational therapies for patients with GEFS+. So far, though, such recommendations are lacking (12). Patients at risk for prolonged or repeated febrile seizures may be prescribed rectal diazepam to be used as needed for these circumstances. There are no formal guidelines for determining when, if ever, one should

initiate prophylactic treatment in children with repeated febrile seizures, particularly those whose febrile seizures are persisting beyond the expected age cutoff of 6 years. Treatment of patients with repeated afebrile seizures would depend upon the seizure type. Treatment of Dravet syndrome and MAE is described in Chapter 17.

## COURSE AND PROGNOSIS

The course is generally favorable. The majority of patients do not have refractory epilepsies, and their epilepsy, if it develops, usually spontaneously remits, often by mid-childhood (2). Patients with a clinical phenotype consistent with Dravet syndrome have a severe prognosis, and those with MAE must be considered to have a guarded prognosis.

## Lennox-Gastaut Syndrome

*Diego A. Morita  
Tracy A. Glauser*

**A**mong the numerous epileptic syndromes occurring during childhood, a subset is characterized by severe, treatment-resistant seizures, usually associated with progressive loss of higher intellectual functions and characteristic electroencephalogram (EEG) abnormalities. These age-dependent epileptic syndromes are often called encephalopathic epilepsies or epileptic encephalopathies, a descriptive terminology that does not shed light on their underlying pathophysiologies or specific etiologies. It has been proposed that these syndromes are age-specific epileptic reactions to nonspecific and diverse exogenous insults (1). This subgroup of pediatric epilepsy syndromes includes early infantile epileptic encephalopathy with suppression-burst (EIEE, Ohtahara syndrome) and infantile spasms (West syndrome), both of which are discussed in detail elsewhere in this book (Chapters 15 and 16). The focus of this chapter is on childhood epileptic encephalopathy with diffuse slow spike-and-waves (Lennox-Gastaut syndrome, or LGS).

### HISTORY

The clinical manifestations of the Lennox-Gastaut syndrome have been recognized for more than two centuries. In 1772, Tissot described a mentally retarded boy who

had multiple daily brief motor seizures with drop attacks (2). In 1886, Jackson reported a young child who had been having stiffening spells (with subsequent falling and facial injury), occurring 20 to 50 times a day, since the age of 2 years (2). In the early twentieth century, Hunt reported more than 10 patients suffering abrupt loss of postural tone, resulting in falls with subsequent significant facial and knee injuries (2).

With the advent of the EEG, neurologists began to look at clinical-electrographic correlates (both ictal and interictal) in patients with epilepsy. In 1935, the 3-Hz spike-and-wave discharge associated with “petit mal” seizures was first described by Gibbs, Davis, and Lennox (3). Subsequently, in 1939, Gibbs, Gibbs, and Lennox identified a similar, yet slower pattern (approximately 2 per second) and proposed to call it a “petit mal variant” to distinguish it from the classic 3-Hz spike and wave (4).

In 1945, Lennox assembled the clinical manifestations and the EEG manifestations into the first semblance of the electroclinical syndrome (5) that we now call childhood epileptic encephalopathy with diffuse slow spike-and-waves, or the Lennox-Gastaut syndrome. Lennox’s triad consisted of the slow spike-and-wave interictal EEG pattern, mental retardation, and three types of seizures considered characteristic: myoclonic jerks, atypical absence, and “drop attacks” (also known as akinetic seizures or astatic seizures) (2, 5–7).

This constellation of symptoms initially was not given a formal syndrome name. Renewed interest in this syndrome began in 1964, when Sorel and Doose each described about 20 cases (8, 9). Three meetings held in Marseille (the 13th, 14th, and 16th Symposia of Marseille in 1964, 1966, and 1968, respectively) examined the syndrome in depth (2). After the first meeting ended with divergent views on the subject, multiple investigators sought to better define the electroclinical manifestations of this syndrome (2). Dravet, in her doctoral thesis in 1965 and two subsequent papers in 1966, reported the results of these intensive studies (10–12). The 1966 Marseille meeting culminated in the proposal to name the syndrome the Lennox-Gastaut syndrome, acknowledging the significant contributions of both the United States and French groups to the understanding of the syndrome (2). The 1968 meeting in Marseille reinforced the existence of this syndrome in each of the participants' countries and solidified its position in the pantheon of epileptic syndromes (2).

The importance of recognizing patients with LGS increased in the early 1990s, when this population was identified as a target group to participate in trials of investigational antiepileptic drugs (AEDs). The factors contributing to the targeting of this group for study with investigational AEDs include their high daily seizure frequency, the lack of very effective therapy, and the desire to examine safety and efficacy issues for investigational AEDs in pediatric populations before general release.

The current definition of LGS by the International League Against Epilepsy (ILAE) classification is as follows (13):

LGS manifests itself in children aged 1–8 years, but appears mainly in preschool-age children. The most common seizure types are tonic-axial, atonic, and absence seizures, but other types such as myoclonic, generalized tonic-clonic seizures (GTCS), or partial seizures are frequently associated with this syndrome. Seizure frequency is high, and status epilepticus is frequent (stuporous states with myoclonias, tonic and atonic seizures). The EEG usually has abnormal background activity, slow spike-and-waves <3Hz and, often, multifocal abnormalities. During sleep, bursts of fast rhythms (10 Hz) appear. In general, there is mental retardation. Seizures are difficult to control, and the development is unfavorable. In 60 percent of cases, the syndrome occurs in children suffering from a previous encephalopathy, but is primary in other cases.

A triad of basic elements needed to make a diagnosis of LGS is usually stated based on this definition, coupled with clinical experience and research:

1. Multiple types of seizures including tonic seizures, atypical absences, and atonic seizures;

2. An EEG pattern consisting of interictal diffuse slow spike-and-wave discharges occurring at a 1.5- to 2-Hz frequency
3. Diffuse cognitive dysfunction and/or mental retardation (2, 13–18)

There is abundant discussion among epileptologists about the minimal necessary and sufficient criteria to diagnose a patient with LGS. Some investigators do not consider cognitive dysfunction or mental retardation indispensable for diagnosis, especially at onset, if the seizures and EEG pattern are typical (15, 19–21). Other authors use a stricter EEG criterion, requiring that the diagnostic EEG pattern include bursts of generalized fast spikes (10 Hz) during non-rapid-eye movement (NREM) sleep (22).

Ohtahara proposed a more comprehensive set of diagnostic criteria consisting of indispensable, supportive, and suggestive criteria (19). The indispensable criteria are the combination of tonic seizures, atypical absences, atonic seizures, myoclonic seizures, and atonic seizures, with an interictal EEG pattern of diffuse slow spike-and-waves. Mental retardation, bursts of generalized fast spikes (10 Hz) during NREM sleep, onset in early childhood, and treatment-resistant seizures are among the supportive features (19).

In the 2001 ILAE proposal for classification and terminology of seizures and epilepsy, LGS was classified as an epileptic encephalopathy in which the epileptiform abnormalities may contribute to progressive dysfunction (23).

## EPIDEMIOLOGY

Overall, LGS accounts for 1% to 4% of all cases of childhood epilepsy, but 10% of cases that start in the first 5 years of life (20, 21, 24–30). Epidemiological studies in the Western or industrialized world (Israel, Spain, Estonia, Italy, and the United States) demonstrated that the proportion of LGS seems relatively consistent across various populations (21, 25–28). The annual incidence of LGS in childhood is 2 per 100,000 children (30, 31). The prevalence of LGS ranges from 0.1 to 0.28 per 1,000 in Europe and the United States (21, 31–33).

The prevalence and percentage of LGS in mentally retarded children were reported as 0.06 per 1,000 and 7%, respectively (29). The proportion of LGS in institutionalized patients with mental retardation is as high as 16.3% (34).

Males are affected more often than females. Most studies do not report this gender difference to be statistically significant, but in an epidemiological study in Atlanta, Georgia, the difference between males and females was significant ( $P < 0.005$ ) (21, 30, 35, 36). The

relative risk of occurrence of LGS is significantly higher in boys (prevalence rate, 0.1 per 100 for boys, 0.02 per 1,000 for girls; rate ratios 5.31; 95% confidence interval, 1.16–49.35) (32). There are no racial differences in the occurrence of LGS (21). The mean age at epilepsy onset is 26 to 28 months (range, 1 day–14 years) (20, 36). The peak age at epilepsy onset is older in the symptomatic LGS group, but the difference in age of onset between the group with a history of West syndrome compared with the group without such a history was not significant. The average age at diagnosis of LGS in Japan was 6 years (range, 2–15 years) (20). Compared with other patients with less severe epilepsies, patients with LGS have a younger age of onset of epilepsy (30).

Lennox-Gastaut syndrome can be classified according to its suspected etiology as either idiopathic or symptomatic. Patients may be considered to have idiopathic LGS if there is normal psychomotor development before the onset of symptoms, if there are no underlying disorders or definite presumptive causes, and if there are no neurologic or neuroradiologic abnormalities (19). In contrast, patients have symptomatic LGS if there is an identifiable cause for the syndrome.

Population-based studies found that 22% to 30% of patients have idiopathic LGS, and 70% to 78% have symptomatic LGS (19, 20, 35, 37). Examples of underlying pathologies responsible for symptomatic LGS include encephalitis/meningitis, tuberous sclerosis, brain malformations (e.g., cortical dysplasias), birth injury, hypoxic-ischemic injury, frontal lobe lesions, and trauma (18, 19, 38). Infantile spasms precede the development of LGS in 9% to 41% of cases (14, 21, 38).

Some investigators add “cryptogenic” as a different etiological category, in which there is no identified cause when a cause is suspected and the epilepsy is presumed to be symptomatic. In an epidemiological study in Atlanta, Georgia, 44% of all LGS patients were classified in the cryptogenic group (21). Reports of a family history of epilepsy and febrile seizures for patients with LGS range from 2.5% to 47.8% (noted in a series of 23 patients with cryptogenic LGS) (35, 36).

## CLINICAL MANIFESTATIONS

Before onset, 20% to 30% of children with LGS are free from neurologic and neuropsychologic deficits. These problems inevitably appear during the evolution of LGS. Factors associated with mental retardation are symptomatic LGS, a previous history of West syndrome, onset of symptoms before 12 to 24 months of age, and higher seizure frequency (18, 35, 37, 39).

The average intelligence quotient (IQ) in a series of 72 patients with LGS followed up for more than 10 years was significantly lower in the symptomatic

group than in the cryptogenic group (20, 40). At the time of the first examination, the IQ showed a variable degree of mental retardation in 66% of the cryptogenic group and in 76% of the symptomatic group. At the last examination, mental retardation was found in 95% of the cryptogenic group and in 100% of the symptomatic group (20). A significant correlation exists between age of onset of seizures and mental deterioration, with a favorable cognitive outcome more likely to occur in patients with a later age of LGS onset (40). In one study, almost 98% of the patients who had the onset of seizures before age 2 years, and 63% of those with onset after the age of 2 years, had definite cognitive impairment (39). In some patients with LGS, mental retardation could be a result of nonconvulsive status epilepticus (41).

Psychiatric symptoms in young children consist of mood instability and personality disturbances, whereas slowing or arrest of psychomotor development and educational progress characterize the neuropsychological symptoms. Character problems predominate in older children, and acute psychotic episodes or chronic forms of psychosis with aggressiveness, irritability, or social isolation may occur (35). Prolonged reaction time and information processing are the most impaired of the cognitive functions (18). Kaminska et al found that the main characteristics of mental deterioration were apathy, memory disorders, impaired visuomotor speed, and perseveration (42). The major electrographic abnormalities associated with LGS may account for some of the abnormalities found in higher intellectual functions. Commonly, the epileptiform discharges are frequent and may affect the ability of the patient to engage with the surroundings (43).

Several types of seizures occur in LGS including tonic, atonic, myoclonic, and atypical absences, often associated with other less common types.

### Tonic Seizures

Tonic seizures are said to be the most characteristic type of seizure and occur in 17% to 95% of children with LGS (16, 38). Tonic seizures are more frequent during NREM sleep; therefore, researchers who have systematically obtained sleep tracings reported higher prevalences. These seizures can occur during wakefulness or sleep, but if they occur only during sleep they may go unnoticed (35).

Tonic seizures may be (1) axial tonic, involving the head and the trunk, with head and neck flexion, contraction of masticatory muscles, and eventual vocalizations; (2) axorhizomelic tonic, in which there is tonic involvement of the proximal upper limbs, with elevation of the shoulders and abduction of the arm; or (3) global tonic, with contraction of the distal part of the extremities,

sometimes leading to a sudden fall and other times mimicking infantile spasms (18, 22, 35).

Tonic seizures can be asymmetric, and some patients may show gestural automatisms after the tonic phase. Duration is from a few seconds to a minute, and, if prolonged, they can end in a vibratory component. In some seizures, the activity may be limited to upward deviation of the eyes (“sursum vergens”) and a slowing of respiration (18, 35), which may be mistaken for physiologic phenomena.

### Atypical Absences

The reported frequency ranges from 17% to 100% (16, 22). In most studies, the frequency of the different types of seizures reported is based on parental counting of seizures, reviews from charts, or not specifically stated. Unfortunately, parental ability to recognize and identify atypical absences correctly is poor. In one study using video-EEG monitoring in a cohort of children with LGS, parental recognition was 27% for atypical absences, but the sensitivity was as high as 80% for myoclonic seizures and 100% for tonic, atonic, tonic-clonic, clonic, and complex partial seizures (44).

Atypical absences may be difficult to diagnose because the onset may be gradual (18, 22, 35) and there may be an incomplete loss of consciousness that allows the patient to continue activities to some degree. They may be associated with eyelid myoclonias, not as rhythmic as in typical absences, but often associated with perioral myoclonias or progressive flexion of the head secondary to a loss of tone (35). Automatisms may be observed (18). The seizure end may be gradual in some cases or abrupt in others (18, 22, 35).

### Atonic Seizures, Massive Myoclonic Seizures, and Myoclonic-Atonic Seizures

Atonic seizures, massive myoclonic seizures, and myoclonic-atonic seizures can be difficult to differentiate by clinical observation alone, and there are considerable discrepancies in how these terms are used. The reported frequency ranges from 10% to 56% (16, 18, 20, 21, 36, 37). They produce sudden fall, producing injuries (“drop attacks,” “Sturzan-falle”), sometimes limited to the head, resulting in the head falling on the chest (“head drop,” “head nod,” “nictatio capitis”) (2, 35, 45). Ikeno et al found that pure atonic seizures are exceptional and that most so-called atonic seizures had a tonic or myoclonic component (45).

### Other Types of Seizures

Generalized tonic-clonic seizures are reported in 15% of patients with LGS, whereas complex partial seizures occur in 5% (18). Status epilepticus of different types (absence

status epilepticus, tonic status epilepticus, nonconvulsive status epilepticus) can occur (16, 18) and is characterized by a long duration and resistance to treatment.

Donat and Wright reported in patients with LGS, infantile spasms-like seizures with clinical characteristics and ictal EEG changes similar to those typically seen in West syndrome. These seizures consisted of brief myoclonic jerks and brief stiffening or flexion of the upper body at the waist (46).

## EEG FEATURES

### Interictal Manifestations

The interictal EEG is characterized by a slow background that can be constant or transient. Permanent slowing of the background is associated with poor cognitive prognosis (35). The hallmark of the awake interictal EEG is the diffuse slow spike-and-waves. This pattern consists of bursts of irregular, generalized spikes or sharp waves followed by a sinusoidal 35–400-millisecond slow wave (18), with an amplitude that ranges from 200 to 800  $\mu$ V (39), which can be symmetrical or asymmetrical. The amplitude is very often higher in the anterior region and in the frontal or frontocentral areas, but in some cases the activity may dominate in the posterior regions of the head (39). The frequency of the slow spike-and-wave activity is commonly found between 1.5 and 2.5 Hz (39) (Figure 21-1).

Slow spike-and-waves are usually not activated by photic stimulation. In one series of 83 patients with LGS, activation of slow spike-and-waves with photic stimulation occurred in 2 patients (3 tracings), and decrease in slow spike-and-wave activity was noted in 9% of the tracings (39). Hyperventilation rarely induces slow spike-and-waves (18), although in many patients mental retardation prevents an adequate cooperation (39). During NREM sleep, discharges are more generalized, occur more frequently, and consist of polyspikes and slow waves. In rapid eye movement (REM) sleep there is a decrease in spike-and-waves (18). There is a reduction in the total duration of REM sleep during periods of frequent seizures (18).

### Ictal Manifestations

Several types of seizures occur in LGS, including tonic, atonic, myoclonic, and atypical absences, often associated with other less common types.

#### *Tonic Seizures*

The tonic seizure EEG is characterized by a diffuse, rapid (10–13 Hz), low-amplitude activity, mainly in the anterior and vertex areas (“recruiting rhythm”), that progressively decreases in frequency and increases in amplitude (Figure 21-2). When the seizure is limited to brief upward

FIGURE 21-1

Slow spike-wave pattern in a 24-year-old awake male with Lennox-Gastaut syndrome. The slow posterior background rhythm has frequent periods of 2-2.5 Hz discharges maximal in the bifrontocentral areas occurring in trains up to 8 seconds without any clinical accompaniment.

deviation of the eyes, the EEG activity may be accentuated in the posterior regions (22). A brief generalized discharge of slow spike-and-waves or flattening of the recording may precede this pattern. Diffuse slow waves and slow spike-and-waves may follow it. These fast discharges are common during NREM sleep. Unlike tonic-clonic seizures, no postictal flattening occurs. Clinical manifestations appear 0.5 to 1 seconds after the onset of EEG manifestations and last several seconds longer than the discharge (18, 35). Yaqub also reported synchronous 3-Hz spike-and-waves associated with tonic seizures (22).

#### *Atypical Absences*

The atypical absence seizure EEG is characterized by diffuse, slow (2–2.5 Hz) and irregular spike-and-waves, which may be difficult to differentiate from interictal bursts (18). Discharges of rapid rhythms may be seen preceded by flattening of the record for 1 to 2 seconds, followed by a progressive development of irregular fast rhythm in the anterior and central regions, ending with brief spike-and-waves (22, 35).

#### *Atonic Seizures, Massive Myoclonic Seizures, and Myoclonic-atic Seizures*

The EEG in these seizures is characterized by slow spike-and-waves, polyspike-and-waves, or rapid diffuse

rhythms (26, 35). Simultaneous video-EEG recording and polygraphy is necessary for precise diagnosis. In 95% of affected patients, all three types of seizures occur in the same patient (35). Myoclonic seizures in LGS show different neurophysiologic patterns compared to other specific epileptic syndromes such as myoclonic astatic epilepsy (MAE). Epileptic myoclonus in MAE appears to be a primary generalized epileptic phenomenon. In contrast, epileptic myoclonus in LGS seems to be secondarily generalized, originating from a stable generator in the frontal cortex, with interhemispheric spread, likely through transcallosal pathways (47).

#### *Other Types of Seizures*

The EEG during absence status epilepticus reveals continuous spike-and-wave discharges, usually at a lower frequency than at baseline, and rapid rhythms during tonic status epilepticus (35). Donat and Wright reported in patients with LGS, infantile spasms-like seizures with clinical characteristics, and ictal EEG changes similar to those typically seen in West syndrome. The interictal EEG showed generalized slow spike-wave discharges (1–2.5 Hz) with occasional multifocal spike waves. The ictal changes consisted of generalized decrement in cerebral activity, identical to the pattern that can be observed with infantile spasms (46).

FIGURE 21-2

Tonic seizure with arm extension in a 24-year old male with Lennox-Gastaut syndrome. Before the seizure, the patient is watching television and then has a sudden body jerk, leans forward with arms extended and fixed at shoulder level. The EEG shows a diffuse burst of high-voltage polyspike and slow wave activity followed by 1 second of relative attenuation and then paroxysmal fast activity maximal in the bifrontocentral regions of the head.

### PATHOPHYSIOLOGY

The pathophysiology of LGS is not well known (14), and there are no animal models (18). A variety of possible pathophysiologies have been proposed including developmental, immunologic, and metabolic. One hypothesis is that there is excessive permeability in the excitatory interhemispheric pathways in the frontal areas at the time the anterior parts of the brain mature. This maturation commonly occurs around the age of onset of LGS and would allow for synchronization of both frontal lobes (18).

Immunogenetic mechanisms are hypothesized to play a role in triggering or maintaining some cases of LGS. A strong association between LGS and the HLA class I antigen B7 (48) was found in one study, but another group found no statistical difference in the presence of HLA class I antigens, including the antigen B7 (49). This latter study found an increased frequency of HLA class II antigen DR5 and a decrease in DR4 antigen (49).

Two hypotheses have been proposed to explain the cognitive outcome of patients with LGS. It has been suggested that the key LGS electrographic feature of

slow spike-and-wave discharges and the paroxysmal fast activity reflect excessive neocortical excitability and subsequent abnormal patterns of central nervous system activity and connectivity. These processes would successfully compete with normal developmental mechanisms, leading to cognitive impairment (50, 51). Another hypothesis postulates a genetic predisposition that is responsible for both the clinical manifestations and the mental retardation (51).

No clear-cut or homogeneous metabolic pattern was noted in six positron emission tomography (PET) studies done in a total of 50 patients with LGS (52–57). Although most studies suggested a focal abnormality, a few others showed diffuse changes or normal findings. Gur et al found temporal lobe unilateral hypometabolism in 2 patients (52). Theodore studied 10 patients with LGS and did not find a region of persistent focal hypometabolism. One of the patients showed hypermetabolism in association with increased epileptiform discharges in EEG (55). Chugani's findings showed four predominant metabolic patterns in 15 children with LGS: unilateral focal hypometabolism, unilateral diffuse hypometabolism, bilateral diffuse hypometabolism, and normal

metabolism (56). Iinuma et al reported unilateral hypometabolism in 4 of 5 patients with LGS, particularly in the inferior frontal gyrus or in the posterior portion of the superior temporal gyrus (53). Miyauchi et al found hemispheric metabolic differences in 3 patients with LGS, with hypometabolism in the frontal to the temporal regions (57). Ferrie et al studied 15 patients with LGS and found no areas of hypometabolism in 5 typical cases of LGS, whereas he found them in 3 of 4 atypical cases and in 5 of 6 patients with previous history of West syndrome (54).

Single-photon emission computed tomography (SPECT) in 3 children with LGS showed multiple hypoperfused areas, which contrasted with single areas of hypoperfusion in 11 children with partial secondary generalized epilepsy (58).

### DIAGNOSTIC EVALUATION AND DIFFERENTIAL DIAGNOSIS

The diagnosis of LGS is based on the criteria previously defined, which include multiple types of seizures, in particular tonic seizures; an EEG pattern consisting of interictal diffuse slow spike-and-wave discharges occurring at a 1.5–2-Hz frequency, with or without bursts of generalized fast spikes (10 Hz) during NREM sleep; and diffuse cognitive dysfunction, mental retardation, or both.

Because of the nonspecific nature of multiple seizure types and cognitive dysfunction, multiple other pediatric epilepsy syndromes may be confused with LGS. A useful approach to understanding and differentiating these syndromes is to first consider LGS and similar epilepsy syndromes as part of a continuum and then to try to identify characteristics that separate the syndromes. Two scenarios have been proposed. In both scenarios, LGS is at one end of the spectrum. In one scenario, the other end of the continuum is placed in the broad term *myoclonic epilepsies* (16), and another scenario places the end at MAE (42). In both scenarios, the epilepsy syndromes encountered when moving from one end of the spectrum to the other are in the same order: LGS, the “myoclonic variant” of LGS, MAE, and then the lumped “myoclonic epilepsies” (e.g., benign myoclonic epilepsy of infancy, severe myoclonic epilepsy of infancy, and progressive myoclonic epilepsy) (17).

Compared with classic LGS, the “myoclonic variant” of LGS has less frequent and less severe mental retardation; rarer tonic seizures, usually of late onset and almost exclusively nocturnal; an “unusually marked myoclonic component”; a less unfavorable outcome; and frequently faster (>2.5 Hz) spike-and-wave complexes on EEG (16, 38).

Myoclonic astatic epilepsy and LGS have in common myoclonic seizures, atonic seizures, and atypical

absences. However, there are major differences: MAE is predominantly idiopathic, is genetically determined, usually has a favorable outcome, and does not follow West syndrome, whereas LGS is mainly symptomatic, is not genetically determined, usually has an unfavorable outcome, and can follow West syndrome (18, 42). Kaminska and coworkers differentiate LGS and MAE using a sophisticated statistical approach called multiple correspondence analysis to study different clinical and EEG parameters. They recognized a group of children with LGS characterized by later onset of epilepsy, atypical absences, tonic and partial seizures, no myoclonus or vibratory tonic seizures, mental retardation, and an EEG pattern with slow spike-and-waves that were, as a group, different from those in the group with MAE features (42). In addition, myoclonic seizures in LGS and MAE show different neurophysiologic patterns, as shown by Bonanni et al using video-EEG, simultaneous surface electromyography, and, when necessary, burst-locked EEG averaging techniques (47).

Compared with patients with LGS, patients with myoclonic epilepsies (in the broadest sense) have myoclonic seizures as the clearly predominant seizure type, only occasionally have tonic seizures, only occasionally have slow spike-and-waves on EEG, almost always have fast (>2.5 Hz) spike-and-wave complexes on EEG, and have variable frequency and levels of mental retardation (16, 17).

Multiple etiologies have been associated with LGS. Knowledge of the cause may affect prognosis and, at times, selection of the best therapy. Neuroimaging is an important part of the search for an underlying etiology in a patient with LGS. Abnormalities revealed by neuroimaging associated with LGS include tuberous sclerosis, brain malformations (e.g., cortical dysplasias), hypoxic-ischemic injury, or frontal lobe lesions. In general, magnetic resonance imaging (MRI) is the preferred neuroimaging study for a patient with LGS rather than a computed tomography (CT) scan. CT scans may be preferred in selected situations (e.g., evaluation of suspected intracranial injury, hematoma, or both in a patient with head trauma resulting from an atonic or tonic seizure). No current indication exists for routine PET or SPECT scanning in patients with LGS. However, PET and SPECT scans may be useful when patients are undergoing evaluation for potential epilepsy surgery.

An EEG in patients with suspected LGS is critical, because the diagnosis depends on the presence of specific electrographic findings. Recording of a prolonged EEG is desirable, because a routine 30-minute EEG may not capture the patient’s electrographic activity both awake and asleep and thus may miss crucial specific EEG findings. It is important to capture and classify each of the patient’s multiple seizure types. Video-EEG telemetry should be strongly considered because it may also help to educate

the parents on which of the patient's events are seizures and which are nonepileptic behavioral events (44).

When assessing learning disability, it is important to differentiate "permanent learning disability" and "state-dependent learning disability." The former refers to the learning disability as a result of an underlying brain damage that leads to both epilepsy and learning disability, or to the epilepsy that leads to brain damage, which in turn results in learning disability (e.g., prolonged status epilepticus). The latter depends on factors affecting the patient, such as adverse medication effects or increased seizures (ictal and postictal effects), both of which are not necessarily permanent and are potentially treatable and reversible (43). Review of the ongoing treatment and recording of a prolonged video-EEG may be of help.

## TREATMENT

### Overview

The goals of treatment for patients with LGS are the same as for all patients with epilepsy: the best quality of life with the fewest seizures (hopefully none), the fewest treatment side effects, and the least number of medications.

The various treatment options for patients with LGS can be divided into the following three major groups (Table 21-1):

1. First-line treatments based on clinical experience or conventional wisdom

2. Suspected effective treatments based on open-label uncontrolled studies
3. Effective treatments based on double-blind placebo-controlled studies

In the first and second groups, the efficacy and safety of individual treatment options have not been formally tested. Only options in the third group have been rigorously and scientifically evaluated and found to be effective and safe for specific seizure types in LGS patients. Each treatment group can be subdivided into medical, dietary, and surgical therapies. Unfortunately, no treatment by itself in any of the three groups gives satisfactory relief for all or even a majority of patients with LGS. Combination of treatment modalities is frequently needed (59).

### First-Line Treatments Based on Clinical Experience or Conventional Wisdom

#### Medications

Over the past two decades, valproic acid (VPA) has been considered as a first-line treatment option for children with LGS (24, 52, 53). From a practical viewpoint, by the time a clinician makes a diagnosis of LGS, the patient has already been diagnosed with epilepsy and treatment has been initiated. Because these children have multiple types of generalized seizures and at times coexisting partial seizures, clinicians may initially select a broad-spectrum AED such as VPA. Valproic acid has been reported to be more effective in cryptogenic LGS than in symptomatic LGS (60).

Benzodiazepines, specifically clonazepam, nitrazepam, and clobazam, are also first-line AED therapy options (38, 61, 62). All are considered effective against seizures associated with LGS, but side effects and the development of tolerance limit their usefulness over time (38). Side effects of clonazepam include hyperactivity, sedation, drooling, and incoordination, which can significantly affect the quality of life for patients with LGS (38). The efficacy and tolerability profile of nitrazepam is similar to that of clonazepam (38). Clobazam is considered the least sedating benzodiazepine, with the longest time to the development of tolerance (62). Some recommendations to slow the development of tolerance include dosing on an every-other-day schedule or alternate two different benzodiazepines on an alternate-day basis (63, 64). Unfortunately, not all benzodiazepines are beneficial: intravenous diazepam and lorazepam have been reported to induce tonic status epilepticus in some patients (65, 66). Based on clinical experience, some authors believe a combination of valproic acid and a benzodiazepine may be better than either drug alone, but no data exist to confirm this impression (38).

Rufinamide

Although carbamazepine, phenobarbital, phenytoin, and ethosuximide may be first-line therapy for a variety of seizure types or other epilepsy syndromes, none is considered first-line therapy for LGS. Carbamazepine may exacerbate atypical absence seizures despite reducing generalized tonic-clonic seizures (67, 68). Phenobarbital may be effective against a variety of seizures but can exacerbate hyperactivity and aggressiveness or produce sedation and drowsiness (which may exacerbate tonic seizures) (38, 60). Phenytoin can be effective for tonic seizures and tonic status epilepticus but not for atypical absence seizures (69). In contrast, ethosuximide may be useful in atypical absence seizures but is ineffective in other seizure types (59).

Because patients with pyridoxine (vitamin B<sub>6</sub>) dependency may have seizures and a slow spike-and-wave pattern on EEG, some clinician investigators have suggested trials of vitamin B<sub>6</sub> in all children with treatment-resistant epilepsy who are younger than 5 years old (61). One study examined the efficacy of high-dose vitamin B<sub>6</sub> in five patients with LGS and found mixed results; three of the five patients with LGS had no response, whereas the others had a more noticeable response (70). Given the lack of serious side effects and the ease of performing a therapeutic vitamin B<sub>6</sub> trial, it is reasonable and appropriate to conduct a vitamin B<sub>6</sub> trial early in treatment of a child with LGS (71). Doses and duration of vitamin B<sub>6</sub> therapy vary widely. In the aforementioned clinical trial, vitamin B<sub>6</sub> was given at 50 to 100 mg/day fiiiintramuscularly for the first 5 days, and then 200 to 300 mg/day orally (70). Some clinicians (mainly in Japan) administer high doses of pyridoxal phosphate (30–40 mg/kg/day) (61). Wheless and Constantinou prescribe 100 mg of vitamin B<sub>6</sub> three times daily for 2 weeks, discontinuing vitamin B<sub>6</sub> if there is no response to therapy after 2 weeks (61).

#### *Dietary Treatment*

At this time, the ketogenic diet is not a first-line therapy for the seizures associated with LGS.

#### *Surgical Treatment*

At this time, neither corpus callosotomy nor the vagus nerve stimulator are first-line therapies for the seizures associated with LGS.

### **Suspected Effective Treatments Based on Open-Label Uncontrolled Studies**

#### *Medications*

Medications suspected to have some effectiveness against seizures associated with LGS based on open-label uncontrolled trials include (in alphabetical order):

adrenocorticotrophic hormone (ACTH) (72, 73), corticosteroids (35, 61, 74), intravenous immunoglobulin (IVIG) (75, 76), vigabatrin (77), and zonisamide (ZNS) (78).

Both ACTH and corticosteroid therapy are proposed to be effective against the seizures associated with LGS. Roger et al propose that prolonged corticosteroid therapy initiated at the onset of cryptogenic LGS can yield “excellent” results (35). Despite this effectiveness, there are multiple potentially significant side effects associated with therapy, and relapse frequently occurs when the drugs are withdrawn (38, 61, 71–74).

The efficacy of adjunctive high-dose IVIG in patients with LGS has been investigated in at least seven open-label trials (75). The results of these trials were very encouraging because 30% to 92% of LGS patients receiving IVIG experienced at least 50% seizure reduction during treatment (75). Dosing schedules varied between studies. Later well-controlled trials (detailed in following discussion) did not confirm the effectiveness of IVIG against seizures associated with LGS (79, 80).

Six studies involving 78 patients treated with vigabatrin showed that 15% of these patients became completely seizure free and 44% of the patients had at least 50% reduction in their seizure frequency (77, 81–85). The best results were noted in an open-label, dose-ranging, adjunctive therapy study of vigabatrin in 20 children with LGS in which monotherapy with VPA did not control their seizures. Seventeen children (85%) experienced at least 50% reduction in their seizure frequency, and eight children (40%) were seizure free at doses ranging from 1 to 3 g/day at study end (77). The authors concluded that vigabatrin and VPA duotherapy was effective and well tolerated in children with LGS (77).

The most common adverse effects of vigabatrin are generally central nervous system related and include hyperactivity, agitation, weight gain, drowsiness, insomnia, facial edema, ataxia, stupor, and somnolence (83, 86–88). Not only can vigabatrin exacerbate myoclonic seizures and even absence seizures in some patients, but it can also cause visual field constriction in children (82, 83, 86, 89, 90). The aforementioned side effects limit significantly the consideration of vigabatrin as long-term therapy for patients with LGS (87).

The effectiveness of ZNS in LGS has been investigated in three small studies. Although Sakamoto et al reported that ZNS was “effective” in 39% of patients with LGS, the definition of effectiveness was not clear (78). In 1991 Yamatogi and Ohtahara reported 50% (10 of 20) of Lennox-Gastaut patients treated with ZNS had at least 50% reduction in seizure frequency (91). Iinuma and Haginoya found that 26% (10 of 39) of patients with LGS treated with ZNS responded with a 50% or greater reduction in seizure frequency (92).

There have been no formal published open-label studies investigating the effectiveness and safety of gabapentin,

tiagabine, levetiracetam, or oxcarbazepine in the treatment of seizures associated with LGS. Single reports have suggested that L-tryptophan (transient improvement), amantadine, thyrotropin-releasing hormone, and its analog, DN-1417, may reduce seizure frequency in patients with LGS (93–96).

### *Dietary Treatment*

A number of studies have shown the ketogenic diet to be useful for patients with LGS (71, 72, 97, 98). Response to the diet usually is evident within 1 month of starting the diet (61). Freeman and Vining reported that atonic or myoclonic seizures in 17 consecutively treated patients with LGS at The Johns Hopkins Hospital decreased “by more than 50% immediately,” after being started on the ketogenic diet (99). Overall, the benefits of the diet can include fewer seizures along with less drowsiness, better behavior, and fewer concomitant AEDs (61).

### *Surgical Treatment*

Surgical procedures that have been reported to be beneficial for patients with LGS include corpus callosotomy, focal resection (rarely), and electrical stimulation, in particular vagus nerve stimulation (VNS) and the electrical stimulation of the centromedian thalamic nuclei (100, 101).

Corpus callosotomy is effective in reducing drop attacks but typically does not appear to be helpful for other seizure types (38, 102, 103). A recent study from Taiwan reported that anterior corpus callosotomy was effective for “all kinds of medically intractable seizures, especially generalized” in a cohort of 74 patients (80% had LGS) (104). In general, callosotomy is considered palliative rather than curative, and seizure freedom is rare, although it can occur (60, 104).

In six studies, VNS appears effective for patients with LGS (105–110). The three earlier studies reported that a total of 13 of 18 (72%) patients with LGS experienced at least 50% reduction in seizure frequency with follow-up as long as 5 years (105–107). Hosain et al (108) reported on the use of VNS in 13 patients with LGS (age range, 4–44 years; mean, 16.7 years). During the first 6 months of treatment the median seizure rate reduction was 52% (range, 0–93%;  $P = 0.04$ ). At 6 months of follow-up, three patients had >90% reduction in seizure frequency, two patients had >75% reduction, one patient had >50% reduction, six had >25% reduction, and one patient did not improve. The main reported side effects were hoarseness, coughing, and pain in throat. These results suggest VNS could be an effective and safe adjunct therapy for the treatment of LGS (108). Aldenkamp and collaborators in the Netherlands studied the long-term effects of 24 months of treatment with VNS on cognition in 19 patients with LGS or LGS-like

syndromes (13 patients with LGS). The average reduction of seizure frequency was 20.6% after 24 months. No deterioration on cognition was seen when baseline was compared to follow-up measurements. The authors concluded that VNS does not have long-term, higher-order functions adverse effects (109). A previous report from the same group reported on the cost-effectiveness of VNS in 16 children with LGS at the 6-month follow-up. There was a significant reduction in direct non-health-care costs and the number of days of suboptimal functioning of the child. Comparing the costs pre and post VNS placement, the payback period was 2.3 years (110). In the largest cohort of LGS patients treated with VNS, Frost et al reported the effectiveness, tolerability, and safety of VNS therapy in 50 patients (median age, 13 years) with LGS. At 6 months after VNS implantation, 58% median reduction in seizure frequency was seen. Quality of life was improved in some patients and the most common adverse effects were voice change and coughing during stimulation (111).

In rare cases, resection of a localized lesion (e.g., vascular lesion or tumor) can improve seizure control in patients with LGS (38, 112).

## **Effective Treatments Based on Double-Blind Placebo-Controlled Studies**

### *Medications*

The gold standard for evaluation of the safety and efficacy of an anticonvulsant medication is the randomized, double-blind, placebo-controlled clinical trial. Six drugs have undergone this rigorous testing to determine safety and efficacy in patients with LGS: cinromide, IVIG, felbamate, lamotrigine, topiramate, and rufinamide. The latter four AEDs successfully demonstrated efficacy against seizures in patients with LGS, whereas the former two did not. Despite the lack of proven efficacy for cinromide and immunoglobulins in double-blind studies, both therapies had open-label trials suggesting efficacy in patients with LGS, reinforcing the need for randomized double-blind controlled trials to definitively establish the efficacy of any proposed therapy.

*Cinromide.* In 1980 cinromide was reported to be effective for seizures associated with LGS in an open-label uncontrolled trial (113). These results prompted a subsequent double-blind, placebo-controlled adjunctive therapy trial of cinromide in patients with LGS (114). Overall, 73 patients enrolled, but “sufficient data for analysis” were available only for 56 patients (26 receiving cinromide, 30 receiving placebo). There was no difference between cinromide adjunctive therapy and placebo adjunctive therapy in terms of seizure reduction or global

evaluations (114). The development of cinromide was halted in 1981 (114).

**Immunoglobulins.** Two blinded placebo-controlled studies have been published examining the efficacy of IVIG in children with LGS (79, 80). The first study enrolled 10 children, aged 4 to 14 years, in an add-on, placebo-controlled, single-blind study design. Only 2 children showed a response to IVIG (42% and 100% decrease in seizure frequency), and the remaining 8 children were “unaffected” (79). Sixty-one patients with various forms of refractory epilepsy (including LGS and West syndrome) participated in a randomized, double-blind, placebo-controlled, dose-ranging (three different doses) trial of IVIG. Despite 52.5% of the IVIG group having a greater than 50% reduction in seizure frequency, compared with 27.8% in the placebo group, this difference did not reach statistical significance (80).

**Felbamate.** Felbamate (FBM) was found to be safe and effective in patients with LGS in a randomized, double-blind, placebo-controlled adjunctive therapy trial (115). Seventy-three patients with LGS aged 4 to 36 years enrolled. The FBM dose in the double-blind portion was 45 mg/kg/day (maximum 3,600 mg/day). The FBM treatment group experienced a 34% reduction in atonic seizures compared with 9% in the placebo group ( $P < 0.01$ ). Total seizure frequency dropped 19% in the FBM group compared with a 4% increase in the placebo group ( $P < 0.002$ ). The percentage of patients experiencing at least 50% reduction in atonic seizures was 57% for the FBM group compared with 9% in the placebo group ( $P < 0.001$ ). The percentage of patients experiencing at least 50% reduction in total seizure frequency was 50% for the FBM group compared with 11% in the placebo group ( $P < 0.001$ ) (Table 21-2). FBM was significantly better than placebo in improving global evaluation scores. The types and frequency of side effects were similar in the two treatment groups (107). A 12-month follow-up in

patients who completed the controlled part of the study confirmed long-term efficacy (116).

Unfortunately, FBM is associated with dangerous idiosyncratic reactions involving the blood and liver. The most common severe FBM-associated idiosyncratic reaction is aplastic anemia, which has been seen to date in 34 patients receiving FBM (117, 118). The incidence of FBM-associated aplastic anemia is approximately 127 cases per million treated with FBM (approximately 1 in 4,000 to 8,000 FBM-treated patients) versus 2 to 6 per million people in the general population (87, 117, 119, 120). Another report estimates the risk of aplastic anemia in patients receiving FBM to be 1:3,000, with a death rate of 1 in 10,000 FBM-treated patients (87, 121). In perspective, this estimated risk is approximately 20 times greater than that for carbamazepine-associated aplastic anemia (117). Risk factors for FBM-associated aplastic anemia are Caucasian, adult, female, history of autoimmune disorder, a positive antinuclear antibody titer, history of prior AED toxicity or allergy, prior cytopenia, and treatment with FBM for less than 1 year (117, 118, 122).

The second most common severe FBM-associated idiosyncratic reaction is hepatotoxicity. Reported in 18 patients receiving FBM, its estimated incidence is between 64 and 164 per million (approximately 1 in 18,500–25,000 FBM-treated patients) (117). This suggests that the frequency of FBM-associated hepatotoxicity and VPA-associated hepatotoxicity are approximately the same (117). Based on the reported 5 felbamate-related liver failure fatalities, which occurred in approximately 130,000 to 170,000 exposed persons, the estimated incidence would be between 1 per 26,000 to 1 per 34,000 exposures (103). In perspective, the risk of hepatic-related fatalities in the population taking VPA is between 1 in 10,000 and 1 in 49,000, with the risk in high-risk pediatric patients younger than 2 years being 1 in 500 (118). There is no evidence that laboratory monitoring of blood counts and liver function during FBM therapy anticipates these severe idiosyncratic reactions

**TABLE 21-2**  
**Responder Rates (at Least 50% Reduction in Seizure Frequency) for Four Antiepileptic Medications Tested in Double-Blind, Placebo-Controlled Trials in Lennox-Gastaut Syndrome**

SEIZURE TYPE	FELBAMATE VS. PLACEBO	LAMOTRIGINE VS. PLACEBO	TOPIRAMATE VS. PLACEBO	RUFINAMIDE VS. PLACEBO
Total seizures	50% vs. 11%*			
All major seizures (drop attacks plus tonic-clonic)		33% vs. 16%*	33% vs. 8%*	
Drop attack or atonic seizures	57% vs. 9%*	37 vs. 22%*	28% vs. 14%	42% vs. 17%*
Tonic-clonic seizures	60% vs. 23%*	43% vs. 20%*		

\* $P < 0.05$ .

(117). A suggested management strategy is to use careful clinical monitoring, perform routine laboratory testing, and discontinue the drug if no substantial clinical benefit is observed after 3 to 6 months of therapy.

Although effective, there are significant risks associated with FBM use. In general, it is regarded as a good third-line or fourth-line drug for LGS.

**Lamotrigine.** The efficacy of lamotrigine (LTG) against seizures associated with LGS has been examined in multiple open-label studies and two controlled trials. In five open-label trials of LTG in patients with LGS, 58% (31 of 53) experienced at least 50% reduction in seizure frequency (123–127). A double-blind, placebo-controlled, crossover study of LTG as adjunctive therapy in 30 patients with treatment-resistant generalized epilepsy was reported in 1998. Twenty study patients had LGS. Seven of the 20 children with LGS responded to LTG therapy with a greater than 50% reduction in seizure frequency. Two patients became seizure-free (128).

Lamotrigine was found to be safe and effective in patients with LGS in a randomized, double-blind, placebo-controlled, adjunctive therapy trial (129). A total of 169 patients enrolled and were randomized to either LTG ( $n = 79$ ) or placebo ( $n = 90$ ) adjunctive therapy. Patients receiving the LTG treatment arm had a greater median percent reduction from baseline in weekly seizure counts (for drop attacks, tonic-clonic seizures, and all major seizures—defined as drop attacks plus tonic clonic seizures) compared with patients on the placebo treatment arm. The responder rate (percentage of patients experiencing at least 50% reduction in seizures) for major seizures (drop attacks and tonic-clonic seizures) was greater in the LTG group (33%) than in the placebo group (16%,  $P < 0.01$ ). For drop attacks, 37% of LTG-treated patients responded, compared with 22% of the placebo-treated patients ( $P < 0.04$ ). Finally, for tonic-clonic seizures, 43% of the LTG-treated patients responded, compared with 20% of patients receiving placebo ( $P < 0.007$ ) (129) (Table 21-2).

Unfortunately, LTG can be associated with idiosyncratic reactions, predominantly involving the skin. The most common skin manifestation is a rash affecting 10% to 12% of LTG patients (130–132). The rash rapidly resolves following LTG withdrawal; sometimes the rash may even resolve without changing LTG dosage (133). However, this dermatologic reaction can progress in some patients to erythema multiforme, Stevens-Johnson syndrome, or even toxic epidermal necrolysis (87, 130, 133). Stevens-Johnson syndrome and toxic epidermal necrolysis are related severe mucocutaneous disorders with mortality rates of 5% and 30%, respectively (130). The risk of a potentially life-threatening rash (based on clinical trials and postmarketing reports) in adults is 0.3% and approximately 1% in children 16 years old and younger (133).

Risk factors for LTG-associated severe dermatologic reactions include younger age (children more than adults), comedication with VPA, a rapid rate of LTG titration, and a high LTG starting dose (87, 133, 134). Careful attention should be given to initial LTG starting dose, titration rate, and comedications. The prompt evaluation of any rash is prudent.

Despite the risk of idiosyncratic reactions, LTG is a very valuable medication for patients with LGS and should be considered for use as soon as the diagnosis of LGS is made. Proper attention to concomitant medications, a low starting dose, and a very slow titration can minimize the risk of dermatologic idiosyncratic reactions.

**Topiramate.** Topiramate (TPM) was found to be safe and effective as adjunctive therapy for patients with LGS in a multicenter, double-blind, placebo-controlled trial (135). Ninety-eight patients with LGS (older than 1 year and younger than 30 years) were randomized to either TPM adjunctive therapy (target dose, 6 mg/kg/day) or placebo adjunctive therapy. The median percent reduction from baseline in average monthly seizure rate for drop attacks was 14.8% for the TPM group and 5.1% (an increase) for the placebo group ( $P < 0.041$ ). Using parental global evaluations, TPM-treated patients demonstrated greater improvement in seizure severity than did placebo-treated patients ( $P < 0.037$ ). The responder rate for major seizures (drop attacks and tonic-clonic seizures) was greater in the TPM group (15 of 46, or 33%) than in the control group (4 of 50, or 8%;  $P < 0.002$ ). The responder rate for drop attacks in the TPM group was higher than in the placebo group (28% vs. 14%) but did not reach statistical significance (135) (Table 21-2).

In the long-term, open-label extension portion of the above trial, 97 patients were followed up and had their TPM dose adjusted as clinically indicated (136). The mean TPM dose in those patients who had completed 6 months of therapy was 10 mg/kg/day. For those patients who had completed 6 months of TPM therapy, drop attacks were reduced at least 50% in 55% of patients; 15% of patients were free of drop attacks for at least 6 months at the last visit. The median percent reduction in drop attacks was 56%. The median percent reduction in overall seizure frequency was 44%, with 45% of the patients having at least 50% reduction in all seizure types and 2% being seizure-free for the previous 6 months. Long-term TPM therapy was well tolerated. The most common adverse events were somnolence, injury, and anorexia. Behavioral problems during the last 6 months of long-term TPM therapy were reported in only 5% of the patients. During long-term therapy, TPM is effective and well tolerated in controlling drop attacks and seizures associated with LGS (136).

**Rufinamide.** The efficacy and tolerability of rufinamide adjunctive therapy for patients with LGS was examined in a multicenter, double-blind, placebo-controlled, randomized, parallel-group study (137, 138). A 28-day baseline phase was followed by an 84-day double-blind phase (14-day titration phase followed by a 70-day maintenance phase). Eligible patients were between 4 and 30 years old, had 90 seizures in the month prior to the baseline phase, and were taking one to three concomitant AEDs. The rufinamide target dose was 45 mg/kg/day. Overall, 138 patients with a mean age of 14.1 years (range, 4 to 37 years) were randomized to either rufinamide ( $n = 74$ ) or placebo ( $n = 64$ ). The median dose in both groups was 1,800 mg/day (42–45 mg/kg/day) (137, 138).

The median percent reduction in total seizure frequency per 28 days, relative to the baseline phase, in the rufinamide group was significantly higher than in the placebo group (32.7% vs. 11.7%,  $P = 0.0015$ ). In the rufinamide group, the median percent reduction in tonic-atonic seizure frequency per 28 days, relative to the baseline phase, was significantly higher compared with the placebo group (42.5% vs. 1.4%,  $P < 0.0001$ ). The tonic-atonic seizure responder rate was significantly higher in the rufinamide group compared with the placebo group (42.5% vs. 16.7%,  $P = 0.0020$ ) (137, 138).

The most common adverse events experienced included somnolence (24.3% rufinamide, 12.5% placebo), vomiting (21.6% rufinamide, 6.3% placebo), pyrexia (13.5% rufinamide, 17.2% placebo), and diarrhea (5.4% rufinamide, 10.9% placebo). A lower percentage of patients in the rufinamide group (17.6%) experienced cognitive/psychiatric adverse events of interest, such as psychomotor hyperactivity and lethargy, compared with the placebo group (23.4%). Rufinamide was efficacious and well tolerated as an adjunctive therapy for the treatment of resistant seizures in patients with LGS (137, 138).

#### **Dietary Treatment**

In a recent study, Freeman and collaborators reported in abstract form their findings of a blinded, crossover, placebo-controlled trial. Twenty children with LGS were fasted for 36 hours and introduced to the ketogenic diet. Glucose or saccharin was randomly used in a blinded fashion to negate or sustain the effect of the diet. Although the initial fasting to start the ketogenic diet resulted in a significant reduction in median seizures (30 to 10 seizures per day,  $P < 0.0001$ ), the randomized part of the study failed to show a significant effect of ketogenic diet on seizure frequency (139). In a preliminary study, these investigators were able to negate urinary ketosis in patients on the ketogenic diet by giving a drink containing glucose (85). However, in the more recent study, none of

the patients in the placebo arm, the ones who received glucose, was completely ketone free (139).

#### **Surgical Treatment**

There are no double-blind trials examining the efficacy of surgical intervention in patients with LGS, completed or under way, at this time.

### **PROGNOSIS**

The long-term prognosis is variable, but overall it is unfavorable. Several studies have followed cohorts of children with LGS over time and illustrate this unevenness. Beaumanoir found that 47% of the patients with LGS still had typical characteristics after 10 years of follow-up (33). Roger et al followed 338 patients with LGS until adulthood. In 46.9% of patients, the clinical characteristics and EEG findings persisted into adulthood. In 15.5% of patients, mainly symptomatic cases, the syndrome disappeared, but a severe, multifocal epilepsy persisted. About 17% of patients in which LGS followed another type of epilepsy seemed to have been cured (140). Ohtahara et al reported persistent seizures in 76.4% of patients, and mental retardation present in 91% of patients with LGS in a long-term follow-up study (141). Yagi examined a cohort of 102 patients with LGS, followed up for an average of 16 years; 11.8% of them worked normally, 35.3% worked part-time or at a sheltered workshop, and the remaining 52.9% were under home care or institutionalized (142). The characteristic clinical symptoms and EEG pattern remained in one-third of the patients at the end of the study. In the remaining patients, seizures decreased in type and frequency with treatment (142). In another long-term follow-up of patients with LGS over 42 years, the disappearance of the characteristic slow spike-waves pattern was followed by focal discharges, and focal and diffuse slow waves, which were seen in the majority of patients. Complex partial seizures also became more frequent in this population (143). Hoffman-Riem et al identified by multivariate analysis four independent risk factors for severe mental retardation in patients with LGS: nonconvulsive status epilepticus, odds ratio (OR) 25.2, previous history of West syndrome (OR 11.6), a symptomatic etiology (OR 9.5), and an early age (before age 3 years) at onset of epilepsy (OR 4.7) (41). Long-term follow-up of patients with LGS reveals that only few of them will become seizure free (20, 123). Many authors consider that early and effective seizure treatment might prevent some of the long-term impairments and improve global prognosis (43, 144). However, patients that achieve seizure control and are seizure free for several years may continue to have severe cognitive impairments (51). One hypothesis proposes that this could be due to a genetic predisposition responsible for

the mental retardation. Another theory suggests that the treatment may come too late in the course of the disease, at a time when the damage has already occurred.

A worse prognosis is associated with symptomatic LGS, particularly those with a prior history of West syndrome (37), early onset of seizures (37), higher frequency of seizures (18), or constant slow EEG background activity (35). In one report, tonic seizures became more difficult to control over time and persisted (97.8% of the patients), whereas myoclonic and atypical absences appeared easier to control, persisting in 22.5% and 39.3% of the patients, respectively (145). The characteristic diffuse slow spike-and-wave pattern of LGS gradually disappears with age and is replaced by focal epileptic discharges, especially multiple independent spikes. This may reflect that subcortical epileptic discharges are suppressed and focal cortical discharges gain preponderance with brain

maturation (37). Mortality has been reported to range from 3% (mean follow-up of 8.5 years) to 7% (mean follow-up of 9.7 years) (35).

The severity of the seizures, frequent injuries, developmental delays, and behavioral problems take a large toll on even the strongest parents and family structures. Attention must be paid to the psychosocial needs of the family (especially siblings). The proper educational setting is also important to help the patients with LGS reach their maximal potential. Because of the high rate of injuries associated with atonic/tonic seizures, some patients with LGS may need to wear a protective helmet. Helmets need to have a faceguard to maximize protection of the patient's forehead, nose, and teeth. Unfortunately, some patients will not tolerate a helmet with a faceguard, and even if tolerated, helmets are often uncomfortable and rarely "cosmetically acceptable" (38).

## Childhood Absence Epilepsies

**Phillip L. Pearl**  
**Gregory L. Holmes**

**T**he absence seizure is characterized by sudden discontinuation of activity with loss of awareness, responsiveness, and memory, and an equally abrupt recovery. The first description of such an event was by Poupart in 1705 (1). The use of the term *petit mal* to describe all nonconvulsive seizures, proposed by Esquirol in 1815, has contributed to confusion that persists today. “Petit mal” was used to imply the severity of a seizure, more or less, before the electroencephalographic (EEG) description of 3-Hz spike-and-wave by Gibbs, Davis, and Lennox in 1935 (2). Clarification and delineation of absence seizure types was advanced by systematic neurophysiological studies using video-EEG monitoring techniques, which led to the description of protean manifestations and clinical syndromes associated with absence seizures.

Absence seizures are classified by the International League Against Epilepsy (ILAE) as generalized seizures among the self-limited seizure types. Those seizure types that conform to the absence seizure include several entities: typical absence seizures, atypical absence seizures, myoclonic absence seizures, and eyelid myoclonia with absences (Table 22–1). In addition, absence status epilepticus is classified as a type of generalized status epilepticus among the continuous seizure types.

The conceptualization of the epilepsy syndrome, comprising the predominant and associated seizure types associated with other clinical and electroencephalographic characteristics, was a major advance in understanding the patient’s underlying condition and, further, to allow for optimal management. Most physicians use the term “petit mal epilepsy” or “childhood absence epilepsy” to describe a syndrome of simple absence seizures in school-age children who are otherwise neurologically and intellectually normal. Of the ILAE epilepsy syndromes, absence seizures are an important component in several entities that would fit the original operational definition of the idiopathic generalized epilepsies (IGE) (Table 22–2) (3): childhood absence epilepsy, epilepsy with myoclonic absences, epilepsy with myoclonic-astatic seizures, juvenile absence epilepsy, and juvenile myoclonic epilepsy (JME). Other proposed syndromes that feature absence seizures include Jeavons syndrome, perioral myoclonia with absences, and phantom absences. The latter two entities are lifelong and associated with absence status epilepticus. “Phantom absences” refers to a type of mild absence occurring before a first generalized tonic-clonic seizure that usually occurs in adulthood. Jeavons syndrome refers to a purely reflex IGE with eyelid myoclonia and EEG abnormalities on eye closure (4). The scope of this chapter encompasses childhood absence epilepsy,

epilepsy with myoclonic absences, and eyelid myoclonia with absences.

### EPIDEMIOLOGY

Absence seizures comprise 2% to 11% of seizure types in all ages (5–10). The prevalence is highest in the first decade (11, 12). The incidence is 9.6 per 100,000 in the age group 0 to 15 years (11). Sato and coworkers (13), in a study of 83 patients with absence seizures, reported the age of onset was most commonly in the 5- to 9-year-old group (versus 4 years or younger, or 10 years or older), whereas Wirrell and colleagues (14) found an average age of onset of 5.7 years in 72 children. Occasional cases begin during infancy (15). A population-based case control study found that only a history of febrile seizures was a significant risk factor for the development of absence seizures ( $P < 0.01$ ) (16). None of the other factors studied were significant, including those that were historically suggested such as twin pregnancy, breech presentation, being firstborn, and perinatal asphyxia. A recent population based study in Sweden determined that the syndrome childhood absence epilepsy was diagnosed in 5.9% of children aged 1 month to 16 years with active epilepsy (17).

### CLINICAL MANIFESTATIONS

The terms *typical absence seizure* (TAS) and *atypical absence seizure* (AAS) were used by the International Classification of Epileptic Seizures to delineate these two distinct types of absences (18). The simple typical absence seizure consists of the sudden onset of impaired consciousness, usually associated with a blank facial appearance without other motor or behavioral phenomena. This subtype is actually relatively rare and comprised only 9% of 374 absence seizures video recorded from 48 patients by Penry and associates (19). The complex typical absence seizure, alternatively, is accompanied by other motor, behavioral, or autonomic phenomena.

**TABLE 22-2**  
**Epilepsy Syndromes (ILAE) Featuring Absence Seizures**

A. Childhood absence epilepsy
B. Epilepsy with myoclonic absences
C. Epilepsy with myoclonic-astatic seizures
D. Juvenile absence epilepsy
E. Juvenile myoclonic epilepsy

Clonic components may be quite subtle and most frequently consist of eye blinking. Clonic activity may range from nystagmus (20) to rapid jerking of the arms. Changes in tone may include a tonic postural contraction, leading to flexion or extension of the trunk (21). Decreases in tone leading to head nodding or dropping objects may also occur, although they rarely cause a fall.

In a study of 476 typical absence seizures monitored by simultaneous video-EEG telemetry, automatisms were the most common clinical accompaniment, occurring in 44% of 27 patients (22). Automatisms are semipurposeful behaviors of which the patient is unaware and which the patient subsequently cannot recall. They may be either perseverative, reflecting continuation of preictal activities, or *de novo*. Simple behaviors, such as rubbing the face or hands, licking the lips, chewing, grimacing, scratching, or fumbling with clothes tend to be *de novo* automatisms. Complex activity such as dealing cards, playing patty cake, or handling a toy are generally perseverative. If it occurs, speech is usually perseverative and often slowed and dysarthric, but it may be totally normal and include both expressive and receptive abilities (23).

Autonomic phenomena associated with absence seizures include pupil dilatation, pallor, flushing, sweating, salivation, piloerection, and even urinary incontinence (21, 24). Neither the autonomic changes nor the automatisms allow one to distinguish absence seizures from other seizure types.

Atypical absence seizures have traditionally been characterized as having less abrupt onset or cessation, more pronounced changes in tone, and longer duration than typical absence (18). They usually begin before 5 years of age and are associated with other generalized seizure types and mental retardation. The ictal EEG is more heterogeneous, showing 1.5- to 2.5-Hz slow spike-and-wave or multiple spike-and-wave discharges that may be irregular or asymmetrical (5, 6). The interictal EEG is usually abnormal, with slowing and multifocal epileptiform features (25).

Using the aforementioned ictal EEG criteria to differentiate atypical from typical absence seizures operationally, Holmes and coworkers (22) compared 426

typical and 500 atypical absence seizures in 54 children. The average duration of the AAS, 10.24 seconds, was longer than that of the TAS, 8.69 seconds ( $P < 0.01$ ). A change in facial expression or appearance of a blank stare was the most common initial clinical manifestation in either type. A pause or slowing of motor activity was also frequently noted as the initial finding in either seizure type. Either diminished postural tone or tonic or myoclonic activity was significantly more likely to be the initial clinical feature in AAS than in TAS. A blank stare or change in facial expression was the sole clinical finding in only 16% of TAS and 28% of AAS. Automatisms, eye blinking, and lip smacking occurred more commonly in TAS. A change in postural tone, either an increase or a decrease, was more commonly seen in AAS. Automatisms were more common in TAS than in AAS and are usually perseverative, such as often playing with a toy or game. De novo automatisms were associated with longer spells and most commonly consisted of rubbing the face or hands in TAS and smiling in AAS.

In the study by Holmes and coworkers (22), the authors found that both TAS and AAS started abruptly without an aura, lasted from a few seconds to half a minute, and ended abruptly. Both were frequently associated with eye blinking, lip smacking, decrease in tone, and automatisms. Although statistically significant differences can be identified between TAS and AAS, there is considerable overlap between the two seizure types, and they more likely represent a clinical continuum. This overlap pertains to the EEG as well as the proposed pathophysiology.

Most patients with typical absence seizures have normal neurologic examinations. In two large studies, abnormalities were found in 23% of patients by Sato and associates (13) and 16% by Dalby (8). Neurologic abnormalities tend to be mild and nonprogressive.

Intelligence scores are more variable, largely attributable to the diverse patient populations. In patients with typical 3-Hz spike-and-wave discharges, Dalby (8) found 17% of patients had IQs below 90, whereas Sato and coworkers (13) found 52% had IQs below 90. Holmes et al (22) found 22% of 27 patients with typical absence seizures to be mentally retarded, whereas 93% of 27 patients with atypical absence were retarded.

Between 40% and 60% of patients with typical absence seizures have generalized tonic-clonic seizures (8, 11, 13, 26–29). The time from the first absence to the first generalized tonic-clonic seizure may range from 1 to 16 years (mean, 6.6 years) (29). Nearly all patients with atypical absence seizures have generalized tonic-clonic seizures, and many also have myoclonic, tonic, and atonic seizures. There appears to be a spectrum of clinical conditions associated with atypical absence seizures, so that children with exclusively atypical absence have a less severe educational disability than children with atypical absence seizures plus other seizure types (30).

The syndrome of childhood absence epilepsy, named *pyknolepsy* for the frequent clustering of seizures in a day (*pyknos* = “cluster” in Greek), is defined as a disorder of typical absence seizures with occurrence in school age, having peak manifestations during ages 6 to 7 years, with a strong genetic predisposition in otherwise normal children. It is seen more frequently in girls than in boys. The EEG demonstrates bilateral, synchronous, and symmetrical 3-Hz spike-wave paroxysms on a normal background. More recent attempts to fine-tune this definition, especially for research purposes, have provided stricter inclusion criteria (onset between 4 and 10 years, normal neurologic state and development, brief duration [4 to 20 seconds, exceptionally longer], and EEG ictal discharges with generalized high-amplitude spike) and exclusion criteria (other seizure types including generalized tonic-clonic seizures or myoclonic, eyelid myoclonia, perioral myoclonia, rhythmic massive limb jerking, single or arrhythmic myoclonic jerks, mild or no impairment of consciousness during the ictal discharge, brief EEG paroxysms < 4 seconds duration, multiple spikes [more than 3], and visual [i.e., photic] and other sensory precipitation of clinical seizures) (31). Such criteria remain under debate. For example, photosensitivity is well accepted by other authors in childhood absence epilepsy with typical absence seizures (32, 33). Eyelid myoclonia with absences (EMA) is characterized by eyelid myoclonia and absences provoked by eye closure and photosensitivity. This may be seen in idiopathic or symptomatic epilepsies (34).

## EEG FEATURES

The EEG signature of a typical absence seizure is the sudden onset of 3-Hz generalized symmetrical spike- or multiple spike-and-slow-wave complexes (Figure 22–1). The voltage of the discharges is often maximal in the frontocentral regions. The frequency tends to be faster, about 4 Hz, at the onset and slows to 2 Hz toward the end of discharges longer than 10 seconds. The ictal discharges during an atypical absence seizure are more variable. They occur at frequencies between 1.5 and 2.5 Hz or may be faster than 2.5 Hz but are irregular or asymmetrical in voltage.

The interictal EEG background is generally normal in TAS and abnormal in AAS. Using the aforementioned ictal EEG criteria to classify absence seizures, Holmes and colleagues (22) found that only 44% of 27 patients with TAS had normal EEG backgrounds. Diffuse slowing was seen in 22%, paroxysmal spikes or sharp waves in 37%, and posterior rhythmic delta (less than 4 Hz) slowing in 15%. Conversely, only 11% of 27 patients with AAS had a normal interictal EEG. Diffuse slowing and focal or multifocal spikes or sharp waves were seen in 85%.

**FIGURE 22-1**

Typical 3-Hz generalized synchronous and symmetrical spike-and-wave EEG discharge during hyperventilation in an 8-year-old girl with pyknopsy. Note the drop out of finger tapping 2 seconds into the paroxysm and return on cessation of the discharge.

The discharges are more numerous during all sleep states except rapid eye movement (REM) (35–37). The bursts have a modified appearance in sleep, as they may be briefer, less regular, and slower with a 1.5- to 2.5-Hz frequency range. Hyperventilation, photic stimulation, and hypoglycemia activate typical absence seizures, but hyperventilation is the most effective procedure (8, 38).

Clinical effects are generally perceived accompanying discharges lasting longer than 3 seconds. Detailed neuropsychological investigations have demonstrated functional impairment from a spike-and-wave burst of any duration. Auditory reaction times were delayed 56% of the time when a stimulus was presented at the onset of the EEG paroxysm (39). They were abnormal in 80% when the stimulus was delayed 0.5 second. Responsiveness may improve as the paroxysm continues (40).

## ETIOLOGY

Both acquired and inherited factors are implicated in the etiology of absence seizures, reflecting the heterogeneity of the patient population. Genetic factors predominate in children who match the syndromes of idiopathic generalized epilepsy. Alternatively, acquired disorders are frequently found in retarded children with abnormal neurologic findings, abnormal interictal EEGs, and atypical absence seizures. Typical absence seizures, both clinically and electrographically, have been rarely seen in patients with mesial frontal lesions, with diencephalic lesions, and after withdrawal from sedatives (41–44). Nonconvulsive status epilepticus of frontal lobe origin can mimic absence status epilepticus once it has progressed to a full-blown phase (45). A 6-year-old girl with typical (albeit intractable) absence seizures and diffuse 3-Hz spike-and-wave EEG discharges induced by hyperventilation was diagnosed with Moyamoya disease (46). The epilepsy remitted after bilateral revascularization procedures were performed.

The lack of structural pathology and the age-specific window observed in most patients with typical absence seizures implicate a hereditary etiology. Metrakos and Metrakos (47) showed that absence seizures and generalized spike-and-wave EEG discharges are both inherited traits. Generalized spike-and-wave activity was seen in 37% of siblings of patients with generalized spike-and-wave activity on EEG and absence or generalized tonic-clonic seizures compared with 9% of controls. Only 25% of the family members with the EEG trait actually had seizures. They theorized that the inheritance of generalized spike-and-wave discharges is autosomal dominant with age-dependent penetrance, regardless of whether seizures occur. Dose and associates (48) suggested a multigenic inheritance, with both independent and interactive genetic factors. In general, the idiopathic generalized epilepsies are considered genetic in origin, and usually represented by

familial but complex, non-Mendelian traits. It has become increasingly clear that a variety of gene defects can result in absence seizures (49). Familial clustering of absence, myoclonic, and generalized tonic-clonic seizures has been demonstrated in the idiopathic generalized epilepsies, providing evidence for distinct genetic effects vis-à-vis seizure type (50). There are also patients with concomitant childhood absence epilepsy (CAE) and localization-related epilepsy, suggesting gene effects that transcend the traditional epilepsy syndrome classification (51).

More recent investigations of the pathophysiology of absence seizures, pointing to altered thalamocortical circuitry with key roles for T-type calcium channels and GABAergic mechanisms (*vide infra*), have spurred a new generation of molecular studies. The Cav3.2 T-type calcium channel gene has been linked to childhood absence epilepsy with mutations associated with altered channel gating properties (52). Mutations in GABA receptor genes have been invoked in CAE (53, 54). A significant association between a polymorphism in GABAR3 in chromosome 15q11 was found in 50 families with CAE. Mutations of the GABA<sub>A</sub> receptor gamma-1 subunit gene (GABRG2) on chromosome 5 were identified in a large family with CAE and febrile seizures. Multiple mutations and polymorphisms in the calcium channel CACNA1H gene were found in the highly conserved residues of the T-type calcium channel gene (55). Linkage analysis of a five-generation family with childhood absences plus generalized tonic-clonic seizures identified a locus on chromosome 8q24, designated as ECA 1, although the gene remains to be identified (56). Yet another study found no evidence that genes encoding GABA<sub>A</sub> and GABA<sub>B</sub> receptors, voltage-dependent calcium channels, and the ECA region on chromosome 8q account independently for the childhood absence trait in a majority of families (57). The precise mode of inheritance and the genes involved in CAE remain largely unidentified (58).

## PATHOPHYSIOLOGY

The observation that 3-Hz spike-and-wave discharges in absence seizures appear simultaneously and synchronously in all electrode locations led early investigators to speculate that the pathophysiologic mechanisms must involve “deep” structures with widespread connections between the two hemispheres (59–61). The term “centrencephalon” was coined to describe this unknown structure. Although this term was historically useful in emphasizing the fundamental differences between partial seizures and generalized seizures, later investigations have led to a better understanding of the basic mechanism of this disorder.

In the generalized penicillin epilepsy model, parenteral injections of penicillin—a weak GABA<sub>A</sub> receptor

agonist—produce behavioral unresponsiveness associated with bilateral synchronous slow waves on EEG. Thalamic and cortical cells become synchronized during this event through reciprocal thalamocortical connections. Although it is not clear whether activity in the cortex precedes that in the thalamus in primary generalized seizures, recordings from cortical neurons show an increase in the number of action potentials during a depolarizing burst. This is followed by powerful GABAergic feedback inhibition that hyperpolarizes the cell for approximately 200 milliseconds after each burst. The summated activity of the bursts produces the “spike,” which is dependent on alpha-amino-3-hydroxy-5-methylisoxazole-4-propionic acid (AMPA) receptors and T-type calcium channels, and the summated inhibition produces the “wave,” due to GABA-mediated inhibition as well as voltage- and calcium-dependent potassium conductances (62).

A number of studies have demonstrated that the basic underlying mechanism in generalized absence epilepsies involves thalamocortical circuitry and the generation of abnormal oscillatory rhythms in this neuronal network (63–66). Studies using both in vivo and in vitro models have demonstrated the neuronal circuit responsible for the generation of the oscillatory thalamocortical burst firing observed during absence seizures. The key role of the thalamus is corroborated by a selective increase in blood flow during absence seizures using positron emission tomography (PET) imaging and functional magnetic resonance imaging (fMRI) technology (67–69).

This circuit includes cortical pyramidal neurons, thalamic relay neurons, and the nucleus reticularis thalami (NRT) (66, 70). The principal synaptic connections of the thalamocortical circuit include glutamatergic fibers between neocortical pyramidal cells and the NRT, and GABAergic fibers from NRT neurons that activate GABA<sub>A</sub> and GABA<sub>B</sub> receptors on thalamic relay neurons. In addition, recurrent collateral GABAergic fibers from the NRT activate GABA<sub>A</sub> receptors on adjacent NRT neurons. As can be seen in Figure 22–2, the NRT is in a position to influence the flow of information between the thalamus and cerebral cortex (71). The NRT cells have rhythmic burst firing (oscillatory firing) during periods of sleep (critical for sleep spindle formation) and continuous single-spike firing (tonic firing) during wakefulness.

The cellular events that underlie the ability of NRT neurons to shift between an oscillatory and tonic firing mode are the low-threshold Ca<sup>2+</sup> spikes that are present in thalamocortical and NRT neurons (71). Low-threshold, transient Ca<sup>2+</sup> channels (T-channels) are a key membrane property involved in burst firing excitation and are associated with rhythmic discharges in thalamocortical cells during absence seizures (64, 65, 72, 73). Mild depo-

larization of these neurons is sufficient to activate these channels and to allow the influx of extracellular Ca<sup>2+</sup>. Further depolarization produced by Ca<sup>2+</sup> inflow exceeds the threshold for firing a burst of action potentials. After T-channels are activated, they become inactivated rather quickly, hence the name “transient.” Deactivation of T-channels requires a relatively lengthy hyperpolarization. GABA<sub>B</sub> receptor-mediated hyperpolarization is able to deactivate T-channels.

There is considerable evidence that the pathophysiological basis of absence seizures is the generation of excessive abnormal oscillatory rhythms (74). These abnormal oscillatory rhythms could be caused by abnormalities of the T-channels or enhanced GABA<sub>B</sub> function (59, 75). In some animal models of absence seizures T-channel activation in the NRT is significantly different from that in control animals (76). These aberrant T-channels may be one basis for absence seizures. In other models, there has been an increase in GABA<sub>B</sub> receptors in thalamic and neocortical neuronal populations compared with controls (74). As would be predicted from the thalamocortical circuits involved in absence seizures, in animal models of absences GABA<sub>B</sub> agonists produce an increase in seizure frequency, whereas GABA<sub>B</sub> antagonists reduce absence seizure frequency (77–79).

As demonstrated in Figure 22–2, recurrent collateral GABAergic fibers from the NRT neurons activate GABA<sub>A</sub> receptors on adjacent NRT neurons. Activating GABA<sub>A</sub> receptors in the NRT therefore results in inhibition of output to the thalamic relay neurons and serves to reduce hyperpolarization and delay deactivation of the T-channels. In animal studies, injection of the GABA<sub>A</sub> agonists bilaterally into the NRT reduces absence seizure frequency. This occurs because the GABA output to the thalamic relay neurons is reduced. Because of the decreased GABA<sub>B</sub> activation, there would be a reduced likelihood that the Ca<sup>2+</sup> deactivation would occur. This would result in decreased oscillatory firing. However, direct GABA<sub>A</sub> and GABA<sub>B</sub> activation of thalamic relay neurons would be expected to have detrimental effects, increasing depolarization and deactivation of the T-channels.

As would be expected from these animal findings are the clinical observations that three drugs that are effective in the treatment of absence seizures—valproate, ethosuximide, and trimethadione—all suppress T-currents. In addition, there is some clinical evidence that vigabatrin, which increases endogenous GABA levels and thereby increases the activation of GABA<sub>B</sub> receptors, worsens absence seizures in patients. However, clonazepam, which preferentially activates GABA<sub>A</sub> receptors in the NRT, can be a highly effective antiabsence drug (80). Hosford and Wang (74) evaluated the effects of a number of antiepileptic drugs (AEDs) on seizure frequency in the *lethargic (lh/lh)* mouse model of absence seizures. Previous studies

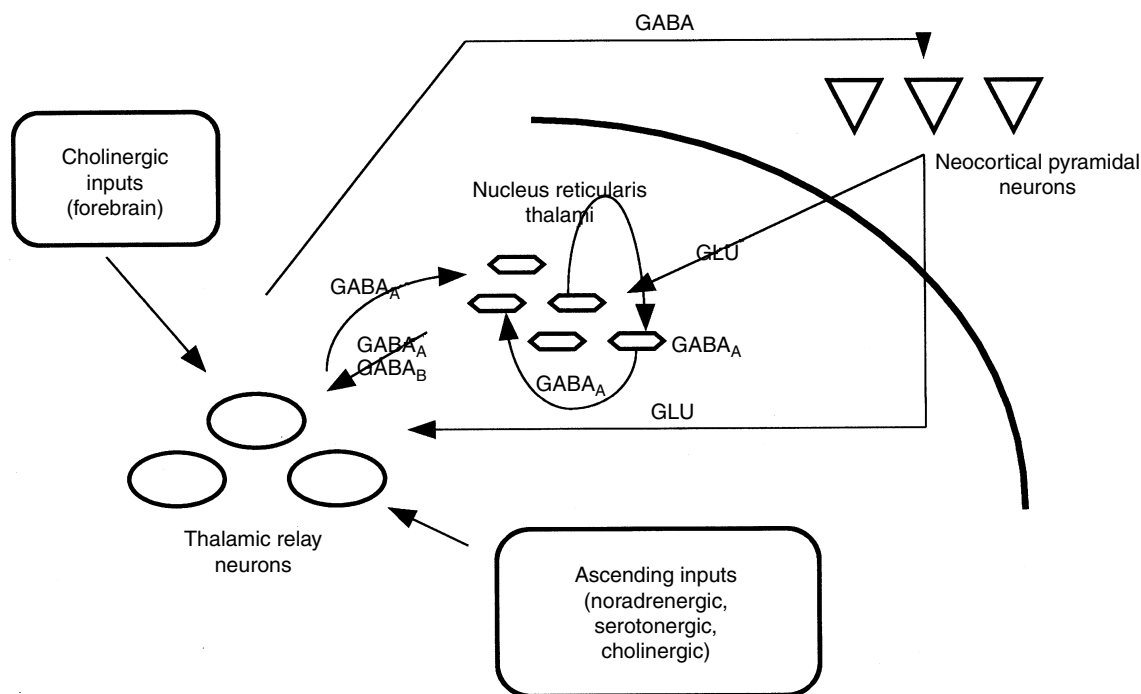

FIGURE 22-2

Thalamocortical circuits and neuronal networks implicated in the genesis of absence seizures. For discussion, see text.

had demonstrated the efficacy of ethosuximide, clonazepam, and valproate in this model. The authors found that lamotrigine significantly reduced seizure frequency, whereas vigabatrin and tiagabine increased seizure frequency and duration. Gabapentin and topiramate had no significant effects on seizure frequency.

The molecular characterization of T-type  $\text{Ca}^{2+}$  channels identified a family of genes that encode ion channels,  $\alpha 1\text{G}$ ,  $\alpha 1\text{H}$ , and  $\alpha 1\text{I}$ , with characteristics similar to T-type  $\text{Ca}^{2+}$  channels in neurons (81). Thalamic relay neurons express mainly the  $\alpha 1\text{G}$  form. A transgenic mouse model with lack of expression of the  $\alpha 1\text{G}$  protein fails to exhibit spike-and-wave discharges in response to  $\text{GABA}_B$  receptor activation (82). The human analogs to these genes have been designated  $\text{CACNA1G}$ ,  $\text{CACNA1H}$ , and  $\text{CACNA1I}$ . This provides further support for the critical role of T-type  $\text{Ca}^{2+}$  channels in absence seizures.

Other neurotransmitter systems (i.e., serotonergic, noradrenergic, and cholinergic) can influence the thalamocortical circuits and therefore influence absence seizure frequency. Diffuse monoamine projections from the locus coeruleus (noradrenergic), raphe magnus (serotonergic), and ventral tegmentum (dopaminergic) are implicated. For example, the mutant *tottering* mouse model has suggested a role for diffuse noradrenergic hyperinnervation of the cortex from the locus coeruleus in the genesis of paroxysmal spike wave discharge and the phenotype of behavioral arrest (83).

## DIAGNOSTIC EVALUATION AND DIFFERENTIAL DIAGNOSIS

The primary diagnostic considerations to be differentiated from absence seizures are complex partial seizures and daydreaming (Table 22-3). Complex partial seizures are more common than absence seizures and are also manifested by an alteration in consciousness with staring, automatisms, changes in tone, and autonomic symptoms (84). The complex partial seizure tends to be longer and less frequent, but clinically there maybe no absolute distinguishing factor. The presence of an aura or postictal impairment is strongly suggestive of a complex partial seizure. When positive, the EEG is the best confirmation of either seizure type.

Daydreaming is associated with boredom, can be "broken" with stimulation, and is not associated with motor activity. Absence seizures, however, may sometimes be terminated with stimulation and tend to increase during periods of relaxation and tiredness. Tics and pseudoseizures may need to be considered as well. A normal EEG that includes several trials of 3 to 5 minutes of hyperventilation, however, virtually rules out absence seizures. Repeated studies or prolonged monitoring occasionally are necessary when diagnostic confusion persists (85).

Childhood absence epilepsy describes typical absence seizures (i.e., both simple and complex) in children between the ages of 3 to 5 years and puberty who are otherwise normal. There is a strong genetic predisposition, and girls

**TABLE 22-3**  
*Differential Diagnosis of Typical Absence Seizures*

CLINICAL DATA	ABSENCE	COMPLEX PARTIAL	DAYDREAMING
Frequency/day	Multiple	Rarely over 1–2	Multiple; situation-dependent
Duration	Frequently <10 sec	Average duration over 1 min, 10 sec	Seconds to minutes; rarely more, rarely less
Aura	Never	Frequently	No
Eye blinking	Common	Occasionally	No
Automatisms	Common	Frequently	No
Postictal impairment	None	Frequently	No
Seizures activated by:			
HV	Very frequently	Occasionally	No
Photic	Frequently	Rarely	No
EEG			
Ictal	Generalized spike and wave	Usually unilateral or bilateral temporal frontal discharges	Normal
Interictal	Usually normal	Variable; may be spikes or sharp waves in frontal or temporal lobes	Normal

are more frequently affected. The absences are very frequent, occurring at least several times daily, and tend to cluster. The EEG reveals the classic bilateral, synchronous symmetrical 3-Hz spike-and-wave discharge with normal interictal background activity. The absences may remit during adolescence.

The syndrome of epilepsy with myoclonic absences, as recognized by Tassinari and Bureau (86), is characterized by absence seizures accompanied by severe bilateral rhythmical clonic, and sometimes tonic, activity. Age of onset averages 7 years, and boys are more often affected. The ictal EEG discharges are similar to those of pyknolepsy. Seizures are frequent and less responsive to medication than those of CAE. The episodes of myoclonic absence last 10 to 60 seconds' duration and are precipitated by hyperventilation, awakening, and occasionally intermittent light. About half of affected children are normal and half have mental retardation before seizure onset. The majority of cases develop other seizure types, including generalized tonic-clonic seizures, pure absence without myoclonias, and drops. Mental deterioration and evolution to Lennox-Gastaut syndrome may occur (87).

Eyelid myoclonia with (and without) absences is a form of epileptic seizures manifest by myoclonic eyelid jerks and brief absences. These are precipitated by eye closure and lights. The syndrome has genetic underpinnings, is age related, and affects neurologically normal children with a female predominance. The semiology involves an initial and prominent eyelid myoclonia, which may or may not progress to a mild absence. The duration is typically

brief, between 3 and 5 seconds. Head deviation or jerking of the hands may occur. The eyelid jerking becomes less violent as the absence component proceeds. Impairment of consciousness is mild and may appear incomplete. Some patients will self-induce the events, with some reports of an associated pleasurable feeling. The events are precipitated by eye closure (in a lit, not dark, environment), whether voluntary, involuntary, or reflex. They may only appear during photic stimulation. The accompanying EEG reveals generalized polyspike and polyspike-slow wave discharges of 3- to 6-Hz frequency and typically duration of 3 to 5 seconds. The symptoms require differentiation from ocular tics, with which they are often confused, and occipital seizures because forced eyelid closure and eyelid blinking are also described in occipital epilepsy. There also appears to be a group of patients having photosensitive epilepsy and concomitant nonepileptic paroxysmal eyelid movements (88). Lifelong treatment is recommended in eyelid myoclonia with absences, as remission is not anticipated (89).

## TREATMENT

The extent of diagnostic evaluation required in patients with absence seizures is variable and depends somewhat on which epileptic syndrome might best "fit" the patient. A patient who meets the criteria for one of the idiopathic generalized syndromes by clinical and EEG criteria requires no further studies. Not every patient, however, fits these descriptions. The presence of typical absence

seizures with consistent EEG ictal and interictal features and normal intelligence and neurologic examinations is reassuring that further tests are not necessary. Atypical features or history of developmental delay warrant cranial MRI and possibly more specific tests such as lumbar puncture, metabolic studies, and tissue examinations.

AED therapy is recommended for all children with adequate documentation of absence seizures. Although they are not life-threatening, they may lead to poor school performance, ridicule, and accidents. Because even a 1-second generalized spike-and-wave discharge sometimes affects cognitive function (39), it is prudent to try to control the seizures as well as possible with minimal drug toxicity.

Injury prevention counseling should not be underestimated. Accidental injury is common in patients with absence epilepsy and indeed usually occurs after anticonvulsant medication is already started (90). Specific recommendations, including mandatory use of bicycle helmets and avoidance of unsupervised swimming or climbing without protection, are common-sense precautions for any child.

The primary drugs of choice are ethosuximide, valproic acid or disodium valproate, and lamotrigine (91, 92). For the reader's convenience, in this chapter valproic acid and disodium valproate will both be called valproate. Comparative studies of the older AEDs have indicated equivalence in efficacy for ethosuximide and valproate (93–97). A Cochrane Database review indicated that randomized treatment trials possessing good methodological quality or sufficient power to detect a difference in efficacy when these agents are compared to each other or placebo are lacking, and concluded there is insufficient evidence to inform clinical practice (98). A multicenter trial addressing this question, coupled with neuropsychological testing of patients, is in progress at the time of this writing.

In standard clinical practice, a single agent is chosen and, after appropriate laboratory studies, initiated at a low dose and gradually increased. AED levels may be helpful, but dose changes in either direction should follow clinical indications. Upon dosage modifications, drug levels should be obtained only after sufficient time has elapsed to reach steady-state serum concentrations. Some clinicians will begin therapy with ethosuximide, primarily because of the rare but severe hepatotoxicity and pancreatitis associated with valproate (45, 99–101). Valproate is generally considered the drug of choice in the patient who has both absence seizures and generalized tonic-clonic seizures (20, 76). Published expert consensus opinion indicates that if initial monotherapy with ethosuximide, valproate, or lamotrigine is ineffective, other appropriate options are zonisamide or topiramate (91).

The combination of ethosuximide and valproate may be more effective than either drug alone (96, 102), although drug interactions do occur, requiring monitoring of clinical toxicity and serum drug levels (103). Clonazepam has been used in refractory cases, although it is limited because of its

side effects of sedation and tachyphylaxis. The combination of valproate and clonazepam has been associated with precipitation of absence status (104), but this is rare.

Lamotrigine appears to be a promising drug in the treatment of absence seizures, with a number of studies demonstrating efficacy (105–108). Lamotrigine has demonstrated some efficacy in the treatment of myoclonic absence seizures (109). In a small, open-label extension study Biton found that four of five patients with absence seizures had a 50% or greater reduction in seizure frequency with topiramate (110). Based on animal studies and limited clinical experience, it does not appear that vigabatrin is effective in the treatment of absence seizures (111). Felbamate may sometimes be useful in the treatment of absence seizures, although the drug is rarely used for this indication because of the associated aplastic anemia (112). Gabapentin also does not appear to be effective in the treatment of absences (113, 114). Small open-label studies suggest potential efficacy for levetiracetam (115). Although trimethadione is rarely used because of its side effect profile and significant teratogenic potential, it is an effective compound, to be considered only in truly refractory absence seizures (116). Aggravation of idiopathic generalized epilepsy syndromes has been increasingly recognized as an iatrogenic complication of AEDs, and carbamazepine, phenytoin, gabapentin, tiagabine, and vigabatrin should be avoided (117).

The cellular mechanisms of action of the antiabsence drugs remain unclear. Valproate increases GABA levels through several possible pathways, but the relevance of this mechanism to its clinical effect has not been demonstrated (118). Valproate has been shown to limit sustained high-frequency repetitive firing of action potentials at therapeutic levels using mouse neurons in cell culture (119). Clonazepam, along with other benzodiazepines and phenobarbital, augments postsynaptic GABA responses (119). The active metabolite of trimethadione, dimethadione, blocks the low threshold, transient (T-type) calcium current in thalamic neurons, an effect shared by ethosuximide but not phenytoin or carbamazepine (116).

As discussed in the section on pathophysiology, the *lh/lh* genetic mouse model has contributed extensively to the investigation of the cellular and molecular mechanisms underlying absence seizures. The model has correctly predicted the therapeutic effects of ethosuximide, clonazepam, and valproate, in contrast to phenobarbital, phenytoin, and carbamazepine, against absence seizures. This same model demonstrated antiabsence efficacy of lamotrigine, proabsence effects of vigabatrin and tiagabine, and lack of effects by gabapentin and topiramate (74).

The duration of therapy is variable, although gradual taper from medication is recommended in general in patients who are seizure free for 2 years. The EEG is indicated in this situation, because even a 1-second generalized spike-and-wave discharge can result in subtle functional

impairment (39). A brief discharge in sleep, however, would not preclude drug withdrawal. Hyperventilation should be performed during the EEG for 3 to 5 minutes, and the presence of discharges indicates a high recurrence risk.

Withdrawal seizures may occur with ethosuximide and valproic acid but are more likely to be precipitated by rapid reduction of clonazepam (120). Clonazepam should not be tapered faster than 0.25 mg per week (121). Withdrawal seizures may be delayed weeks after stopping valproate.

Absence status epilepticus is a unique form of nonconvulsive status epilepticus manifested by sustained impairment of consciousness associated with generalized, irregular, approximately 3-Hz spike-and-wave EEG discharges. Most patients are dull and confused but partially responsive and able to carry out tasks of daily living (122). They often exhibit facial twitching, eye blinking, staring, or automatisms (41, 123–125). Absence status may present as periods of stupor in adolescents or adults with a history of childhood absences after a relatively long seizure-free interval. The EEG may also show polyspike-and-wave discharges or prolonged generalized bursts of spike activity or irregular slow spike-and-wave discharges (122). Treatment is usually with intravenous diazepam (125), although intravenous acetazolamide (500 mg, or 250 mg for children weighing less than 35 kg) has been advocated (126). Intravenous valproate is likely to be useful for treatment of absence status.

### COURSE AND PROGNOSIS

The average age of cessation of absence seizures is 10.5 years (12); however, some children continue to have absence seizures beyond puberty. Typical absence seizures generally have a favorable prognosis, with remission rates of approximately 80% (7, 127–129). An analysis of 52 patients with childhood absence by Loiseau and coworkers (130) demonstrated complete control in 95% of patients with absence seizures only and in 77% of patients with absence plus generalized tonic-clonic seizures. In contrast, of 62 patients with juvenile absence epilepsy, control was achieved in 77% of patients with absence seizures only and in 37% of patients with absence plus generalized tonic-clonic seizures (130).

Patients with CAE have a favorable response to medication and good prognosis for remission when taken off medication. Sato and colleagues (25) identified favorable prognostic signs for “outgrowing” both absence seizures and other seizure types as a negative family history of epilepsy, normal EEG background activity, and normal intelligence. A subsequent long-term follow-up study of 72 patients having mean seizure onset at 5.7 years (range, 1–14 years) and studied at a mean age of 20.4 years (range, 12–31 years) determined only a 65% remission rate, and furthermore that 15% of the total cohort developed JME. Adverse prognostic factors were cognitive impairment at diagnosis, history of absence status, presence of generalized tonic-clonic or myoclonic seizures during AED treatment, abnormal EEG background, and family history of generalized seizures in first-degree relatives (14). Also troubling is the observation of psychosocial difficulties, in the areas of academic-personal and behavioral categories, in a recent report on 56 young adults having a history of typical childhood absence epilepsy. Remission occurred in 32 (57%) of the patients, and the least favorable outcomes correlated with persistence of seizures (131).

In a study of treatment outcome in 86 children with childhood and juvenile absence epilepsy, initial drug treatment was successful in 52 (60%). Adverse prognostic factors were coexistence of generalized tonic-clonic or myoclonic seizures. As with other epilepsies, ultimate remission was more likely if the initial drug was successful than if it was not (69% vs. 41%,  $P < 0.02$ ) (132). More recent studies of the evolution and prognosis of childhood absence epilepsy have identified that strict ILAE classification criteria impact the ability of a clinician to impart an accurate prognosis. In patients fulfilling strict criteria for CAE compared to children with absence seizures who did not fulfill syndromic criteria, there were significantly better rates of seizure control (95% vs. 77%), terminal remission (82% vs. 51%), fewer generalized tonic-clonic seizures (8% vs. 30%), and shorter mean treatment duration (2.2 vs. 3.8 years) (133). Unfavorable prognostic factors were the presence of generalized tonic-clonic seizures in the active stage of absences, myoclonias, eyelid or perioral myoclonia, and atypical EEG features.

## Benign Focal Epilepsies of Childhood

**Colin D. Ferrie**  
**Douglas R. Nordli, Jr.**  
**Chrysostomos P. Panayiotopoulos**

**T**he International League Against Epilepsy's (ILAE's) definition of a benign epilepsy (syndrome) is "A syndrome characterized by epileptic seizures that are easily treated, or require no treatment, and remit without sequelae" (1). In approximately 60% of children with epilepsy seizures will cease, antiepileptic drugs (AEDs) can be withdrawn, and seizures will not recur (2). This indicates that a majority of children with epilepsy have benign conditions.

In its 2001 diagnostic scheme, the ILAE listed around 40 epilepsy syndromes and conditions with recurrent epileptic seizures (3). Only a small number of them satisfy the ILAE criteria for the diagnosis of benign epilepsy. These are (in order of the age at which they characteristically begin):

- Benign familial neonatal seizures
- Benign nonfamilial neonatal seizures
- Benign familial and nonfamilial infantile seizures
- Benign childhood epilepsy with centrottemporal spikes
- Early onset benign childhood occipital epilepsy (Panayiotopoulos type)

If a less rigorous definition is used, the following conditions could reasonably be added:

- Benign myoclonic epilepsy in infancy
- Childhood absence epilepsy
- Late onset childhood occipital epilepsy (Gastaut type)
- Idiopathic photosensitive occipital lobe epilepsy

Although some of these disorders are common, together they still account for well under half of all children with epilepsy. This emphasizes two important points when considering benign childhood epilepsy syndromes. First, among the many children with epilepsy who do not fit within any of the currently recognized syndromes, there are many whose epilepsy follows a benign course. Second, many children who have epilepsy syndromes that are not usually considered benign, nevertheless, have a good outcome. This is perhaps best illustrated by children with congenital hemiplegia who develop focal seizures. Many such children have only a few seizures, respond well to medication, and eventually successfully discontinue treatment. However, even with syndromes usually considered anything but benign (or even "malignant") significant numbers of individuals have a good outcome. For example, this is so in 12% to 25% of children diagnosed with West syndrome (4). This chapter will therefore consider only a fraction of those children with benign forms of focal epilepsy. Idiopathic generalized epilepsies, including those whose courses are usually benign, are considered

elsewhere, as are the benign focal epilepsies that occur in the neonatal and infantile periods. The “core group” of benign focal epilepsies left to consider in this chapter (with their official ILAE names in brackets) are

- Rolandic epilepsy (benign childhood epilepsy with centrotemporal spikes)
- Panayiotopoulos syndrome (early onset benign childhood occipital epilepsy—Panayiotopoulos type)
- Idiopathic childhood occipital epilepsy (late onset childhood occipital epilepsy—Gastaut type and idiopathic photosensitive occipital lobe epilepsy)

The main features of these disorders are compared in Table 23-1.

### A NOTE ON TERMINOLOGY

We prefer “rolandic epilepsy” to “benign childhood epilepsy with centrotemporal spikes” for the following reasons:

- The term is widely used by pediatricians.
- Centrotemporal spikes are located mainly in the central (rolandic) fissure; they are rarely located in the temporal electrodes.
- Rolandic epilepsy may occur without centrotemporal spikes and conversely centrotemporal spikes occur in children without seizures and in children with other benign focal epilepsies.
- The term “temporal” may suggest the occurrence of temporal lobe symptoms during seizures despite these not being a feature of the condition.

**TABLE 23-1**  
*Comparison of the Clinical and EEG Features of the Three Idiopathic Childhood Focal Epilepsies of Childhood*

	PANAYIOTOPOULOS SYNDROME	ROLANDIC EPILEPSY	IDIOPATHIC CHILDHOOD OCCIPITAL EPILEPSY
<b>Prevalence among children</b>			
<i>1–15 years with afebrile seizures, %</i>	6	15	1-2
<b>Mean age at onset (range), years</b>	4–5 (1–14)	8–9 (1–15)	8-9 (3-16)
<b>Sex prevalence, %</b>	54 males	60 males	50 males
<b>Seizure characteristics</b>			
Main type of seizures	Autonomic and often with emesis	Focal sensory-motor	Focal visual
Duration	Long (usually 9 minutes or longer)	Moderate (usually 2–4 minutes)	Brief (seconds to 1–2 minute)
Focal nonconvulsive status epilepticus (>30 min), %	44	Rare	Exceptional
Frequency of seizures	Infrequent	Infrequent	Many, sometimes daily
Single seizures only, %	30	10–20	Exceptional
Circadian distribution, %	Mainly in sleep (64)	Mainly in sleep (70)	Mainly when awake (>90)
Reflex provocation of clinical seizures	Probably none	Probably none	10–20% photosensitivity
<b>Interictal EEG</b>			
Reflex provocation of spikes, %	Multifocal spikes Fixation-off sensitivity (10) and less often somatosensory stimulation (<5)	Centrotemporal spikes Somatosensory stimulation (20–25)	Occipital spikes Fixation-off sensitivity and 20% occipital photosensitivity
<b>Prophylactic continuous treatment</b>			
	Often not needed	Often not needed	Needed
<b>Prognosis</b>			
Risk of epilepsy as an adult, %	Excellent	Excellent	Uncertain
Risk of epilepsy as an adult, %	2?	3	20?
Remission within 1–3 years from first seizure	Common	Common	Uncommon
Similar seizures after remission	None	Only one case is reported	Common
Developmental and social prognosis	Normal	Normal	Usually good

Modified from Ferrie et al (54), with the permission of the Editor of *Developmental Medicine and Child Neurology*.

We prefer “Panayiotopoulos syndrome” to “early onset benign childhood occipital epilepsy (Panayiotopoulos type),” because evidence now suggests that it is a form of multifocal epilepsy with autonomic ictal symptoms rather than an occipital lobe epilepsy.

We use the term “idiopathic childhood occipital epilepsy” to include both late onset childhood occipital epilepsy—Gastaut type and idiopathic photosensitive occipital lobe epilepsy. This is because both conditions share many common features and it is not clear that they merit separation into two distinct syndromes.

### CONSIDERATIONS REGARDING THE ETIOLOGY, INCLUDING THE GENETIC BASIS, OF THE BENIGN FOCAL EPILEPSIES OF CHILDHOOD

The benign focal epilepsies of childhood are all idiopathic epilepsies, the ILAE’s definition of which is “A syndrome that is only epilepsy, with no underlying structural brain lesion or other neurologic signs or symptoms. These are presumed to be genetic and are usually age-dependent” (3). In keeping with their presumed genetic origin, there is an increased risk of epileptic seizure disorders in the family members of children with benign focal epilepsies, although it is rare to find family members with the same benign focal seizure disorder. Febrile seizures are common both in probands and family members (5). However, to date the likely genetic basis of these disorders has eluded us. Panayiotopoulos has suggested that they (and possibly also febrile seizures) share a common age-related origin and all might be considered as manifestations of a “benign childhood seizure susceptibility syndrome” (5, 6). This is a common, genetically determined, mild and reversible, functional derangement of the brain cortical maturational process. Benign childhood seizure susceptibility is often clinically silent and manifests in more than 90% with electroencephalographic (EEG) sharp and slow waves with an age-related localisation. The remaining 10% have infrequent focal seizures with symptoms that are also localization—and age related—and dependent. It is possible that a few of these children, with or without seizures, also have usually minor and fully reversible neuropsychologic symptoms that are rarely clinically overt and that can only be detected by formal neuropsychologic testing. Finally, there may be a very small number of patients (<1%) in whom this derangement of the brain maturation process may be further derailed in a more aggressive condition with seizures, neuropsychologic manifestations, and EEG abnormalities of various combinations and various degrees of severity, such as in Landau-Kleffner syndrome, and epilepsy with continuous spikes and slow waves during sleep (5, 6).

The benign focal epilepsies of childhood do not, as a whole, follow simple Mendelian inheritance. Vadlamudi et al found strong concordance for idiopathic generalized epilepsies in 26 monozygotic twins, but no concordance for rolandic epilepsy in 6 monozygotic twins (7). Of course, this does not exclude Mendelian inheritance in individual families with forms of benign focal epilepsy. Moreover, the EEG trait characterizing these disorders may show Mendelian inheritance, even if the seizure phenotype does not (8–10). If this is so, by implication, other genetic, environmental factors, or both must also be involved in producing the clinical seizure disorder (7). So far, the only genetic linkage reported for any of the benign focal epilepsies of childhood is to 15q14 for rolandic epilepsy (10, 11).

One of the most significant developments in epileptology in the last decade has been the demonstration that many seizure disorders, albeit to date rare ones, arise as a consequence of mutations in genes encoding neuronal ion channels (12–14). Benign familial neonatal seizures, which are autosomal dominant with high penetrance, is caused by mutations in the voltage-gated potassium channel subunit gene *KCNQ2* on chromosome 20q13.3 and *KCNQ3* on chromosome 8q.13.3 (12–15). Similarly, benign familial neonatal-infantile seizures, also an autosomal dominant condition, is caused by mutations in the sodium channel subunit gene *SCN2A* (16). Given this evidence, the likelihood that the benign focal epilepsies of childhood also result from mutations on genes encoding channel ions is high, although other mechanisms are not precluded (94).

Further fascinating clues regarding the pathogenesis of these disorders are descriptions linking them with non-epileptic paroxysmal disorders. Families are described in which benign infantile seizures and paroxysmal choreo-athetosis or dystonia occur (17). In some subjects one or other of these disorders is recognized, whereas in others both occur together, or else the benign infantile seizures subside but later the movement disorder begins. A pedigree has also been described with three members in the same generation who had rolandic epilepsy, paroxysmal dystonia, and writer’s cramp (18).

### Rolandic Epilepsy

*Introduction and Definition.* This disorder (19, 20), also called benign epilepsy of childhood with centrotemporal spikes (BECTS), was, in 1958, the first of the benign focal epilepsies to be recognized (by Beaussart et al [21]). Later its recognition in the United States was established by Lombroso (22). It is probably the single most common epilepsy syndrome after febrile seizures.

Rolandic epilepsy can be defined as an idiopathic benign focal seizure disorder of childhood manifested with seizures, which are usually infrequent and often single, and whose semiology reflects onset in the lower

part of the pre- and postcentral gyri. They are characterized by unilateral facial sensorimotor symptoms, oropharyngolaryngeal manifestations, speech arrest, and hypersalivation. Secondary generalization is frequent. Interictal EEG shows high amplitude sharp and slow wave foci, which are usually localized to the central or centrotemporal electrodes.

**Epidemiology.** Rolandic epilepsy can start as early as 1 year of age or as late as 15 years of age (23). However, three-quarters of cases have onset of seizure between 7 and 10 years. Boys are more often affected, with a ratio of 3:2. Overall around 15% of children with seizures aged 1 to 15 years of age are considered to have rolandic epilepsy. The EEG trait characteristic of rolandic epilepsy is considered to be inherited in an autosomal dominant manner.

**Clinical Manifestations.** Rolandic epilepsy, being idiopathic, is expected to occur in children who are otherwise normal. Three-quarters of seizures occur in non-rapid-eye movement (non-REM) sleep, usually shortly after sleep commences or before waking. The most recognizable seizure manifestations involve oropharyngolaryngeal symptoms and hemifacial motor, sensory, or more usually sensorimotor symptoms. Oropharyngolaryngeal symptoms occur in just over one-half of seizures, with hemifacial sensorimotor manifestations occurring in around one-third of seizures.

Oropharyngolaryngeal symptoms consist of unilateral sensory (numbness and parasthesia) and motor manifestations affecting the structures inside the mouth (i.e., tongue, inner cheeks, teeth, and gums) and the pharynx and larynx. The motor manifestations are responsible for gurgling, grunting, and guttural noises, sometimes producing a so-called death rattle.

The motor manifestations of the hemifacial seizures consist of sudden, continuous, or bursts of clonic contractions usually localized to the lower lip and often accompanied by ipsilateral tonic deviation of the mouth. In a minority of cases the motor manifestations are more widespread with hemifacial clonic activity, sometimes with spread to the ipsilateral upper limb. The sensory manifestations of the hemifacial seizures are usually described as numbness or tingling in the corner of the mouth.

Speech arrest is very common in rolandic seizures, occurring in about 40% of patients. The cause is disputed. Some refer to it as aphemia (implying a motor aphasia), others as aphonia (implying an inability to produce sound as a consequence of laryngeal dysfunction). Panayiotopoulos has argued that it is an anarthria or dysarthria (implying an articulatory disturbance) (19). In support of this, it appears to occur equally in left- and right-sided seizures. The child with speech arrest

will often try to communicate using other means, such as gestures.

Hypersalivation is reported to occur in around one-third of rolandic seizures, and recently ictal syncope (described in detail later) has also been reported as a rare feature of rolandic seizures (5).

In more than one-half of rolandic seizures consciousness is retained throughout the seizure, such that the child can often give a vivid description of his or her experiences after the seizure. However, spread of rolandic seizures is common, leading to impairment of consciousness and secondarily generalized tonic-clonic seizures (GTCS). Such spread is much more likely with seizures occurring in sleep; rolandic epilepsy is one of the commonest causes of nocturnal GTCS in children, whereas it is said to be only exceptionally associated with GTCS when awake.

Seizures in rolandic epilepsy are usually brief, mostly lasting 1–2 minutes. However, they may be longer if they progress to GTCS. Focal motor status epilepticus and hemiconvulsive status epilepticus, although rare, are well described. The latter is probably more common when the syndrome occurs in younger children. It may be followed by Todd's paresis, usually sparing the face. Opercular status is encountered as part of the atypical evolution sometimes encountered in the syndrome (24). Convulsive status epilepticus is exceptional.

**EEG Features.** The interictal EEG in children with rolandic epilepsy usually shows a normal background but with the hallmark centrotemporal (or rolandic) spikes (Figure 23-1). Despite their name, these are usually high amplitude sharp and slow wave complexes localized to the central (C3/C4) electrodes or midway between the central and temporal electrodes (C5/C6). They may be unilateral or bilateral, synchronous or asynchronous.

Centrotemporal spikes have been studied with EEG single- or multiple-dipole modeling computerized techniques. The consensus is that their main negative spike component can usually be modeled by a single and stable tangential dipole source along the central (rolandic) region, with the negative pole maximal in the centrotemporal and the positive pole maximal in the frontal regions (25, 26).

Centrotemporal spikes are highly activated by sleep; normal sleep architecture is preserved.

The interictal EEG (especially if there is no sleep recording) may rarely be normal. Mild background slowing may be a postictal effect, reflect antiepileptic drug medication, or may be seen if centrotemporal spikes are particularly abundant. Rarely small inconspicuous spikes may be seen, rather than those with the more characteristic morphology. Sharp- and slow-wave complexes in areas outside the centrotemporal regions, such as occipital, parietal, frontal, and midline regions, may occur concurrently with centrotemporal spikes. They are of similar

FIGURE 23-1

Centrotemporal spikes recorded from an 11-year-old girl with rolandic seizures that had been in remission for the last 3 years. Note that the spikes have their maximal amplitude in the central rather than temporal electrodes. (Top) EEG in wakefulness. (Top, left) Infrequent spikes occur independently in the right or left central electrodes (C4 or C3). (Top, right) Stimulation of the tips of the fingers elicited high amplitude central spikes, which were contralateral to the side of stimulation. Self-stimulation of the fingers elicited simultaneous bilateral central spikes. In clinical EEG practice, asking the child to tap together the palmar surface of the tips of his or her fingers of both hands is an easy method of testing for evoked spikes. The child should be instructed to strike them with sufficient strength and at random intervals. This may elicit either bilateral or unilateral central spikes. (Bottom) Frequency and amplitude of central spikes is markedly increased in sleep. In previous EEGs their abundance approached that of electrical status epilepticus in sleep. Despite marked EEG abnormalities over many years, the child was otherwise normal, did well in school, and had no linguistic or neuropsychologic deficits.

morphology to centrotemporal spikes. Rarely, generalized discharges occur.

An unusual feature of the EEG apparent in some children with rolandic epilepsy is the provocation by tapping of the fingers or toes of extreme somatosensory evoked spikes (giant somatosensory evoked potentials) in the contralateral hemisphere (5, 27, 28). These are of identical morphology to centrotemporal spikes. It should be noted that although most often encountered in rolandic epilepsy, the phenomenon is not confined to this syndrome.

Centrotemporal spikes, the EEG hallmark of rolandic epilepsy, peak at 8–9 years of age and occur in 2% to 3% of normal children; they are also common in children with neurologic deficits who do not have epileptic seizures (29–31).

The frequency, location, and persistence of centrotemporal spikes do not determine the clinical manifestations, severity, and frequency of seizures or the prognosis (5).

There are very few ictal EEG recordings of rolandic seizures. Before the onset of the ictal discharge, centrotemporal spikes become sparse. The ictal discharge then appears and consists of unilateral slow waves intermixed with fast rhythms and spikes located in the central regions (19, 20, 32). The ictal EEG features of rolandic epilepsy are shown in Figure 23-2 and compared to those of Panayiotopoulos syndrome.

Magnetoencephalography (MEG) studies have shown that the dipoles of the prominent negative sharp waves of rolandic discharges appear as tangential dipoles in the central (rolandic) region, with positive poles being situated anteriorly (32, 33). MEG findings in children with rolandic epilepsy are shown in Figure 23-3 and compared with those in Panayiotopoulos syndrome.

*Diagnostic Evaluation and Differential Diagnosis.* There is controversy as to the extent to which children with suspected rolandic epilepsy require investigation. Investigations, other than EEG, are expected to be normal. Many, but not all authorities, consider that neuroimaging is not required if the clinical picture, taking into account age, the absence of any comorbidities, seizure semiology, and EEG features, are typical. Neuroimaging, preferably magnetic resonance imaging (MRI), is certainly indicated if atypical features are present or if the evolution is not as expected. Structural lesions in the rolandic regions may occasionally be found (34). If neuroimaging is routinely performed it may detect coincidental abnormalities (35). The significance of reports of hippocampal abnormalities in a minority of children with rolandic epilepsy remains to be determined (36–38).

*Treatment.* The ultimate prognosis in rolandic epilepsy is almost certainly not influenced by regular AED treatment. Many authorities do not recommend such

treatment routinely, reserving it for children whose seizures are unusually frequent or unpleasant (for example, occurring while awake). Some are concerned about the risk of sudden unexpected death in epilepsy (SUDEP), although there is no strong evidence that this is a risk in rolandic epilepsy. If it is decided to treat, it is generally considered that seizures are easily controlled in most cases. However, a recent study suggested that only secondary GTCS, not focal seizures, were significantly reduced by such treatment (38). The evidence base for choosing a particular medication is poor; carbamazepine is probably used most often.

*Course and Prognosis.* Most children with rolandic epilepsy will have fewer than 10 seizures; indeed, single seizures are common (an argument for considering this as a benign seizure disorder rather than an epilepsy (23, 39). However, perhaps up to one-fifth of subjects will have frequent seizures, especially at the start of the disorder. The prognosis, however, remains excellent, with remission usually occurring within 1–2 years of onset and certainly before the age of 16 years (23). The risk of GTCS in adult life is less than 2% (similar to the normal population). There is probably a higher risk, however, of developing absence seizures (5).

The term “benign” should not be used to imply “trivial” or to suggest that rolandic epilepsy has no neurodevelopmental effects. Transient cognitive impairment has been demonstrated as a consequence of centrotemporal spikes, raising interesting questions concerning the boundary between interictal and ictal EEG abnormalities (40–46). Some children with rolandic epilepsy develop mild, but not insignificant, speech, reading, and behavioral problems (40–46). It is not established whether AED treatment is useful in the management of such problems; the potential adverse cognitive and behavioral effects of such drugs should certainly be borne in mind.

### **Panayiotopoulos Syndrome**

*Introduction and Definition.* This condition (47–54) was first described by Panayiotopoulos in a 30-year prospective study starting in 1973 (47, 50, 51, 53, 55–57). After rolandic epilepsy, it is the most common of the benign focal epilepsies of childhood and is typically manifested with autonomic seizures and autonomic status epilepticus. Autonomic seizures can be defined as epileptic seizures characterized by altered autonomic function occurring at the onset of the seizure or as the sole manifestation of the seizure. Autonomic status epilepticus is an autonomic seizure that lasts for more than 30 minutes (50, 51, 58).

Panayiotopoulos syndrome, because of its unusual ictal manifestations, is especially likely to be misdiagnosed as a nonepileptic disorder.

## Video-EEG recorded seizure in Rolandic epilepsy

## Video-EEG recorded autonomic status epilepticus in Panayiotopoulos syndrome

FIGURE 23-2

Samples from video-EEG recorded seizures of rolandic epilepsy and Panayiotopoulos syndrome. (Top) Onset of a rolandic seizure captured during routine sleep video-EEG of a 9-year-old girl. Right-sided centrotemporal spikes (oblique arrows) and brief (2 to 4 seconds) generalized discharges of sharp slow waves intermixed with small spikes occurred in the interictal EEG only during sleep. The exact onset of the electrical ictal event is not clear but started in the right centrotemporal regions (open horizontal arrows) with 2- to 3-Hz slow waves and irregular, random, and monophasic medium-voltage spikes intermixed and superimposed on the slow waves. This activity tended to spread, and the amplitude of the spikes rapidly increased before the first clinical symptoms of left hemifacial convulsions, which occurred approximate 30 seconds from the onset of the EEG ictal changes (black vertical arrow). At age 18 years, she is entirely normal and is not taking medication. Modified from Reference 5 with the permission of the publisher. (Bottom) Onset of autonomic status epilepticus captured during routine video-EEG of a 4-year-old boy with Panayiotopoulos syndrome. High amplitude spikes and slow waves are recorded from the bifrontal regions (oblique arrows) before the onset of the electrical discharge, which is also purely bifrontal (open horizontal arrows). The first clinical symptoms (black vertical arrow) with three or four coughs and marked tachycardia appeared 13 minutes (see time at the bottom of the figure) after the onset of the electrical discharge, when this had become bilaterally diffuse. Subsequent clinical symptoms were tachycardia, ictus emeticus (without vomiting), and impairment of consciousness. No other ictal manifestations occurred until termination of the seizure with benzodiazepines 70 minutes after onset. Another lengthy autonomic seizure was recorded on video EEG 1 year later. The onset of symptoms was different with mainly tachycardia and agitation despite similar EEG manifestations. Modified from Reference 71 with the permission of the authors and the editor of *Epilepsy & Behavior*.

**FIGURE 23-3**

Magnetoencephalography (MEG) studies from two patients with rolandic epilepsy (left two columns) and a patient with Panayiotopoulos syndrome (right two columns). In rolandic epilepsy, equivalent current dipoles of spikes are located and concentrated in the rolandic regions and have regular directions. In Panayiotopoulos syndrome, equivalent current dipoles of spikes are located and concentrated bilaterally in the rolandic regions and right occipital area. The directions of each equivalent current dipole in each area are quite regular as if three small round toothbrushes are placed in each of the three areas. Small yellow circles represent locations and yellow arrows represent directions of equivalent current dipoles. Blue circles and arrows represent bilateral somatosensory evoked magnetic field. Figure courtesy of Dr. Osamu Kanazawa.

Panayiotopoulos syndrome can be defined as an idiopathic benign focal seizure disorder of childhood manifested with autonomic seizures, which are usually infrequent and often single. Characteristically, seizure semiology includes emetic symptoms, which may be combined with other autonomic features. Syncopal-like episodes may occur. Seizures are often prolonged (autonomic status epilepticus). Interictal EEG shows focal high amplitude sharp and slow wave complexes that, in serial EEGs, shift between various EEG electrodes.

*Epidemiology* (47, 50, 54, 59). Panayiotopoulos syndrome can start as early as 1 year of age or as late as 14 years of age. However, 76% of cases begin between 3 and 6 years of age and onset peaks at 4 to 5 years of age. It affects boys and girls equally. In those children with epilepsy who are 1–15 years old, prevalence is estimated to be 6%, rising to 13% in those 3–6 years old. Therefore, a clinician might expect to see at least one case of

Panayiotopoulos syndrome for every three cases of rolandic epilepsy.

*Clinical Manifestations* (47, 50, 54, 56, 57, 59–65). Panayiotopoulos syndrome, being idiopathic, is expected to occur in children who are otherwise normal. Two-thirds of seizures occur during sleep, including daytime naps. No precipitants can be identified, although it has been noted that seizures appear to be particularly likely while traveling.

Seizures usually begin with emetic symptoms. These include one or more of nausea, retching, and vomiting. If asleep at seizure onset, the child may be found in bed retching or vomiting. However, many will first awaken and complain of nausea. Seizures that occur when awake usually begin with a complaint of nausea often accompanied by behavioral changes, particularly agitation. During the seizure the child commonly vomits a few times; but occasionally vomiting may be repeated many times,

sometimes over hours. Seizures in Panayiotopoulos syndrome without at least one feature of the “emetic triad” are rare but do occur.

Other autonomic features may occur concurrently with or follow the emetic features. Pallor is very common; cyanosis and flushing are less common (50). Pupillary abnormalities, especially mydriasis but also miosis, are frequently noticed by eyewitnesses, but will usually require prompting to obtain a report of them. Urinary and occasionally fecal incontinence may occur. A raised temperature may be suspected or measured during or immediately after a seizure and may represent a true ictal symptom, rather than being a precipitant of the seizure. Rarer ictal symptoms that have been reported include headache and other “cephalic sensations,” hypersalivation, and coughing (50, 59).

Once it was realized that autonomic features dominated the seizures of Panayiotopoulos syndrome, it was natural to ask whether respiratory and cardiovascular irregularities might occur and, if so, whether these might be dangerous. Breathing changes are sometimes reported, particularly before convulsions (50). Tachycardia is certainly a feature of seizures recorded on EEG with simultaneous ECG recording (50, 66). Cardiorespiratory arrest during a typical seizure of Panayiotopoulos syndrome has been reported (67), and three other children with a diagnosis of Panayiotopoulos syndrome are also suspected to have had cardiorespiratory arrest (50).

When seizures occur in the awake state (or if the child awakens at the start of the seizure), the initial seizure symptoms usually occur in full consciousness (simple focal seizure). However, and after a variable time, consciousness usually becomes impaired (complex focal seizure), although some awareness and ability to respond is often retained. Some observers report behavioral changes such as restlessness, agitation, and terror, apparently in full consciousness (50, 59).

Some seizures in Panayiotopoulos syndrome include features suggestive of syncope, with the child becoming pale, flaccid, and unresponsive (50). Often these features occur along with more typical ones, but can occasionally occur in isolation. The term “ictal syncope” or “ictal syncopal-like episodes” have been used to denote these (50, 51, 53). It is not known if they are a result of transient hypoperfusion of the brain as in a true syncope.

When Panayiotopoulos syndrome was first described, ictal deviation of the eyes and often also the head were reported as prominent features. Reevaluation of the data has confirmed that such versive features are common. However, they usually occur around the time consciousness is becoming impaired, rather than at the start of the seizure.

Seizures in Panayiotopoulos syndrome often end in hemiconvulsions (around one-fifth of seizures) or GTCS (also around one-fifth of seizures).

An important feature of the seizures is that they are generally prolonged. Of those reported in the literature, 44% lasted for 30 minutes or more (maximum reported is 7 hours). These episodes, therefore, represent a form of nonconvulsive status epilepticus and might reasonably be classified as autonomic status epilepticus. They may end spontaneously or as short hemiconvulsions or GTCS. The child is expected to have returned to normal within a few hours of such episodes. Convulsive status epilepticus is exceptional. The mean duration of nonstatus seizures in Panayiotopoulos syndrome is around 9 minutes.

*EEG Features (47, 50, 54–57, 59–65).* The interictal EEG of Panayiotopoulos usually shows a normal background with high amplitude sharp and sharp and slow wave foci (functional spikes), similar in morphology if not location to those seen in rolandic epilepsy. Previously the occipital location of these was emphasized, along with their occurrence in long trains (occipital paroxysms) and abolition by central fixation (fixation-off sensitivity). It now appears that these features were overemphasized, and in Panayiotopoulos syndrome the characteristic functional spikes can occur in multiple locations, albeit with a posterior predominance. Multifocal spike foci are now considered a characteristic finding in Panayiotopoulos syndrome. These sometimes take the form of cloned-like, repetitive, multifocal spike wave complexes in which repetitive spike or sharp and slow wave complexes appear concurrently in different brain locations of one or both hemispheres. The EEG abnormalities in Panayiotopoulos syndrome are accentuated in sleep. Figure 23-4 illustrates the variability of the interictal EEG in Panayiotopoulos syndrome.

Rarer EEG findings in Panayiotopoulos syndrome include small, sometimes inconspicuous, spikes, slow waves intermixed with small spikes and brief generalized discharges. Focal or diffuse slowing may be seen post-ictally. Occasionally, repeated EEGs can all be normal. Although fixation-off sensitivity is common, photosensitivity is exceptional.

The frequency, location, and persistence of spikes do not determine the clinical manifestations, severity, and frequency of seizures or the prognosis of Panayiotopoulos syndrome (53, 54).

A number of ictal EEGs in Panayiotopoulos syndrome have been reported showing focal discharges of rhythmic theta or delta, often with spikes. Onset is usually posterior (61, 66, 68–70), but may be anterior as shown in Figure 23-2 (61, 71).

In MEG combined with MRI, equivalent current dipoles cluster preferentially in cortical locations along the parietal-occipital, the calcarine, or the central fissure. The equivalent current dipole clustering may be unilateral or bilateral, monofocal or multifocal (33, 72, 73). These findings are in keeping with

## EEG variability in 11 children with Panayiotopoulos syndrome

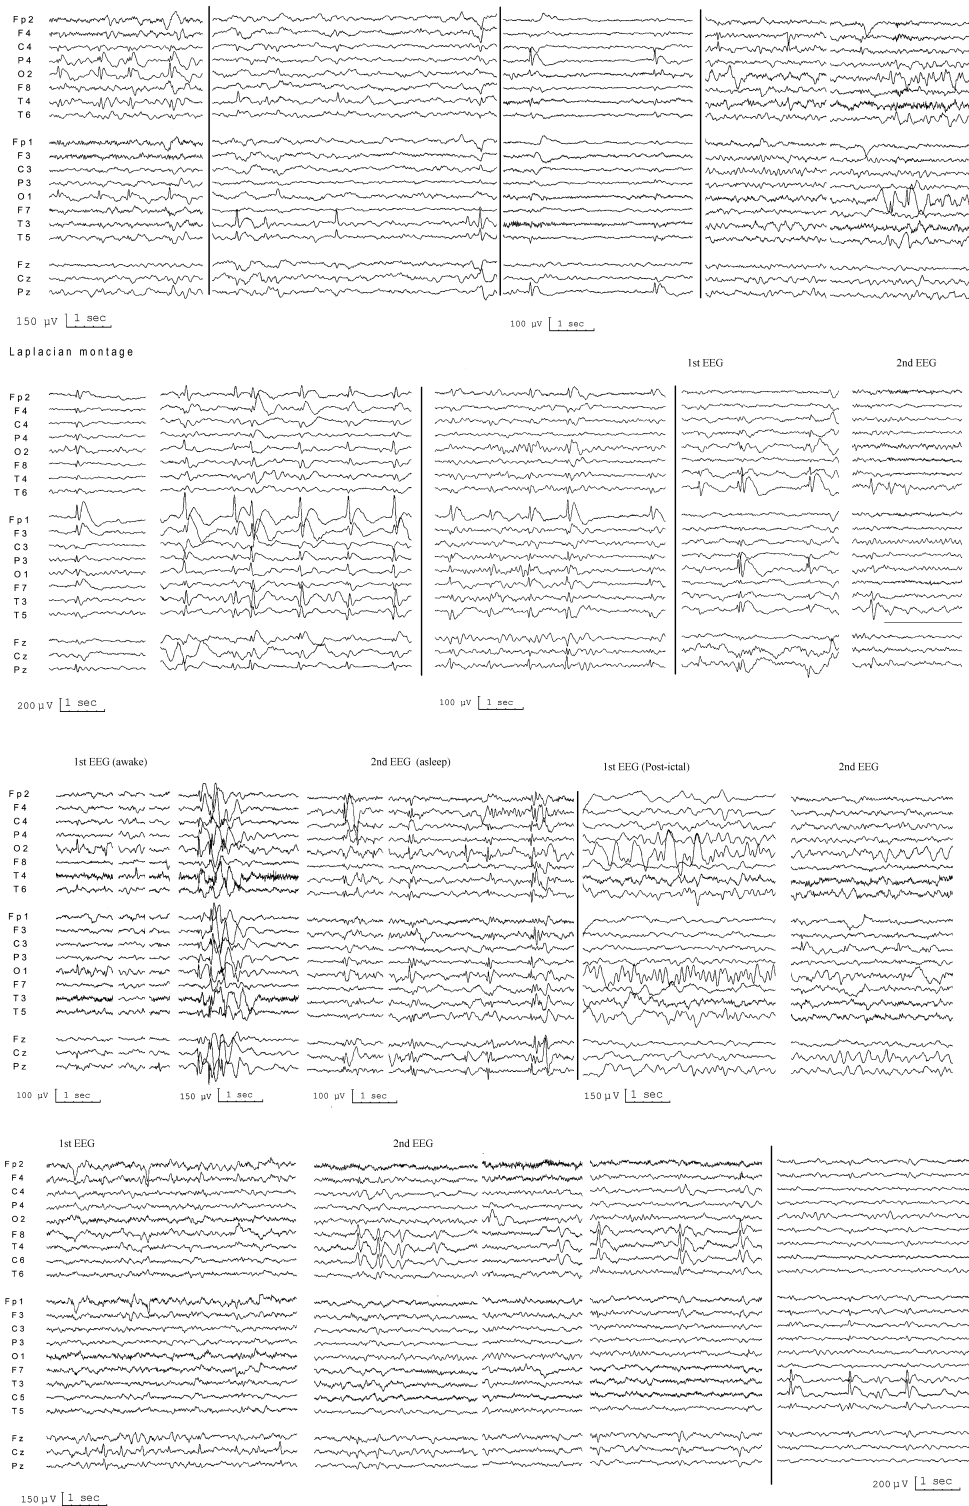

FIGURE 23-4

Interictal EEG variability in 11 children with Panayiotopoulos syndrome. Despite similar clinical features, EEG spikes are often located in different, often shifting, brain locations. EEG may show a single focus, but multifocal locations are more usual. Some interictal EEGs are similar to those seen in rolandic or idiopathic childhood occipital epilepsy. Brief generalized discharges may occur. Of particular interest are the clonedlike, repetitive, multifocal spike wave complexes; these are as common in children with single seizures as in those with multiple seizures. Vertical bars separate the EEGs of an individual patient.

the condition being a multifocal rather than a purely occipital epilepsy.

*Diagnostic Evaluation and Differential Diagnosis.* Panayiotopoulos syndrome is frequently mistaken for nonepileptic disorders and occasionally for other types of epilepsy. This reflects its unusual ictal clinical features and, for a benign epilepsy, its somewhat unusual interictal EEG features.

Because of the prolonged nature of seizures in Panayiotopoulos syndrome, many children present with it to emergency departments while they are still in an ictal state. However, if the main features of this are impaired consciousness and vomiting, an epileptic state may not even come into the differential diagnosis. Conditions such as encephalitis and meningitis are often considered. If the ictus terminates in a hemi- or generalized convulsion, this may merely strengthen the presumptive (but erroneous) diagnosis. Many such children end up intubated and treated in pediatric intensive care units with antibiotics and antiviral agents. The prolonged seizures of Panayiotopoulos syndrome may also be confused with acute confusional migraine and, if vomiting is particularly prominent, with cyclical vomiting syndrome or gastroenteritis. Some seizures may simply be dismissed as travel sickness.

The EEG of Panayiotopoulos syndrome may be similar or identical to that of idiopathic childhood occipital epilepsy or rolandic epilepsy, and these conditions may be mistakenly diagnosed if the clinical history is ignored (74). More importantly, multifocal spike discharges and cloned-like repetitive multifocal spike wave complexes may suggest more malignant epilepsies such as the Lennox-Gastaut syndrome, although clinically these conditions are completely different.

Unlike the other conditions described in this chapter, children with Panayiotopoulos syndrome commonly present to emergency departments while still seizing or in the immediate postictal period. Panayiotopoulos syndrome should be considered in the differential diagnosis of all previously well young children, especially those between the ages of 3 and 6 years, who have rapid onset of emetic symptoms followed by impaired (often fluctuating) consciousness. Eye or head deviation may be a useful finding. However, it may still be appropriate to manage the child for a suspected encephalopathy.

In the office setting, if Panayiotopoulos syndrome is suspected from the history, the most useful investigation is likely to be the EEG (including sleep if necessary). Symptomatic epilepsies may mimic Panayiotopoulos syndrome, so even if the history is typical, most authorities recommend neuroimaging. However, if MRI will require sedation or general anesthetic, CT may be appropriate. No other investigations are required.

*Treatment.* A recent consensus statement concluded that regular prophylactic AED medication was probably best

reserved for children whose seizures were unusually frequent, distressing, or otherwise significantly interfering with the child's life (54). There are no high quality studies of what treatment is most appropriate. Carbamazepine and sodium valproate appear equally efficacious. Given the benign nature of the condition, it is particularly important to avoid adverse effects. Withdrawal of treatment after 1 or 2 seizure-free years is appropriate. The EEG is not helpful in deciding when to withdraw medication. Whether these recommendations will stand if it is confirmed that seizures in Panayiotopoulos syndrome can be associated with cardiorespiratory arrest remains to be seen.

*Course and Prognosis.* Total seizure count in Panayiotopoulos syndrome is usually low. Around one-third of patients have a single seizure and only 5% to 10% will have more than 10; sometimes seizures are very frequent. The duration of active seizures is short; remission usually occurring within 1 to 2 years from onset. About one-fifth of subjects with Panayiotopoulos syndrome will have one or more seizures typical of one of the other benign focal epilepsies of childhood, especially rolandic epilepsy (50, 53). However, the likelihood of seizures in adult life is probably no greater than in the general population.

### **Idiopathic Childhood Occipital Epilepsy (Late-Onset Childhood Occipital Epilepsy— Gastaut Type and Idiopathic Photosensitive Occipital Lobe Epilepsy)**

*Introduction and Definition.* Idiopathic childhood occipital epilepsy (5, 52, 75–80) with and without photosensitivity was first established as an epileptic syndrome by Gastaut (75, 76). Recently, such subjects have generally been classified separately by the ILAE Task Force as late-onset childhood occipital epilepsy—Gastaut type and idiopathic photosensitive occipital lobe epilepsy (3). The likelihood of remission in these syndromes is considerably less than it is for rolandic epilepsy and Panayiotopoulos syndrome. Their inclusion in this chapter could reasonably be questioned. However, it is convenient to consider them here because undoubtedly some children with these conditions remit completely.

Idiopathic childhood occipital epilepsy can be defined as an idiopathic focal seizure disorder of childhood manifested mainly by elementary visual seizures and ictal blindness, which are often frequent and usually occur without impairment of consciousness. EEG shows occipital epileptiform abnormalities, particularly so-called occipital paroxysms. Idiopathic photosensitive occipital epilepsy is an idiopathic focal seizure disorder mainly of childhood manifested mainly by elementary visual seizures provoked by various forms of environmental light stimulation. EEG shows occipital or generalized

photoparoxysmal responses to intermittent photic stimulation and often spontaneous, mainly occipital, epileptiform abnormalities.

*Epidemiology.* Idiopathic childhood occipital epilepsy is reported as starting in children as young as 3 years of age and as old as 15 years of age. Peak age of onset is around 8 years. Boys and girls are equally affected. Idiopathic photosensitive occipital epilepsy may start as early as the second year of life or as late as young adult life. However, it peaks at around 12 years of age. There is probably a slight female preponderance, but nowhere near as great as for photosensitivity per se. Both these epilepsies are rare. Panayiotopoulos estimated that idiopathic childhood occipital epilepsy accounted for about 2–7% of all benign focal epilepsies of childhood (78).

*Clinical Manifestations.* In both these syndromes the seizures are most characteristically manifested with elementary visual hallucinations. These usually consist of small multicolored circular patterns (79). Often they are reported as arising unilaterally in the periphery of a visual field, becoming larger and multiplying as the seizure progresses. They may move horizontally across the visual field, and other more complex movements are described. In some subjects normal vision is obscured by the hallucinations; in others it is retained. More complex visual hallucinations, such as of formed shapes and faces, and visual illusions may also occur but are much less common. Visual illusions include distortions of shape and distance.

After elementary visual hallucinations, ictal blindness is the second most common visual manifestation of seizures in these syndromes. It usually involves both visual fields but may be unilateral or involve only part of a hemifield. The subject usually reports everything as black, but occasionally everything goes white. Ictal blindness is usually an initial manifestation of the seizure but may follow visual hallucinations.

Other ictal ocular symptoms are relatively common. Some subjects report sensations of their eyes being tugged or of ocular pain. Eye deviation, often with simultaneous head deviation, is also common, possibly occurring in about 70% of cases. It usually follows after the hallucinations begin, although the latter may persist. Forced eye closure and eyelid blinking are other reported phenomena.

Most seizures are short lived, many lasting only a few seconds. However, some last a matter of minutes. Seizures with ictal blindness often last longer. Occasionally, seizures (including those with blindness) can last for hours (status amauroticus).

There is a particularly strong association between seizures in these epilepsies and headache. This can be an ictal or postictal phenomenon, although the latter is more common. It often has a migrainous character. Indeed, it is likely that in many cases the seizure provokes

a true migraine. In idiopathic photosensitive occipital lobe epilepsy, seizure symptomatology may also include autonomic features, including emesis, which characterizes Panayiotopoulos syndrome (77, 81).

Consciousness is preserved during most seizures but occasionally may become impaired. This often precedes secondary generalization with GTCS. In exceptional cases spread to cause temporal lobe type symptoms is reported.

In idiopathic childhood occipital lobe epilepsy seizures are mainly diurnal and are usually quite frequent (often several each day or week). Occasional nocturnal seizures, often with hemiconvulsions or GTCS, are not infrequent.

In idiopathic photosensitive occipital lobe epilepsy, seizures are provoked by light factors. Video-game playing appears to be the most provocative, followed by watching TV. Some subjects are very photosensitive, and this is likely to be reflected in a high seizure frequency. Other subjects are less photosensitive and may have very few seizures. However, spontaneous seizures may also occur. It is also reported that some subjects with this epilepsy have other seizure types such as absences and myoclonic jerks provoked by photic factors.

*EEG Features (5, 52, 75–82).* The interictal EEG in both idiopathic childhood occipital epilepsy and idiopathic photosensitive occipital epilepsy is expected to have a normal background. In the former, occipital paroxysms are characteristic. However, in some subjects only isolated occipital spikes may be seen. Extraoccipital paroxysmal abnormalities may occur, but are much less common than in Panayiotopoulos syndrome. In some subjects EEG abnormalities may only be seen in sleep; occasionally both awake and sleep EEGs may be consistently normal. Figure 23-5 illustrates occipital paroxysms and fixation-off sensitivity.

The ictal EEG is expected to show attenuation of occipital paroxysms followed by appearance of an occipital discharge of fast rhythms, fast spikes, or both.

In idiopathic occipital lobe epilepsy there may be no spontaneous epileptiform abnormalities or else there may be occipital spikes or paroxysms. Extraoccipital epileptiform abnormalities may also be seen. Intermittent photic stimulation will, in all subjects, show occipital or generalized photoparoxysmal responses.

*Diagnostic Evaluation and Differential Diagnosis.* These syndromes, like all occipital epilepsies, are very prone to misdiagnosis as migraine. In part, this is understandable, because headache, often migrainous, as previously described, is common both ictally and postictally. However, the elementary visual hallucinations are unlike those of migraine. In the latter they tend to be black and white, rather than colored, and have jagged or sharp contours rather than being predominantly rounded.

Boy aged 10 years with idiopathic childhood occipital epilepsy

FIGURE 23-5

Occipital paroxysms with fixation off sensitivity of an 11-year-old boy with idiopathic childhood occipital epilepsy. Occipital paroxysms occur immediately after and as long as fixation and central vision are eliminated by any means (eyes closed, darkness, plus 10 spherical lenses, Ganzfeld stimulation). Under these conditions, even in the presence of light, eye opening does not inhibit the occipital paroxysms. Conversely, occipital paroxysms are totally inhibited by fixation and central vision. Symbols of eyes open without glasses indicate conditions in which fixation is possible. Symbols of eyes with glasses indicate conditions in which central vision and fixation are eliminated. At age 18 years, he is entirely normal and is not receiving medication.

These syndromes may mimic symptomatic occipital lobe epilepsies, and neuroimaging, preferably MRI, is indicated. No other investigations, except EEG, are routinely required.

**Treatment.** Given the frequency of seizures in idiopathic childhood occipital epilepsy, including the likelihood of occasional GTCS, regular AED treatment is considered necessary in most if not all subjects. There are no controlled studies comparing alternatives, although carbamazepine appears to be most often used in subjects who are not photosensitive. It is appropriate to attempt withdrawal after two seizure-free years, although there is a significant risk of relapse.

Some subjects with idiopathic photosensitive occipital lobe epilepsy who are only mildly photosensitive and who do not have spontaneous seizures can remain seizure free by avoiding precipitants. Others will require AED treatment. Broad spectrum agents,

such as sodium valproate and levetiracetam, active against focal and generalized seizures and photosensitivity, would appear to be reasonable choices. However, it appears that carbamazepine, not usually considered a useful drug for photosensitivity, may sometimes be effective.

**Course and Prognosis.** The prognosis for both idiopathic childhood occipital epilepsy and idiopathic photosensitive occipital lobe epilepsy is variable. A majority of the former, perhaps 50% to 60%, have remission of seizures within 2–4 years of them starting. However, in a significant minority seizures will continue into adulthood. In those with idiopathic photosensitive occipital lobe epilepsy who are only mildly photosensitive and can control their exposure to relevant provoking factors, freedom from seizures may be easy. For others, particularly those who are highly photosensitive, the likelihood of seizures continuing into adult life is high.

### Atypical Evolutions of the Benign Focal Epilepsies of Childhood

Less than 1% of children with rolandic epilepsy have so-called atypical evolutions (24, 32, 83). These include the development of severe linguistic, cognitive, or behavioral problems. If such problems develop in a child with rolandic epilepsy, a sleep EEG should be obtained, because continuous spike-and-wave during slow-wave sleep (CSWS) may be present. The Landau-Kleffner syndrome is sometimes said to develop from rolandic epilepsy. CSWS may also be seen in children with opercular status characterized by continuous positive or negative myoclonias around the mouth or elsewhere in the face and pseudobulbar problems. Atypical focal epilepsy of childhood in which other seizure types, including tonic and atypical absence seizures, occur may also develop in children with otherwise typical rolandic epilepsy.

There are also case reports of atypical evolutions in Panayiotopoulos syndrome, including the development of absences and drop attacks (32, 84, 85) and in idiopathic childhood occipital epilepsy with cognitive deterioration and CSWS (86).

Carbamazepine is sometimes implicated in precipitating such atypical evolutions (87, 88).

### Other Described Benign Focal Epilepsies of Childhood

The syndromes discussed previously are the only benign focal epilepsies of childhood currently recognized by the ILAE. However, others have been proposed and are more or less well characterized. They include the following.

*Benign Childhood Seizures with Affective Symptoms* (89). This is reported to have its onset between 2 and 9 years of age and is characterized by multiple, usually short, daytime and nighttime seizures in which the predominant symptom appears to be fear or terror, accompanied by autonomic disturbances (pallor, sweating, abdominal pain, and salivation), arrest of speech, and mild impairment of consciousness with automatisms. Interictal EEG shows sharp and slow wave complexes similar to those in rolandic epilepsy but located in the frontotemporal and parietotemporal electrodes. Remission in 1 to 2 years from onset is expected. This is likely to be an intermediate phenotype between Panayiotopoulos syndrome and rolandic epilepsy.

*Benign Childhood Epilepsy with Parietal Spikes and Frequent Giant Somatosensory Evoked Potentials* (28, 90). This putative disorder is mainly defined by its interictal EEG features reflected in its name. These features are, however, said to often be associated with a phenotype characterized by mainly daytime versive seizures, which are infrequent and have an excellent prognosis.

*Benign Childhood Focal Seizures Associated with Frontal or Midline Spikes* (5). Again this putative disorder is mainly defined by its interictal EEG features. These EEG features can be seen in children with febrile seizures, rolandic epilepsy, Panayiotopoulos syndrome, and idiopathic childhood occipital epilepsy.

*Benign Focal Epilepsy in Infants with Central and Vertex Spikes and Waves During Sleep* (91, 92). Benign focal epilepsy in infants with central and vertex spikes and waves during sleep has been recently described as a new benign syndrome. In terms of age of onset, it is on the borderline between benign infantile seizures and Panayiotopoulos syndrome. Age at onset is in the first 2 years of life with both sexes equally affected. Infants are normal and all tests other than EEG are normal. Seizures consist mainly of staring, motor arrest, facial cyanosis, loss of consciousness, and stiffening of the arms. Clonic convulsions and automatisms are rare. Duration is from 1 to 5 minutes. Seizures are mainly diurnal (but may also occur during sleep) and may occur in clusters, but are generally infrequent (1–3 per year). Interictal EEG abnormalities are seen only in non-REM sleep and consist of small, mostly singular, spikes and waves localized at the vertex and central electrodes.

There is a strong family history of epilepsy with benign epilepsies prevailing. The prognosis is excellent with remission of seizures, normal development, and normalization of the EEG before the age of 4 years.

*Benign Focal Seizures of Adolescence* (5, 93). This syndrome of the second decade, and predominantly occurring in males, features a single seizure or a single cluster of seizures over a period of up to 36 hours. The seizures are mainly diurnal, with consciousness initially preserved. The main manifestations are focal clonic jerking, usually without a Jacksonian march, and somatosensory symptoms. Secondary GTCS occur in about 50% of cases. EEG and brain neuroimaging are normal. The prognosis is excellent and treatment is not required.

## The Landau-Kleffner Syndrome and Epilepsy with Continuous Spike-Waves during Sleep

*James J. Riviello, Jr.  
Stavros Hadjiloizou*

**T**he Landau-Kleffner syndrome (LKS) and epilepsy with continuous spikewaves during slow-wave sleep (CSWS) are recognized as specific epilepsy syndromes by the International League Against Epilepsy (ILAE) (1–3). They were first classified as epilepsies and syndromes undetermined as to whether they are focal or generalized (2). They are now classified as an epileptic encephalopathy, defined as disorders in which the epileptiform abnormalities may contribute to progressive dysfunction (3). Other epileptic encephalopathies are early myoclonic encephalopathy, Ohtahara syndrome, West syndrome, Dravet syndrome, myoclonic status in nonprogressive encephalopathies, and the Lennox-Gastaut syndrome (3). LKS and CSWS are also considered special syndromes of status epilepticus (4).

Overt clinical seizures are not present in all children with LKS or CSWS. Both syndromes typically present with regression in cognitive abilities, either a language regression, predominantly in LKS (1, 5), or a more global neuropsychiatric regression in CSWS (5–7), with each demonstrating marked sleep-activated epileptiform activity on electroencephalogram (EEG). Patry et al defined the term “electrical status epilepticus of sleep” (ESES) (6) before the identification of CSWS by the ILAE. However, ESES and CSWS are synonymous terms, and “status epilepticus during sleep” (SES) is also used (8). The strict definition of

ESES requires the presence of sleep-activated epileptiform activity in greater than 85% of slow-wave sleep (6, 7). Veggiotti and colleagues emphasized the difference between the EEG pattern of CSWS and the epileptic syndrome of CSWS (9). Not all patients with a sleep-activated pattern consistent with ESES have the age-related epileptic syndrome of CSWS. We prefer using the term ESES to describe the EEG, and CSWS to describe the epileptic syndrome.

Regression in intellectual or cognitive abilities, associated with behavioral problems, is the hallmark of these syndromes, and regression may even be the presenting manifestation. In general, cognitive regression should always raise the suspicion of a sleep-activated epileptic encephalopathy, especially in those with underlying developmental or neurological disorders. LKS and CSWS may respond to treatment with the standard antiepileptic drugs (AEDs) but often require other therapies, such as corticosteroids (10–15), high dose benzodiazepine (16, 17), and other immune-modulating therapies such as intravenous immunoglobulin (IVIG) (18–21), or the ketogenic diet (22, 23).

### EPIDEMIOLOGY

LKS and CSWS are rare syndromes among the pediatric epilepsy syndromes. In a recent 20-year epidemiologic study of childhood epilepsy, Kramer and colleagues reported LKS

and CSWS in 0.2% each, compared with West syndrome in 9%, myoclonic seizures in 2.2%, and Lennox-Gastaut syndrome in 1.5% (24). Ohtahara syndrome and myoclonic astatic epilepsy also occurred in 0.2% each.

In a review of LKS, Smith and Hoepfner (25) noted that only 81 cases had been reported between 1956 and 1980, whereas 117 cases were reported between 1980 and 1990. For ESES, 19 cases had been reported between 1971 and 1984 by Tassinari et al and another 25 were reported in the medical literature (7).

### CLINICAL MANIFESTATIONS

The onset of LKS usually occurs in children older than 4 years (26), with a range of 3 to 10 years (27). LKS may first manifest as an apparent word deafness or a verbal auditory agnosia. Seizures and behavior disturbances, particularly attention deficits and hyperactivity, each occur in approximately two-thirds of children with LKS (5). The majority of cases are classified as idiopathic, although any pathologic process affecting the auditory cortex may cause LKS. Symptomatic cases have been described (see the section on differential diagnosis), and we have seen symptomatic LKS caused by a left temporal oligodendroglioma, with clinical improvement noted after resection.

The classical features of LKS are a verbal auditory agnosia (word deafness) followed by language regression, seizures, or both in a previously normal child who has an epileptiform EEG. An important corollary is normal hearing, because a central disorder cannot be diagnosed in the presence of peripheral dysfunction. Children with sleep-activated epileptiform activity without the classic features of LKS have been referred to as children with LKS variant (28). These variants include children with involvement of more anterior language areas with dysfunction characterized by oral-motor apraxia, sialorhea, seizures, and an abnormal EEG (29), referred to as anterior LKS; children with pervasive developmental disorder (PDD, autism) with language regression and abnormal EEGs (30–32); and children with congenital aphasias (33), also called developmental language disorders, with or without clinical regression but with epileptiform EEGs, also referred to as developmental LKS.

The evaluation of LKS should include a baseline history, physical examination, sleep-deprived EEG, a formal neuropsychological evaluation, neuroimaging, with magnetic resonance imaging (MRI) preferred, long-term video-EEG monitoring (LTM), and if needed, dipole analysis, functional neuroimaging with single-photon emission computed tomography (SPECT), positron emission tomography (PET), or magnetoencephalography (MEG), and the frequency-modulated auditory evoked response (FM-AER). The FM-AER is an evoked response that tests receptive language function and is usually absent with a verbal auditory agnosia (34).

The hallmark of CSWS is regression in cognitive functioning and behavior, but not primarily language, as occurs in LKS. Although children with CSWS commonly have seizures, these may not be frequent. Tassinari et al reported 29 children with CSWS (7); all except 1 child had seizures, 1 had a single seizure, and 1 had only three seizures. Eighteen of these children had normal, and 11 had abnormal, psychomotor development before onset. In the 18 with normal development, all had severe loss of IQ and behavioral disturbances, including decreased attention span, hyperactivity; aggression, difficulties with interaction and inhibition, and two children developed a psychotic state. In the 11 with abnormal psychomotor development, mental deterioration occurred in all, 3 developed a marked hyperactivity, and 1 showed “massive regression” including language and a loss of interest in all activities. Intellectual regression occurs in virtually all children, although we have seen several in which no regression has been seen. Attention deficits and hyperactivity occur in the majority, and language disturbances, aggression, disinhibition, emotional lability, anxiety, and psychotic behavior may also occur. An expressive aphasia occurs, in contrast to LKS, which is characterized by verbal auditory agnosia (35).

The presence of ESES alone does not diagnose these specific epileptic syndromes. These are identified by the combination of the clinical manifestations and EEG findings. Both LKS and CSWS may have the EEG pattern of ESES; LKS clinically consists predominantly of a language regression, with a more focal ESES pattern, whereas CSWS is characterized clinically by a more global neurobehavioral disorder with a more generalized EEG pattern (36, 37). LKS and ESES have been classified as benign epileptic syndromes; that term refers only to the evolution of the actual seizures and EEG patterns over time. Given the devastating neuropsychological deficits that occur, we prefer to consider these malignant epileptic syndromes.

### EEG FEATURES (INTERICTAL, ICTAL)

The EEG pattern of ESES may be seen with both syndromes, but not all children with the ESES pattern may have these specific syndromes. Veggiotti et al emphasized the difference between the EEG pattern of CSWS and the epileptic syndrome of CSWS (9). In their series of 32 patients with CSWS, only 10 (34%) had features of the CSWS syndrome, whereas in the remainder, 4 had LKS, 3 had the acquired opercular syndrome, and 15 had symptomatic epilepsy. Van Hirtum-Das and colleagues identified 102 children with ESES, using a spike-wave index greater than 25% (38). In this group, only 18% had LKS. Although CSWS was named for sleep activation during slow-wave sleep, this term is misleading because EEG activation occurs in non-rapid-eye movement (NREM) sleep, typically starting in drowsiness (8). This is our experience

as well. The spike-waves become fragmented during REM sleep, when focality may be seen, and the spike-wave index usually decreases below 25% (8). Upon awakening, the spike-wave frequency dramatically decreases again.

The EEG in LKS shows bilateral, multifocal spikes and spike-and-wave discharges, occurring usually in the posterior regions, especially the more posterior regions, with a marked activation during NREM sleep (Figure 24-1). However, discharges occur in many locations and may even be generalized. The strict definition of ESES (spike-wave index greater than 85%) is not absolutely necessary to diagnose LKS, because the spike-wave index may reach only 50% (25). The EEG may improve over time, either spontaneously or with treatment (39, 40).

There is speculation that EEG abnormalities are more likely present during the actual period of language regression, with subsequent EEG improvement. This may have been more likely in the past, before the recognition of LKS and CSWS. In the first 20 patients diagnosed with LKS or LKS variant at Children's Hospital, Boston,

reviewed by Bolanos et al, the EEG became normal in 4 patients within a year (39).

Guilhoto and Morrell reported that when the ESES pattern was more focal, the LKS with language regression was the most prominent symptom, whereas when the ESES pattern was more generalized, the CSWS syndrome with generalized neurobehavioral dysfunction was the predominant symptoms (36). Guilhoto and colleagues subsequently reported 17 children with ESES. Five had LKS and the EEG showed diffuse activity with accentuation in the centroparietal region, whereas the others had widespread discharges (37). Therefore, LKS and CSWS may have similar clinical and electrographic features. The EEG abnormalities in LKS may be an epiphenomenon (41).

### PATHOPHYSIOLOGY

The underlying mechanisms of LKS and CSWS are complex and not yet specifically identified. However, it is

FIGURE 24-1

Electrical status epilepticus of sleep (ESES) electroencephalogram in a child with Landau-Kleffner syndrome.

presumed that the neuropsychological deficits are, at least partially, the result of the epileptiform activity. Landau and Kleffner (1) suggested that “persistent convulsive discharges in brain tissue largely concerned with language communication result in the functional ablation of these areas.” Hirsch and colleagues agree with the hypothesis of a functional ablation (27). Poor daytime alertness due to sleep fragmentation may contribute to the neuropsychological deficits (42). Alternatively, the previous potential interrelations are a hypothesis, and a causal relation between abnormal interictal discharges and neuropsychological deficits is still controversial (43). A valid argument is that the dysfunction may represent different manifestations of the same unknown, possibly genetically determined, underlying pathogenic mechanism. An argument against this hypothesis is that the suppression of discharges with medical or surgical therapy may, at least partly, reverse these cognitive deficits (44, 45).

Despite the controversy regarding the underlying pathophysiology of epileptic encephalopathies, the following three crucial questions await answers: (1) what are the mechanisms involved in the generation of such a significant, interictal, sleep activation; (2) what are the mechanisms involved in the cognitive or developmental regression that accompanies these conditions; and (3) what is the interrelation between the two, if any?

Although a genetic predisposition was questioned, there is no strong evidence to support such predilection (46). The response of the epileptiform discharges to corticosteroids raised the question of an autoimmune pathogenesis at least in a subset of patients including central nervous system (CNS) vasculitis or demyelination. IgG and IgM antibodies to brain endothelial cells have been identified in these disorders (28, 47), with higher levels in the patients than in controls. Brain-derived neurotrophic factor (BDNF), BDNF autoantibodies, and IgM and IgG antibodies were elevated in some children with autism and childhood disintegrative disorder (CDD). The authors concluded that these findings suggest a previously unrecognized interaction between the immune system and BDNF (47). Autoantibodies to rat brain auditory cortex, brainstem, and cerebellum have been identified in children with LKS (48).

There is increasing evidence that interictal EEG abnormalities can produce transient cognitive impairment (49–55). Furthermore, benign rolandic epilepsy may be not so benign, because the interictal discharges may have a substantial effect on cognitive function (56, 57), at least for a subset of patients. Additionally, the presence of continuously abnormal discharges during sleep may cause disruption of hippocampal function and interfere with the consolidation of memory (58–60). Hence, the potential impact of the persistent interictal discharges on brain plasticity is proposed as a mechanism for the resulting neuropsychological impairment in these children. More specifically, the occurrence of epileptiform discharges

during a critical time of brain development may result in defective synaptogenesis and thalamocortical circuit formation. Secondary bilateral synchrony, facilitated by the corpus callosum with involvement of thalamocortical connections, was hypothesized as a possible mechanism for the generation of the epileptiform discharges (61–64).

## DIAGNOSTIC EVALUATION AND DIFFERENTIAL DIAGNOSIS

The diagnosis starts by establishing an epileptic disturbance in the child with regression, usually first with a routine EEG. All pediatric epilepsy syndromes are classified as symptomatic, cryptogenic, or idiopathic. Symptomatic cases exist for both LKS and CSWS, although symptomatic cases are more frequent with CSWS. We have seen only one case of a symptomatic LKS, in a child with a left temporal oligodendroglioma. However, other categories reported include infectious disorders, such as cysticercosis and toxoplasmosis; inflammatory disorders, such as CNS vasculitis; demyelinating disease and acute disseminated encephalomyelitis (ADEM); congenital brain malformations, such as polymicrogyria; and tumors, including temporal lobe astrocytomas and dysembryoplastic neuroepithelial tumors (DNET) (4, 5). Therefore, neuroimaging is warranted.

Typically in the idiopathic cases, no structural abnormalities are seen with routine neuroimaging, although bilateral volume reduction using an MRI cortical parcellation technique has been reported in the superior temporal gyrus (65) and perisylvian polymicrogyria has been reported in a single case (66). Functional neuroimaging has demonstrated temporal dysfunction with SPECT (67, 68), PET (69, 70), or MEG scans (71). These studies are usually done when a patient has failed treatment and epilepsy surgery is considered.

The differential diagnosis of a sleep-activated EEG includes (3): LKS, CSWS, and PDD with regression, congenital aphasia or developmental language disorders, or the epilepsy syndromes benign focal epilepsy with centrotemporal discharges, benign focal epilepsy with occipital discharges, atypical benign partial epilepsy of childhood, the Lennox-Gastaut syndrome, and myoclonic-astatic epilepsy (Doose syndrome). Language or intellectual regression associated with behavioral problems in any of these syndromes may make the differential diagnosis difficult and not all pediatric epilepsy syndromes are readily classified. In our experience, children with PDD with regression and an epileptiform EEG are the largest numbers of children referred for evaluation.

Clinical symptoms other than language regression have been reported with ESES. Hirsch and colleagues suggested that the definition of LKS should be expanded to include the acquired deterioration of any higher cortical function in association with sleep-activated paroxysmal

features (72) and not limited just to language regression. Clinical manifestations include epileptic dysgraphia (73), visual agnosia (74), and an acquired frontal syndrome (75). We have seen one child with blindness (Figure 24-2) and another child with a prosopagnosia, with both demonstrating a more posterior ESES on EEG.

## TREATMENT

All children with LKS and CSWS should have a formal neuropsychological evaluation to guide their educational program and track developmental changes. Children with LKS will, especially, require intensive speech and language therapy. These two syndromes are associated with significant neuropsychiatric comorbidities, and treatment for hyperactivity, attention deficit disorder, mood instability, behavior problems, and even an autistic picture may require referral to a psychopharmacologist and psychologist. Despite control of seizures and EEG abnormalities, these children may have significant residual neurologic, psychological, and psychiatric dysfunction.

LKS and ESES have similar treatment but the specifics are debated. Smith and Hoepfner recommend that the treatment goal is the complete elimination of epileptiform activity within 2 years (25). Treatment options include standard AEDs, corticosteroids (adrenocorticotropic hormone [ACTH] or prednisone), high-dose benzodiazepines, intravenous immunoglobulins, or multiple subpial transections (MST). Although AEDs may control seizures, the language dysfunction may not improve, whereas corticosteroid treatment may control seizures and decrease the epileptiform activity and improve language (10–12). Early corticosteroid treatment has been considered the treatment of choice for LKS (12). Because relapse may occur, LKS often requires long-term corticosteroid treatment, which increases the risk of side effects (15). Despite either AED or corticosteroid treatment, many children continue with language dysfunction. Regardless of treatment, 50% to 80% of children have long-term language or neurobehavioral abnormalities (76–78).

Landau and Kleffner reported a positive relationship between AED treatment and aphasia improvement (1). In 1967, Deuel and Lenn reported a case with a clear relationship between AED treatment and language improvement (79), and there have been subsequent reports of improvement with various AEDs. However, the conventional wisdom is that the AEDs control the actual clinical seizures but not the aphasia (11, 12). McKinney and McGreal reported a better response with steroids (10). Some children who had not responded to AEDs improved after steroid therapy (11, 12). They also thought that the rapidity of the response and the sequelae depend on the duration and severity of symptoms before treatment, that initial high doses are more effective, and that brief

treatment is ineffective or leads to a high relapse rate. Both ACTH and prednisone have been used.

Both carbamazepine and valproate have been widely used, but there are no data suggesting that any one AED is better than others. We have seen several cases of children treated with carbamazepine for seizures with focal epileptiform abnormalities on EEG who subsequently developed language regression with ESES. We prefer using AEDs with antiepileptogenic properties as first-line AEDs. The term *anticonvulsant* refers to suppression of seizures, whereas *antiepileptogenic* refers to suppression of the development of epilepsy or the underlying process that leads to epilepsy (80). We have historically preferred valproic acid (VPA) because it has both anticonvulsant and antiepileptogenic properties, and it may normalize EEGs. It is well known that carbamazepine may worsen the generalized epilepsies and may even worsen focal spike-and-wave discharges and activate the EEG (81–83). For ESES, VPA, benzodiazepines, and ethosuximide have been the most successful AEDs (7), and lamotrigine and levetiracetam have also been used. However, we have seen seizures worsen with every AED used. In general, for either LKS or ESES, if AEDs do not work, then high-dose corticosteroids are used. These may work through GABAergic effects rather than immune mediation (84).

De Negri and colleagues introduced a high-dose diazepam protocol for electrical status epilepticus (ESE) (85). They gave a rectal dose of 1 mg/kg with EEG monitoring and continued a dose of 0.5 mg/kg orally for several weeks in those that responded. They found that those on chronic benzodiazepine treatment did not respond as well to this treatment. When a clinical relapse occurred, this dosing schedule was repeated. In the group of De Negri and colleagues with ESE, only 1 child had LKS and 1 had ESES. We modified this high-dose diazepam protocol, using 1 mg/kg either orally or rectally under EEG guidance, but then treated all children with a dose of 0.5 mg/kg, orally for 3 to 4 weeks (17). If EEG showed no improvement, we rapidly tapered the diazepam. If EEG showed an improvement, we tapered then by 2.5 mg/month. In our series, every child who initially responded and then had a rapid diazepam taper had either a clinical or electrographic regression. We now continue a maintenance diazepam dose, usually at a dose of 2.5 to 5 mg, for 2 years. The best responders to high-dose diazepam have been children with idiopathic LKS.

Tassinari et al recommend trials with several different drugs, and they report that a long-lasting effect has been achieved with VPA along with clobazam, lorazepam, and clonazepam (8). Smith and Hoepfner recommend initial treatment with high-dose VPA, with or without a benzodiazepine, and, in the absence of response, then several months of corticosteroid therapy (25). Inutsuka and colleagues (86) reported their treatment results in 15 children, using the following protocol: (1) VPA at

FIGURE 24-2

(A) Electroencephalogram (EEG) in child with blindness and posterior electrical status epilepticus of sleep (ESES). (B) EEG after high dose diazepam treatment; vision has recovered.

levels greater than 100 mg/L, (2) combination of VPA plus ethosuximide, (3) short cycles of high-dose diazepam, (4) or intramuscular ACTH. Treatment with short cycles of ACTH (duration 11 to 43 days) or diazepam (DZP) (duration for 6 to 7 days) did not achieve long-term remission, whereas either high-dose VPA alone ( $n = 7$ ) or in combination with ethosuximide ( $n = 3$ ) achieved remission in 10 children (67%). We retrospectively analyzed our experience with ESES treatment in 12 children (87). Only 1 of 12 responded to initial short-term therapy with VPA. We used prednisone for 6 months in 6 children with the dose schedule outlined in Table 24-1 (88); 5 of 6 had a positive response, but 4 of 5 (80%) relapsed and required another course. Before the elective use of corticosteroids, immunizations should be up to date.

Alternate treatments including immunoglobulins and the ketogenic diet have been tried, with case reports documenting efficacy, but long-term follow-up data are limited (18–22). MST has been performed in selected children who failed medical therapy, and it may provide benefit (62, 89).

## COURSE AND PROGNOSIS

In general, the outcome of epilepsy is favorable in both LKS and CSWS (90), whereas cognitive dysfunction occurs in the majority (25). The prognosis for LKS has varied, depending on the series. Mantovani and Landau conducted a long-term follow-up of the original children reported by Mantovani and Landau (91). In nine patients, with follow-up that varied from 10 to 28 years, four patients had full recovery, one had a mild language disability, and four had moderate disability. Later studies have not reported as positive an outcome. Bishop did a literature review of 45 children with LKS. The age of onset was related to

**TABLE 24-1**  
**Six-Month Dosing Schedule for Oral Prednisone**

2 mg/kg/day for 1 month (maximum dose 60 mg)
1.5 mg/kg/day for 1 month
1 mg/kg/day for 1 month
1 mg/kg every other day for 1 month
0.75 mg/kg every other day for 1 month
0.5 mg/kg/day every other day for 1 month

Note: Immunizations should be up to date before the elective use of corticosteroids.

the outcome, which was less favorable if onset occurred before 4 years of age (26). Shinnar and colleagues reported residual language dysfunction in 88% of children who had language regression, and most had autism or autistic features (76). Deonna et al reported that only one of seven adult patients had normal language, with the six others demonstrating varying degrees of language deficits, some with complete absence of language (75). In a recent article on the neuropsychological follow-up of 12 patients, Soprano et al reported that 9 of 12 had a variable degree of persistent language deficit (78). Only 50% have been able to lead a normal life (62, 69).

The prognosis is poor in CSWS (92). In an adult follow-up study of seven patients, only one had active epilepsy, but only two had been in a normal school setting (93). The two patients with LKS had a normal IQ, but had language deficits, whereas the five patients with ESES had global mental deficiency. Scholtes et al (94) performed a long-term follow-up of 10 children with ESES, with a good recovery in only 1 child and a partial recovery in only 4. There are more residual deficits in CSWS, because this syndrome is more likely to be symptomatic, compared to LKS, which is more likely to be idiopathic.

## Idiopathic Generalized Epilepsy of Adolescence

**Reza Behrouz**  
**Selim R. Benbadis**

**C** Idiopathic generalized epilepsies (IGEs) are a distinct group of epilepsies, clearly defined in the 1989 International Classification of Epileptic Syndromes and Epilepsies. This classification established an important dichotomy between the idiopathic epilepsies on the one hand, and the symptomatic or cryptogenic epilepsies on the other (1). In prior versions of this classification, IGEs were referred to as primary generalized epilepsies, and symptomatic/cryptogenic generalized epilepsies were categorized under secondary generalized epilepsies. This nomenclature was revised because the term “secondary generalized” was confusing when applied to epilepsy, where it meant that the epilepsy was secondary to some other cause, whereas when applied to seizures, it means that the generalization is secondary from an originally focal seizure.

Unfortunately, the term “idiopathic” in the current classification is also confusing in the context of current medical terminology, because in every other area of medicine “idiopathic” means “of an unknown cause.” It is now clearly understood that IGEs are primarily of genetic origin.

IGEs are age-dependent, meaning that a given genotype may express itself differently at different ages. This chapter will focus on the IGE seen in adolescence.

### GENETICS & PATHOPHYSIOLOGY

IGEs represent a group of epilepsies best described as a genetically determined low threshold for generalized seizures, as opposed to symptomatic or cryptogenic generalized epilepsies, where there is an underlying anatomic (pathologic) abnormality. Investigations for microscopic lesions (e.g., microdysgenesis) in IGE, using structural imaging, have yielded inconsistent results (2). Functional imaging, not surprisingly, can show evidence for diffuse dysfunction. Proton magnetic resonance spectroscopy (MRS) has revealed frontal lobe (3) or thalamic (4) abnormalities.

Because they have “overlapping” genetic origins, it is appropriate and practical to view IGEs as a continuum of genetic conditions exhibiting variable phenotypes. Recent advances have identified IGEs linked to defects in genes encoding the subunits for voltage- or ligand-gated ion channels including sodium, potassium, calcium, or chloride channels affecting the gamma-aminobutyric acid (GABA)<sub>A</sub> receptors. Hence, they are categorically referred to as “ion channelopathies” (5). For the classic and well-defined forms of IGE—juvenile myoclonic epilepsy (JME) or childhood absence epilepsy (CAE), a few mutations, including the KCNQ potassium channels and the ClC-2 chloride channel, have been implicated (6).

The pathophysiology (e.g., the concept of channelopathies) and genetics of IGE are gradually being elucidated. Fundamentally, IGEs appear to be “phenotypes of many, often individually rare, gene defects” (7, 8).

The inheritance of IGEs is complex in the sense that it does not follow a well-defined Mendelian pattern. Moreover, phenotypic expression influencing semiology and frequency of a specific genotype may be quite variable from one individual to another. This is likely due to different degrees of alteration of neuronal excitability induced by gene errors. At least for JME, a maternal inheritance has been proposed and confirmed by some (9). Nevertheless, it is reasonable to state that the genetic complexity of IGEs necessitates additional investigation in order to reach a conclusion regarding their precise mechanism of inheritance.

### EPIDEMIOLOGY AND NATURAL HISTORY

IGEs constitute approximately 15–20% of all epilepsies (10). They affect all races equally and may have a slight predilection for women (11). Seizures usually, but not always, have an onset early in life, from childhood to early adulthood. In fact, IGEs are the most frequent group of epilepsies with an adolescent onset (12). IGEs are generally associated with low mortality and favorable response rate to treatment. The morbidity from IGE is primarily a function of how well the condition is treated. As it will be mentioned further in this chapter, the response rate to antiepileptic drugs (AEDs) is good. Additionally, 50% of patients with IGE can outgrow them. A recent intriguing finding is the association between IGE and type 1 diabetes (13).

### CLINICAL FEATURES (OF IGE IN GENERAL)

Overall, there are much more similarities than there are differences among the various types of IGE. These epilepsies manifest themselves by the same three seizure types, have similar electroencephalographic (EEG) findings, are said to “evolve” into one another, and have overlapping genetic origins (family members may express different IGE syndromes). In all, IGEs are best viewed as a spectrum of conditions, and many of them may indeed represent a single entity with slightly different clinical phenotypes (14–19). Thus, there are good reasons to study them as a group. In addition, as will be discussed subsequently, making a diagnosis of IGE as a group (as opposed to localization-related epilepsy or a symptomatic/cryptogenic generalized epilepsy) has critical implications for patient care, whereas differentiating among the specific syndromes is relatively less important. The IGEs are genetically determined and have no structural or anatomic cause, and seizures are the only manifestation

of the condition. Age of onset is very important, since IGE usually (but not always) begin early in life, from childhood to early adulthood. Neurologic examination is normal, intelligence is normal, imaging studies are normal, and EEG is normal other than for the epileptiform abnormalities (i.e., there is no abnormal slow activity or evidence for diffuse encephalopathy).

Seizure types in IGE include a combination of generalized tonic-clonic (GTC), absence, and myoclonic seizures.

- *Absence seizures* are clinically characterized by a brief (5–15 sec) impairment of consciousness, with few or no other symptoms. More specifically, patients with IGE have *typical* absence seizures, characterized by an abrupt onset and termination and the classic monomorphic 3-Hz spike-wave complexes (ictally and interictally) with no other EEG abnormality. By contrast, atypical absence seizures occur in symptomatic generalized epilepsy of the Lennox-Gastaut type and are less discrete in time, longer, and with slower and more polymorphic spike-wave complexes on EEG. Absence seizures are the defining and predominant seizure type in CAE and juvenile absence epilepsy, but they do occur in the other IGEs.
- *Myoclonic seizures* consist of sporadic jerks, usually appendicular and symmetrical, associated electrically with generalized epileptiform discharges, typically polyspikes (Figure 25-1). Patients sometimes report them as an electric shock sensation. Myoclonic seizures are the defining and predominant seizure type in JME, but they do occur in the other IGEs.
- *Generalized tonic-clonic (GTC) seizures* are of course the most common type of seizures. GTC seizures in the IGEs are by definition “primarily generalized” GTC seizures. They are typically characterized by a tonic phase that which is gradually interrupted by quiescence, thus giving rise to the clonic phase, with rhythmic spikes and spike-wave complexes decreasing in frequency. Often, primarily generalized GTC seizures begin with clonic or myoclonic jerks before the tonic phase, thus in reality being clonic-tonic-clonic rather than tonic-clonic.

The *morning predominance* of convulsive seizures is a general feature in IGE that must be specifically asked about during history taking.

### EEG FEATURES (OF IGE IN GENERAL)

The EEG findings of IGEs are characteristic, and consist of generalized epileptiform discharges with normal background activity (i.e., no abnormally slow background and no superimposed slow activity). Epileptiform discharges

FIGURE 25-1

Typical generalized polyspike during drowsiness in a 17-year-old adolescent with typical juvenile myoclonic epilepsy. Note the high amplitude (see scale) and the aftergoing slow wave and suppression. This discharge was asymptomatic.

can take the form of spikes, sharp waves, spike-wave complexes and polyspikes. Spike-wave complexes can be viewed as the EEG correlate of absence seizures, and polyspikes as the EEG correlate of myoclonic seizures. Just as patients with IGE have various combinations of the three seizure types described in the preceding section, they also have various combinations of generalized epileptiform abnormalities. Although epileptiform discharges are typically generalized and symmetric, minor EEG asymmetries may occasionally be present (20–23) and should not lead to a diagnosis of partial seizures (24).

- *Spikes and sharp waves* are of high amplitude, with aftergoing slow waves disrupting the ongoing background. Those seen in IGE are generalized and typically maximal frontally (F3/F4 or Fp1/Fp2).
- *The spike-wave complexes* seen in IGE are very monomorphic and have the classic frequency of 3 Hz, but this may vary between 2.5 and 3.5 Hz and is often faster at the onset of the discharges

(3.5 to 4.5 Hz). The near perfect monomorphism of the spike-wave complexes is as important as the 3-Hz frequency in distinguishing this pattern from the “slow” spike-wave complexes seen in the *symptomatic* generalized epilepsies of the Lennox-Gastaut type. They are generalized and symmetric with a maximum negativity frontally, almost always at F3 and F4. The onset and offset are abrupt. The 3-Hz spike-wave complexes are both an interictal and ictal pattern. The border between the two is imprecise because the clinical impairment may be difficult to detect during short discharges. It is generally stated that a discharge of about 3 seconds or more is associated with detectable impairment of awareness, but this depends of how well short impairments can be detected. The use of a clicker to test responsiveness can be very useful to document very brief impairments in awareness. Clinical seizures and the 3-Hz spike-wave complexes discharges are often precipitated by hyperventilation. The 3-Hz

frequency, and also the striking monomorphism of the spike-wave discharges, distinguish absence epilepsy from other syndromes. Spike-wave complexes can be faster (i.e., 4–6 Hz), especially in patients with IGE of adolescence, as opposed to those with typical CAE.

- *Polyspikes* (Figure 25-1) are also of high amplitude, generalized, bilateral, and grossly symmetric, and followed by significant slowing. Polyspikes are the electrical correlate of myoclonic seizures, and as such they are typically seen in IGE syndromes that include this seizure type, most characteristically JME. Polyspikes can be repetitive and described as polyspike-wave complexes.
- *Photosensitivity* is particularly frequent and, in fact, quite typical of IGE (25). Photosensitivity can be purely an EEG phenomenon, where photic stimulation elicits a photoparoxysmal response (Figure 25-2). It can also be a clinical phenomenon, where photic stimulation triggers a clinical seizure as well (typically motor seizures, i.e., myoclonic and GTC seizures).

Just as convulsive seizures tend to predominate in the morning in IGE, epileptiform discharges on awakening appear to be typical of IGE (26).

## TREATMENT

Fortunately, IGEs respond well to therapy if the correct AED is administered. In general, 80-90% will become fully controlled. As mentioned earlier, some (such as typical childhood absence epilepsy) have a tendency to be outgrown.

Correct diagnosis of IGEs (at least as a group) is critical, as the choice of pharmacologic treatment matters. There is good evidence that not all AEDs are optimal choices for IGEs, and some may potentially worsen the condition (27–36, see Table 25-1). In fact, up to 70% of patients with IGE initially receive an ill-advised AED, which causes the seizures to increase in frequency or appear intractable (pseudo-intractability) (37). The use of inadequate AEDs in IGE can also result in absence or myoclonic status epilepticus (36). In general, sodium channel blockers, including phenytoin, carbamazepine, and oxcarbazepine, and GABAergic molecules, such as gabapentin, vigabatrin, and tiagabine, are not advisable in patients with IGE. The exact mechanism for these agents' lack of therapeutic effect and occasional harmful effect has not been established.

Valproic acid is the classic drug of choice for the treatment of IGEs. Both ethosuximide and valproic acid are very effective against absence seizures. In patients

FIGURE 25-2

Photoparoxysmal response in an 18-year-old girl with generalized tonic clonic seizures. Photic stimulation (bottom channel) on 2 occasions triggers a brief but clear burst of spike-wave complexes. This discharge was asymptomatic. The patient also had similar discharges of spike-wave complexes without photic stimulation.

with both absence and generalized tonic-clonic (GTC) seizures, valproic acid is the medication of choice. A good argument can be made to select valproic acid over ethosuximide even in absence epilepsy, since 50% of patients with absence will develop GTC seizures. However, since

children with typical (pure) childhood absence epilepsy rarely develop GTC seizures until the second decade, ethosuximide can be the drug of choice in young children. The limiting factors in the use of valproic acid are its potential long-term side effects, including weight gain, hair loss, tremor, teratogenicity, and polycystic ovarian disease. Ethosuximide is generally associated with a favorable side effect profile. It should be used cautiously with patients who have blood dyscrasias or abnormal renal function.

The newer AEDs are promising based upon growing evidence (38), and their place in the treatment of IGE is evolving. Newer AEDs are typically approved initially as adjunct for partial epilepsies, and only later are some of them tested for and approved for IGE. Thus, their use in IGE may be “off-label” (39–53, Table 25-2). In this regard, however, it should be pointed out that no AED, even standard ones like VPA, has specific indications for epilepsy syndromes, so that the “off-label” terminology in this context is a little artificial. In the recent years, topiramate, levetiracetam, and lamotrigine have received specific approval for IGE (Table 25-2). Lastly, levetiracetam has also recently (August 2006) received specific approval as “adjunctive therapy in the treatment of myoclonic seizures in JME,” which in practice means JME (with both GTC and myoclonic seizures), and probably implies efficacy in the IGEs as a group. As usual newer AEDs first obtain approval as adjunctive therapy. However, no AED has ever been found to work as adjunctive therapy and not in monotherapy, and there is no doubt that these newer AEDs will work in monotherapy.

## INDIVIDUAL SYNDROMES

Juvenile myoclonic epilepsy, juvenile absence epilepsy, and epilepsy with generalized tonic-clonic seizures (GTCS) on awakening are the three syndromes of idiopathic generalized epilepsy of adolescent onset currently included in the ILAE classification. Childhood absence epilepsy is discussed in Chapter 22.

### Juvenile Myoclonic Epilepsy (JME)

JME is one of the most common forms of epilepsy seen in the adolescent population, and is one of the best-defined syndromes. Although there is some controversy, JME appears to represent a unique phenotype among IGEs (54). The genetic abnormality in JME has been linked to a gene locus on chromosome 6 (55). In about 80% of cases, it has an age onset of between 12 and 18 years (mean 14.6 years) (56). Seizures occur predominantly in the morning, just upon awakening, in a cluster fashion, and are highly sensitive to sleep deprivation, stress, fatigue, or alcohol. Clusters of myoclonic seizures typically herald a GTC seizure. In fact, this pattern of clonic-tonic-clonic rather than tonic-clonic seizures is quite typical of JME, or at least IGE. Because JME begins as sporadic myoclonic seizures before the patient develops GTC seizures, it is often underdiagnosed and requires careful history taking, specifically inquiring about morning jerks.

Photosensitivity is very common in JME and is found in 30% of patients, the highest rate of all epilepsies (25). The characteristic EEG pattern in JME consists of discharges of high-amplitude generalized symmetric and synchronous 4–6 Hz polyspike-wave complexes.

Probably the most unique feature of JME among IGEs is that it is not outgrown and requires lifelong treatment, as the rate of recurrence is very high after discontinuation of medication, even after a long remission.

### Juvenile Absence Epilepsy (JAE)

The individualization of JAE as a separate syndrome is relatively recent (1, 57, 58), because the clinical boundaries of JAE are rather imprecise. JAE falls somewhere in-between childhood absence epilepsy and JME on the spectrum of IGE, and it can have features of both. Most cases begin near or after puberty, typically between 10 and 17 years of age (59).

Absence seizures are similar though, less “pure” than those of CAE. They are clinically characterized by a brief (5–15 seconds) impairment of consciousness with abrupt onset and termination represented electrographically with a classic pattern of 3-Hz spike-wave complexes. During these episodes, the patient often displays automatisms manifesting as lip-smacking, eye blinks, or repetitive head movements. The spells have an abrupt onset (without

warning) and termination, a feature distinguishing them from complex partial seizures. In general, these seizures can be reliably provoked by having the child hyperventilate for 3 to 5 minutes.

### “Other” IGE or IGE “NOS” or Adult-Onset IGE

In addition to the preceding well-defined syndromes, many patients with IGE, perhaps the majority (37), either have features that do not meet criteria for a specific syndrome or have hybrid features. Seizures typically begin in young adulthood, and neurologic examination is normal. A positive family history is not uncommon. Seizures may predominate in the morning, may be photosensitive, and are sensitive to sleep deprivation. The 1989 ILAE epilepsy classification individualized “epilepsy with grand-mal seizures on awakening” and “epilepsies with specific modes of precipitation,” but these entities are less well defined and too restrictive. In that scheme, most adults with IGE would not fit into any syndrome. Thus the evolving classification of IGEs uses more inclusive terms such as “IGE with GTC seizures only” (60). Other terms for the same condition include the “adult-onset IGE” (61) and IGE with pure grand mal (62). This common syndrome is typically characterized by GTC only, and likely the same as GTC “on awakening” in which seizures are not limited to the morning. When other seizure types exist in these IGEs, the seizures can clinically include mixed features, giving rise to confusing names. For example, seizures with features of both absence and myoclonic jerks can be referred to as “myoclonic absence.” Examples of questionable syndromes include some reflex epilepsies, such as photosensitive GTC seizures (63), epilepsy with GTC seizures on awakening (1), epilepsy induced by thinking and spatial tasks (64, 65), or adult myoclonic epilepsy (66). In fact, many such variants can be described as, or hypothesized to be, individual syndromes, but it is more practical to view them as variations within the continuum of IGE (60).

Similarly, the EEG patterns can show mixtures of generalized epileptiform discharges of any type (spikes, sharp waves, spike-wave complexes, and polyspikes) and photosensitivity, but can vary to become a hybrid of spike-wave complexes, polyspikes, polyspike-wave complexes, and spikes (21).

Thus, in many patients (especially adolescents and young adults), pigeonholing the IGE syndrome is not necessary and may be futile, but it is critical to diagnose the patient correctly as having an IGE rather than a localization-related epilepsy, since this has crucial therapeutic and prognostic implications.

### MEDICALLY INTRACTABLE IGE

The entity of “medically intractable” IGE is not well recognized and has received little attention because the vast

majority of patients with IGE are fully controlled with AEDs. In addition, most patients with IGE that are not controlled are not truly intractable but instead have been treated with inadequate AEDs (37, 67, 68). Nevertheless, epilepsy centers encounter patients with clear IGE who are refractory to medications. For these patients, there is some preliminary evidence that vagus nerve stimulation (VNS) is a good option. VNS may have comparable efficacy against IGE as it does in localization-related epilepsy (69, 70), but this (like newer AEDs) is off-label use. One study in an animal model of absence epilepsy found no benefit of VNS (71). Another option in truly intractable IGE may be the ketogenic diet, but no data are available to support this.

Secondary bilateral synchrony, in which frontal lobe epilepsy masquerades as IGE, should be considered when seizures appear refractory, but in the absence of a structural lesion or other clear evidence for focality, this should not be pursued surgically (24).

### CONCLUSION: THE IMPORTANCE OF MAKING THE DIAGNOSIS OF IGE

Making a diagnosis of IGE is a critical step in the management of patients with seizures. Making a diagnosis of the specific type of IGE is often not possible, usually controversial, and is not necessarily important, but a diagnosis of IGE (as a group) is critical. First, the cause is not “unknown.” Rather, it is a genetically determined

low threshold for seizures. This is easier for patients and families to accept. Second, not all AEDs are equal for IGE. Missing the diagnosis of IGE results in inadequate drug treatment and poor seizure control (37). Third, a diagnosis of IGE has important (usually optimistic) prognostic implications.

Unfortunately, it is often taught that adults with epilepsy should be assumed to have partial (focal) epilepsy. Staring spells are loosely labeled “complex partial” seizures, and GTCs are assumed to be secondarily generalized (61). This assumption should be avoided, as it will be wrong at least 25% of the time in adults, and even more so in adolescents. A significant proportion of IGEs begin beyond childhood and adolescence: 28% after age 20 (61), and 35% after age 18 (72). And in a study of 300 patients with new-onset seizures (a mean age of 31), a quarter turned out to have an IGE (73). The EEG, when abnormal, is extremely helpful and clearly points to IGE. Occasionally the diagnosis will require video-EEG monitoring. In practice, young adults with rare GTCs often have normal EEGs, and it may be difficult to determine whether they have IGE or a focal (e.g., frontal lobe) epilepsy. In this situation, one should keep an open mind and not assume partial epilepsy. In a patient with infrequent GTC seizures and a normal (not helpful) EEG, the diagnosis should not be assumed to be localization-related epilepsy. Instead, it is prudent to keep an open mind, using a diagnosis such as “epilepsy with GTC seizures, type (IGE vs focal) uncertain,” and to use broad-spectrum AEDs.

## Progressive Myoclonus Epilepsies

*Samuel F. Berkovic*

**T**he syndrome of progressive myoclonus epilepsy (PME) consists of myoclonic seizures, tonic-clonic seizures, and progressive neurologic dysfunction, particularly ataxia and dementia. Onset may be at any age but is usually in late childhood or adolescence. Myoclonus in PME is typically fragmentary and multifocal and often is precipitated by posture, action, or external stimuli such as light, sound, or touch. It is particularly apparent in facial and distal limb musculature. Bilateral massive myoclonic jerks, which tend to involve proximal limb muscles, may also occur (1, 2).

In its fully developed form with florid, unremitting myoclonic seizures and progressive neurologic deterioration, diagnosis of the PME syndrome can hardly be missed. Diagnosis may be more difficult in the early stages, and confusion with more benign epilepsies is common. There are a large number of causes of the PME syndrome; most are due to specific genetic disorders, which can now be accurately diagnosed in life. Spectacular advances in the molecular genetics of these disorders have occurred in the last few years (Table 26-1).

Diagnosis of the specific type of PME is challenging, as most individual clinicians have limited experience with these rare disorders. The main causes of PME are described in this chapter, which is largely derived from

another publication (3). Description of the rarer forms can be found elsewhere (1–3).

### UNVERRICHT-LUNDBORG DISEASE

Unverricht-Lundborg disease is the prototypic cause of PME (4, 5). No storage material is present, but there is neuronal loss and gliosis, particularly affecting the cerebellum, medial thalamus, and spinal cord (6).

#### Clinical Features

Clinical onset is with myoclonus or tonic-clonic seizures between the ages of 8 and 13 years (mean 10, range 6–16).

The myoclonus usually is quite severe and may be precipitated by movement, stress, or sensory stimuli. Repetitive morning myoclonus is also typical, frequently building up and culminating in a major tonic-clonic seizure (7, 8). Seizures may be difficult to control, but progression in terms of ataxia and dementia is mild and late. The clinical course is variable, and there may be considerable intrafamily variation in the severity of the seizures. Some patients are relatively mildly affected and survive to old age. Others have a more fulminant course, with death within a few years of onset; this outcome seems

**TABLE 26-1**  
*Molecular Genetics of Major Progressive Myoclonus Epilepsies*

Sialidosis type I	6p21	Neuraminidase	
Sialidosis type II	20q13	Protective protein/ cathepsin A	

to be rare now and may have been due to unrecognized deleterious effects of phenytoin (9, 10).

The electroencephalogram (EEG) background may show some diffuse theta that increases over years as well as some frontal beta activity. Epileptic activity consists of 3–5 Hz spike-wave or multiple spike-wave activity with the maximum field being anterior. Sporadic focal spikes, particularly in the occipital region, may be seen but are usually not prominent. Photosensitivity typically is marked. The spike-wave activity is diminished during non-rapid-eye-movement (non-REM) sleep (8, 11).

### Genetics

Unverricht-Lundborg disease is an autosomal recessive condition (12) initially recognized as a geographic cluster in Finland and eastern Sweden (hence the name “Baltic myoclonus”). An erroneous but frequently held view is that this disorder is confined to the Baltic region. Clusters of a phenotypically identical disorder, the so-called “Mediterranean myoclonus,” occur in southern Europe and North Africa (13). It is also found sporadically worldwide in Caucasians, blacks, and Japanese (9, 14, 15).

The disorder was linked to the long arm of chromosome 21 in Finnish cases in 1991 (16), and the gene for cystatin B was identified as the responsible gene in 1996 (17). The clinical prediction that similar cases seen outside the Baltic region have the same condition was confirmed by showing the identification of mutations in the cystatin B gene (CSTB) in families from around the world. The commonest mutation, responsible for about 90% of abnormal alleles, is an unstable expansion of a dodecamer repeat in the 5' untranslated promoter region. The remaining mutations are missense mutations (18–21).

### Diagnosis

Unverricht-Lundborg disease is recognized clinically by its characteristic age of onset and clinical pattern, with an absence of other clinical or pathologic features. Diagnosis is confirmed by molecular genetic study of the cystatin B gene.

### MYOCLONUS EPILEPSY WITH RAGGED RED FIBERS

The syndrome of myoclonus epilepsy with ragged red fibers (MERRF) has emerged as one of the most common causes of PME. It may be familial or sporadic, and its clinical features and severity are extremely variable.

### Clinical Features

Myoclonus epilepsy with ragged red fibers was first described in cases with a florid clinical myopathy and myoclonus epilepsy (22, 23). It is now clear that the clinical spectrum of MERRF is extremely broad. It should be suspected in a wide variety of situations, even when clinical and pathologic evidence of myopathy are absent (24). Symptoms may begin at any age, and there may be marked intrafamily variation in the age of onset and clinical severity (24, 25). The clinical features include myoclonus, tonic-clonic seizures, dementia, and ataxia, with less common findings of myopathy, neuropathy, deafness, and optic atrophy. Some cases show striking axial lipomas. Occasional patients or families have focal neurologic events, and there is an overlap with the syndrome of mitochondrial encephalomyopathy, lactic acidosis, and strokelike episodes (MELAS), in which strokelike

episodes, frequently preceded by migrainous headaches with vomiting, are characteristic.

The EEG shows slowly progressive background slowing, paralleling the degree of clinical deterioration. There are generalized spike-and-wave discharges at 2–5 Hz or multiple spike-and-wave discharges. Sporadic occipital spikes and sharp waves may be seen. Prominent photosensitivity may occur. Non-REM sleep is disorganized, and spike-and-wave discharges are diminished (11, 26).

### Genetics

Virtually all familial cases of MERRF are transmitted through the maternal line and are examples of mitochondrial inheritance (25). The peculiarities of mitochondrial inheritance provide an explanation for the wide phenotypic variability in patients with MERRF and the extraordinary intrafamily variation.

A single base substitution at nucleotide pair 8344 of mitochondrial DNA, causing an A-to-G substitution in the tRNA<sup>Lys</sup> gene, occurs in many familial cases of MERRF (27). The fact that this mutation affects tRNA rather than a gene for a respiratory enzyme probably explains the heterogeneous results for respiratory enzyme assays reported in MERRF. This tRNA<sup>Lys</sup> mutation has been confirmed in numerous laboratories around the world and appears to underlie most but not all familial cases and some sporadic examples of MERRF. Other rare identified molecular causes of MERRF are mutations at nucleotides 8356 and 8363 in the same tRNA<sup>Lys</sup> (28, 29) and mutations in tRNA<sup>Ser</sup> (30), but in some cases no molecular defect has been found. Recently, autosomal recessive mutations in the nuclear encoded mitochondrial gene polymerase gamma (POLG) have been identified in some MERRF cases (31).

### Diagnosis

Diagnosis can usually be suspected clinically but may be difficult to confirm with laboratory markers. The clinical clues to the diagnosis include deafness, optic atrophy, myopathy, lipomas, intrafamily variation in age of onset and severity, and a pattern of inheritance compatible with maternal transmission. Serum lactate, ragged red fibers, and respiratory enzyme activities in muscle can all be normal in patients known to be affected (e.g., family members of proven cases). Magnetic resonance spectroscopy (MRS) of muscle may show elevated levels of inorganic phosphate and a decrease of the phosphocreatine:inorganic phosphate concentration ratio (32). When present, molecular defects in mitochondrial DNA can be detected in peripheral blood or muscle (33, 34).

## LAFORA DISEASE

Lafora disease is characterized by the presence of Lafora bodies, which are polyglucosan inclusions found in neurons and in a variety of other sites, including the heart, skeletal muscle, liver, and sweat gland duct cells (35, 36).

### Clinical Features

Onset of Lafora disease is between the ages of 10 and 18 years, with a mean age of onset of 14 years. Clinical features are myoclonus, tonic-clonic seizures, and relentless cognitive decline. Focal seizures, particularly that arise from the occipital regions, occur in approximately half the patients. Recognition of Lafora disease in its fully developed form is not difficult. At the onset, however, the disorder may resemble a typical benign adolescent generalized epilepsy with no evidence of cognitive decline. It also may present as a dementing illness with relatively infrequent seizures, or it may mimic a nonspecific secondary generalized epilepsy because myoclonus is not obvious (37, 38). The prognosis of Lafora disease is dismal, with death occurring 2 to 10 years after onset and the mean age of death being 20 years.

The clinical picture, including the relatively narrow age range of onset and relentlessly progressive course to death within 2 to 10 years of onset, is constant in all reports with the exception of a few cases. These cases, sometimes erroneously labeled “type Lundborg,” had symptoms beginning in late adolescence or early adult life with a milder protracted course. They may represent a genetic subtype of Lafora disease separate from the classic form (39, 40).

At onset the EEG background is well organized, and there are multiple spike-and-wave discharges that are increased by intermittent photic stimulation. Erratic myoclonus is seen without EEG correlation. Spike-and-wave discharges are not accentuated during sleep. Over the next few months to years, the background deteriorates, the physiologic elements of sleep become disrupted, and only REM sleep can be identified. Multifocal, particularly posterior, epileptiform abnormalities appear in addition to the generalized bursts, and in the terminal phase of the illness the EEG is quite disorganized (41).

### Genetics

Lafora disease is an autosomal recessive condition. The largest series have been reported from southern Europe (41), but it is found worldwide, apparently without a marked racial or ethnic predilection. Approximately 90% of cases have mutations in the gene EPM2A, which encodes a dual phosphatase known as laforin (42, 43), or in EPM2B (also called NHLRC1), which codes for an E3 ubiquitin ligase known as malin (44, 45). There is evidence for a third, as yet unknown, locus (46).

### Diagnosis

The age of onset, eventual inexorable dementia, and frequent occurrence of focal occipital seizures are clinical clues to the diagnosis (38). Lafora bodies can be demonstrated in many tissues, but diagnosis is most simply made by examination of eccrine sweat gland ducts by a simple skin biopsy (36) and can now be confirmed in most cases by molecular study of EPM2A and EPM2B (47).

## NEURONAL CEROID LIPOFUSCINOSES

The neuronal ceroid lipofuscinoses (NCL) are characterized by the accumulation of abnormal amounts of lipopigment in lysosomes. Seven types—late infantile (Jansky-Bielschowsky, CLN2), late infantile variants (CLN5, CLN6, CLN7, CLN8), juvenile (Spielmeyer-Vogt-Sjögren, CLN3), and adult NCL (Kufs, CLN4)—may cause the PME syndrome (48). The infantile form (CLN1) presents differently, with regression, hypotonia, and impaired vision, and it is not considered here. The childhood forms are sometimes collectively referred to as Batten's disease.

### Clinical Features

The late infantile form has an onset between 2.5 and 4 years. Seizures usually are the first manifestation, with myoclonic seizures, tonic-clonic seizures, atonic seizures, and atypical absences. Ataxia and psychomotor regression are seen within a few months of onset, with visual failure generally developing late.

Examination of the optic fundi reveals attenuated retinal vessels and macular degeneration. The seizures are usually intractable, dementia is relentless, and there is progressive spasticity, with death approximately 5 years after onset (37). The EEG shows background slowing and disorganization with generalized epileptiform discharges. Photosensitivity is marked, and single flashes may provoke giant posterior evoked responses. Visual evoked potentials (VEPs) are abnormally broad and of high amplitude, and sensory evoked potentials (SEPs) are enlarged. The electroretinogram (ERG) becomes progressively attenuated (37, 49).

The late infantile variant form, described in Finland, differs in that onset is later, between 5 and 7 years; psychomotor regression and visual failure occur earlier; myoclonic and tonic-clonic seizures generally appear at approximately age 8 years; and progression is somewhat slower (50). Electrophysiologic findings are similar to those of the late infantile form except that the marked response to photic stimulation develops at approximately age 7–8 years and disappears by age 10–11 years, and the visual evoked response (VER), which initially is large,

progressively attenuates (50). Other variants of the late infantile form have been described in other geographic regions (48).

Juvenile NCL begins between the ages of 4 and 10 years. The majority of patients present with visual failure and have gradual development of dementia and extrapyramidal features, with seizures being a relatively minor manifestation. Other patients present with myoclonus and tonic-clonic seizures with visual, cognitive, and motor signs developing later. This is sometimes called the early juvenile variant. Fundoscopy reveals optic atrophy, macular degeneration, and attenuated vessels. Inheritance is autosomal recessive. The course is variable, with death approximately 8 years after onset (37, 51). The EEG shows background slowing and generalized epileptiform discharges that often are of the slow-spike-and-wave type. Sleep activates the epileptic abnormality, but photic stimulation does not. VEPs are of low amplitude and sometimes cannot be elicited. The ERG is flat (37, 49).

The adult form is considerably rarer. It can present as a PME syndrome around the age of 30, although other patients present with a picture of dementia and extrapyramidal or cerebellar disturbance. Visual auras may occur before some seizures. Blindness is notably absent, and the optic fundi are normal. The clinical course from onset to death is approximately 12 years (52). The EEG shows generalized fast spike-and-wave discharges with marked photosensitivity. Single flashes may evoke paroxysmal discharges. The background activity may be normal in the early stages, and ERGs are normal (11, 52).

### Genetics

The various forms are genetically distinct and occur worldwide, but with peculiar patterns of geographic clustering. In Finland there are large numbers of infantile and juvenile cases, whereas in Newfoundland late infantile and juvenile cases occur with increased frequency (53, 54). All forms are autosomal recessive disorders. Kufs' disease, however, also occurs in families with dominant inheritance (55).

The storage material(s) in the NCLs has been extremely difficult to characterize and for many years was thought to be lipid. Subunit c of mitochondrial ATP synthase, a very hydrophobic protein, subsequently was identified as the major storage protein in an ovine model (56) and in human late infantile, juvenile, and adult cases (56, 57).

Considerable progress in the molecular genetics of this complex group of disorders has recently occurred. The causative gene has been identified for five of the currently identified seven variants causing PME. The classical late infantile form is due to mutations in the gene CLN2, which encodes a lysosomal enzyme tripeptidyl peptidase (TPP1) (48). CLN3, CLN5, CLN6, and CLN8 encode various lysosomal or intracellular membrane proteins whose functions remain to be elucidated (48).

### Diagnosis

Diagnosis may often be suspected clinically, particularly if there are visual changes. The electrophysiologic findings previously described may be helpful. Vacuolated lymphocytes may occur in the juvenile form. Neuroradiologic studies show cerebral atrophy and particularly cerebellar atrophy. Definitive diagnosis presently requires the demonstration of characteristic inclusions by electron microscopy. These can be found most simply in eccrine secretory cells. The inclusions take various forms, with curvilinear profiles being characteristic of a late infantile NCL, fingerprint profiles being usual in the juvenile and adult forms, and granular osmiophilic deposits occurring in the infantile form. Considerable expertise may be required in the pathologic interpretation of the electron micrographs (58). In the case of suspected CLN2, enzymatic assays for TPP1 are available, and molecular testing can be performed for CLN2, CLN3, CLN5, CLN6, and CLN8 (48).

### SIALIDOSES

The sialidoses are the least common of the major forms of PME. They are autosomal recessive disorders associated with deficiencies of alpha-N-acetyl-neuraminidase.

#### Clinical Features

In sialidosis type I (“cherry-red spot-myoclonus syndrome”), there is onset in adolescence with myoclonus, gradual visual failure, tonic-clonic seizures, ataxia, and a characteristic cherry-red spot in the fundus. The myoclonus is usually very severe. Lens opacities and a mild peripheral neuropathy with burning feet may occur. Dementia is absent (37, 59).

Juvenile sialidosis type II presents as a PME with features similar to those of sialidosis type I except that onset is sometimes a little later. There may be additional features of coarse facies, corneal clouding, dysostosis multiplex, hearing loss, and low intellect, which may be present from early life (59, 60).

The EEG background shows low-voltage fast activity, but some slowing can be seen in demented patients. Generalized spike-and-wave bursts are absent or infrequent; rather massive myoclonus is associated with trains of 10- to 20-Hz small vertex positive spikes preceding the electromyogram (EMG) artifact. Non-REM sleep is disorganized, and although myoclonus diminishes, the vertex spikes persist and become very frequent in deep sleep (37).

#### Genetics

Sialidosis type 1 is due to mutations in the alpha-N-acetyl-neuraminidase gene (NEU1) on chromosome 6 (61). Many of the published cases were of Italian origin (59).

Sialidosis type II comprises a complex group of phenotypes. The juvenile form presents as a PME and occurs predominantly in Japan. In addition to the neuraminidase deficiency, a partial deficiency of beta-galactosidase is also found in most if not all cases (58, 59). The combination of neuraminidase and beta-galactosidase deficiency (galactosialidosis) is due to a lack of protein that is required to protect galactosidase from degradation and is essential for the catalytic action of neuraminidase (62). Missense mutations in the gene that encodes lysosomal protective protein/cathepsin A (PPCA) on chromosome 20 cause the juvenile form with PME (63–65).

### Diagnosis

Sialidoses should be identified clinically because of the characteristic optic fundus. Periodic acid-Schiff-positive inclusions may be seen in lymphocytes, bone marrow cells, neurons, and Kupfer cells. Diagnosis is confirmed by grossly elevated urinary sialyloligosaccharides and by a deficiency of cryolabile alpha-N-acetylneuraminidase in leukocytes or cultured fibroblasts (59).

### DISTINGUISHING PME FROM OTHER EPILEPSIES AND MYOCLONIC SYNDROMES

It usually is not difficult to diagnose the syndrome of PME some years after onset with the distinctive diagnostic triad of myoclonic seizures, tonic-clonic seizures, and progressive neurologic decline. At the beginning of the illness, however, the clinical and EEG features may be similar to those of benign idiopathic generalized epilepsies, particularly mimicking juvenile myoclonic epilepsy. Initial response to therapy may be relatively favorable. However, seizures may become more frequent with the passage of time, and progressive neurologic decline occurs. Failure to respond to therapy and progressive neurologic signs should lead to consideration of the presence of a PME. Conversely, the clinical picture of patients with idiopathic generalized epilepsies may mimic that of PME if they are inappropriately treated and intoxicated with antiepileptic drugs (AEDs), leading to ataxia, impaired cognitive function, and poorly controlled seizures.

Myoclonus in PMEs is usually quite severe, but in some patients it may be relatively obscure, with convulsive seizures and intellectual decline dominating the clinical picture, leading to a misdiagnosis of a nonspecific symptomatic (secondary) generalized epilepsy or Lennox-Gastaut syndrome. In such cases, a careful search for myoclonus should lead to consideration of the PME syndrome.

Neurophysiologic assessment may also provide clues to the presence of a PME. The EEG background rhythm may be relatively well preserved in the early phases, but generalized slow activity appears as the condition

progresses. This is particularly so in those forms of PME associated with relentless dementia, such as Lafora disease and NCL. Generalized epileptiform abnormalities are seen during the resting record, usually in the form of fast spike-and-wave, multiple spike-and-wave, or multiple spike discharges. Photosensitivity is common and may be marked. Focal, particularly posterior, epileptiform abnormalities are common in Lafora disease but also may occur in other forms (11). Somatosensory evoked potentials (SEPs) frequently show giant responses (66).

PMEs should be distinguished from degenerative disorders in which seizures and/or myoclonus can occur but do not form part of the clinical core or usual initial presentation of the disorder. The causes of such progressive encephalopathies with seizures are numerous and include GM2 gangliosidosis, nonketotic hyperglycinemia, Niemann-Pick type C, juvenile Huntington's disease, Alzheimer's disease, and so forth. The distinction between this diverse group of disorders and the PMEs, while not absolute, is clinically useful and provides a practical framework on which to begin specific differential diagnosis. For example, typical Alzheimer's disease may have myoclonus as a relatively late feature and would not be confused with a PME. Rare early-onset cases may, however, present as a PME in early adult life (67). Myoclonus is also prominent in certain static encephalopathies, of which postanoxic myoclonus (Lance-Adams syndrome) is the best known. The absence of progression and the usual clear history of the causative encephalopathy enable clear distinction from PME.

The PME syndrome should also be distinguished from the progressive myoclonic ataxias. The latter term was introduced to denote a group of patients, usually adults, with progressive ataxia and myoclonus but with few, if any, tonic-clonic seizures and little or no evidence of dementia (14). Previously, some authors used the term "Ramsay Hunt syndrome" for these patients' condition, although others used this term for quite different clinical groups, which led to considerable confusion in the literature. The causes of progressive myoclonic ataxia partially overlap with those of PME but also include spinocerebellar degeneration, celiac disease, and Whipple's disease. Although it is now possible to specifically diagnose most patients with the PME syndrome in life (see next section), a larger proportion of carefully studied cases with progressive myoclonic ataxia remain without a known specific cause (14, 68).

Japanese authors have highlighted a condition of benign myoclonic epilepsy of adulthood. In this autosomal dominant disorder, onset is usually between 20 and 40 years, with myoclonus and rare tonic-clonic seizures. Generalized epileptiform EEG abnormalities and giant SEPs are present, but there is little or no evidence of progression (69, 70). This condition may be the same as or similar to that previously described in the German literature as myoclonus epilepsy of Hartung type (39).

Finally, the condition of benign familial myoclonus should be distinguished. In this autosomal dominant disorder, nonepileptic myoclonus begins in the first three decades of life but is not associated with major seizures, epileptiform EEG abnormalities, or neurologic deterioration (71).

### DIAGNOSING THE SPECIFIC TYPE OF PME

Once the clinician is convinced that a patient has the PME syndrome, the critical question is to determine which specific disorder is present. This is essential for proper clinical and genetic counseling of the family (see "Treatment" section).

It is now possible to provide a specific diagnosis in life for the majority of patients with PME using clinical methods and minimally invasive investigations. An approach to this problem has been described previously. The clinician should first consider the five major disorders causing PME. Once these conditions are excluded, the rarer disorders should be considered (1-3).

### Clinical Features

Although patients with the PME syndrome superficially may appear to have similar clinical features, knowledge of the specific clinical patterns of the common causes of PME often allows the differential diagnosis to be narrowed. Age at onset of symptoms provides some guidance in making the diagnosis, although MERRF may begin at any age. Certain seizure patterns are helpful; very prominent myoclonus suggests Unverricht-Lundborg disease, MERRF, or sialidosis. Partial seizures, particularly of occipital origin, can occur in a variety of the disorders but are often noted in Lafora disease. Characteristic fundal changes are almost invariable in sialidosis and are frequent in the NCLs. Dementia is a constant feature of Lafora disease and NCLs, whereas it is characteristically absent or mild in Unverricht-Lundborg disease and sialidosis type I. The presence of deafness, lipomas, optic atrophy, myopathy, or neuropathy are clinical pointers to MERRF. Neuropathy may also occur in sialidosis. Dysmorphic features are usual in sialidosis type II and may occur in MERRF.

### Family History

A detailed family history, including examination of relatives, is essential. Recessive inheritance is usual, and the finding of parental consanguinity or early clinical signs in asymptomatic siblings would support this pattern. Maternal transmission is characteristic of MERRF. In MERRF and the autosomal dominant disorders, older relatives may be found to have mild, incomplete forms of the condition.

## Neurophysiology

Findings that may be useful in specific diagnosis include vertex spikes as the main epileptiform abnormality in sialidosis, activation of epileptiform abnormalities in non-REM sleep in the sialidoses and the late-infantile and juvenile forms of NCL, photosensitivity to single flashes in late infantile and adult NCL, and absent ERG in late infantile and juvenile NCL (11).

## Laboratory Findings

Hematologic examination may reveal lymphocyte vacuolation in sialidosis and in certain cases of NCL. Routine biochemical tests are not helpful, with the exception of elevated lactate levels in blood and cerebrospinal fluid in some cases of MERRF.

## Pathologic Studies

A tissue diagnosis is essential for a number of these disorders. Skin biopsy with or without skeletal-muscle biopsy is the initial procedure. Lafora disease can be reliably diagnosed by examining eccrine sweat gland duct cells with stains for polysaccharides (36). The diagnosis of NCL may be suggested by an acid phosphatase stain, but electron microscopy of the skin biopsy specimen is essential for the definitive identification of inclusions. These inclusions are detectable in many cell types in the late infantile form of the disease, but diagnostic inclusions may be limited to eccrine secretory cells in the juvenile and adult varieties (58). False negative skin biopsies in Lafora disease and in late infantile and juvenile NCL are due to failure to examine the appropriate cell type properly. In suspected Lafora disease, sweat gland ducts must be included in the biopsy and properly examined. Where doubt remains, skin biopsy should be repeated because of the serious prognostic implications of the diagnosis of Lafora disease. The reliability of diagnosis of Kufs' disease from skin biopsy is not yet clear.

Study of muscle biopsy specimens with modified Gomori's trichrome and oxidative enzyme reactions may demonstrate ragged red fibers in MERRF. Abnormal mitochondria may be identified in muscle or skin using electron microscopy. Normal light and electron microscopic studies of muscle do not rule out the diagnosis of MERRF, and a second biopsy may be indicated in clinically suspicious cases.

## Molecular Biological Studies

Molecular biological studies are playing an increasing role in the diagnosis of the PMEs. Simple DNA tests for the dodecamer repeat in Unverricht-Lundborg disease and mitochondrial DNA mutations in MERRF are readily available. Testing for mutations associated with Lafora disease, neuronal ceroid lipofuscinoses, and sialidoses is available from more specialized or research-oriented laboratories (see <http://www.genetests.org>).

## TREATMENT

Treatment of these disorders may be distressingly difficult. Accurate diagnosis is the first step, as informed genetic counseling must be given. It is very important to distinguish MERRF, which may show maternal inheritance, from autosomal recessive disorders, such as Unverricht-Lundborg disease, Lafora disease, sialidoses, and the NCLs, and from rare dominant families with Kufs' disease. Genetic counseling may now be extended to prenatal diagnosis in some cases. Specific diagnosis also allows an accurate prognosis to be given, including a realistic appraisal of the educational and vocational goals of the patient.

Valproate and/or clonazepam should be used for symptomatic control of myoclonus. Phenytoin has a clear deleterious effect in Unverricht-Lundborg disease (9, 10), and neither should it be used in the other PMEs. Small doses of barbiturates may be helpful, but sedation should be avoided. Piracetam may be useful in certain cases (72, 73). Care must be taken not to intoxicate the patient with drugs, although there is some evidence that carefully monitored polytherapy may be more effective in some patients than the usual practice of aiming for monotherapy (74). Zonisamide (75, 76) and levetiracetam (77-79) may be quite effective. Programs of physical therapy may be of benefit, and attempts should be made to search for strategies that allow movement without precipitating myoclonus in individual patients. Alcohol may provide symptomatic benefit in some patients, but must be used judiciously (80).

Strategies for replacing enzymes in the storage disorders and augmenting mitochondrial function in the mitochondrial disorders are being developed, but presently they remain in the experimental phase, and results to date have been disappointing.

## Localization-Related Epilepsies: Simple Partial Seizures, Complex Partial Seizures, and Rasmussen Syndrome

*Prakash Kotagal*

**T**he International Classification of Epilepsies and Epileptic Syndromes (1) divides epilepsy, first, on the basis of whether the seizures are partial (localization-related epilepsies) or generalized (generalized epilepsies) and, second, by etiology (idiopathic, symptomatic, or cryptogenic epilepsy). Idiopathic epilepsies are defined by age-related onset, clinical and electroencephalographic characteristics, and a presumed genetic etiology. Symptomatic epilepsies comprise syndromes based on anatomic localization and are considered to be the consequence of a known or suspected disorder of the central nervous system. Cryptogenic epilepsies are presumed to be symptomatic, but the etiology is not known. Localization-related epilepsies include the following types of seizures:

1. Simple partial seizures
2. Complex partial seizures
  - a. With impairment of consciousness at onset
  - b. Simple partial onset followed by impairment of consciousness
3. Partial seizures evolving to generalized tonic-clonic (GTC) convulsions
  - a. Simple partial evolving into GTC
  - b. Complex partial evolving into GTC including those with simple partial onset

### DEFINITIONS

A simple partial seizure is one that arises from a localized area within one hemisphere without impairment of consciousness. A complex partial seizure is a partial-onset seizure that is characterized by impaired consciousness, unresponsiveness, and automatic behavior often followed by postictal confusion. Impaired consciousness is defined as the inability to respond normally to exogenous stimuli by virtue of altered awareness or responsiveness (2). *Awareness* refers to the patient's contact with events during the period in question and its recall (2), whereas *responsiveness* is the ability of the patient to carry out simple commands or willed movements.

### ETIOLOGY

By definition, partial seizures imply the presence of a focal abnormality in one cerebral hemisphere. A definite etiological factor can be identified by magnetic resonance imaging (MRI) in approximately 75% to 90% of patients with partial seizures (3–5). These include birth asphyxia, intrauterine infections (toxoplasmosis, cytomegalovirus, rubella, or syphilis), congenital anomalies, head trauma, meningitis, viral encephalitis, parasitic infections (cysticercosis and echinococcosis), neoplasms,

arteriovenous malformations, cerebral embolization from congenital heart disease, or disorders affecting the intracranial vessels, as in fibromuscular dysplasia and moyamoya disease. Head injury and viral encephalitis have a predilection for the temporal lobe (6, 7). Approximately 30% of patients who undergo surgical treatment for intractable partial seizures have a foreign tissue lesion detected on pathologic examination (8). Mesial temporal sclerosis (MTS) has been established as a causative factor in 50% to 60% of adolescents and adults with temporal lobe epilepsy (TLE) (9–11). Hippocampal pathology shows neuronal loss and gliosis in the Sommer sector, end folium, and dentate gyrus in 50% of cases (12). However, other etiologies predominate in children below the age of 12 years. Duchowny and coworkers found that in their surgical series of 16 patients with TLE, only 2 had MTS, 7 had abnormalities of neuroblast migration, and 3 had ganglioglioma (13). The common tumors associated with intractable partial epilepsy include low-grade gliomas, gangliogliomas, and dysembryoplastic neuroepitheliomas (DNT) (14, 15). Neuronal migration disorders have been increasingly recognized as a cause of epilepsy. Focal cortical dysplasia (16–18), lissencephaly (19), band heterotopia (20), nodular heterotopia (21), the bilateral perisylvian syndrome (22, 23), and schizencephaly (24) often present with seizures. In a study correlating pathology and MRI findings in children with intractable partial seizures, Kuzniecky and coworkers (25) described the presence of cortical lesions in 23% of patients. Tuberos sclerosis, Sturge-Weber syndrome, neurofibromatosis, epidermal nevus syndrome, and hypomelanosis of Ito are neurocutaneous disorders associated with early-onset seizures (26). Coexistence of certain tumors such as ganglioglioma and DNT with cortical dysplasia, most frequently observed in the pediatric population, may suggest a hamartomatous nature of the neoplasms (27, 28). The association of hippocampal sclerosis with cortical dysplasia remote from the mesial structures is well established in patients with TLE (29, 30).

## SEIZURE PHENOMENA

The symptomatology of partial seizures depends greatly on the location of the seizure focus within the cerebral cortex. Although a given symptom may occur with seizures arising from different locations, the combined information from seizure symptomatology and electroencephalogram (EEG) findings enables one to determine the location of seizure focus. Simple partial seizures with motor manifestations may result from ictal onset within or propagation to the precentral and postcentral gyri of the contralateral hemisphere or the supplementary motor area (31). The ictal symptomatology of epileptic seizures in general is a reflection of activation of symptomatogenic

zones. This activation is usually the result of spreading of the epileptiform discharges from the epileptogenic zone to adjacent cortex, which when activated produces the ictal semiology. Auras consist exclusively of subjective warning symptoms and usually occur at the beginning of a seizure; depending on methodology and selection of patients, auras have been reported anywhere from 20% to 90% of those with partial-onset seizures (32–34). Complex partial seizures (CPS) arise from the temporal lobes in the majority of cases. However, in 15% to 20% of CPS an extratemporal focus in the mesial frontal, opercular insular region, cingulate gyrus, orbitofrontal cortex is seen (35). Postictal dysfunction has localizing value but does not reliably identify the site of ictal onset. The International Classification of Epileptic Seizures provides a useful approach to understanding the symptomatology of partial seizures (2). This classification is electroclinical—in other words, based on both seizure semiology and EEG findings—whereas a recently proposed semiological seizure classification by Lüders is independent of EEG or imaging findings (36).

### Simple Partial Seizures with Motor Signs

Simple partial seizures with motor signs are the most common form of simple partial seizures because of the prominent representation of the motor cortex and high epileptogenicity of the frontal cortex. These symptoms are contralateral (at least at onset) and usually consist of positive (irritative) symptoms, less often negative (inhibitory) symptoms, or a combination of the two.

### Focal Motor Seizures with and without March

Motor seizures can be clonic or tonic, involving any portion of the body, depending on the site of origin of the ictal discharge. Focal motor seizures may remain strictly focal, or they may spread to contiguous cortical areas, producing a sequential involvement of body parts in an epileptic march. This pattern is often referred to as a Jacksonian march. Postictally, a temporary weakness, Todd's paralysis, may be seen, especially if the seizure is severe or prolonged (7). Focal clonic seizures can occur with ictal discharges in any cortical region. The name *epilepsia partialis continua* (EPC) is given to continuous focal motor seizure activity.

### Versive Seizures

Seizures beginning in or spreading to area 8, the frontal eye field, and the supplementary motor area or mesial part of premotor area 6 produce contralateral conjugate deviation of the eyes and turning of the head. When this movement is unquestionably forced and involuntary, the seizures are termed versive seizures and lateralize seizure

onset to the contralateral hemisphere (37). Forced and sustained head and eye version, continuing through generalization or occurring within 10 seconds before generalization, was the best lateralizing sign, identifying a contralateral seizure focus in more than 90 percent of seizures (38).

### **Supplementary Sensorimotor Area Seizures**

The supplementary sensorimotor area (SSMA) may be activated during seizures arising in patients with an epileptogenic zone in the posterior mesial or superior frontal area of one hemisphere. Seizures are frequent, brief, and usually out of sleep with abrupt bilateral asymmetric tonic posturing of the extremities. The posturing predominantly affects the proximal musculature with stiffening and gross flailing movements (15, 16, 39, 40). Speech arrest and vocalization are common, but consciousness is often preserved. Ictal contraversive head and eye version may serve as a lateralizing feature if they precede secondary generalization. SSMA seizures may be confused with psychogenic seizures and parasomnias such as night terrors or confusional arousals.

### **Aphasic Seizures**

Ictal language disturbances during epileptic seizures include speech arrest, aphasia, or vocalization. Seizures that begin with aphasic speech arrest, without altered consciousness, are generally considered to originate in the dominant posterolateral temporal region (41, 42). Lüders and coworkers (43) demonstrated the presence of a basal temporal language area (BTLA) by electrical stimulation with subdural electrodes (43, 44). Speech arrest has been demonstrated in seizures originating in the dominant BTLA (45, 46). Seizures arising in the frontal operculum of the dominant hemisphere can give rise to epileptic aphasia (47). Vocalizations, sounds of no speech quality, may be seen with simple partial seizures affecting the suprasylvian area of the frontal lobe as well as complex partial seizures. They have no lateralizing value (48). Following the end of a simple or complex partial seizure, postictal aphasia may be detected by asking the patient to name items or read and is 80–90% reliable in lateralizing seizure onset to the language-dominant hemisphere (49, 50).

### **Simple Partial Seizures with Somatosensory or Special Sensory Signs**

Sensory or motor phenomena are often the initial symptom of seizures starting in or near the postcentral area. Sensory phenomena include tingling, numbness, or paresthesias contralateral to the epileptogenic focus. The sensory phenomena may march to adjacent sensory or

motor areas. The frequency of motor phenomena is due to intimate connections between the sensory and motor areas (6), as shown by motor phenomena observed in 25% of cases during electrical stimulation of the postcentral gyrus. Sensory symptoms that are ipsilateral or bilateral in distribution and identical to those occurring only contralaterally are believed to originate in the second sensory area at the base of the motor strip in the frontoparietal operculum (51). Benign rolandic epilepsy often manifests with focal motor seizures with preserved consciousness or as partial-onset, secondarily generalized tonic-clonic seizures. They usually involve the face, oropharyngeal muscles, or arm on one side, and less commonly the leg. Sometimes they are associated with sensory phenomena such as tingling or numbness.

Visual seizures are simple partial seizures involving the visual cortex in the region of the calcarine fissure. They usually consist of flashes of light or colors in the contralateral hemifield. Visual seizures should be distinguished from migraine, which usually produces negative phenomena such as scotomas or hemianopsia. More elaborate visual phenomena (i.e., formed visual hallucinations) are seen with seizures starting in the posterior temporal regions. Seizures starting from the occipital cortex may spread to the temporal lobes producing complex partial seizures (52).

Auditory seizures are seen with onset from the auditory cortex in the superior temporal gyrus. They usually manifest with sounds such as humming, buzzing, roaring, or whistling. More elaborate hallucinations (music, voices, etc.) result from involvement of the auditory association areas (6).

Olfactory and gustatory seizures present with an aura of an unpleasant odor or a bad taste in the mouth. They are usually observed with seizures arising from the anterior temporal lobe or insular region.

Vertiginous phenomena are sometimes reported by patients as the aura preceding their complex partial seizures. This may be a light-headed feeling or actual vertigo. Vertiginous phenomena are encountered with CPS of posterior temporal lobe onset (53, 54).

### **Simple Partial Seizures with Autonomic Symptoms or Signs**

Autonomic symptoms in the form of flushing, pallor, sweating, pupillary dilation, nausea, vomiting, borborrymi, piloerection, or epigastric sensations are often seen in CPS, especially those starting in the anterior temporal lobe, opercular-insular region, and orbitofrontal cortex (54–56). Ictal gastrointestinal symptoms that are limited to visceral sensations are more common in children; they include painful cramping, periumbilical pain, bloating, nausea, vomiting, and diarrhea. Pallor and cold sweating may accompany the abdominal symptoms in children

and may be misdiagnosed as psychogenic pain (57). Sinus tachycardia, the most frequent cardiac concomitant of seizures, has been reported in several case studies (58, 59). Sinus bradycardia, sinus arrest, atrioventricular block, and prolonged asystole occur much less frequently. Sudden unexplained death has been postulated to be a result of autonomically mediated fatal cardiac arrhythmia or sudden “neurogenic” pulmonary edema associated with seizures (62–64).

### Simple Partial Seizures with Psychic Symptoms

Simple partial seizures with psychic symptoms refer to alterations of higher cerebral function—dysphasia, dysmnesia (*déjà vu* or *jamais vu*), affective (fear, anger), cognition (distortion of time sense, dreamy states), illusions (*micropsia* or *macropsia*), or hallucinations (voices, music, or scenes). They are usually followed by a complex partial phase; only rarely do they occur in isolation.

As mentioned previously, simple partial seizures may evolve to secondarily generalized tonic-clonic seizures directly or after a complex partial phase. Likewise, CPS may give rise to secondarily generalized tonic-clonic seizures (2). The ictal discharge may spread from the focus to contiguous areas or to distant regions by way of specific pathways or callosal fibers connecting homologous areas of the cortex in the opposite hemisphere.

### Complex Partial Seizures

Approximately 50% of patients with CPS report a warning symptom or aura. An aura is, by definition, a simple partial seizure. It may take different forms depending on the location of the seizure focus, as described previously. CPS of mesial temporal onset are most commonly preceded by a rising epigastric sensation. Young children sometimes run to their mother and cling to her fearfully (63). The aura is more clearly expressed as the child gets older. The aura is followed by the complex partial phase with partial or complete loss of consciousness, unresponsiveness often with a vacant stare, behavioral arrest, and some stiffening of the body. Duchowny and coworkers (64) noted that CPS in infants under 2 years of age frequently consisted of behavioral arrest with forced lateralized deviation of the head and eyes and tonic upper extremity extensor stiffening. Automatisms defined as more or less coordinated, involuntary movements occurring during a period of altered awareness are frequently seen in CPS. These invariably take place during the ictus, less commonly in the postictal period. They may consist of stereotyped movements of the mouth and lips, oroalimentary automatisms such as lip smacking or swallowing, fumbling or grasping movements of the hands, blinking, grimacing, bicycling movements of the legs, walking or running about, laughing, crying, or

complex motor activity. Automatisms tend to be simpler in the younger children, whereas highly organized behavioral sequences and complex gestural automatisms are observed in the older children and adults (64–66). The motor phenomena in preschool children may consist of symmetric tonic or clonic movements of the limbs and atonic phenomenon such as head nodding resembling infantile spasms or hyper-motor turning movements and postures similar to frontal lobe seizures in adults. Unilateral dystonic posturing is more often seen in CPS of temporal lobe origin and has good lateralizing value (67–68). Posturing in frontal lobe CPS tends to be more often tonic, and bilaterally asymmetric. Temporal lobe CPS usually last 60 to 90 seconds and are followed by a postictal period lasting several minutes or hours (69). The child is often lethargic during the postictal period and may complain of headache. Postictal dysphasia may also be seen. The patient is usually confused postictally and may engage in automatic behavior. Attempts to restrain the patient may result in aggressive behavior, which is usually nondirected (70). One-third to one-half of patients with CPS may go on to have a secondarily generalized tonic-clonic seizure, more often out of sleep. Version may occur during such a seizure and is of lateralizing significance (37). It tends to occur earlier in frontal lobe seizures, probably as a result of rapid propagation (71, 72). During the tonic phase of a partial seizure with secondarily generalization, the contralateral arm may be extended while the other arm is flexed, resembling a figure 4, which has lateralizing value (73).

Occasionally, patients may develop complex partial status epilepticus, which may present as a prolonged confusional state, similar to absence status. This may last several hours or even days. The patient appears to be in a daze, is slow to respond, frequently is unable to talk, and often is restless and disoriented. The diagnosis is established by the finding of a continuous focal ictal pattern on the EEG (76).

### Frontal Lobe Seizures

Frontal lobe seizures represent the largest subgroup of extratemporal epilepsy, accounting for 30% of partial epilepsy (75, 76). The most recent epilepsy classification scheme (42) suggests seven different types of frontal lobe seizures related to specific regions of seizure origin (Table 27-1). In practice, large epileptogenic zones, high speed and pattern of seizure propagation, and extensive overlap among different types make it difficult to subclassify CPS of frontal lobe origin accurately into distinct anatomic subregions based on clinical characteristics. Frontal lobe CPS (72, 77–80) can usually be distinguished from CPS arising from the temporal lobes and other regions (Table 27-2). These seizures often have a bizarre clinical presentation, have minimal or absent interictal and

**TABLE 27-1**  
*Summary of International League Against Epilepsy (ILAE) Classification of Frontal Lobe Epilepsies*

REGION	CLINICAL FEATURES
Primary motor cortex	Contralateral tonic or clonic movements according to somatotopy, speech arrest and swallowing with frequent secondary generalization
SMA	Simple focal tonic seizures with vocalization, speech arrest, fencing postures, and complex focal motor activity
Cingulate	Complex focal motor activity with initial automatisms, sexual features, vegetative signs, changes in mood and affect, and urinary incontinence
Frontopolar	Early loss of consciousness, "pseudo absence," adverse and subsequent contraversive movements of head and eyes, axial clonic jerks, falls, autonomic signs with frequent generalization
Orbitofrontal	Complex focal motor seizures with initial automatisms or olfactory hallucinations, autonomic signs, and urinary incontinence
Dorsolateral (premotor)	Simple focal tonic with versive movements and aphasia and complex focal motor activity with initial automatisms
Opercular	Mastication, salivation, swallowing and speech arrest with epigastric aura, fear, and autonomic phenomena. Partial clonic facial seizures may be ipsilateral, and gustatory hallucination is common

ictal EEG abnormalities, and sometimes are mistaken for psychogenic seizures.

### **Autosomal Dominant Nocturnal Frontal Lobe Epilepsy**

Autosomal dominant nocturnal frontal lobe epilepsy (ADNFLE) was first described as a distinct clinical syndrome in six families in 1994 (81, 82). Mutations have been found in two genes, *CHRNA4* and *CHRN2*, which

code for the neuronal nicotinic acid receptor subunits (83). Seizures begin in childhood (mean age 11.7 years, range 2 months–52 years) and usually persist through adult life. Individuals frequently have an aura followed by a gasp, grunt, or vocalization, and thrashing hyperkinetic activity or tonic stiffening with or without superimposed clonic activity (84). Seizures typically occur in clusters during sleep, and awareness is usually retained. Patients are of normal intellect with normal neurologic examination and neuroimaging tests. Interictal EEG is usually normal. When

**TABLE 27-2**  
*Differentiating Features of Frontal versus Temporal Lobe CPS*

	FRONTAL	TEMPORAL
Duration	Brief < 30 seconds	60–90 seconds
Time of day	Night > day	Day > night
Clusters	Common	Uncommon
Aura	General body sensation; cephalic aura	Epigastric, psychic
Automatisms	Proximal and coarse; bicycling movements, pelvic thrusting	Distal and discrete, oroalimentary, manual, gestural, mimetic, ictal speech, perseverative, ictal vomiting
Motor posturing	Bilateral, asymmetric tonic	Contralateral dystonic posturing, often with automatisms on the opposite side
Vocalizations	Prominent	Less common
Partial loss of consciousness	Noted earlier in the seizure	Noted later in the seizure
Version	Ipsilateral head deviation followed by contralateral version before secondary generalization; is usually < 18 seconds after onset	Contralateral version precedes generalization, usually occurs after 18 seconds

not obscured by movement artifact, ictal EEG may show bifrontal epileptiform discharges. Seizures are often misdiagnosed as parasomnias, paroxysmal nocturnal dystonia (which may in actuality be ADNFLE), familial dyskinesia, or a psychiatric disorder. The seizures frequently respond to carbamazepine or oxcarbazepine monotherapy.

### RASMUSSEN SYNDROME

Rasmussen syndrome (RS) is characterized by intractable focal motor seizures, declining cognitive function, progressive hemiparesis, visual field abnormality, and contralateral focal, predominantly perisylvian cortical atrophy. Changes in signal intensity may also be seen in the deep gray and white matter. The onset of the disease occurs at 10 years or younger in 85% of patients (85). Epilepsia partialis continua or focal motor status occurs in one-half of patients at some point in their course (86). The etiology is not known, but an autoimmune process is important in the pathogenesis of RS, and it is believed that the glutamate receptor subunit, GluR3 may be an important autoantigen (87–89). Neuropathology characteristically shows perivascular lymphocytic cuffing and proliferation of microglial nodules in the cortex of the affected hemisphere (90–92). In-situ hybridization techniques were reported to show most Rasmussen patients to have neurons with cytomegalic inclusion virus (93); this, however, has not been confirmed by others. T-cell-mediated cytotoxicity may also play a role (94). Following cleavage of the GluR3 protein by Granzyme B, the immunogenic section of the GluR3 protein becomes exposed to the immune system (95).

The EEG may show background slowing, disruption of sleep architecture, and frequent epileptiform discharges over the affected hemisphere; with progression of the disease, the spikes may become bilaterally synchronous and appear in the contralateral hemisphere (96–98). Computed tomography (CT) and MRI scans may show diffuse atrophy of the involved hemisphere (99). Proton MR-spectroscopy may reveal decreased *N*-acetylaspartate (NAA) concentration in patients with RS (100). This finding correlates well with brain atrophy and neuronal loss. For reasons that are not yet clear, Rasmussen encephalitis is essentially a unilateral disease.

Rasmussen syndrome is notoriously difficult to treat and does not show the same dramatic response to IV medications as do other forms of status. IV immunoglobulin, high-dose steroids, or both may produce some reduction of seizure frequency in the short term in a few cases (101), but surgical removal of the affected hemisphere is the standard therapy (102). A trial of tacrolimus was found to slow the rate of neurologic deterioration, but it did not improve seizure frequency (103).

In the Johns Hopkins experience, 88% of children who underwent hemispherectomy became seizure free or

have occasional, nondisabling seizures (102, 104, 105). Early hemispherectomy, although increasing the hemiparesis, reduces the overall burden of the illness because of a marked decrease in both frequency and severity of seizures. Because hemiplegia is inevitable with or without surgery, early surgery may allow the child to return to a more normal life by preventing the cognitive decline that is the result of constant seizures.

### DIFFERENTIAL DIAGNOSIS

Pseudoseizures are in the differential diagnosis of any seizure, especially if presenting with bizarre and unusual patterns or prolonged generalized seizures with intact memory for the event. There usually is no postictal confusion. Pseudoseizures often can be terminated abruptly with suggestion (108, 109). The frequency of pseudoseizures may be unrelated to antiepileptic drug (AED) levels. Video-EEG monitoring reveals no seizure pattern during the episode. Psychogenic unresponsiveness (that is, unresponsiveness during the presence of a preserved alpha background rhythm) is also very helpful. Pseudoseizures occasionally coexist with true seizures, and the monitoring must document all the seizure types reported by the family. Migrainous phenomena (108) may be difficult to distinguish from CPS, especially if they are associated with visual hallucinations or confusion. Migraine and partial seizures may coexist, or at times migraine may be followed by a partial seizure. The prodrome of the migraine attack usually develops more slowly than the epileptic aura. The frequent occurrence of vomiting and family history make this diagnosis more likely. The recording of a typical episode in the laboratory with EEG and video monitoring is helpful.

### Radiologic Findings

MRI is the imaging modality of choice in a child with partial or localization-related epilepsy because of its inherent advantages in soft tissue contrast, spatial resolution, multiplanar capabilities, and lack of bone artifact. Kuzniecky and coworkers correlated the MRI imaging results with pathology in 44 children with intractable epilepsy and showed a potential epileptogenic abnormality in 86% of patients (109). CT scanning is inferior in detecting lesions that may be seen only on MRI, with the exception of revealing intracranial calcification in Sturge-Weber syndrome, congenital brain infections such as toxoplasmosis, or cytomegalovirus. MRI reliably demonstrates hippocampal atrophy in 70% to 90% of patients with mesial TLE (110, 111). Accurate assessment of hippocampal size by volumetric studies has been shown to correlate with severity of neuronal loss in the hippocampus (112) and seizure outcome following resection (113). MRI has led to increased recognition,

better characterization, and improved understanding of malformations of cortical development (MCD). The generalized MCDs include lissencephaly, pachygyria, band or laminar heterotopia, and subependymal heterotopias. Localized forms of MCDs include focal cortical dysplasia, polymicrogyria, focal subependymal heterotopias, and schizencephaly (114, 115). The identification of a focal MCD and complete removal of the lesion is followed by good seizure control in 77% of the patients (116). MRI is very sensitive in detection of tumors; vascular malformations such as cavernous hemangiomas, arteriovenous malformations, and subependymal nodules; and cortical tubers in tuberous sclerosis. Positron emission tomography (PET) scans may show an area of hypometabolism interictally and a focus of hypermetabolism on ictal scans (98, 99). Unilateral temporal lobe hypometabolism is present in 70% to 80% of patients with TLE (117) and corresponds pathologically and anatomically to the depth electrode localization of the epileptic zone (118). Focal cortical dysplasia (FCD) may be difficult to visualize in very young children because of incomplete myelination. Interictal PET is useful in demonstrating areas of hypometabolism corresponding to FCD in infants and children with catastrophic epilepsy. In the early stages of Rasmussen encephalitis, the MRI may be normal, but the PET scan may show focal or diffuse hemispheric hypometabolism. Flumazenil PET reveals a reduction in benzodiazepine receptor binding in the epileptic focus of partial epilepsy (119). Carfentanil PET studies of TLE have revealed increased mu-opiate receptor binding in the neocortex of the epileptogenic temporal lobe, correlating directly with a decrease of glucose metabolism seen on FDG-PET (120). Single-photon emission computed tomography (SPECT) has been used in patients with refractory seizures considered for epilepsy surgery. Interictal SPECT demonstrates hypoperfusion in 40% to 70% of patients with focal epilepsy (121). Ictal SPECT has been reported to have a localization accuracy of 70% to 100% in TLE (122) and in up to 90% of selected patients with frontal lobe epilepsy (123, 124).

### Interictal EEG

The interictal EEG may be normal in 30% to 40% of patients with clinically documented partial seizures. A normal EEG, however, does not rule out the diagnosis of epilepsy. The chance of finding an abnormality is increased by performing repeated or prolonged EEGs, sleep recordings, additional closely spaced electrodes, appropriate montages, and hyperventilation. With these techniques, the yield may be increased up to 90% (125–127). A unilateral temporal lobe focus is found in most cases of CPS. Bitemporal sharp wave foci are seen in 25% to 33% of patients (118). An extratemporal focus is seen in 15% to 20% of patients, usually in the frontal lobe (13). Focal intermittent rhythmic slowing may be seen

intermittently in approximately half the patients with focal seizures (125–128) and has the same significance as focal spikes. One may also find focal slowing that is nonrhythmic with suppression of the normal background rhythms in 75 percent of patients (125). It is important to exclude nonepileptiform sharp transients such as small sharp spikes, psychomotor variant, or 14- and 6-Hz spikes. Additionally, benign focal epileptiform discharges of childhood may occur in asymptomatic children (129). These usually are found in the central or midtemporal location, have a characteristic stereotyped waveform, and are markedly activated during sleep.

### Ictal EEG

According to Gastaut (130), the ictal EEG is abnormal in more than 95% of cases. In 75% of patients, the interictal spikes or sharp waves show an abrupt cessation or decrease just before ictal onset. This is then followed by rhythmic activity that shows a progressive buildup of amplitude and frequency (most often in the 13- to 30-Hz range, but possibly in the theta or delta range). This may be well localized to the area of the focus, or it may be more widespread over that hemisphere (125). Focal beta activity at seizure onset seen in scalp recordings occurs in 25% of patients with FLE and is felt to be predictive of good outcome after focal resection (131). Postictally, one may find slowing or flattening, which, if focal, may be helpful in lateralization (132). Sometimes it is difficult to localize or lateralize the seizure onset from scalp recordings. Invasive recordings with subdural or depth electrodes may be indicated in such cases (132–138).

### PROGNOSIS

Contrary to previous reports that stated that up to one-third of patients with CPS became seizure-free (139), our experience and that of others indicates that although some patients do become seizure free on medication, spontaneous remission (that is, seizure free off medications) is rare (140). Pazzaglia and coworkers reported that good seizure control was achieved in 31% of patients with simple partial seizures, 37% of those with complex partial seizures, and 61% of those with secondarily generalized epilepsy (141). Loiseau and coworkers found that seizure control could be predicted after 1 year of treatment (142). Thus, it should be possible to document medical intractability within a couple of years after seizure onset. Such patients should undergo prolonged video-EEG monitoring, high-resolution MRI, nuclear imaging (PET, ictal SPECT), and functional assessment. If found to be suitable candidates, epilepsy surgery should be performed sooner rather than later to minimize compromise of psychosocial and intellectual function.

## Selected Disorders Associated with Epilepsy

*Lawrence D. Morton*

**C**ertain diseases and clinical syndromes should be suspected by their presentation with particular types of epilepsy, seizures, or EEG characteristics. A case in point would be the infant who presents with infantile spasms and is found to have hypsarrhythmia on the electroencephalogram (EEG). The clinical evaluation should include an ultraviolet light (Wood's lamp) examination of the skin for hypomelanotic macules (1, 2). The diagnosis of tuberous sclerosis may be confirmed by neurologic evaluation and brain imaging with either computed tomography (CT) or magnetic resonance imaging (MRI). In a similar manner a variety of uncommon diseases in which epilepsy is a prominent symptom can be suspected by recognizing distinctive forms of epilepsy. Additionally, seizures may arise in disorders that otherwise do not have prominent neurologic features. In this context, seizures are important "red flags" that may indicate a cerebral insult and the potential for serious neurologic complications or may be an important prognostic marker. This chapter discusses important examples of childhood disorders in which epilepsy plays a major role.

### NEUROCUTANEOUS DISORDERS

#### Tuberous Sclerosis

Tuberous sclerosis complex is a congenital neurocutaneous disease of autosomal-dominant inheritance and variable expressivity (2). However, only one-third of cases are inherited. Two different mutations have been described that cause the tuberous sclerosis complex: TSC1 (9q34.3) and TSC2 (16p13.3) (3, 4). A mutation in one of these genes can be seen in up to 85% of patients fulfilling clinical criteria for tuberous sclerosis (5). TSC1 encodes a protein called hamartin. Hamartin forms a complex with the tuberin protein, which is encoded by the TSC2 gene, and the complex is thought to function in part as a negative regulator of the cell cycle (6). These proteins appears to participate in normal brain development (7).

Hamartomas, or benign growths, may affect almost any organ but notably the skin, central nervous system (CNS), retina, heart, and kidney. The incidence of tuberous sclerosis varies in different studies from 1 in 10,000 to 1 in 170,000, but with increased evaluation, the disease appears to be more prevalent and not rare (2).

Tuberous sclerosis most often presents with seizures. In all, 80% to 90% of patients develop seizures at some point in their lifetime. Generalized seizures are the most frequent. Infantile spasms occur in 68% of cases presenting in infancy. Tonic, atonic, and atypical absences are also seen, especially in patients who have slow spike-wave EEG patterns and thus conform to the Lennox-Gastaut syndrome. Tonic-clonic seizures usually occur after 1 year of age, replacing other seizure types (8). Complex partial seizures also occur frequently.

Various EEG abnormalities have been documented, depending on the clinical seizure type. Infantile spasms are associated with a hypsarrhythmia, which may progress to multifocal EEG abnormalities including, most frequently, sharp-and-slow-wave discharges and spike-and-wave discharges. In general, the EEG abnormalities relate to the age of onset of the seizures (9, 10).

The neurologic examination is frequently nonfocal; however, focal or diffuse signs occur with increasing size of subependymal or cortical lesions. These include hydrocephalus, movement disorders, visual disturbances, mental retardation, and rare focal motor deficits. The prognosis depends on the number and location of intracerebral lesions. The presence of numerous multifocal lesions correlates with an early onset of difficult-to-control seizures and mental retardation. Approximately 37% of patients with tuberous sclerosis have average intelligence; 50% to 60% are mentally retarded. Seizure-free children usually have normal intelligence. Involvement of other organ systems, especially the heart and kidneys, may affect longevity. Aberrant behavior frequently becomes the most difficult management issue in these children as they become older.

Seizures are surprisingly refractory to treatment. Patients with infantile spasms and myoclonic seizures need to be treated immediately. The treatment of choice for each patient depends on their seizure type, age, and comorbidity (2, 11, 12). Infantile spasms are treated with adrenocorticotrophic hormone (ACTH), valproate, vigabatrin, zonisamide, or topiramate (13, 14). Vigabatrin has been reported to be efficacious in the treatment of refractory infantile spasms.

Surgical treatment for focal abnormalities, or tubers, primarily correlated by EEG evidence of partial seizures, has been quite successful (12) (see Chapters 62 and 63). Traditionally, patients with tuberous sclerosis were considered poor surgical candidates. Recently, centers have been performing more epilepsy surgery in these patients and with good results (15). Agreement between EEG, imaging of tubers, and clinical seizures allows this group to compare favorably with other lesional epilepsy surgery outcomes, and seizure-free rates of over 80% have been reported (16).

### **Neurofibromatosis (von Recklinghausen's Disease)**

Neurofibromatosis is inherited as an autosomal-dominant disorder. There are two main types: NF1 (also known as Von Recklinghausen's disease or peripheral neurofibromatosis) and NF2 (also known as bilateral acoustic neurofibromatosis). NF1 is by far the more common and the classic form. NF1 has an incidence of 1 in 4,000 births. Central or acoustic neurofibromatosis, NF2, causes acoustic neuromas, not cutaneous or bony abnormalities. NF1 has been mapped to 17q11.2 and NF2 to the long arm of chromosome 22 (17, 18).

Classic neurofibromatosis is characterized by pigimentary abnormalities and neurofibromas (17, 19). Skin lesions include café-au-lait spots (6 or more > 0.5 cm in prepubertal children and > 1.5 cm in postpubertal children) and intertriginous freckles. Lisch nodules in the iris are present in a minority of affected young children but increase with age. Neurologic features include seizures in 3% to 6% (20, 21), though an incidence as high as 10% has been reported (22); occasional mental retardation, learning disorders, and a heightened risk of developing glial CNS tumors, with visual path glioma being most common in NF1. Although cortical heterotopias are found in rare cases, most often the pathogenesis of epilepsy and learning problems is unclear. Other features include growth disturbances, osseous aplasia or hyperplasia, macrocephaly, scoliosis, precocious puberty, and cerebrovascular lesions causing stroke. There is an increased risk of malignancies, which can limit longevity.

The treatment of seizures associated with neurofibromatosis is dependent on seizure type and whether a specific intracranial mass lesion is present. Most patients are treated with chronic antiepileptic drug (AED) therapy, with very few having spontaneous remission of their epilepsy.

### **Sturge-Weber Syndrome**

Sturge-Weber syndrome is characterized by a portwine stain unilaterally over the upper face, superior eyelid, or supraorbital region, corresponding to the sensory component of the ophthalmic branch of the trigeminal nerve. Buphthalmos or glaucoma is the most characteristic and constant ocular lesion (23). Intracranial calcification occurs in 90% of cases. Seizures are often the presenting symptom and usually in early childhood. The percentage of patients manifesting partial or secondarily generalized seizures increases steadily with age, so that by age 5 years nearly 95% of patients have seizures (24). Seizures are more common with bilateral cutaneous manifestations (87–93%) than unilateral (71%) (24, 25). EEG reveals decreased amplitude and frequency over the affected hemisphere with diffuse multiple and independent spikes (26).

Surgical removal of the affected lobe or hemisphere should be considered when seizures are refractory. Significant improvement in seizure control with no disabling deficit is often seen. Seizure freedom has been seen in up to 81% (27). Results of limited cortical resection were not as dramatic, though there was also relief of seizure activity (28). Tuxhorn and Pannek reported two children with bilateral Sturge-Weber syndrome who benefited from hemispherectomy, suggesting that removal of the dominant epileptogenic focus can be considered in some patients with bilateral disease (29).

### **Hypomelanosis of Ito**

Hypomelanosis of Ito is characterized by macular cutaneous hypopigmentation in patterns of whorls, streaks, and patches, as well as generalized abnormalities. Associated neurologic abnormalities, seen in 61% to 100% of patients, include developmental delay and refractory seizures, sometimes manifesting as infantile spasms (30, 31). Cortical atrophy is seen on imaging studies. The EEG abnormality shows no consistent pattern (32). Seizures occur in 53% (33). No specific antiepileptic drug treatments tailored to the underlying etiology have been recommended; instead, medications are usually selected to treat the seizure type. Surgery has been used successfully but with very few patients (34).

### **Incontinentia Pigmenti**

The skin lesion of incontinentia pigmenti, which is seen mostly in girls, has three stages. Initially, one sees macular papular vesicular and even bullous lesions occurring in the first 2 weeks of life and located primarily over the limbs or trunk. This stage is followed by a keratotic verrucous lesion over the limbs, followed by hypopigmentation or skin atrophy. Subsequent pigmentation then occurs. The CNS is commonly involved, with generalized and focal seizures in 9 percent to 13 percent of patients, typically satisfactory control is often achieved (35). Retardation, spasticity, and microcephaly occur in 5% to 16%. Ocular abnormalities occur in one-third of the patients (36).

### **Epidermal Nevus Syndrome**

Epidermal nevi may be present at birth or may develop later, usually around the time of puberty. The skin lesions are slightly raised, ovoid, or linear plaques. As the patient approaches puberty, the lesions may change from skin-colored to an orange-brown and become verrucous (37). Epilepsy, mental retardation, and focal motor deficits are the most commonly encountered neurologic manifestations. Seizures are present in the majority of patients with linear sebaceous nevus (38). A variety of congenital malformations

of the CNS have been described including hemimegalencephaly, heterotopias, and schizencephaly (39). A wide variety of seizure disorders may be seen in this disorder.

## **METABOLIC DISORDERS**

Various diseases with underlying inborn metabolic abnormalities may cause epilepsy characterized by a particular EEG abnormality (40). Early identification and appropriate treatment of these specific disorders frequently leads to the best treatment of seizures and optimal developmental outcome. AEDs, however, are sometimes necessary adjuncts.

### **Urea Cycle Disorders**

Urea cycle disorders occur in 1 in 30,000 births. Seizure activity may be the presenting symptom associated with hyperammonemia, which can be precipitated or worsened by valproate therapy in unrecognized ornithine transcarbamylase deficiency (41). Deficiencies of ornithine transcarbamylase and arginosuccinic acid lyase have resulted in abnormal EEG activity characterized mainly by multiple spikes, spike waves, or slow-and-sharp-wave activity. The EEG normalizes with successful treatment of the metabolic disorder (42). Citrullinemia also has presented with seizure activity and an EEG with multifocal spikes (43). However, there is a lag in EEG normalization after treatment (peritoneal dialysis) in this condition. Neurologic deficits persist in reported cases (44).

### **Phenylketonuria**

Phenylketonuria, when untreated, may be associated with infantile spasms and hypsarrhythmia. Phenylketonuria is caused by a deficiency in hepatic phenylalanine hydroxylase, whose gene is located at 12.q24.1 (45). In treated phenylketonuria there is an increased prevalence of EEG abnormalities manifesting as generalized slowing with or without spikes (46). With advancing age, the EEG abnormalities increase but lack any relationship to IQ or dietary treatment (47).

### **Menkes Disease**

Menkes kinky hair disease, a sex-linked disorder with its gene located on the long arm of the X chromosome, causes a marked reduction of serum copper and serum ceruloplasmin levels. Patients typically present at 2–3 months of age. The clinical findings consist of mental retardation, poorly pigmented fragile hair, hypotonia, and generalized seizure activity, frequently infantile spasms (48). Milder forms have been described with less or minimal neurologic sequelae; the mildest Menkes variant is known as

occipital horn syndrome, in reference to the pathognomonic wedge-shaped calcification that forms within the trapezius and sternocleidomastoid muscles at their attachment to the occipital bone in affected individuals (49). Parenteral copper benefits some patients with Menkes disease. This may reflect preservation of some activity of certain copper ATPase alleles (50).

### **Glycine Encephalopathy**

Glycine encephalopathy, also known as nonketotic hyperglycinemia, is an autosomal recessive disorder caused by defective function of the multimeric glycine cleavage enzymes. The most common defect, affecting the P protein, is encoded by a gene localized to 9p22. Glycine is elevated in the plasma, urine, and cerebrospinal fluid (CSF). The lack of ketones helps differentiate between nonketotic hyperglycinemia and organic acidurias such as methylmalonic acidemia and propionic acidemia. Infants with the classic form of the disease present in the first week after birth with apnea, lethargy, and hypotonia (51). Intractable seizures develop; the EEG demonstrates burst-suppression or hypersarrhythmia (52). Brain imaging in nearly one half of patients with glycine encephalopathy shows congenital abnormalities including atrophy and agenesis of the corpus callosum (41C). Valproate is contraindicated, because it induces hyperglycinemia (53).

### **GM2 Gangliosidosis**

GM2 gangliosidosis (Tay-Sachs and Sandhoff diseases) have seizures as a frequent complication, particularly in the infantile form. The first symptom is an excessive startle in response to noise, tactile stimuli, or light flashes. This startle response in patients with Tay-Sachs disease, which differs from the Moro response of normal infants, consists of a quick extension of the arms and legs, frequently with clonic movements. There is arrest in development, and axial hypotonia ensues. During the second year after birth, macrocephaly develops, and seizures become more prominent. These may be myoclonic or gelastic and can be induced by auditory or tactile stimulation (54). Later, blindness develops and patients become increasingly less responsive. Autonomic dysfunction is a frequent finding including apnea. In Sandhoff disease the only clinical differences compared to Tay Sachs's disease are mild hepatosplenomegaly, secondary to storage of globoside, and bony deformities (54).

### **Pyridoxine-Dependent Seizures**

Seizures beginning in the first week after birth may have pyridoxine dependency. Associated symptoms may include episodes of restlessness, irritability, and feeding difficulties. The seizures are refractory to standard

anticonvulsant medications but respond well to pyridoxine administration (55). Atypical forms are common and may outnumber the classical form. Features include late onset after the first week but typically in the first months after birth, transient response to standard therapy, and atypical seizures (56). Very late forms have been described (57), as well as response following failed trials during infancy (58). Some cases have localized to the gene at chromosome 5q31.2–q31.3 (59).

### **Porphyria**

Although porphyria does not become symptomatic until after puberty, it occasionally affects older adolescents. Seizures commonly occur in 15 percent of patients with porphyria, usually during an acute attack. Seizures may be partial or generalized. Therapy of chronic seizures in these patients must avoid drugs that increase porphyria precursors and induce attacks. This includes all commonly used AEDs (60), although gabapentin and levetiracetam should be safe and effective.

### **Biotinidase Deficiency**

Skin rashes and striking neurologic symptoms with seizures are prominent signs of biotinidase deficiency. Hypotonia, developmental delay, and seizures are presenting features in the neonatal form. In the late-onset type, 1 week to 2 years onset, the most common presenting feature is seizures. The most common seizure type is myoclonus, although generalized tonic-clonic and focal clonic seizures have been described (61). Ataxia and hypotonia are present, as are rash and alopecia. Hearing loss may occur. Treatment is oral biotin with rapid response within 24 hours (61, 62).

### **Other Inborn Errors of Metabolism**

Other inborn errors of metabolism may be associated with generalized seizure activity. These include maple syrup urine disease, galactosemia, organic acidurias, hyperammonemia, and peroxisomal disorders, to mention only a few.

## **INFECTIONS**

Infants with prenatal intracranial infections often present with postnatal seizures. A common infection is cytomegalovirus (63). In particular, infants with neonatal herpes simplex encephalitis may have specific EEG patterns consisting of periodic or quasiperiodic patterns. Thus, a periodic pattern in a young infant with partial motor seizures and lymphocytic CSF pleocytosis is highly suggestive of herpes virus encephalitis (64), cytomegalovirus, or toxoplasmosis (65).

### Human Immunodeficiency Virus

HIV has emerged as a major prenatal infection with significant neurologic morbidity. Approximately 90 percent of prepubertal cases reflect intrauterine or intrapartum infection. The predominant clinical finding is a triad of impaired brain growth, progressive motor dysfunction, and plateau or loss of developmental milestones (66, 67). In children, CNS effects usually result from direct HIV-1 infection, not from tumors or opportunistic infections, in contrast to adults (66). Seizures occur at only a slightly higher incidence in the pediatric HIV-1 population (68) than in the uninfected population. Seizures may be the presenting symptom in children with new stroke as a complication of HIV (69, 70). The incidence of new-onset seizures in HIV patients has been found to be between 4% and 11%, with most having advanced AIDS (71). The presence of a seizure leads to a workup, including neuroimaging, to look for coexisting focal pathology (72) or opportunistic infection.

### Subacute Sclerosing Panencephalitis

This condition was first reported in 1993 as an inclusion body encephalitis. Measles virus is the causal agent and persists in the CNS. Virus persistence appears to be a result of a defect in replication. The progression of the illness has been broken into four stages, with stage I including mild behavioral and intellectual changes and stage IV including flexor posture, mutism, and autonomic instability. Seizures typically develop in stage II. Myoclonus is the best known and typically is periodic and stereotypic. The EEG demonstrates periodic complexes of high-amplitude delta waves occurring every 4 to 12 seconds and are synchronous with the myoclonic jerks (73). Other seizure types include akinetic, atypical absence, generalized tonic-clonic, and focal clonic (74). The prognosis is grave even with treatment, with a median survival of 1 year. Although this condition had become quite rare, an outbreak due to overall low vaccination rates in 1989 to 1991 caused a 10-fold increase in biopsy-proven cases from 1992 through 2003 (75).

### Acute CNS Infections

Any acute infection of the CNS may lead to seizures, including bacterial meningitis, viral encephalitis, focal cerebritides, and parasitic infections. Bacterial meningitis should be suspected and excluded by lumbar puncture in any child with seizures in the setting of headache, fever, and meningeal signs. The causal agent typically varies with patient age.

Acute viral encephalitis may produce seizures. Herpes simplex is the most common infectious encephalitis associated with seizures (76). In herpes simplex encephalitis,

patients may have a prodrome of malaise, fever, headache, and nausea. This is followed by acute or subacute onset of an encephalopathy whose symptoms include lethargy, confusion, and delirium. Headaches, seizures, aphasia, and other focal deficits may follow. Even with modern treatment, mortality in children may be as high as 20%, and an even larger percentage suffer permanent neurologic sequelae (77). Other viral encephalitides associated with seizures include California, Japanese, and St. Louis encephalitides as well as Eastern and Western encephalitides.

Parasitic infections of the central nervous system may lead to seizures. Although this is more common in the immunosuppressed, some infections may occur in immunocompetent patients. Cysticercosis is caused by the metacystode, or larval stage, of *Taenia solium*, the pork tapeworm. Cysticerci that enter the CSF are initially viable but do not cause much inflammation in surrounding tissues; this phase of infection is usually asymptomatic. The host develops a state of immune tolerance to the parasite, and cysticerci can remain in this stage for many years. Most patients remain in this stage for life. Cysticerci do not produce clinical symptomatology until the cysts begin to degenerate. The leaking cyst leads to a surrounding inflammatory reaction. The most common neurologic manifestation is seizures, occurring in about 75% (78). Trichinosis results from ingesting the nematode parasite *Trichinella* from contaminated pork. Trichinosis has two stages: an intestinal stage and a muscle stage, during the latter of which neurologic symptoms may occur. Involvement of the CNS occurs in 10% to 20% of patients. The mortality rates may be as high as 50% (79). Neurologic disease may develop early or late, and can be diffuse or focal in nature and may include seizures.

### Systemic Infections

Systemic infections may lead to seizures, mostly by alterations in electrolytes or other effects such as hypoxia, such as in pneumonia. *Shigella*, however is associated with a high frequency of seizures in young children, occurring in one series at 5% (80). This large study also suggested that factors other than *Shigella* toxin were the cause of the seizures.

### CHROMOSOMAL ABNORMALITIES AND CONGENITAL BRAIN ABNORMALITIES

Chromosomal abnormalities, including trisomy 13 and 21, may result in infants and children with seizure activity. Approximately 20 percent of patients with fragile X syndrome have seizures (generalized or partial) with spikes similar to rolandic spikes, which are noted during sleep tracings (81, 82). Five percent to 6% of children with

Down syndrome (trisomy 21) have seizures (83). Infantile spasms may occur but are fairly responsive to therapy.

Congenital malformations with neurologic deficits can cause infantile spasms and hypsarrhythmia as well as other seizure types. The Aicardi syndrome, an X-linked dominant syndrome limited to females, is marked by agenesis of the corpus callosum, mental retardation, vertebral anomalies, and chorioretinal lacunae. In patients with seizures, 97% have had infantile spasms, with many having other seizure types (84). Patients with septo-optic dysplasia, with absence of septum pellucidum, optic nerve hypoplasia, and hypothalamic-pituitary dysfunction, can also present with infantile spasms (85). Various brain gyral malformations such as lissencephaly, agyria-pachygyria, and others may cause infantile spasms or other seizure types (86–88).

### Angelman Syndrome

Angelman syndrome occurs in children with a history of nonprogressive delayed development from infancy. Jerky limb movements, stiff ataxic-like gait, paroxysms of inappropriate laughter, and lack of speech are characteristic. Distinctive facial features with a prominent lower jaw, wide mouth, frequent tongue thrusting, and a thin upper lip are consistent. A chromosomal abnormality of maternal origin 15q11–13 has been detected in patients with Angelman syndrome (89).

Seizure activity is a frequent presenting symptom and is found in 86 percent of patients (90). Seizures commence at an early age, appearing by age 11 months at the earliest but often by 2 years of age. Myoclonic, atypical absence, generalized tonic-clonic, and unilateral clonic seizures are the typical clinical patterns, whereas infantile spasms are rare (91–93). In one series almost all patients had nonconvulsive seizures (94). The EEG demonstrates large-amplitude generalized spike-wave activity that may precede the clinical manifestation of seizures. Runs of rhythmic delta may be seen with either a frontal or an occipital predominance. There are often admixed spikes which have an inconsistent relationship to the slow waves, sometimes occurring on the descending portion of the slow wave and giving a “notched” appearance. This large rhythmic activity persists in sleep. The spike-wave activity also tends to be accentuated with eye closure. Thus, this facilitation of the EEG pattern with eye closure and the general pattern present from 1 year of age is suggestive of Angelman syndrome (95). This EEG pattern appears to persist, is not modified by AEDs, and may not be consistently correlated with clinical features. Other EEG findings include high-amplitude 4–6-Hz activity and posterior spike and sharp waves (96). Brain imaging shows variable results, with brain atrophy in perhaps 50 percent of patients. Correlation exists between epilepsy phenotypes and genotypes (97).

### Prader-Willi Syndrome

Prader-Willi syndrome consists of short stature, small hands and feet, obesity, and mental retardation preceded in infancy by hypotonia and feeding difficulty. Boys have hypoplastic, flat scrotums with inguinal or abdominal testes. Seizures occur in 15% to 20% (98–100). It is rare to find the distinct EEG features of Angelman syndrome in Prader-Willi syndrome, though some cases exist (100). Although most cases are sporadic, concordance in monozygotic twins has been reported (101).

The disorder results from the specific deletion of 15q11–13 of paternal origin (102). The same region is deleted in Angelman syndrome; the different syndromes result from genetic imprinting (103).

### Miller-Dieker Syndrome

Miller-Dieker syndrome includes microcephaly and lissencephaly, epilepsy, profound mental retardation, and occasional anomalies of the heart and genitalia (104, 105). Characteristic features include flat midface, prominent forehead, protuberant upper lip, and small jaw. It results from a deletion of the terminal end of the long arm of chromosome 17p13.3. Smaller deletions in chromosome 17 have also resulted in lissencephaly but without the typical facial features (106, 108). Overall, about 25 syndromes of different genetic basis and varying associated symptoms have been described (108). Infantile spasms are found in almost all Miller-Dieker and isolated lissencephaly syndrome patients. The infantile spasms usually respond to corticotropin. The other seizure types may respond to any seizure medicine. Corpus callosotomy has been used to treat an 11-month-old with bilateral lissencephaly and intractable tonic seizures (109).

## MITOCHONDRIAL ENCEPHALOMYOPATHIES

The mitochondrial encephalomyopathies consist of a heterogeneous group of multisystem disorders. Seizures are a common finding in this class of disease. Seizures are a defining symptom in myoclonic epilepsy with ragged red fibers (MERRF) and are a common feature in mitochondrial encephalomyopathy, lactic acidosis, and stroke-like episodes (MELAS). Seizures are uncommon in Kearns-Sayre syndrome.

### Myoclonic Epilepsy with Ragged Red Fibers

Ataxia, intention and action myoclonus, and progressive mental deterioration have been reported in MERRF. Associated with these features, aggregates of mitochondria in skeletal muscle, known as ragged red fibers, are demonstrated by muscle biopsy. A specific mutation in

mitochondrial DNA was discovered, a missense mutation in the gene for transfer RNA for lysine that accounts for 80% to 90% of MERRF cases (110). Generalized tonic-clonic seizures that are photosensitive are a feature and may be a presenting symptom. Spike-wave complexes occurring spontaneously and coinciding with myoclonic activity occur (111).

Mitochondrial myopathies associated with myoclonic epilepsy have been described occurring in families. Recently, mitochondrial abnormalities have been reported in Rett syndrome (112), discussed in a later section. In most reported mitochondrial myopathies, EEGs typically show generalized spike-wave activity. Seizure control is difficult in severe cases (113). The seizures of MERRF have been treated with typical antiseizure agents. Levetiracetam has shown encouraging results in a small number of patients (114).

### **Mitochondrial Encephalomyopathy with Lactic Acidosis and Strokelike Episodes**

MELAS has among its defining features strokelike episodes, typically before age 40; encephalopathy characterized by dementia, seizures, or both; and evidence of a mitochondrial myopathy with ragged red fibers, lactic acidosis, or both. A variety of point mutations have been described that are causal, though one mutation accounts for about 80% of cases (115). Patients with MELAS frequently have seizures. In one group, seizures were the initial clinical symptom in 28%. They were sometimes associated with a strokelike episode. Seizures were both generalized and partial (116). Partial seizures were most typically motor. Seizures typically respond to conventional antiseizure agents, though valproate may exacerbate the disorder (117).

## **AUTISM AND AUTISTIC SPECTRUM DISORDERS**

Autism is a heterogeneous, pervasive developmental disorder (118). Markedly abnormal or impaired development in social interaction and communication skills are evident in the first 3 years. Patients are often described as either passive or overly irritable as infants, and they fail to anticipate being picked up. Dysfunctional behaviors may start to appear, such as self-stimulatory behaviors (i.e., repetitive, non-goal-directed behavior such as rocking or hand flapping), self-injury, sleeping and eating problems, poor eye contact, insensitivity to pain, hyperactivity, and attention deficits (119, 120). More than a third, 41.9%, fall in the severe to profound range of mental retardation (121). However, cognitive skills in individuals with autism may show uneven development.

Underlying disorders include congenital infections (rubella, cytomegalovirus), phenylketonuria, tuberous

sclerosis, fragile X, and Rett syndrome, though an etiology is not determined in up to 90% (122). Researchers have located several brain abnormalities in individuals with autism; however, the reasons for these abnormalities is not known, nor is the influence they have on behavior. Selective hypoplasia of the neocerebellar vermis has been reported on midsagittal MRI of autistic patients (123), while in another study, total cerebellar volume has been increased (124). Recent studies show that the cerebellum may have a modulatory role in a wide array of neurobehavioral functions including learning (125), communication, attention, and socialization in addition to motor behavior. Abnormalities have been seen in the amygdala and hippocampus; damage to this region in monkeys has led to autistic-like behavior (126). Dysregulation in serotonin has also been found in some patients with autism (127), while others have implicated dopamine, norepinephrine, or neuropeptide function. There is some indication of a genetic influence in autism. A 60% concordance for autism was found in monozygotic twin pairs versus 0% in dizygotic twins, with an estimated heritability of over 90% in one study (128).

Electroencephalographic abnormalities are present in 27% to 77% of individuals (129, 130). However, many individuals have abnormal EEGs but not clinical epilepsy. Incidence of clinical epilepsy has been observed to be as high as 40% with higher rates in children in the more impaired range of autism (131).

Treatment has focused primarily on the behavioral aspects. In addition to medications, behavioral, educational, and language training have been employed. Commonly used medications include selective serotonin reuptake inhibitors (SSRIs) as well as classic and newer neuroleptics; stimulants are also commonly used. Many of the antiseizure medications, particularly valproate, have been used to treat behavior problems in a variety of patients with different medical and psychiatric problems. This has been true in autism as well. Many experts have found antiseizure medications to be of benefit for behavior problems as well as treating seizures (132). Antiseizure medications may be employed in children with autism who do not also have seizures. There is preliminary evidence supporting the hypothesis that there is a subgroup of autistic children and seizures who preferentially respond to antiseizure medications (133, 134).

### **Acquired Epileptic Aphasia (Landau-Kleffner Syndrome)**

Landau-Kleffner syndrome is typified by the loss of receptive and expressive language in association with paroxysmal EEG changes and, in some cases, seizures (135). Partial seizures in the dominant hemisphere both acutely and postictally may be associated with transient aphasia. However, in this disorder children who have

developed normal language then experience a progressive deterioration of language (136). Age of onset ranges from 3 to 8 years, and boys are more frequently affected than girls (137). Diffuse or focal spike-waves with temporal preponderance are present, as are temporal metabolic abnormalities. Magnetoencephalography shows a vertical dipole located in the superior surface of the temporal lobe that is 2–3 cm deep (138). Seizure activity may occur at a much later stage. The aphasia rarely improves with seizure control (139, 140). These children occasionally may have autistic-like features. The first language disturbance is auditory agnosia. Recognition of the progressive nature of the language dysfunction may result in earlier intervention (141). The relationship to young children with a global autistic regression and epileptiform EEG is controversial (142). A consistent cause remains unknown. A relationship between Landau-Kleffner syndrome and continuous spike-wave of slow-wave sleep remains a subject of discussion. Autistic-like features also may be seen in children with epilepsy—generalized tonic-clonic, absence, and partial complex seizures, either primary or secondary (143).

Treatment with standard antiseizure medications may be effective for the seizures but have had little impact on the aphasia. Drugs such as phenytoin, phenobarbital, and carbamazepine may worsen the EEG discharges and neuropsychologic deficit (144). Treatment with high-dose corticosteroids has been the most successful treatment for the aphasia and intellectual disturbance (145, 146). Other treatments have included subpial transection (147, 148), as well as a small series showing possible benefit with the vagus nerve stimulator (149).

### Rett Syndrome

Rett syndrome is a unique disorder that affects girls almost exclusively and is due to a mutation at the Xq28 chromosome affecting methyl-CpG-binding protein 2 (MECP2) (150, 151). Rare cases in males have been determined. Three types of MECP2 mutations occur: missense, frameshift, and nonsense. The type of mutation may affect phenotypic expression; for example, awake respiratory dysfunction and lower levels of CSF homovanillic acid (HVA) occurred more often with truncating mutations, whereas scoliosis was more common with missense mutations (150). A large majority (80–85%) of cases of classical, sporadic Rett syndrome test positive for the MECP2 abnormality, whereas under 50% test positive in the variant and familial cases (152, 153).

Abnormalities of CSF biogenic amines have also been demonstrated, suggesting neurotransmitter dysfunction (151, 154). MECP2 appears to target the DLX5 gene on chromosome 7q (155). DLX5 may function to induce expression of glutamic acid decarboxylase (GAD) and the differentiation of GABA-producing neurons; therefore, alterations

in GABAergic neurons may be involved in the pathogenesis of Rett syndrome (156).

In the classical form after an apparently normal early development (112), girls with Rett syndrome lose acquired skills. This deterioration involves loss of acquired purposeful motor and hand skills and loss of communication and cognitive functions between 6 and 30 months. Of particular significance is the loss of acquired speech. Deceleration of head growth, stereotypic hand-wringing movements, and gait apraxia occur between 1 and 5 years (157). Apnea, hyperpnea, and breath-holding spells occur. Seizures usually appear at 3 to 4 years of age. Aberrant behavior, manifesting as irritability, sleeplessness, screaming spells, and self-abusiveness, is common. Subsequently, hypertonicity and spasticity can occur, and progressive scoliosis develops. Atypical or variant forms include girls who have some clinical evidence of Rett syndrome, but not enough to meet all the specific diagnostic criteria.

The progression of the syndrome has been divided into four stages (158, 159). Stage I is the period of apparently normal development lasting 6 to 18 months. Stage II, the regression period with stereotypy and autistic features, lasts 1 to 4 years. Stage III begins at approximately 3 years of age, when seizures and ataxia occur. The deterioration may stop and the patient may appear stationary. Stage IV is associated with severe disability and scoliosis. These stages can overlap. The ultimate prognosis is dependent on the degree of immobility and scoliosis and on the level of subsequent care (160).

Seizures occur in a large majority of Rett syndrome patients. One large series out of Sweden found that 94% of patients with the classic disease had epilepsy (161). These may be generalized tonic, tonic-clonic, atypical absence, complex partial, myoclonic, or atonic seizures (158). Multiple seizure types occur in 30% to 40% of patients and may be intractable (159). The seizures usually appear at the age of 3 or 4 years. After 10 years of age it is uncommon for seizures to begin. Seizure types may appear refractory; however, some patients spontaneously improve on reaching adulthood (158, 160, 162). The incidence of clinical seizures may be overestimated, as demonstrated in one study that looked at video-EEG in Rett syndrome patients and determined that about half of the events identified as typical seizures were nonepileptic (163). EEG may be helpful in the diagnosis of Rett syndrome in stages I and II by ruling out Angelman syndrome, in which seizures occur before 2 years of age (164).

EEG changes similarly stratify into stages but do not correlate with the clinical course. During stage I the EEG may be normal or minimally slow. In stage II a rapid EEG deterioration occurs with slowing, loss of both occipital rhythms, and loss of normal sleep characteristics during quiet (non-rapid-eye-movement, non-REM) sleep. Focal epileptiform activity, first during sleep and then in

wakefulness, with subsequent multifocal discharges, then occurs. Stage III is represented by further deterioration with generalized slow spike-wave activity and multifocal discharges during sleep and wakefulness. The EEG remains markedly abnormal during stage IV.

The evolution of EEG changes is distinctive and can aid in the diagnosis of Rett syndrome (165). Multifocal central spikes and spike waves of short duration enhanced by sleep and predating seizure activity is a fairly consistent finding (166–168). These parasagittal spikes are present during the early stages of non-REM sleep and in the early morning hours and can help in differentiating the diagnosis of Rett syndrome from primary autism, in which the EEG usually is normal (169). In some of the episodes, apnea may not be seizure activity (163).

### ALPERS DISEASE (POLIODYSTROPHY)

The phrase *progressive infantile poliodystrophy* has been used to designate a pattern of symptoms including seizures and overall deterioration called Alpers disease. The early cases in the literature were heterogeneous, and confusion about diagnosis and nomenclature initially hampered the understanding of this group of diseases (170, 171). Two distinct groups of patients have subsequently emerged. One group has microcephaly with shrunken “walnut” brains, a progressive degeneration (172). The second group indicates a more uniform spectrum of clinical and pathologic phenotypes that are due to several inborn errors that affect energy metabolism, the Krebs cycle, respiratory chain, and mitochondrial function (173–177). Some of these patients have insidious but progressive liver disease (171, 178), while others are without hepatic failure (179). In recent years, when some of these patients have died with liver failure, valproic acid hepatotoxicity has been blamed (171, 180, 181).

Usually thought to be normal at birth, the children develop a progressive illness manifested by developmental delay, failure to thrive, focal myoclonus, seizures with a propensity for status epilepticus, hypotonia, visual disturbances (blindness is common), eventual paralysis, spasticity, and liver failure (177, 182–184). In addition, many of these patients develop multifocal myoclonic twitching or epilepsy partialis continua of the Kojewnikow variety (180, 181, 185). Variable features include deafness, chorea, and ataxia. They often worsen rapidly during an intercurrent illness. Conventional antiseizure agents may be used, though the physician may wish to avoid valproate given the underlying hepatic dysfunction.

At autopsy, there is atrophy of the hemispheres and the cerebellum. The cortex has diffuse foci of degeneration with neuronal necrosis, astrocytosis, and spongiosis with perivascular and pericellular edema. Other affected structures include the basal ganglia, thalamus, brainstem

nuclei, dentate nucleus, cerebellar cortex, and lumbar spinal ganglia. The predominant hepatic lesions are microvesicular fatty infiltration and cirrhosis, sometimes with a micronodular pattern (184).

Distinctive EEG features include slow (1 Hz), high-amplitude (200–1,000  $\mu$ V) background mixed with lower-amplitude polyspikes, often with focal prominence in the occipital area. The polyspikes on the EEG persist despite intravenous doses of barbiturates that suppress clinical seizures. Evoked potentials have been variably abnormal. Flash visual evoked potentials (VEPs) have ranged from normal to absent and often are asymmetric. Brainstem auditory evoked potentials (BAEPs) in some cases have been absent (185).

Several enzyme deficiencies have been reported as a biochemical basis for this disorder. These include abnormalities of the pyruvate dehydrogenase (PDH) complex, pyruvate carboxylase, coenzyme Q, and complexes I and IV, in the second part of the citric acid cycle (after the oxoglutarate dehydrogenase complex) in nicotinamide-adenine dinucleotide (reduced form) (NADH) oxidation, in cytochrome aa<sub>3</sub>, and in pyruvate carboxylase activity (177). Additional defects in cerebral energy metabolism are likely to be discovered. The types of enzyme defects described thus far have been associated with elevated concentrations of lactic acid in CSF.

### COCKAYNE SYNDROME

Cockayne syndrome is characterized by paucity of growth with developmental delay; loss of subcutaneous fat; cold, cyanosed extremities; increased pigmented nevi; and decreased scalp hair. With increasing cachexia the patient's distinctive facies, enophthalmos, and absent fat are prominent features. Mental retardation and microcephaly with ventriculomegaly and questionable normal-pressure hydrocephalus are present. Hypertonicity with various movement disorders and myoclonic jerks is present. Optic atrophy and retinal pigmentary changes occur. The disorder is inherited as an autosomal recessive trait caused by several different mutations on chromosomes 5, 10, 13, and 19. Seizure activity usually has an early onset but can occur initially in adults. Status epilepticus resulting in death has been reported (186, 187).

### INFLAMMATORY AND AUTOIMMUNE DISORDERS

#### Systemic Lupus Erythematosus

Systemic lupus erythematosus (SLE) may manifest primarily or complicate a more systemic presentation.

When neurologic or behavioral symptoms are prominent, the term *neuropsychiatric lupus* [NPSLE] is used. Juvenile-onset lupus carries greater risk of NPSLE and poorer prognosis (188). Eleven percent to 17% of patients with SLE develop seizures unrelated to renal disease, cardiac disease, or drugs. In one large series, 11.6% had seizures, with about a third experiencing seizures at the onset of the disease (189). These generalized or partial seizures usually occur early in the disease. Because a true vasculitis is uncommon, the precise cause is not defined. The pathogenesis of NPSLE is multifactorial and can involve various autoantibodies or immune complexes in mechanisms involving vasculopathic and autoantibody-mediated neuronal injury. Cerebral microinfarcts and subarachnoid hemorrhage have been demonstrated and may be related to antiphospholipid antibodies and lupus anticoagulant that can be present. When seizures are associated with psychiatric symptoms, a generalized vasculitis may be present. However, recently autoantibodies against murine neuronal membrane proteins have been discovered and correlate with psychosis, seizures, or both in lupus patients (190). Infectious causes need to be ruled out in the immunosuppressed patient. Seizures typically appear early in the course and are difficult to control. Phenytoin, ethosuximide, and carbamazepine can cause symptoms similar to those of SLE (191).

### Acute Disseminated Encephalomyelitis

The term *acute disseminated encephalomyelitis* (ADEM) describes any immune-mediated encephalomyelitis resulting from infections, allergies, or vaccinations. Typically this is a monophasic illness occurring in pediatric patients, mostly prepubertal, and follows a preceding illness commonly by 1 to 6 weeks. Presenting symptoms include headache, encephalopathy, depressed level of consciousness, paresis, sensory changes, and ataxia. Approximately 25% will present with seizures (192, 193). Laboratory findings may be unremarkable, though about half will have elevated protein on CSF testing, and a mild pleocytosis is not unusual. The most consistent finding is obtained on MRI, with images typically showing fuzzy, poorly defined lesions and a high lesion load in the white matter, associated with thalamus or basal ganglion lesions (194). Good recovery is seen with most patients, but up to half may have some deficit, mild in most cases but potentially severe. Up to 9% may have a residual seizure disorder (106). Corticosteroids are most commonly used to treat this disorder, though intravenous immunoglobulin has been used with good results (195). Seizure treatment is symptomatic, and any of the standard drugs would be appropriate based on the clinical situation.

### NEOPLASTIC DISORDERS

Seizures may occur in cancer patients from either direct invasion, secondary electrolyte abnormalities, paraneoplastic syndrome, infection, or drug effect from chemotherapy.

Primary tumors of the central nervous system are a rare cause of seizures. In one series, brain tumors accounted for 2.5% of partial epilepsies and 0.7% of generalized epilepsies (196). Although the majority of seizure-producing tumors are supratentorial, focal motor seizures, with or without secondary generalization, have been seen with cerebellar lesions, particularly gangliogliomas (197, 198). Certain tumors are considered more epileptogenic including ganglioglioma (198), hypothalamic hamartoma (199), dysembryoplastic neuroepithelial [DNET] (200), and some low-grade astrocytomas (201). A large number of seizures prior to lesionectomy and residual hyperintense region in the tumor cavity on post-operative MR imaging are associated with uncontrolled seizures (201).

The incidence of seizures complicating the treatment of systemic cancer in children has been between 4.5% and 14% (202, 203). Seizures have been seen with a variety of neoplasms, with about half as a complication of treatment and the rest by direct tumor invasion (203). Leukemia is the most common neoplasm associated with seizures, accounting for about half overall (204). In patients with leukemia, 47% had a cerebral lesion at the time of first seizure (205). Imaging abnormalities seen in leukemia include sinus and cortical vein thromboses, cerebral hemorrhage, meningeal leukemia, infection, leukemic infiltration, leukoencephalopathy, and radiation necrosis (206). Although seizures may result from metabolic derangements, medications may also be the primary risk; examples of these medications would include cyclosporine, tacrolimus, methotrexate, busulfan, and thiopeta (204). Paraneoplastic syndromes, such as limbic encephalitis, may lead to seizures. Although these have neurologic problems less frequently in children than in adults, they may still occur and produce seizures (207).

Because of its noninducing properties, lack of protein binding, and lack of drug-drug interaction, gabapentin has been used to treat seizures in children with systemic cancers (204, 208). Many of these same advantages exist with levetiracetam, and the development of a commercial intravenous form may make this the drug of choice in these patients.

### CONCLUSIONS

Many disease states may present with generalized, partial, or multifocal seizures in infancy and childhood. In certain instances, seizures are caused by an acute irritation to the nervous system (acute symptomatic seizures); in

others, seizures are caused by more chronic neurologic processes (remote symptomatic). Examples of both have been described in this chapter. In either case seizure types are rarely distinctive enough to suggest a specific symptomatic etiology. When seizures are recurrent and due to a remote symptomatic etiology, the EEG features can sometimes be helpful in making a specific diagnosis, such as the “notched delta” pattern in Angelman syndrome or needle-like central spikes in Rett syndrome. More frequently, the epilepsy syndrome and other associated

neurologic findings can provide the most useful clues to the presence of remote symptomatic etiology. Epilepsy syndromes that strongly suggest a symptomatic etiology include neonatal seizures, early infantile epileptogenic encephalopathy, West syndrome, and Lennox-Gastaut syndrome. Patients with these epilepsies should have a thorough, but targeted, search for underlying causes. This information can help to guide effective treatment and provides the most useful information for parental counseling.

**GENERAL PRINCIPLES  
OF THERAPY**

# 29

## Treatment Decisions in Childhood Seizures

*Shlomo Shinnar*  
*Christine O'Dell*

**I**n the past, almost all children with a seizure of any type, febrile or afebrile, were placed on long-term therapy with antiepileptic drugs (AEDs). This was based on several assumptions: first, that almost all children with an isolated seizure would go on to have more seizures (1, 2); second, that seizures, even brief ones, could cause brain damage and lead to progressively intractable epilepsy (1–3); third, that AEDs were not only effective but also safe and that treatment was associated with only minimal morbidity; finally, that seizures “beget” seizures, and that early AED therapy not only prevented seizures but also somehow altered the natural history of the disorder and prevented the development of “chronic” epilepsy (3–6). We now know that these assumptions are not true. Research has provided information that has altered the way physicians think about seizures, their consequences, and the drugs used to treat them. The decision whether and for how long to treat a child with AEDs must be weighed against the possible risks of that treatment and must take into account the large body of data that has accumulated: namely, that many children with a single seizure do not go on to experience further seizures (7–20); that many children with epilepsy ultimately go on to become seizure free (21–24); that most seizures are brief, and that even prolonged seizures rarely cause brain damage unless they

are associated with an acute neurologic insult (25–28); and that antiepileptic medications can cause untoward effects (18, 29–31).

The decision of whether to initiate treatment in a child with one or more seizures must balance the risks and benefits of treatment in each case (18). Similarly, the patient who is seizure free on medications for some time must weigh the risks of possible seizure recurrence if medications are withdrawn against the risks of continuing long-term AED therapy. This chapter reviews the data relevant to these decisions. The data on the probability of seizure recurrence following a first unprovoked seizure is presented. Next, the issue of withdrawing antiepileptic drugs in children with epilepsy who are seizure free for 2 or more years is considered. This is followed by a review of the risks of not treating (i.e., the risks of subsequent seizures) and of the morbidity of therapy. Finally, recommendations for a therapeutic approach to children with seizures are outlined.

### **RECURRENCE RISK FOLLOWING A FIRST UNPROVOKED SEIZURE**

An understanding of the natural history of children who present with a first unprovoked seizure is necessary in order to develop a rational approach to their management. Over

**TABLE 29-1**  
**Risk Factors for Recurrence: Multivariable Analysis using Cox Proportional Hazards Model**

RISK FACTOR	PROPORTIONATE HAZARDS MODEL	RATE RATIO 95% CI	P VALUE
Overall Group (N = 407)			
Abnormal EEG	2.1	1.6, 3.0	<0.001
Remote symptomatic etiology	1.7	1.2, 2.4	0.006
Prior febrile seizures	1.6	1.1, 2.3	0.019
Todd's paresis	1.7	1.0, 2.9	0.038
Seizure while asleep	1.5	1.1, 2.1	0.008
Cryptogenic cases (N = 342)			
Abnormal EEG	2.5	1.7, 3.6	<0.0001
Seizure while asleep	1.7	1.2, 2.5	<0.003
Remote Symptomatic Cases (N = 65)			
Prior febrile seizures	2.3	1.2, 4.5	<0.02
Age < 3 years	2.4	1.2, 4.9	<0.02

Reprinted with permission from Shinnar et al, 1996 (8).

the past two decades there have been many studies that have attempted to address this issue (7–20). For purposes of this discussion, a first unprovoked seizure is defined as a seizure, or flurry of seizures all occurring within 24 hours, in a patient over one month of age with no prior history of unprovoked seizures (18, 32).

The reported overall recurrence risk following a first unprovoked seizure in children varies from 27% to 71% (7–20). Studies that identified the children at the time of first seizure and carefully excluded those with prior seizures report recurrence risks of 27% to 44% (7–11, 19). Studies that recruited subjects later, either retrospectively or from electroencephalogram (EEG) laboratories, but excluded those with prior seizures, report slightly higher recurrence risks of 48% to 52% (14, 15). Lastly, studies that included children who already had recurrent seizures at the time of identification report the highest recurrence risks, 61% to 71% (12, 13). Once methodological issues and differences in the distribution of risk factors among different studies are taken into account, the results are fairly consistent (9). The majority of recurrences occur early, with approximately 50% of recurrences occurring within 6 months and over 80% within 2 years of the initial seizure (7–20). Late recurrences are unusual.

Similar predictors of recurrent seizures were found in the majority of the studies despite variations in methodology and in subject selection (7–20). Factors that are associated with a differential risk of recurrence include the etiology of the seizure, the electroencephalogram (EEG), whether the first seizure occurred in wakefulness or sleep, and seizure type. Factors not associated with a change in the recurrence risk include age of onset and the duration of the initial seizure. The report of a family

history of seizures in a first-degree relative is of unclear significance, with conflicting results in the various studies. Risk factors for seizure recurrence from our large prospective study (8, 20) are shown in Table 29-1.

Selected individual risk factors are discussed in the following subsections.

### Etiology

The recent International League Against Epilepsy (ILAE) guidelines for epidemiologic research (32) classify seizures as acute symptomatic, remote symptomatic, cryptogenic, or idiopathic. Acute symptomatic seizures are those associated with an acute insult such as head trauma or meningitis. Remote symptomatic seizures are those without an immediate cause but with an identifiable prior brain injury such as major head trauma (loss of consciousness greater than 30 minutes, depressed skull fracture, or intracranial hemorrhage), meningitis, encephalitis, stroke, or the presence of a static encephalopathy, such as mental retardation or cerebral palsy, which are known to be associated with an increased risk of seizures. Cryptogenic seizures are those occurring in otherwise normal individuals with no clear etiology. Note that factors such as sleep deprivation are considered trigger factors but do not change the classification of the seizure, as they would be associated with seizures only in susceptible individuals. Until recently cryptogenic seizures were also called idiopathic. In the new classification, the term *idiopathic* is reserved for seizures occurring in the context of the presumed genetic epilepsies, such as benign rolandic and childhood absence epilepsy (32–34), but many papers still refer to cryptogenic seizures as idiopathic.

Children with a remote symptomatic first seizure have higher risk of recurrence. In one large prospective study with mean follow-up of over 10 years, 44 (68%) of 65 children with a remote symptomatic first seizure recurred, compared with 127 (37%) of 347 children with a cryptogenic/idiopathic first seizure ( $P < 0.001$ ) (8, 19). Comparable findings are reported in other studies (9–11, 14, 15).

### Electroencephalogram

The EEG is an important predictor of recurrence, particularly in cryptogenic cases (8–11, 14, 17). Epileptiform abnormalities are more important than nonepileptiform ones, but any EEG abnormality increases the recurrence risk in cryptogenic cases (8). In our study, the risk of seizure recurrence by 5 years for children with a cryptogenic first seizure was 27% for those with a normal EEG, 44% for those with nonepileptiform abnormalities, and 62% for those with epileptiform abnormalities (7, 8). In our data (8, 35), any clearly abnormal EEG patterns, including generalized spike-and-wave, focal spikes, and focal or generalized slowing, increased the risk of recurrence, while Camfield et al (14) report that only epileptiform abnormalities substantially increase the risk of recurrence. Hauser et al (10) state that only generalized spike-and-wave patterns are predictive of recurrence, but they studied mostly adolescents and adults and thus would have not included many children with centrottemporal spikes (benign rolandic epilepsy), which is the most common focal spike pattern found in studies focusing on children with a first seizure (8, 31, 14). In children with a cryptogenic first seizure, the EEG appears to be the most important predictor of recurrence (8, 9). Based on these data, a recent practice parameter of the American Academy of Neurology recommended that an EEG be considered a standard as part of the diagnostic evaluation of the child with a first unprovoked seizure (17).

### Sleep State at Time of First Seizure

Whether the initial seizure occurs while the child is awake or asleep is associated with a differential recurrence risk, particularly in cryptogenic cases (8). In our series the 5-year recurrence risk was 53% for children whose initial seizure occurred during sleep, compared with 36% for those whose initial seizure occurred while awake ( $P < 0.001$ ) (8). On multivariable analysis, etiology, the EEG and sleep state were the only significant predictors of outcome. The group of children with a cryptogenic first seizure occurring while awake and a normal EEG had a 5-year recurrence risk of only 21%. If seizures did recur, then they usually recurred in the same sleep state as the initial seizure.

### Seizure Classification

Some though not all studies indicate that the risk of recurrence following a partial seizure is higher than that following a generalized seizure (9). However, partial seizures are more common in children with a remote symptomatic first seizure and in children with a cryptogenic first seizure who have an abnormal EEG (7). Once the effects of etiology and the EEG are controlled for, partial seizures are not associated with an increased risk of recurrence (7, 8, 10). In the meta-analysis no clear association between seizure type and recurrence risk could be found (9).

### Family History

At the present time, there is insufficient data to determine whether a positive family history of epilepsy is a risk factor for recurrence. Although one study, primarily of adults, found a substantially increased risk of recurrence in those with a positive family history of epilepsy (10), others have failed to find a major effect (8, 14). In our study, family history was important only in children with a cryptogenic first seizure who also had an abnormal EEG. This type of patient constitutes a very small fraction of the population (7). These mixed results suggest that the additional risk of a positive family history, if present, will turn out to be small or else limited to specific subgroups.

### Duration of First Seizure/Status Epilepticus

The duration of the first seizure does not affect the risk of recurrence (8–10). This is true whether one analyzes it as a continuous variable or separates the children into those who had status epilepticus and those who had a briefer seizure (8). Most cases of status occur as the initial seizure. In our series of 407 children, 48 (12%) had status epilepticus as their seizure, but only 7 (4%) of 171 children with recurrent seizures recurred with status. Although the occurrence of status epilepticus as the first seizure did not alter recurrence risks, a recurrence was more likely to be prolonged. Five (21%) of 24 children with recurrent seizures whose initial seizure was status had an episode of status as their second seizure, compared with 2 (1%) of 147 children with recurrent seizures whose first seizure was brief ( $P < 0.001$ ). None of these experienced any sequela (8). Remission rates were not different in those who presented with an episode of status epilepticus (36).

### Age at First Seizure

The majority of studies, in both children and adults, have not found age at first seizure to alter the risk of recurrence

(7–11, 14–16). This was true whether age was analyzed as a continuous variable or broken up into several age ranges. The only exception to this is the National Collaborative Perinatal Project, which found an increased risk of recurrence in children under age 2 with focal motor seizures (13). At the present time, the preponderance of available data is that the age at time of first seizure does not affect the risk of recurrence following a first unprovoked seizure.

### Treatment Following a First Seizure

In observational studies such as those just discussed, whether children were treated or not after their first seizure did not alter the recurrence risk (8, 10). However, these were not randomized treatment trials. The physicians presumably treated those children they thought to have a high risk of recurrence. Following an initial seizure, patients are often started on a small dose of medication, and compliance may be lax. Randomized clinical trials comparing AED therapy with placebo following a first unprovoked seizure in children and adults have found that AED therapy can reduce the risk of a second seizure by half (16, 37). However, with longer follow-up, there was no difference between the two groups in terms of the probability of achieving remission (6, 38). Based on a review of the evidence, the American Academy of Neurology practice parameter on the treatment of the child with a first unprovoked seizure concluded that treatment does not prevent the development of chronic epilepsy or alter long-term outcome and should be reserved for those cases where the risks of a second seizure outweigh the morbidity of AED therapy (18).

### Conclusions
