Knowing these predictors and the recurrence risks, the child with a first unprovoked seizure presents an interesting dilemma. The likelihood that it will be an isolated event that will not repeat itself must be weighed against whether it is the first of many attacks. A thorough evaluation of the patient, including a detailed history and appropriate laboratory studies such as an electroencephalogram (EEG), is indicated regardless of whether AED therapy is started or not (17). Factors such as the seizure type, family history of seizures, and the possible etiology of the seizure must be ascertained. Of particular importance is a careful history of prior events that may be seizures. Many children who first come to medical attention as a result of a convulsive episode are found to have had prior nonconvulsive episodes of absence or complex partial seizures that were not recognized as such by the family (8, 17). These children clearly fall into the category of newly diagnosed epilepsy and not first seizure.

The majority of children with a first unprovoked seizure do not have additional unprovoked seizures. Children with a cryptogenic first seizure and a normal EEG have a particularly favorable prognosis. There are small subgroups of children with multiple risk factors who do have a high risk of recurrence. However, although AED therapy will reduce the likelihood of further seizures, there is no evidence that it alters the long-term prognosis (18). In particular, the data from randomized clinical trials and large epidemiologic studies indicate that delaying therapy will neither alter the response rate to AEDs nor adversely affect the probability of attaining remission (3, 5, 6, 18, 23, 38). Finally, recent data suggest that children who present with a first unprovoked seizure are very unlikely to develop medically refractory epilepsy even if seizures do recur (19, 20). The decision to treat or not after a first seizure must be based on the relative risks and benefits of therapy compared with the risks of further seizures. This risk benefit assessment is discussed at the end of this chapter. The authors rarely treat children with a first unprovoked seizure.

### WITHDRAWING AEDS IN CHILDREN WITH EPILEPSY WHO HAVE BEEN SEIZURE FREE FOR 2 OR MORE YEARS

The available data indicate that children who are seizure free on medication for 2 or more years have a very high likelihood of remaining in remission on medication (39). In selected populations, withdrawal may be feasible after an even shorter seizure-free interval (39–42). How long should a child be maintained on medication before the attempt is made to withdraw it? This decision will be influenced by a variety of factors, including the probability of remaining seizure free after withdrawal in a given patient, the potential risk of injury from a seizure recurrence, and the potential adverse effects of continued AED therapy.

The majority of children who are seizure free on medications for at least 2 years will remain seizure free when medications are withdrawn. A large number of well-designed studies involving over 700 children have been done over the past 20 years (39, 43–54). The overall results have been very similar. Between 60% and 75% of children with epilepsy who have been seizure free for more than 2 (39, 43, 44, 49–53) or 4 (44–48) years on medications remain seizure free when antiepileptic medication is withdrawn. Furthermore, the majority of recurrences occur shortly after medication withdrawal, with almost half the relapses occurring within 6 months of medication withdrawal and 60% to 80% within 1 year (39, 53, 54). These studies are supported by a follow-up of patients for 15 to 23 years after medication withdrawal (47, 55). Although late recurrences do occur, they are rare

(47, 53, 55). In a recent randomized study, the increased risk of relapse following AED withdrawal occurred only in the first 2 years after AED withdrawal. The rate of late recurrences was the same in those who remained on AED therapy and those whose AEDs were discontinued (48).

The important question is, Can one identify risk factors such as etiology, age of onset, type of seizure, EEG features, or the specific epilepsy syndrome, that will enable one to identify subgroups of children with an even better prognosis and subgroups with a much less favorable prognosis for maintaining seizure remission off medication? There is much less consensus in this area. A discussion of the potential risk factors that have been looked at and their possible significance is presented next.

### **Etiology and Neurologic Status**

In general, children with epilepsy associated with a prior neurologic insult have a smaller chance of becoming seizure free in the first place than do children with cryptogenic epilepsy (21, 22, 24). In children with remote symptomatic epilepsy who are seizure free on medication, most studies indicate a higher risk of recurrence following discontinuation of medication than in children with cryptogenic epilepsy (44–47, 49, 50, 53). In a recent meta-analysis of this literature, the relative risk of relapse in those with remote symptomatic seizures was 1.55 (95% CI 1.21–1.98) (54). However, almost half of these children will remain seizure free after withdrawal of medication (45, 53, 54). Furthermore, even within this group one can identify subgroups with favorable and unfavorable risk factors (53).

### **Age of Onset and Age at Withdrawal**

Age of onset above 12 years is associated with a higher risk of relapse following discontinuation of medications (39, 42, 45, 49–51, 53, 54). In our data this was the single most important risk factor for recurrence (relative risk 4.24, 95% CI 2.54–7.08). A meta-analysis (54) also found adolescent-onset seizures to be associated with a higher risk of recurrence than childhood-onset (relative risk 1.79, 95% CI 1.46–2.19). There is some controversy as to whether a very young age of onset (under 2 years) may be a poor prognostic factor (45). In our data, a young age of onset was associated with a less favorable prognosis only in those with remote symptomatic seizures and was associated with more severe neurologic abnormalities (53). As most childhood epilepsy is readily controlled with AED therapy, the age at withdrawal of AEDs will be highly correlated with age of onset. However, the age at AED withdrawal does not appear to be important once age of onset is taken into account. In particular, there is no evidence that discontinuation of AEDs during the pubertal

period is associated with a higher risk of recurrence (39, 43, 44, 53).

### **Duration of Epilepsy and Number of Seizures**

These two variables are closely interrelated. A long duration of epilepsy may increase the risk of recurrence, though the magnitude of the effect is small (39, 42, 46, 47). One study also reported that having more than 30 generalized tonic-clonic seizures was associated with a high risk of recurrence after discontinuation of therapy (45). In a community-based practice, most children will be easily controlled within a short time after therapy is initiated, so these factors will rarely be important.

### **Seizure Type**

Studies on the effect of seizure type on the risk of recurrence after medication withdrawal in children have produced inconsistent results. Children with multiple seizure types have a poorer prognosis (46, 47). The data regarding partial seizures are conflicting (39, 43–54). At this time it is not clear that any specific seizure type is associated with an increased risk of recurrence following discontinuation of medication.

### **EEG**

In several studies (39, 40, 43–45, 53, 54), the EEG prior to discontinuation of medication was one of the most important predictors of relapse in children with cryptogenic epilepsy. However, the specific EEG abnormalities of significance varied across studies. Two other studies found no correlation between the EEG and outcome (46, 50). A meta-analysis found that an abnormal EEG prior to AED withdrawal was associated with a relative risk of relapse of 1.45 (95% CI 1.18–1.79) (54). The preponderance of evidence indicates that an abnormal EEG is associated with an increased recurrence risk in children with cryptogenic/idiopathic epilepsy.

The EEG obtained at the time of initial diagnostic evaluation may also have predictive value. Certain characteristic EEG patterns associated with specific epileptic syndromes, such as benign rolandic epilepsy or juvenile myoclonic epilepsy, provide additional prognostic information (24, 33, 34, 53). Changes in the EEG over time may also have prognostic value (40, 43).

### **Epilepsy Syndrome**

Epilepsy syndromes are known to be associated with a differential prognosis for remission (24, 33, 34). Regrettably, there is little information on the effect of the specific epilepsy syndrome on the risk of relapse following AED withdrawal. The majority of studies of AED withdrawal

**TABLE 29-2**  
*Epileptic Syndromes in Cohort of Children Being Withdrawn from Antiepileptic Drug Therapy After a Seizure-Free Interval: Cryptogenic and Idiopathic Cases*

EPILEPTIC SYNDROME	N	RECURRED (%)	P VALUE
Idiopathic epilepsy syndromes	79	22 (28%)	
Primary generalized epilepsy	61	21 (34%)	
Childhood absence	26	5 (19%)	
Juvenile absence	9	3 (33%)	
Juvenile myoclonic epilepsy	4	4 (100%)	0.006
Other primary generalized	22	9 (41%)	
Idiopathic partial epilepsy	18	1 (4%)	
Benign rolandic epilepsy	14	0 (0%)	<0.001
Benign occipital epilepsy	4	1 (25%)	
Cryptogenic epilepsy syndromes	86	26 (30%)	
Cryptogenic partial epilepsy	50	16 (32%)	
Temporal lobe epilepsy	7	3 (43%)	
Other partial epilepsy	43	13 (30%)	
Unclassified cryptogenic epilepsy	36	10 (28%)	
Total cryptogenic/idiopathic cases	165	48 (29%)	

Adapted from Shinnar et al, 1994 (53).

have not provided information by epilepsy syndrome. The results from our data (53) are shown in Table 29-2. Overall, patients with both idiopathic and cryptogenic epilepsy syndromes have similar prognosis. However, specific syndromes are associated with a differential risk of relapse. Patients with benign rolandic epilepsy have a particularly favorable prognosis, even if their EEGs are still abnormal, whereas all 4 of our patients with juvenile myoclonic epilepsy relapsed. Clearly, future studies will need to focus more on the role of the specific epilepsy syndrome in guiding therapy both in terms of initiating and discontinuing therapy and in the selection of appropriate treatment.

### Type of Medication

The majority of studies have not found that the specific AED used affects recurrence rates. One well designed randomized study in adults (52) suggests that the risk of recurrence may be higher in those treated with valproate than in those treated with other medications. The significance of this finding remains unclear. It may be related to the ability of valproate to normalize generalized spike-wave abnormalities, thus making the subject appear to be at lower risk than is actually the case. At the present time, there is insufficient evidence to justify basing the decision to continue or withdraw AEDs on the type of AED the patient is taking.

The serum drug level does not seem to have a great impact on recurrence risk. Children who have not had

seizures for several years often have “subtherapeutic” levels, and few have toxic levels. Available studies show little or no correlation between drug level prior to discontinuation and seizure recurrence and outcome (43), or a very modest effect (45).

### Duration of Seizure-Free Interval

The chances of remaining seizure free after medication withdrawal is similar whether a 2-year (39, 43, 44, 49–53) or 4-year (39, 44–48) seizure-free interval is used. One study that evaluated seizure-free intervals of one or more years did find that a longer seizure-free period was associated with a slightly lower recurrence risk (44). Note that among children who are 2 years seizure free but remain on medication, approximately 3% to 5% will experience another seizure in the third or fourth year of treatment (21). More recent studies that have utilized a seizure-free interval of 1 year or less have reported higher recurrence risks (39–42). The risk of relapse after a one-year remission compared with a longer seizure-free interval is also higher in patients who continue on AEDs (21).

### Remission Following Relapse

The majority of patients who relapse after medication withdrawal will reattain remission after AEDs are restarted though not necessarily immediately (39, 55–57). The prognosis for long-term remission appears to be primarily a function of the underlying epilepsy

syndrome. A recent randomized study of medication withdrawal found that the prognosis for seizure control after recurrence in patients with previously well-controlled seizures was no different in those who were withdrawn from AED therapy and relapsed and those who relapsed while remaining on AED therapy (56).

### **RISKS OF NOT TREATING OR OF DISCONTINUING AEDS**

Seizure recurrence is the major risk associated with not treating the child with a single seizure or of discontinuing antiepileptic drug therapy. Although a seizure is a dramatic and frightening event, the main impact of a brief seizure is psychosocial. There is no convincing evidence that a brief seizure causes brain damage (3, 6, 58). Serious injury from a brief seizure is a rare event usually related to loss of consciousness and the resultant fall (57). In general, the physical and emotional consequences of a seizure in a child, who is usually in a supervised environment and is not yet driving, are less serious than in the adult, who faces loss of driving privileges and possible adverse effects on his employment (7, 53, 58–60).

In the past there was concern that delaying treatment would result in a worse long-term prognosis (2, 4). This was based on Gowers's statement that "The tendency of the disease is toward self-perpetuation; each attack facilitates the occurrence of the next by increasing the instability of the nerve elements" (1). Proponents of this view, most notably Reynolds, have argued that treatment after the first seizure is necessary to prevent the development of "chronic" epilepsy (4, 12). Similar concerns have been raised about early discontinuation of AED therapy. Current epidemiologic data and data from controlled clinical trials, some of which have already been discussed in this chapter, indicate that this is not the case (3, 5, 6, 18, 23, 38, 61). Prognosis is primarily a function of the underlying epilepsy syndrome, and although treatment with AEDs does reduce the risk of subsequent seizures, it does not alter the long-term prognosis (18, 38). Several comprehensive reviews of this issue, which is fundamental to one's approach to treating seizures but is outside the scope of this chapter, have been recently published (3, 6, 18).

In children, even status epilepticus, defined as a seizure or a series of seizures lasting more than 30 minutes without the patient's regaining consciousness between seizures (25–28, 32), is rarely associated with brain damage attributable to the status per se (25–28). In mature animals, generalized convulsive status epilepticus produces biochemical and neuropathologic changes (28). However, although immature animals are more susceptible to the development of status with relatively mild insults than are adult ones, they are much less likely to experience brain

damage as a result of prolonged seizures (28). Adult rats that had experienced status epilepticus as infants do not show a lower seizure threshold or an increased susceptibility to seizures induced by kindling compared with rats who did not experience seizures as pups (62).

Education is key to empowering the parents and child regardless of which therapeutic option is chosen. Parents need to be reassured that the child will not die during a seizure and that keeping the child safe during the seizure is generally the only action that needs to be taken. Parents will need to be told that most of the child's activities can be continued, although some may need closer supervision by an adult. Specific instructions regarding supervision of activities, such as swimming, should be given to the parents. Counseling of this nature often allays the parents' fear and educates them on safety precautions for the child, thereby reducing the chance for injury from seizures whether or not the child is treated. Educational programs are available for school personnel—teachers, nurses, and students—and information for babysitters is also readily available.

The amount of information and the level of content depends in large part on the medical sophistication of the parents and their ability to attend to the information given them at that particular time. The parents' perception of their child's disorder will be an important factor in their later coping and will ultimately impact on their perception of quality of life. The practitioner's prejudices regarding treatment options will undoubtedly come into play during these discussions, but the different options need to be discussed.

Parents will usually be interested in information that will help them manage the illness or specific problems; lengthy explanations are usually not helpful. It is also important to remember, when giving information to the parents about prognosis, to provide information about how to manage further seizures should they occur. This includes what should be done during a seizure, when it may be necessary to call the physician, and when the child should be taken to the emergency department. Depending on the age of the child, education is needed for the patient. Children may have fear of accidents, fear of the loss of friends, fear of taking "drugs," and other less well-defined fear and apprehension. The practitioner will need to address these issues with the patient and parents for a comprehensive approach to treatment.

### **RISKS OF INITIATING OR CONTINUING TREATMENT WITH AEDS**

Antiepileptic drugs are potent medications whose use is associated with a variety of significant side effects (18, 29–31), which are discussed in detail elsewhere in this volume. The adverse effects of the medications must be

**TABLE 29-3**  
*Potential Adverse Consequences of Antiepileptic Drug Therapy and of Seizures*

ANTIEPILEPTIC DRUG THERAPY	SEIZURES
Systemic toxicity	Physical injury
Idiosyncratic	Loss of consciousness

Adverse effects on behavior	
Psychosocial	Psychosocial
Need for daily medication	Restrictions on activity
Labeling as chronic illness	Physical
Adverse effect on	Social
psychosocial development	Social stigma of seizure
	Fear of further seizures
Economic/temporal	
Cost of medications	
Cost/time of physician visits	
Cost/time of laboratory tests	

balanced against the risk of further seizures. The potential adverse effects of AED therapy and of having a seizure are summarized in Table 29-3. Physicians are familiar with idiosyncratic drug effects as well as the acute toxicities of the drugs. However, subtle behavioral and cognitive effects are often not recognized in children with epilepsy (30), particularly when they have been on medications since their preschool years. Only when medications are stopped does it become apparent that the child's performance was impaired by the drug. For teenage girls, a discussion of the risks of treatment must include consideration of the potential teratogenicity of these compounds (59, 63, 64). A detailed discussion of this problem will be found elsewhere in this text (Chapter 36). As the major teratogenic effects take place in early gestation, and a large number of pregnancies in this group are unplanned, the physician must always consider this issue in advance. For this reason, the author is particularly aggressive in trying to withdraw medications from adolescent females who have been seizure free for 2 years, even if their other risk factors are not favorable.

A hidden side effect of continued AED treatment is that of being labeled. The person with a single seizure or childhood epilepsy who has not had a seizure in many years and is off medications is considered by himself and society to have outgrown his epilepsy. That individual can lead a normal life with very few restrictions. In contrast, remaining on chronic medication implies ongoing illness to both the patient and those around him. Continued use of medication requires ongoing medical care to prescribe and monitor

the medication. It also implies certain restrictions in driving licensure and may have an adverse impact on obtaining employment. In addition to the problems associated with having epilepsy, the perception of any chronic illness will adversely affect the normal psychosocial maturation process, particularly in adolescents (65).

### A THERAPEUTIC APPROACH

Given the consequences of long-term drug therapy, it is recommended that an attempt be made to withdraw medications at least once in most children and adolescents with epilepsy who are seizure free regardless of risk factors. In general, avoid starting medications in the children with only one seizure, and aggressively pursue withdrawal of medications in children who are seizure free for 2 or more years. We rarely treat children with a first seizure even if they have risk factors for recurrence. In many cases, treatment may not be necessary even in children with more than one seizure if the seizures are brief and infrequent and the child's underlying syndrome has a favorable prognosis.

Whatever the decision, it should be made jointly by the medical providers and the family after careful discussion, including not only an assessment of the risks and benefits of treatment, but also a review of measures to be taken in the event of a recurrence. Patient and family education is a key factor whether one decides to treat with

AEDs or not, because both seizures and AEDs are associated with some risks. Even children with good prognostic factors may experience another recurrence. Conversely, children with poor risk factors may nevertheless maintain remission off medications. It is far easier to take these risks while the patient is still in the supervised environment of the home and school. Education assists the family in making an informed decision, helps them to participate fully in the plan of care, and prepares them to deal with psychosocial consequences of the diagnosis. Informed decision making by the physician in consultation with the family will maximize the chances of good long-term outcomes in these children.

The approach presented in this chapter emphasizes that both seizures and the therapies available carry some risk and that optimal patient care requires careful balancing of these risks and benefits. Although this approach is presented here in the context of whether or not to treat

at all, it is also useful in deciding whether or not to add a second drug or to try experimental drugs in a child whose seizures are not fully controlled on the current therapeutic regimen, whether to consider epilepsy surgery for a child who is medically refractory, or to offer the ketogenic diet as a possible treatment modality. As more information and newer therapies become available, the risk/benefit ratios may well change. In order to provide the best care available, the physician needs both to be aware of the available options and to individualize them to the needs of the specific patient.

## Comparative Anticonvulsant Profile and Proposed Mechanisms of Action of Antiepileptic Drugs

*H. Steve White  
Karen S. Wilcox*

**F**or the vast majority of people who develop epilepsy, initial therapy consists of pharmacologic treatment with one or more of the established anticonvulsant drugs. These medications include phenytoin (PHT), carbamazepine (CBZ), valproate (VPA), barbiturates such as phenobarbital (PB), certain benzodiazepines (BZDs), and ethosuximide (ESM). For some patients, complete seizure control with this group of “established” antiepileptic drugs (AEDs) may not ever be achieved at doses that are devoid of various types and severities of AED-related adverse effects.

The 1990s were marked by a number of advances in AED development. Since 1993, several novel AEDs have been commercialized in one or more countries, and several more are in the process of evaluation for worldwide registration. This has been an exciting era for practitioners and their patients who suffer from intractable seizure disorders. For the physician, the new AEDs provide novel therapeutic options for the management of their patients. For the patient with intractable epilepsy, the newer drugs provide renewed hope for complete seizure control and lessening of their AED-associated side-effect profile. This chapter will review the preclinical animal models that led to the initial identification of the “second-generation” AEDs felbamate (FBM), lamotrigine (LTG), gabapentin (GBP), topiramate (TPM), tiagabine (TGB),

vigabatrin (VGB), oxcarbazepine (OCBZ), zonisamide (ZNS), levetiracetam (LEV), and pregabalin (PGB), and the proposed molecular mechanisms of action of the new and the established AEDs.

### **AED DISCOVERY, TESTING, AND PROPOSED MECHANISMS OF ACTION**

The process by which new AEDs are discovered has evolved in the seven decades since phenytoin was identified by Putnam and Merritt (1). The strategies employed in the search for new AEDs are varied but, for the most part, have been based largely on three different approaches: (1) random drug screening and efficacy-based AED discovery; (2) rational drug design, wherein structural modifications of an active pharmacophore are synthesized and tested; and (3) mechanistic-based AED development. All three approaches have led to the successful identification of clinically effective drugs. Unfortunately, even with the introduction of 10 new AEDs since 1993, there continues to be a significant need for more efficacious and less toxic AEDs. Regardless of the process by which a chemical entity is brought forth from the medicinal chemistry laboratory, it must first demonstrate some degree of efficacy in an animal model prior to becoming a candidate for clinical trials.

### In-Vivo Testing

No single laboratory test will, in itself, establish the presence or absence of anticonvulsant activity or fully predict the clinical utility of an investigational antiepileptic drug. Thus, the true test of a drug's efficacy must always await the results of clinical trials. There are many available animal seizure models that have been described over the years that possess appropriate properties to qualify as predictive seizure models. Historically, the maximal electroshock (MES) test, the subcutaneous pentylenetetrazol (sc PTZ) test, and the electrical kindling model represent the three in-vivo systems that have been most commonly employed in the search for new AEDs (2). Today, newer in-vivo models are being introduced that incorporate known genetic defects that more closely resemble the human condition. In addition, the 6-Hz psychomotor seizure model has recently proven useful in identifying compounds that are effective against partial seizures. In particular, LEV, which is inactive in the MES and sc PTZ models (discussed subsequently), was found to be quite effective against seizures induced following corneal stimulation at 6Hz (3).

To gain a full appreciation for a new AED's overall spectrum of activity (narrow or broad), all investigational AEDs should be screened in a variety of different seizure and epilepsy models.

### Correlation of Animal Anticonvulsant Profile and Clinical Utility

The MES test and the kindling model represent two highly predictive models that are useful in the characterization of a drug's potential utility against generalized tonic-clonic and partial seizures, respectively (4–7) (Table 30-1). For some years, positive results obtained in the sc PTZ test were considered suggestive of a drug's potential utility against generalized absence seizures. This interpretation was based largely on the observation that drugs that were active in the clinic (i.e., ETS, trimethadione, VPA, the BZDs) were able to block clonic seizures induced by sc PTZ, whereas drugs such as PHT and CBZ were ineffective against sc PTZ seizures in animals and spike-wave seizures in humans. However, as summarized in Table 30-1, the PTZ test would also suggest that the barbiturates and TGB should also possess efficacy against generalized absence. For the barbiturates (and possibly TGB), this is in direct opposition to what has been reported clinically. For example, phenobarbital worsens human spike-wave discharges (8). On the other hand, PB is useful for the management of myoclonic seizures. In this respect, the sc PTZ test as conducted by most laboratories may have greater utility in the identification of drugs with activity against myoclonic seizures (4).

**TABLE 30-1**  
*Correlation Between Clinical Utility and Efficacy in Experimental Animal Models of the Established and Newer AEDs*

SEIZURE TYPE	EXPERIMENTAL MODEL			
	MES (TONIC EXTENSION)	SC PTZ (CLONIC SEIZURES)	SPIKE-WAVE DISCHARGES <sup>a</sup>	ELECTRICAL KINDLING (FOCAL SEIZURES)
Tonic and/or clonic generalized seizures	CBZ, PHT, VPA, PB [FBM, GBP, LTG, OCBZ, TPM, ZNS] <sup>b</sup>			
Myoclonic/generalized absence seizures		ESM, VPA, PB <sup>c</sup> , BZD [FBM, GBP, TGB]		
Generalized absence seizures			ESM, VPA, BZD [LTG, TPM, LEV]	
Partial seizures				CBZ, PHT, VPA, PB, BZD [FBM, GBP, LTG, OCBZ, TPM, TGB, VGB, ZNS, LEV, PGB]

<sup>a</sup>Data summarized from GBL, GAERS, and *lh/lh* spike-wave models (4–7).  
<sup>b</sup>Brackets [ ] indicate newer AEDs.  
<sup>c</sup>PB blocks clonic seizures induced by sc PTZ but is inactive against generalized absence seizures.

In recent years, three other animal models have emerged that are, to date, perhaps more predictive than the sc PTZ for generalized absence seizures. These include spike-wave seizures induced by the chemoconvulsant gamma-butyrolactone (5), the genetic absence epileptic rat of Strasbourg (GAERS) (6), and the *lethargic* (*lh/lh*) mutant mouse (7, 9). Of these three, the *lh/lh* mouse displays spontaneous spike-wave discharges that are blocked by drugs that have been found clinically effective in reducing spike-wave activity (e.g., the BZDs, ETS, VPA, and LTG). Furthermore, all three models accurately predict the potentiation of spike-wave seizures by drugs that elevate gamma-aminobutyric acid (GABA) concentrations (e.g., VGB and TGB), drugs that directly activate the GABA<sub>B</sub> receptor, and the barbiturates. Given this, any drug being evaluated for potential use against absence seizures should be evaluated in one or more of these three models.

The remainder of this chapter will focus primarily on a description of the anticonvulsant profile and comparative mechanisms of action between the established (pre-1993) and second-generation (post-1993) AEDs.

Where possible, the reader is referred to more comprehensive reviews and primary citations supporting the proposed mechanisms of action that are addressed.

### Mechanism of Action: General Considerations

The mechanisms of action of currently marketed anticonvulsant drugs are not fully understood. Ultimately, there are numerous molecular mechanisms through which drugs can alter neuronal excitability and thereby limit or control seizure activity. However, three primary mechanisms appear to be targeted by most of the established anticonvulsants (10). Thus, as summarized in Table 30-2, drugs that block sustained high-frequency firing through an effect on voltage-sensitive sodium channels can disrupt burst firing; drugs that enhance GABA-mediated neurotransmission can elevate seizure threshold; and drugs that reduce voltage-dependent low-threshold (T-type) calcium currents in thalamocortical neurons can interrupt the thalamic oscillatory firing patterns associated with absence seizures. Likewise, drugs that reduce glutamatergic-mediated excitation can be expected to reduce burst firing elicited

*Functional Consequences of Proposed Mechanism of Action of Established and Newer AEDs*

MOLECULAR MECHANISM OF ACTION	AED	CONSEQUENCES OF ACTION
Na <sup>+</sup> channel blockers	PHT, CBZ, LTG, FBM, OCBZ, TPM, VPA	(1) Block action potential propagation (2) Stabilize neuronal membranes (3) Decrease neurotransmitter release (4) Decrease focal firing (5) Decrease seizure spread
Ca <sup>2+</sup> channel blockers	ESM, VPA, GBP, LTG, PGB	(1) Decrease neurotransmitter release (N & P types) (2) Decrease slow-depolarization (T-type) (3) Decrease spike-wave discharges
GABA <sub>A</sub> receptor allosteric modulators	BZDs, PB, FBM, TPM	(1) Increase membrane hyperpolarization (2) Elevate seizure threshold (3) Attenuate (BZDs) spike-wave discharges (4) Aggravate (barbiturates) spike-wave discharges (5) Decrease focal firing
GABA uptake inhibitors, GABA transaminase inhibitors	TGB, VGB	(1) Increase synaptic GABA levels (2) Increase membrane hyperpolarization (3) Decrease focal firing (4) Aggravate spike-wave discharges
NMDA receptor antagonists	FBM	(1) Decrease slow excitatory neurotransmission (2) Decrease excitatory amino acid neurotoxicity (3) Delay epileptogenesis
AMPA/kainate receptor antagonists	PB, TPM	(1) Decrease fast excitatory neurotransmission (2) Attenuate focal firing
Binds to synaptic vesicle protein, SV2A	LEV	(1) Currently unknown

by synaptic stimulation. Although not a target of standard AEDs, this mechanism does appear to be targeted by some of the new AEDs, including FBM and TPM and the investigational AED remacemide. It should be noted that many of the older established and newer AEDs have been observed to exert a number of different pharmacologic actions that could account for their anticonvulsant action. In those cases where multiple actions have been defined, it is highly likely that the separate mechanisms offer some degree of synergy.

As shown in Table 30-3, inhibition of voltage-sensitive Na<sup>+</sup> and Ca<sup>2+</sup> channels, augmentation of GABA-mediated inhibition, and inhibition of glutamate-mediated excitatory neurotransmission can produce both synaptic and nonsynaptic effects that, when translated to an in-vivo effect, are likely to contribute to a drug's anticonvulsant action. Unfortunately, the ability of an AED to modulate the function of any one of these neuronal processes can have profound consequences on the abnormal firing of epileptic neurons but also on normal neuronal communication. As a result, the same action(s) that decrease seizure frequency are likely to contribute to

a drug's central nervous system (CNS)-related side effect profile. This having been said, some of the drugs display certain properties that lead to a greater separation between therapeutic and toxic effects. For example, it is widely accepted that to be a therapeutically useful Na<sup>+</sup> channel blocker, a drug should possess both voltage- and frequency- dependent actions. These properties confer a certain level of selectivity toward those epileptic neurons that display a paroxysmal depolarization shift and high-frequency sustained repetitive firing (i.e., epileptic neurons within a seizure focus). Thus, at therapeutic concentrations voltage- and use-dependent Na<sup>+</sup> channel blockers would be less likely to affect normal neuronal function than a Na<sup>+</sup> channel blocker that does not display these properties. It is necessary to reconcile this theory with the cognitive impairment that has come to be associated with the voltage- and use-dependent Na<sup>+</sup> channel blockers phenytoin and carbamazepine. This can be done in part by acknowledging the fact that these drugs can, at higher concentrations, attenuate Na<sup>+</sup> currents at resting membrane potentials and thereby modify normal neuronal communication. Furthermore, inhibiting

neuronal voltage-sensitive Na<sup>+</sup> channels can produce a subsequent inhibition of depolarization-dependent neurotransmitter release. Given the critical role that the excitatory neurotransmitter glutamate plays in fast excitatory neurotransmission, slight modification of glutamate release in the absence of abnormal neuronal firing may contribute to the cognitive impairment observed in some patients taking these drugs. In this case, drugs that display greater voltage and use dependence would necessarily offer certain potential advantages over less selective Na<sup>+</sup> channel blockers.

### Correlation Between Anticonvulsant Profile and Mechanism of Action

A question that is commonly asked is whether a drug's anticonvulsant profile suggests anything about its potential mechanism of action. The short answer to this question is, probably not. However, certain trends have been emerging over the years that are worthy of mention. First of all, activity against MES-induced tonic extension has been suggested to identify drugs that are effective in preventing seizure spread; whereas activity against PTZ-induced clonic seizures is suggestive of a drug's ability to elevate seizure threshold (11). Another common theme among drugs that prevent MES-induced seizures is that a large fraction of the marketed AEDs have been demonstrated to inhibit sustained repetitive firing of neurons through an action at the voltage-sensitive Na<sup>+</sup> channel (12). In addition to the Na<sup>+</sup> channel blockers, two other classes of drugs that are very effective against MES-induced seizures are the N-methyl-D-aspartate (NMDA) and non-NMDA glutamate receptor antagonists. For the NMDA antagonists, this would include both competitive (e.g., CPP, CPPene, and CGS 19755) and noncompetitive (e.g., MK801) antagonists, glycine-site antagonists (e.g., ACEA 1021 and felbamate), and polyamine-site antagonists such as eliprodil and ifenprodil. Drugs active at the non-NMDA receptor and also effective against MES-induced tonic extension include topiramate and the non-competitive antagonist NBQX.

Interestingly enough, Na<sup>+</sup> channel blockers and nonselective NMDA and non-NMDA antagonists are for the most part inactive against clonic seizures induced by PTZ. Conversely, drugs that enhance GABA-mediated inhibition (e.g., allosteric modulators, uptake inhibitors, and GABA transaminase inhibitors) are active against PTZ-induced clonus and inactive against MES-induced seizures at nontoxic doses. Likewise, drugs that selectively block T-type voltage-sensitive Ca<sup>2+</sup> channels (e.g., ESM and trimethadione) are active against PTZ-induced clonus but not MES-induced tonic extension.

Whereas the MES and sc PTZ tests may identify a certain mechanistic class of AEDs, the kindled rat model appears to be less discriminating. For example, in the

kindled rat, Na<sup>+</sup> channel blockers, GABA<sub>A</sub> receptor modulators, Ca<sup>2+</sup> channel modulators (GBP and PGB), non-NMDA glutamate receptor antagonists (e.g., NBQX), and modulators of synaptic vesicle protein 2A (LEV) display activity, whereas the NMDA receptor antagonists and T-type Ca<sup>2+</sup> channel antagonists do not. It needs to be noted that the aforementioned correlations between anticonvulsant activity and mechanism of action are based purely on our knowledge regarding the currently available AEDs and experimental compounds that display highly selective mechanisms of action. As new drugs with other well-characterized mechanisms of action become available for testing, it will be interesting to see whether other classes of drugs (e.g., subunit selective NMDA, AMPA, and kainate antagonists; K<sup>+</sup> channel enhancers; other selective Ca<sup>2+</sup> channel antagonists: N, P, and Q type; and selective adenosine agonists) fall into some rational classification scheme. Last, given that a number of the currently available AEDs are active in a variety of experimental models, one might argue that they are likely to possess multiple mechanisms of action and a broader clinical profile than drugs with a narrow anticonvulsant profile. As discussed subsequently, this certainly appears to be the case for VPA, FBM, and TPM.

The value of such an oversimplified discussion lies not in trying to assess the mechanism of action of a drug based on its anticonvulsant profile, but in providing a logical rationale for assessing efficacy of an investigational AED emerging from a mechanistically driven drug discovery program. Thus, based on the available data with reasonably selective drugs, one would not attempt to demonstrate efficacy with a Na<sup>+</sup> channel blocker or NMDA antagonist using the PTZ test, nor would one initially evaluate a T-type Ca<sup>2+</sup> channel blocker or GABA uptake blocker against MES seizures. It could be argued that all drugs should be initially screened in the kindled rat, given the broad spectrum of drugs that are active in this model. Since the kindled rat is an extremely labor-intensive model, it would not necessarily be amenable to high-volume screening. One model not discussed thus far that is often employed as a broad-spectrum screen is the audiogenic mouse (e.g. the DBA/2J and the Frings genetically susceptible mouse). Given that the audiogenic mouse model is nondiscriminatory with respect to clinical classes of AEDs, it serves as a useful model for "proof of principle" screening (13). Once an active molecule has been identified, its clinical potential can be further established using more syndrome-specific models.

The remainder of this review will focus on the most widely accepted mechanism(s) that have been observed at therapeutically relevant concentrations of the first- and second-generation AEDs. As previously mentioned, this is not to imply that a minor, less-established action does not contribute to a drug's anticonvulsant profile. The reader is referred to reviews by Rogawski and Porter (14), Macdonald

and Meldrum (15), Meldrum (16), and White (12) for a more comprehensive discussion of these effects.

## FIRST-GENERATION (PRE-1993) AEDS

### Phenytoin (PHT) and Carbamazepine (CBZ)

The anticonvulsant profiles of PHT and CBZ observed in animal seizure models correlate well with their clinical efficacy in generalized tonic-clonic and complex partial seizures (Table 30-1). Thus, both drugs are effective against tonic extension seizures induced by a number of different stimuli, including MES and various chemoconvulsants (17, 18), and both AEDs are effective against fully expressed kindled seizures (14). Unlike ESM, both drugs are ineffective against clonic seizures induced by PTZ. Studies conducted to date provide compelling evidence that therapeutic concentrations of PHT and CBZ prevent sustained repetitive firing resulting from extended depolarization (Table 30-2). In addition, both drugs prevent post-tetanic potentiation (PTP), a process whereby high-frequency stimulation produces a transiently enhanced responsiveness to subsequent stimulation. The ability of PHT and CBZ to block PTP may explain, in part, their ability to limit seizure spread.

The voltage-sensitive Na<sup>+</sup> channel is thought to underlie the ability of neurons to fire repetitively. As such, anticonvulsants that inhibit sustained repetitive firing are likely to exert an effect on voltage-sensitive Na<sup>+</sup> channels. PHT and CBZ have been found to exert an inhibitory effect on voltage-gated Na<sup>+</sup> channels (19–21) that is both use- and voltage-dependent (Table 30-2). These two properties account for the unique ability of PHT, CBZ, and other voltage-dependent Na<sup>+</sup> channel blockers to limit the high-frequency firing that is characteristic of epileptic discharges without significantly altering normal patterns of neuronal firing.

PHT and CBZ have also been demonstrated to produce a shift in the steady-state inactivation curve in mammalian myelinated nerve fibers to more negative voltages (22), thereby effectively reducing the degree of depolarization required to inactivate Na<sup>+</sup> channels. In addition, both drugs delayed the rate of Na<sup>+</sup> channel recovery from inactivation. Whether slight differences between PHT and CBZ in time dependence of the frequency-dependent block account for differences in anticonvulsant efficacy between these drugs has yet to be established. Thus, by stabilizing the Na<sup>+</sup> channel in its inactive form and slowing its rate of recovery from inactivation, both drugs can prevent sustained repetitive firing evoked by prolonged depolarization such as that found in an epileptic focus.

Similarly, voltage-, frequency-, and time-dependent inactivation of Na<sup>+</sup> channels by PHT has also been

confirmed in isolated rat hippocampal neurons and *Xenopus* oocytes injected with human brain mRNA (23, 24). All of these studies provide strong experimental evidence supporting an interaction of PHT and CBZ with the voltage-dependent Na<sup>+</sup> channel.

### Ethosuximide (ESM)

Unlike PHT and CBZ, ESM is effective against clonic seizures induced by subcutaneously administered PTZ (Table 30-1). It is also active against spike-wave seizures induced by the chemoconvulsant gamma-hydroxybutyrate (6) and against spontaneous spike-wave discharges in the *lh/lh* mouse model of absence (8). ESM is ineffective against tonic extension seizures induced by MES and focal seizures in the kindled rat (25). In this respect, ESM's in-vivo profile is consistent with its clinical efficacy against generalized absence seizures and lack of efficacy in generalized tonic-clonic or partial seizures (Table 30-1).

The mechanism of ESM was not elucidated until 1989, when it was shown to reduce low-threshold T-type Ca<sup>2+</sup> currents in thalamic neurons isolated from rats and guinea pigs (26). Reduction of the T-type current was voltage-dependent and was observed at clinically relevant ESM concentrations, suggesting that this mechanism may be the basis for efficacy of ESM in controlling absence seizures (Table 30-2). This effect of ESM, which is produced at clinically relevant concentrations, is thought to represent the primary mechanism by which it controls absence epilepsy. Activation of T-channels in thalamic relay neurons generates low-threshold Ca<sup>2+</sup> spikes that are thought to contribute to the abnormal thalamocortical rhythmicity that underlies the 3-Hz spike-and-wave EEG discharge of absence epilepsy. By preventing Ca<sup>2+</sup>-dependent depolarization of thalamocortical neurons, ESM as well as dimethadione, the active metabolite of the antiabsence drug trimethadione (27), is thought to block the synchronized firing associated with spike-wave discharges.

### Valproic Acid (VPA)

Of the standard AEDs, VPA appears to have the broadest preclinical and clinical profile (Table 30-1). It is active in a variety of animal seizure models including electrical seizures in the MES test, chemically induced clonic seizures in the sc PTZ test, electrically kindled seizures, GBL-induced spike-wave, and spontaneous spike-wave discharges in the *lh/lh* mouse (6, 8, 25). Clinically, VPA is useful in the management of both partial and primary generalized seizures.

Based on VPA's rather broad preclinical and clinical anticonvulsant profile, it might be anticipated that VPA would possess more than one mechanism of action. Indeed, a number of studies suggest that VPA possesses

at least three different mechanisms of action. First, in-vitro studies with VPA support an action at the voltage-sensitive Na<sup>+</sup> channel (12). For example, VPA has been found to inhibit Na<sup>+</sup> currents in isolated *Xenopus leavis* myelinated nerves (28) and in neocortical neurons in vitro (29). Furthermore, in rat hippocampal neurons VPA decreased peak Na<sup>+</sup> currents in a voltage-dependent manner and produced a 10-mV leftward shift in the Na<sup>+</sup> inactivation curve (30). Such an action may contribute to its ability to prevent MES-induced tonic extension in animals and generalized tonic-clonic and partial seizures in humans. Secondly, VPA, like ESM, has been shown to reduce T-type Ca<sup>2+</sup> currents in primary afferent neurons (31). This effect, albeit modest and observed at high VPA concentrations, may contribute to VPA's clinical efficacy in absence seizures. Lastly, VPA-mediated elevations of whole-brain GABA levels and potentiation of GABA responses are also found at relatively high drug concentrations (14). This effect, coupled with its effect at the voltage-sensitive Na<sup>+</sup> channel, may also contribute to its efficacy against kindled seizures in rats and against human partial seizures.

### Benzodiazepines (BZDs) and Barbiturates

In animal seizure models, the BZDs and barbiturates are effective at low doses against sc PTZ-induced clonic seizures and in the kindled rat model of partial seizures. The barbiturates at low doses and BZDs at higher doses are also active against MES-induced tonic extension. One important distinction between these two classes of compounds lies in their efficacy against spike-wave seizures in the GBL and *Ih/Ih* models of absence. In both models, the BZDs are effective in reducing spike-wave discharges, whereas the barbiturates actually worsen spike-wave discharges (6, 8).

Once released from GABAergic nerve terminals, the inhibitory neurotransmitter GABA binds to both GABA<sub>A</sub> and GABA<sub>B</sub> receptors. The GABA<sub>A</sub> receptor complex is a multimeric macromolecular protein that forms a chloride-selective ion pore. Thus far, multiple binding sites for GABA, anticonvulsant BZDs, barbiturates, neurosteroids, convulsant beta-carbolines, and the chemoconvulsant picrotoxin have been identified (32). The GABA<sub>B</sub> receptor is coupled via a GTP-binding protein to calcium or potassium channels but does not form an ion pore and does not appear to contribute to the anticonvulsant action of either BZDs or barbiturates. The principal anticonvulsant action of the BZDs and barbiturates is thought to be related to their ability to enhance inhibitory neurotransmission by allosterically modulating the GABA<sub>A</sub> receptor complex.

GABA receptor current can be enhanced by increasing channel conductance, open and burst frequency, and/or open and burst duration. Studies indicate that the barbiturates act mainly by increasing the mean channel open

duration without affecting channel conductances or opening frequency; whereas the binding of a BZD to its allosterically coupled GABA<sub>A</sub> binding site increases opening frequency without affecting open or burst duration (33–36). Results from several reconstitution experiments conducted in a variety of laboratories wherein specific GABA receptor subunits were transiently expressed in either *Xenopus* oocytes, Chinese hamster ovary (CHO) cells, or human embryonic kidney cells have suggested a molecular basis for the differential regulation of GABA receptor current by these two classes of drugs. The results from these studies have suggested that the allosteric regulatory site conferring barbiturate sensitivity appears to be contained in the alpha and beta subunits (37, 38). Thus, while GABA receptors formed from alpha1-beta1 subunits are barbiturate-sensitive, they are BZD-insensitive (37, 39). BZD sensitivity is restored when the gamma2 subunit is coexpressed with alpha1 and beta1 subunits (39). Transient coexpression of the gamma2, alpha1, and beta1 subunits in human embryonic kidney cells results in fully functional GABA receptors that are sensitive to the BZDs, barbiturates, beta-carbolines, and picrotoxin. These effects at the GABA<sub>A</sub> receptor are likely to account for the efficacy of the BZDs and barbiturates against kindled seizures in rats and partial seizures in humans.

One important difference between these two classes of GABA modulators is that the barbiturates will directly activate a Cl<sup>-</sup> current in the absence of GABA; whereas the BZDs will not. This difference, coupled with possible anatomical differences in subunit expression, may explain in part why BZDs attenuate spike-wave seizures in both rodents and humans; whereas the barbiturates actually exacerbate spike-wave discharges (40). For example, clonazepam and diazepam selectively augment GABA<sub>A</sub>-mediated inhibition in neurons of the nucleus reticularis thalami (NRT), but not other thalamic neurons. Because the inhibitory synapses in the NRT are primarily reciprocal inhibitory circuits, augmentation of inhibition by the BZDs results in decreased output of NRT onto the thalamus. By decreasing the “pace-maker” activity of the thalamic reticular neurons impinging onto the thalamus, the BZDs selectively and effectively prevent spike-wave discharges. In contrast, barbiturates, by increasing the inhibitory drive within the thalamus, enhance the deinactivation of T-currents, which results in a stronger low-threshold burst and increased thalamocortical rhythms. In contrast to the barbiturates, the BZDs do not augment inhibition within the thalamus and thus do not display the same proconvulsant action.

### SECOND-GENERATION (POST-1993) AEDS

In some circumstances, the mechanisms of action of those AEDs introduced after 1993 display a marked overlap with those just defined for the pre-1993 AEDs. However, some

of these compounds display a unique mechanistic profile relative to the older drugs. Increasingly, AED development has produced novel molecules that enhance inhibitory neurotransmission by acting on GABA receptors, GABA transporters, and GABA metabolism or reduce excitatory neurotransmission mediated by glutamate.

### Felbamate (FBM)

Felbamate (2-phenyl-1,3-propanediol dicarbamate) received FDA approval in mid-1993 and was the first new AED approved in the United States since 1978. Results from preclinical studies conducted by the NINDS Anticonvulsant Drug Development Program demonstrated that FBM possessed a broad anticonvulsant profile in animal seizure models (41, 42; Table 30-1). It is effective against tonic extension seizures induced by MES and the glutamate agonists NMDA and quisqualic acid. Like VPA, FBM is also active against clonic seizures induced by a number of chemoconvulsants. In animal models of partial epilepsy, FBM has been found to reduce the seizure severity in corneal kindled rats and PTZ-kindled rats and to raise the seizure threshold in amygdala-kindled rats (43, 44). In addition to its anticonvulsant properties, FBM has also been demonstrated to possess neuroprotectant properties both *in vitro* and *in vivo* (45–48). Consistent with FBM's broad preclinical profile is its rather broad clinical spectrum. Upon entry into the U.S. market, FBM was approved for treatment of partial seizures, primary and secondary generalized tonic-clonic seizures, and Lennox-Gastaut syndrome.

FBM also possesses a broad mechanistic profile (12), which provides a basis for understanding its broad preclinical and clinical anticonvulsant profile, as well as its neuroprotectant action. FBM reduces sustained repetitive firing in mouse spinal cord neurons in a concentration-dependent manner. This action suggests an interaction with voltage-dependent Na<sup>+</sup> channels, an effect that was confirmed in rat striatal neurons (49; Table 30-2). FBM, at low concentrations, also appears to inhibit dihydropyridine-sensitive high-threshold voltage-sensitive Ca<sup>2+</sup> currents (50), an effect that is consistent with decreased excitability. One mechanism that appears to be unique to FBM is related to its ability to modulate glutamate receptor function through an action at the strychnine-insensitive glycine site of the NMDA receptor. FBM has been shown to displace a competitive antagonist at the strychnine-insensitive glycine-binding site of the NMDA receptor in rat brain membranes (51) and postmortem human brains (52). Furthermore, FBM exerts a neuroprotective effect in the rat hippocampal slice that is reversed by glycine (53). Likewise, its anticonvulsant effect is reversed by strychnine-insensitive glycine receptor agonists (54–56). In addition, FBM has been found to inhibit NMDA-evoked currents directly (57). FBM's ability to

block NMDA-evoked currents is unique among both the standard and the newer AEDs. Despite its interaction with this receptor complex, FBM does not appear to produce either the behavioral or pathologic impairment of the CNS that has been associated with either competitive or noncompetitive NMDA antagonists (43).

At substantially higher concentrations, FBM has also been reported to enhance GABA-evoked chloride currents (57). The mechanism by which FBM enhances GABA-evoked currents is unknown. For example, FBM in concentrations up to 1 mM does not appear to affect ligand binding to the GABA, BZD, or picrotoxin binding sites on the GABA<sub>A</sub> receptor ionophore, nor does it enhance GABA-stimulated <sup>36</sup>Cl<sup>2-</sup> flux into cultured mouse spinal cord neurons (58).

FBM remains a mechanistically very interesting AED with an apparently broad anticonvulsant profile. However, its clinical utility has been markedly limited by the serious hematologic and hepatic toxicity reported after its commercialization in the United States (59). A thorough understanding of the mechanisms underlying these idiosyncratic adverse effects and the ability to identify patients at risk will likely lead to an increased use of this highly effective drug in therapy-resistant patients.

### Gabapentin (GBP)

The second of the newer generation AEDs to be marketed in the United States is gabapentin (GBP). GBP, 1-(aminomethyl)cyclohexanecarboxylic acid, was originally designed and synthesized as a drug to enhance GABA-mediated inhibition by mimicking the steric conformation of GABA (60). Thus, GBP is one of the few examples of rational drug design resulting in a potent anticonvulsant.

In animal seizure models, GBP is active in a number of anticonvulsant tests (9, 61–63). It reduces electrically and chemically induced tonic extension seizures, as well as clonic seizures induced by sc PTZ (Table 30-1), and it blocks sound-induced seizures in DBA mice but not absence-like spike-wave seizures. GBP is also effective against fully kindled seizures in the kindled rat. These findings support its clinical efficacy against human partial seizures and secondarily generalized seizures.

Although the chemical structure and steric conformation of GBP were originally designed to enhance GABA-mediated inhibition, GABA mimetic activity was surprisingly absent in early studies. Despite demonstrated efficacy in both animal and human studies and numerous *in-vitro* studies that have described several potential mechanisms of action, the precise mode of action of GBP remains unknown.

Findings from *in-vitro* studies suggest that GBP can increase the concentration of GABA in both the glial and neuronal compartments (64). GBP has also been shown to increase *in-vivo* occipital lobe GABA levels in patients

with epilepsy (65, Table 30-2). GBP may increase brain GABA turnover by interacting with a number of different metabolic processes. It has been demonstrated to enhance glutamate dehydrogenase and glutamic acid decarboxylase and inhibit branched-chain amino acid aminotransferase and GABA aminotransferase. Although any one of these effects could singly, or in concert with each other, contribute to the anticonvulsant action of GBP, it is not clear at this point which effects are important (61, 64). After prolonged administration, a voltage- and frequency-dependent limitation of Na<sup>+</sup>-dependent sustained action potential firing in mouse cortical neurons was observed at clinically relevant concentrations of GBP (66). GBP's ability to limit sodium-dependent sustained action potential firing in cultured mouse spinal cord neurons was voltage- and frequency-dependent. The precise mechanism of this effect is not known; however, it is unlikely that GBP inhibits sodium currents in a manner similar to that of established sodium channel blockers PHT and CBZ. The delayed effect of GBP against sustained repetitive firing is consistent with the substantial time lag between the appearance of peak plasma and brain concentrations and GBP's time to peak anticonvulsant effect observed following intravenous administration (67). This delay in anticonvulsant effect suggests that prolonged synaptic and/or cytosolic exposure to GBP is important and supports an indirect mechanism of action for GBP.

GBP has also been reported to bind to a novel site in rat brain that is not affected by any of the standard AEDs and is not significantly displaced by NMDA or AMPA (alpha-amino-2,3-dihydro-5-methyl-3-oxo-4-isoxazolepropanoic acid) receptor ligands (61). GBP is displaced stereospecifically by certain L-amino acids, demonstrating a relationship between the GBP binding site and system-L transporter membrane. GBP has also been found to bind to the alpha<sub>2</sub>delta regulatory subunit of the voltage-sensitive Ca<sup>2+</sup> channel (68). The precise function of this auxiliary subunit is not known, but it has been suggested that GBP may modify monoamine neurotransmitter release through its interaction with Ca<sup>2+</sup> channels (64).

In summary, GBP displays a unique anticonvulsant profile in animal studies and has demonstrated efficacy in human trials. Furthermore, results from a number of in-vitro and in-vivo studies would also suggest that the mechanism of action of GBP is unique among the existing AEDs. The two that appear most closely associated with its anticonvulsant action are its ability (1) to enhance GABA turnover and release and (2) to interact with the alpha<sub>2</sub>delta regulatory subunit of the voltage-sensitive Ca<sup>2+</sup> channel.

### Lamotrigine (LTG)

Lamotrigine (3,5-diamino-6-{2,3-dichlorophenyl}-1,2,4-triazine) was the third new generation AED to be

marketed in the United States since 1993. LTG was derived from an antifolate drug development program based on the observation that chronic use of phenobarbital, primidone, and phenytoin reduced folate levels (69) and that folates induce seizures in laboratory animals (70). However, despite its structural similarity to other antifolate drugs, LTG displays only weak antifolate activity. Furthermore, results from structure-activity studies suggest that there is little correlation between antifolate activity and anticonvulsant potency (14).

In some respects the preclinical profile of LTG is very similar to that observed with PHT and CBZ (Table 30-1). For example, LTG is active in the kindled rat and against tonic extension seizures in the MES test but is ineffective against sc PTZ-induced clonus (62, 71, 72). However, the preclinical profile of LTG differs significantly from that of PHT and CBZ in one important manner. LTG is effective in the *lh/lh* model of absence (9); whereas PHT and CBZ not only are ineffective but can, upon occasion, actually worsen spike-wave seizures (6, 8, Table 30-1). In this respect, the preclinical profile of LTG supports its clinical utility against partial, generalized tonic-clonic, and generalized absence seizures (73-75).

In in-vitro experiments, LTG selectively blocks veratrine-evoked but not potassium-evoked release of endogenous glutamate (76). These findings suggested that LTG, like PHT, acts at voltage-sensitive Na<sup>+</sup> channels to stabilize neuronal membranes (Table 30-2). Evidence favoring this mechanism includes the documented capacity of LTG to inhibit [<sup>3</sup>H]batrachotoxin binding and veratrine-stimulated [<sup>14</sup>C]guanidinium transport into synaptosomes (77, 78), its capacity to inhibit sustained repetitive firing (77), and its demonstrated concentration-dependent inhibition of Na<sup>+</sup> currents in mouse neuroblastoma cells (19). Effects of all three AEDs on Na<sup>+</sup> currents were voltage-dependent, and all three slowed recovery from inactivation.

However, as mentioned above, the clinical profile of LTG appears broader than would be expected based on this single mechanism. Given the lack of efficacy of other Na<sup>+</sup> channel blockers against generalized absence seizures, LTG's efficacy against this seizure type is likely unrelated to this mechanism, unless, as suggested by Coulter (40), LTG exerts an effect on a particular isoform of the brain Na<sup>+</sup> channel that either is anatomically involved in the generation of spike-wave discharges or is expressed in a way that is selectively altered in the thalamocortical circuitry of absence patients. LTG has been found to decrease voltage-gated Ca<sup>2+</sup> currents (50). This effect may contribute to a decrease in neurotransmitter release and thereby contribute to its anticonvulsant action (Table 30-3). Additional investigations are required to resolve whether this effect contributes to the broader clinical profile of LTG versus that of PHT and CBZ.

### Levetiracetam (LEV)

Levetiracetam (LEV; (*S*)-alpha-ethyl-*e*-oxo-pyrrolidine acetamide) is the (*S*)-enantiomer of the ethyl analog of the nootropic drug piracetam. Levetiracetam displays a unique preclinical profile in animal seizure and epilepsy models. For example, it was found to be inactive in the traditional MES and sc PTZ-seizure models but highly active against audiogenic and fully kindled partial seizures (79). Furthermore, LEV has been found to inhibit PTZ-induced spike-wave discharges (80) and spontaneous spike-wave discharges in the genetic absence epilepsy rat from Strasbourg (GAERS) (81). In addition, LEV decreases the afterdischarge duration in the amygdala-kindled rat and inhibits bicuculline-induced increase in hippocampal population spike amplitudes (82–85). Levetiracetam has also been found to be uniquely active in the 6-Hz psychomotor seizure model of pharmacoresistance (3). For example, at a current intensity equivalent to two times the current necessary to evoke a seizure, levetiracetam and valproate were the only two AEDs that retained their ability to block 6-Hz seizures, although there was a marked decrease in the potency of both drugs at two times the critical current needed to induce seizures in 97% of the population (CC<sub>97</sub>) (3).

In in-vitro studies using rat hippocampal slices, LEV has also been observed to reduce the amplitude and number of repetitive population spikes induced by exposure to high K<sup>+</sup>-low Ca<sup>2+</sup> perfusion medium (86). LEV has also been found to inhibit bicuculline-induced bursts of action potentials and to decrease the frequency of NMDA-evoked bursting in hippocampal pyramidal neurons (87). Despite these observations, a unified molecular mechanism(s) has yet to be clearly defined. This is perhaps not so surprising given LEV's unique anticonvulsant profile. LEV has been demonstrated to bind to a specific, saturable, and stereoselective binding site in rat brain membranes that displays a high density in the hippocampus, cortex, and cerebellum (88). The finding that there is an excellent correlation between LEV binding and anticonvulsant activity in the audiogenic mouse suggests a possible functional role for the LEV binding site. Of the various actions that might be ascribed to LEV, its ability to modulate neuronal high-voltage Ca<sup>2+</sup> currents (Tables 30-1 and 30-2) appears to be the one most likely to contribute to its ability to dampen neuronal hyperexcitability (89). At higher concentrations, LEV has also been found to prevent the negative modulatory effects of Zn<sup>2+</sup> and beta-carbolines on GABA- and glycine-gated currents (90). These effects would be expected to prolong the hyperpolarization associated with GABA- and glycine-mediated neurotransmission. More recently, the LEV binding site has been found to be highly homologous with a novel site identified as synaptic vesicle protein 2A (SV2A) (91). The precise mechanism by which

modulation of SV2A protein contributes to the anticonvulsant efficacy of LEV is not presently known. SV2A is an abundant protein that is closely associated with synaptic vesicles and is thereby thought to contribute to docking and release of neurotransmitter substances. Thus, it is highly possible that LEV, by binding to SV2A protein, modifies neurotransmitter release.

### Oxcarbazepine (OCBZ)

Oxcarbazepine (10,11-dihydro-10-oxo-carbamazepine) is structurally related to CBZ (92). The keto substitution at the 10,11 position of the dibenzazepine nucleus does not affect the therapeutic profile of OCBZ but does contribute to better tolerability in humans (93–96). In vivo, OCBZ is rapidly and completely reduced to its active metabolite (10,11-dihydro-10-hydroxy-carbamazepine, HCBZ), which is thought to be responsible for the anticonvulsant action of OCBZ (97). HCBZ is a racemate that can be separated into two enantiomers, both of which appear to contribute to the anticonvulsant activity of HCBZ (98).

The anticonvulsant profile of OCBZ and HCBZ is virtually identical to that of CBZ (Table 30-1). For example, they are both active against tonic-extension seizures induced by MES and essentially inactive against clonic seizures induced by PTZ, picrotoxin, and strychnine (98, 99). Both compounds were found to possess activity against focal seizures in monkeys with chronic aluminum foci (97). In comparative clinical trials OCBZ was demonstrated to be as efficacious and better tolerated than CBZ (94–96). Clinically, OCBZ seems to represent a less toxic and equally efficacious alternative to CBZ that appears to exert its anticonvulsant effect through a similar mechanism of action. Furthermore, OCBZ appears to be highly efficacious and safe as a first-line treatment in adults with partial and generalized tonic-clonic seizures (100).

OCBZ, HCBZ, and CBZ all appear to share a similar mechanistic profile (Table 30-2). (101). OCBZ and HCBZ, like other drugs that block MES seizures, both block sustained repetitive firing in cultured spinal cord neurons in a voltage- and frequency-dependent manner (102). Additional results from electrophysiologic studies suggest that HCBZ may mediate some of its anticonvulsant effect through an action at high-threshold voltage-gated Ca<sup>2+</sup> channels (50).

### Pregabalin (PGB)

Pregabalin (*S*-(+)-3-isobutyl-gamma-aminobutyric acid) was approved for use as adjunctive therapy for the treatment of partial seizures in 2005. PGB is a structural analog of GABA, but, like the similar compound gabapentin, has no activity at either GABA<sub>A</sub> or GABA<sub>B</sub> receptors.

The preclinical profile of PGB revealed that it is more potent and bioavailable than gabapentin. In animal models of seizure activity, PGB effectively protects against tonic extension seizures induced by MES, clonic seizures induced by sc PTZ, and audiogenic seizures in the DBA/2 mouse (103). The ability of PGB to block kindled seizures accurately predicted that PGB would be effective against partial seizures. PGB was found to block bicuculline and strychnine-induced seizures only at high concentrations, and it was unable to block absence seizures in the GAERS rat.

Although it is known that PGB binds to the  $\alpha_2\delta$  auxiliary subunit of the voltage-gated calcium channel, it is still not completely clear how it exerts its anti-convulsant activity. Recent work in cultured hippocampal neurons suggests that PGB may reduce spontaneous and evoked neurotransmitter release, most likely by targeting the readily releasable pool of synaptic vesicles (104).

### Topiramate (TPM)

Topiramate, 2,3:4,5-bis-O-(1-methylethylidene)-beta-D-fructopyranose sulfamate, is a chemically novel AED. In animal tests, the anticonvulsant profile of TPM most closely approximates those of PHT, CBZ, and LTG. For example, it is active against MES-induced tonic extension seizures. TPM does not prevent seizures induced by sc PTZ; however, it does elevate the seizure threshold for PTZ-induced seizures (105, 106). In the amygdala-kindled rat, TPM reduced both the seizure score and the afterdischarge duration of fully expressed kindled seizures (107) and, with pretreatment, appears to delay the acquisition of kindling (108). This latter effect suggests an antiepileptic vs purely anticonvulsant effect. In the spontaneously epileptic rat, which displays both tonic extension seizures and absence-like spike-wave discharges, TPM was as effective as PHT in reducing tonic extensions and, like ESM, decreased the duration of spike-wave discharges in a dose- and time-dependent fashion (109, Table 30-1). Furthermore, topiramate has been shown to be effective in the GAERS model of absence epilepsy (110). These findings support the apparent broad clinical profile that has emerged for TPM. For example, it appears to be effective against a broad range of seizure types, including partial and generalized tonic-clonic seizures (Table 30-1). In addition, TPM was recently approved for the prophylactic treatment of migraines, further indication of its broad spectrum activity in the CNS. Anecdotal reports have suggested that TPM may be effective against uncomplicated absence seizures, an action supported by findings in the spontaneously epileptic rat (109) but not the *lh/lh* mouse (9).

In studies conducted thus far, TPM has been found to possess multiple potential mechanisms of action ((105, 111, Table 30-2). In cultured hippocampal neurons, therapeutic concentrations (3–30  $\mu\text{M}$ ) of TPM inhibit

sustained repetitive firing in a use- and concentration-dependent manner (112) and reduce voltage-activated  $\text{Na}^+$  currents in cultured neocortical neurons (113).

TPM has also been shown to reduce kainate-evoked inward currents, block kainate-evoked cobalt influx, and block kainic acid receptor-mediated postsynaptic currents in the amygdala, indicating that TPM has antagonistic effects on the kainate/AMPA subtype of glutamate receptor (114–116). The effect of TPM on kainate-evoked currents appears to be unique to TPM among the new AEDs, is consistent with a decrease in neuronal excitability and may, when coupled with its effects against  $\text{Na}^+$  currents, contribute to its efficacy against partial and generalized convulsive seizures.

Effects at the  $\text{Na}^+$  channel and AMPA/kainate receptor do not necessarily support the ability of TPM to block absence-like spike-wave discharges in the spontaneously epileptic rat and anecdotal reports suggesting efficacy against generalized absence epilepsy. TPM has been reported to enhance GABA-evoked chloride single-channel currents in cultured neocortical neurons (117, 118). Kinetic analysis of single-channel recordings from excised outside-out patches demonstrated that TPM increased the frequency of channel opening and the burst frequency but was without effect on open-channel duration or burst duration. This effect of TPM on  $\text{GABA}_A$  channel activity was similar to that observed with BZDs; however, the ability of TPM to enhance  $\text{GABA}_A$ -evoked current was not reversed by the BZD antagonist flumazenil. Although consistent with TPM's ability to block spike-wave discharges and its apparent efficacy against absence epilepsy, enhancement of GABA-mediated inhibition would not be predicted from previous in-vitro studies in which TPM did not displace radiolabeled ligand binding to known binding sites on  $\text{GABA}_A$  receptors (106).

In other preclinical studies, TPM was shown to inhibit certain carbonic anhydrase isoforms, an activity that may, through an alteration of  $\text{HCO}_3^-$  homeostasis, contribute to TPM's mechanism of action (119). Topiramate has also been reported to hyperpolarize hippocampal neurons reversibly in rat hippocampal slices (120) and to inhibit neuronal repetitive firing in rat olfactory cortical neurons by inducing a slow outward membrane current. Both of these effects are thought to be the result of activating an outward current carried by  $\text{K}^+$  ions (120, 121). Furthermore, TPM has been observed to decrease high-voltage activated  $\text{Ca}^{2+}$  currents (HVACC) in CA1 pyramidal (122). This effect at both L- and non L-type  $\text{Ca}^{2+}$  channels required a short preincubation period.

The results to date suggest that the effects of TPM on  $\text{Na}^+$  channels,  $\text{GABA}_A$  receptors, HVACC, and AMPA/kainate receptors are unique as compared to prototypical modulators of these processes. For example, TPM's effects on all four of these protein complexes can be highly variable. TPM has been observed to produce

both immediate and delayed effects; sometimes its effect is reversible and sometimes it is not; in some preparations TPM's action appears to be dependent on the age of neurons in culture. All of these observations, albeit frustrating, are suggestive of a unique interaction with a target protein that may be dependent in part on its molecular structure. Indeed, recent results suggest that the effects of TPM, at least on GABA<sub>A</sub> receptor function, depend on the expression of specific subunits (123). Clearly, additional studies are required to elucidate its precise mechanism of action further.

### Tiagabine (TGB)

Tiagabine, (R)-N-(4,4-di-(3-methyl-thien-2-yl)but-3-enyl)nipecotic acid hydrochloride, is a selective GABA uptake inhibitor (Table 30-3) that emerged from a mechanistic-based drug discovery program designed to identify lipophilic GABA uptake inhibitors for the treatment of epilepsy (124).

In animals, TGB is effective against several types of chemically induced seizures, including methyl-6, 7-dimethoxy-4-ethyl-beta-carboline-3-carboxylate (DMCM)-induced clonic seizures and sc PTZ-induced tonic (potent inhibitor) and clonic (partial inhibitor) seizures (124, Table 30-1). TGB reduced both seizure severity and afterdischarge duration in the amygdala-kindled rat, was active against audiogenic seizures in DBA/2 mice, and was only partially effective against photically induced myoclonus in the photosensitive baboon. However, it is active in the MES test, but only at doses two- to three-fold higher than that producing motor impairment. TGB, like VGB, also worsens spike-wave discharges in the GAERS, GBL, and *lh/lh* models of absence (9).

In-vitro studies have shown TGB to be a potent inhibitor of neuronal and glial GABA uptake (124, Table 30-2). TGB binds selectively and reversibly to the GAT-1 GABA uptake carrier of both glia and neurons, but it does not stimulate GABA release. It is ineffective at other receptor-binding and uptake sites evaluated to date, including the glutamate receptor, Na<sup>+</sup>, and Ca<sup>2+</sup> channels. Inhibition of GABA uptake by TGB leads to increased synaptic concentrations of GABA and a consequent enhancement and prolongation of GABA-mediated inhibitory neurotransmission, an effect that is assumed to be the basis of TGB's anticonvulsant activity against partial seizures and its ability to aggravate spike-wave seizures in rodents and, potentially, humans. Indeed, TGB treatment has been demonstrated to increase extracellular fluid GABA levels in vivo in both animal (125) and human brains (126). The mechanism of its proconvulsive action is probably much like that of VGB (see following paragraphs) in that elevated synaptic concentrations of GABA at the level of the thalamus are thought to potentiate GABA<sub>B</sub>-mediated slow after-hyperpolarization, which leads to enhanced deinactivation of T-currents

and increased amplification of thalamocortical rhythms necessary to support spike-wave discharges.

### Vigabatrin (VGB)

Vigabatrin (4-amino-5-hexenoic acid or gamma-vinyl GABA), is available in Europe, Mexico, and Canada for the treatment of partial seizures. In experimental seizure models, VGB is active in photosensitive baboons, strychnine- and sound-induced seizures, and amygdala kindling. VGB is essentially inactive in the MES test and in DMCM-induced clonic seizures and worsens spike-wave seizures in the *lh/lh* mouse and GAERS rat (9, 12, 14, 127). Further, direct injection of VGB into the median part of the lateral thalamus of GAERS significantly increased the cumulative duration of spike-and-wave discharges (128, 129). VGB's anticonvulsant activity in the kindled rat and worsening of spike-wave seizures in the *lh/lh* mouse and GAERS correlate well with its clinical utility against partial seizures and its potential exacerbation of spike-wave seizures, respectively.

VGB, a close structural analog of GABA, arose from a synthesis program designed to develop molecules that target GABA alpha-oxoglutarate transaminase (GABA-T; EC 2.6.1.19), the enzyme responsible for GABA metabolism. VGB binds to GABA-T and permanently inactivates the enzyme, thereby increasing brain GABA levels and enhancing GABAergic neurotransmission (Table 30-2). VGB administration to laboratory animals produces a prolonged, dose-related inhibition of GABA-T and corresponding elevation of whole-brain GABA levels (130, 131). An increase in all brain regions examined was observed; however, quantitative differences between brain regions were noted (132). Likewise, in human studies VGB produces a dose-dependent increase in cerebrospinal fluid GABA levels (133–135). In animal studies, there does appear to be a preferential increase in the GABA concentration in the synaptosomal pool over the nonsynaptosomal pool (136). Thus, VGB treatment leads to an increased amount of presynaptic GABA available for release, which indirectly leads to increased GABAergic activity at postsynaptic GABA receptors.

The consequent increased activity of GABA on postsynaptic GABA receptors results in increased inhibition of neurons involved in seizure activity and represents the most likely basis for VGB's clinical activity against partial seizures. The same mechanism that affords efficacy in partial seizures likely contributes to aggravation of generalized absence seizures (9, 40, 123). For example, increased GABA release in the thalamus will lead to a greater activation of GABA<sub>B</sub> receptors. Enhanced GABA<sub>B</sub> receptor activation leads to a prolonged hyperpolarization and subsequent deinactivation of T-type Ca<sup>2+</sup> currents, which contribute to the synchronized burst firing of thalamocortical neurons.

Unfortunately, vigabatrin use has been associated with an irreversible visual field defects in both children and adults; see Ben-Menachem 2002 (137) for review and references. Unfortunately the emergence of this idiosyncratic adverse event has had a significant impact on the use of this very effective AED in children with infantile spasms.

### Zonisamide (ZNS)

Zonisamide (1,2-benzisoxazole-3-methanesulfonamide) was discovered as a result of routine biological screening of 1,2-benzisoxazole derivatives. ZNS possesses a broad anticonvulsant profile in animal seizure models (14, 138; Table 30-1). It blocks MES seizures in a number of different species and restricts the spread of focal cortical seizures in cats. In addition, ZNS blocked tonic extension seizures in spontaneous epileptic rats and audiogenic seizures in DBA/2 mice (109). In cats and rats, ZNS also suppresses focal seizure activity induced by cortical freezing and tungstic acid gel, respectively. Moreover, in hippocampal-kindled rats, amygdala-kindled rats, and cats ZNS suppresses subcortically evoked seizures. In geniculate-kindled cats, ZNS decreases photically induced myoclonus. In the spontaneous epileptic rat, ZNS did not affect spike-wave discharges (109). Clinically, ZNS appears to possess efficacy against a number of seizure types including partial and secondarily generalized seizures, generalized tonic-clonic, generalized tonic, atypical absence, atonic, and myoclonic seizures (138).

ZNS's broad anticonvulsant profile can likely be accounted for by a similarly broad mechanistic profile (Table 30-2). For example, it blocks sustained repetitive firing in cultured spinal cord neurons (139) through an effect on voltage-sensitive Na<sup>+</sup> channels (140). In voltage-clamped *Myxicola* giant axons, ZNS, like PHT, CBZ, and LTG, appears to retard recovery from fast and slow Na<sup>+</sup> channel inactivation and produces a hyperpolarizing shift in the steady-state inactivation curve. ZNS has also been demonstrated to reduce voltage-dependent T-type calcium currents in cultured neurons (141) and neuroblastoma cells (142). ZNS also appears to modulate GABA-mediated inhibition. For example, ZNS has been reported to decrease (<sup>3</sup>H)flunitrazepam and (<sup>3</sup>H)muscimol binding to the BZD and GABA<sub>A</sub> receptors, respectively. Similarly, (<sup>3</sup>H)ZNS binding to rat whole brain membranes is reduced by clonazepam and enhanced by GABA (143). In contrast, ZNS did not affect ion currents evoked by iontophoretically applied GABA (139). Obviously, additional experiments are required to resolve this apparent discrepancy.

Effects on voltage-sensitive Na<sup>+</sup> channels are likely to contribute to ZNS's ability to block MES-induced tonic extension in animals and generalized tonic seizures in humans, whereas effects on low voltage-activated T currents and perhaps GABA receptors are more likely

to correlate with its efficacy against generalized absence and myoclonic seizures, respectively.

### CONCLUSIONS

In recent years, an improved understanding of the mechanisms associated with epileptiform events and the anticonvulsant activity of AEDs has contributed to the synthesis of new AEDs specifically designed to reduce excitation or to enhance inhibition. This mechanistic approach has been successful in identifying two new drugs that modify GABA-mediated inhibition by either blocking reuptake of synaptically released GABA (i.e., TGB) or inhibiting metabolism of neuronal and glial GABA (i.e., VGB). In addition, knowledge that the binding site for gabapentin (i.e., alpha<sub>2</sub>delta auxiliary subunit of the voltage-gated calcium channel) correlated with its anticonvulsant profile led to the search for more potent analogs and the subsequent development of pregabalin. These three examples clearly support the validity of the mechanistic approach.

Unfortunately, at the excitatory synapse, the mechanistic approach has been less successful, despite an extensive understanding of the processes underlying excitatory neurotransmission. For example, the drugs developed thus far to target specifically the NMDA-preferring glutamate receptor have not only lacked efficacy in the limited clinical trials conducted to date but have also resulted in intolerable side effects (144). Increased understanding of the molecular biology of not only the NMDA, but also the AMPA and kainate receptors may ultimately lead to the development of selective, less toxic, and clinically efficacious glutamate antagonists. To this point, both felbamate and topiramate demonstrate that a drug that modulates activity at these two molecular targets can be clinically useful for the treatment of patients.

Many of the new AEDs appear to act through a combination of mechanisms that likely extend beyond effects on Na<sup>+</sup> and Ca<sup>2+</sup> channels and GABA receptors. However, these effects alone are probably not sufficient to account for the apparent efficacy of the newer AEDs in highly refractory seizure patients. Two of the newer drugs (FBM and TPM) appear to possess a unique ability to inhibit glutamate-mediated neurotransmission through an effect on NMDA (FBM) and AMPA/kainate (TPM) receptors. The finding that these drugs limit glutamatergic neurotransmission without producing the typical behavioral disturbances associated with selective glutamate antagonists may suggest that they target a different glutamate receptor subtype. Newly developed molecular biologic techniques will undoubtedly make it possible to address this issue in the future.

Mechanisms of action beyond those discussed are likely to contribute to the underlying efficacy of the new AEDs. The continued search to understand the molecular

mode of action of the available drugs thoroughly will indirectly provide important information concerning the underlying causes of seizure disorders. Ultimately the results obtained from these and other studies will continue to assist in the rational design of newer, more effective, and less toxic drugs.

It is worth noting that several investigated AEDs are currently winding their way through the development process and that some of these are likely to come into use in the next few years. Many of these drugs share a similar mechanistic profile with the marketed AEDs. On the other hand, the molecular mechanism of a few of these AEDs has yet to be defined. It is strongly hoped that the “inability” to define a specific mechanism to a given drug would translate into the development of a novel therapy with improved efficacy over the established AEDs.

Perhaps equally important is the finding that several of the drugs in development have been found to prevent neuronal damage secondary to an acute brain insult. It is possible that this action may one day lead to the development of a “disease-modifying” therapy that slows, halts, or prevents the development of epilepsy in the susceptible individual. Such a therapy would be a major leap forward for the patient with newly diagnosed epilepsy, or even the person at risk for developing epilepsy. The challenges associated with the development of a disease-modifying therapeutic are immense, but worthy of pursuit. Last, it is likely that we will eventually identify novel drugs that not only inhibit acute seizures but also interfere with the pathologic processes that underlie the development of drug-resistant epilepsy. Only at that point will we be able to conclude the search for the ideal AED.

## Evidence-Based Medicine Issues Related to Drug Selection

*Tracy A. Glauser  
Diego A. Morita*

**W**hen selecting an antiepileptic drug (AED) for a patient with epilepsy, a clinician integrates his or her own experience, education, cultural beliefs, and personal values with patient-specific variables and AED-specific variables to select the appropriate AED (Figure 31-1) (1, 2). The overlap between a physician's background and specific AED characteristics can be called the physician's "internal" knowledge base used to make a clinical decision. Similarly, the doctor-patient interaction depends on the physician's background and the patient's characteristics; this "interface" knowledge also plays a role in medication selection.

However, internal and interface knowledge are only two legs of the clinical decision tripod. The third component could be called "external" knowledge—the unbiased third-party evaluation of relevant available scientific evidence about an AED's characteristics or performance within specific patient situations (e.g., partial onset seizures, children, etc.). This last component is represented by various types of rigorous evaluations called systematic reviews, guidelines, or practice parameters. The integration of these three forms of knowledge allows the clinician to make an evidence-based decision and therefore practice evidence-based medicine (EBM).

This chapter will examine a variety of EBM issues related to drug selection for patients with epilepsy. These

issues will include a brief review of some historical events leading to the development of the EBM approach; key definitions; description of the evolution, structure, and examples of two types of EBM tools (systematic reviews and practice guidelines); and discussion of the limitations of EBM.

### HISTORICAL EVENTS LEADING TO EBM

The development of the controlled clinical trial was essential to the development of modern EBM. From biblical references through bloodletting experiments to James Lind's classic trial of treatments for scurvy, the methodology of the controlled clinical trial slowly developed (3, 4). The subsequent development of EBM in the second half of the twentieth century was a worldwide effort involving numerous people and organizations. Due to space constraints, only three different yet complementary contributions to the development of EBM will be highlighted (3).

The British epidemiologist Professor Archibald Leman Cochrane, CBE, FRCP, FFCM (1909–1988), was a major contributor to the development of EBM. His 1972 book, *Effectiveness and Efficiency: Random Reflections on Health Services*, proposed that, since resources are limited, focus should be on providing health care that

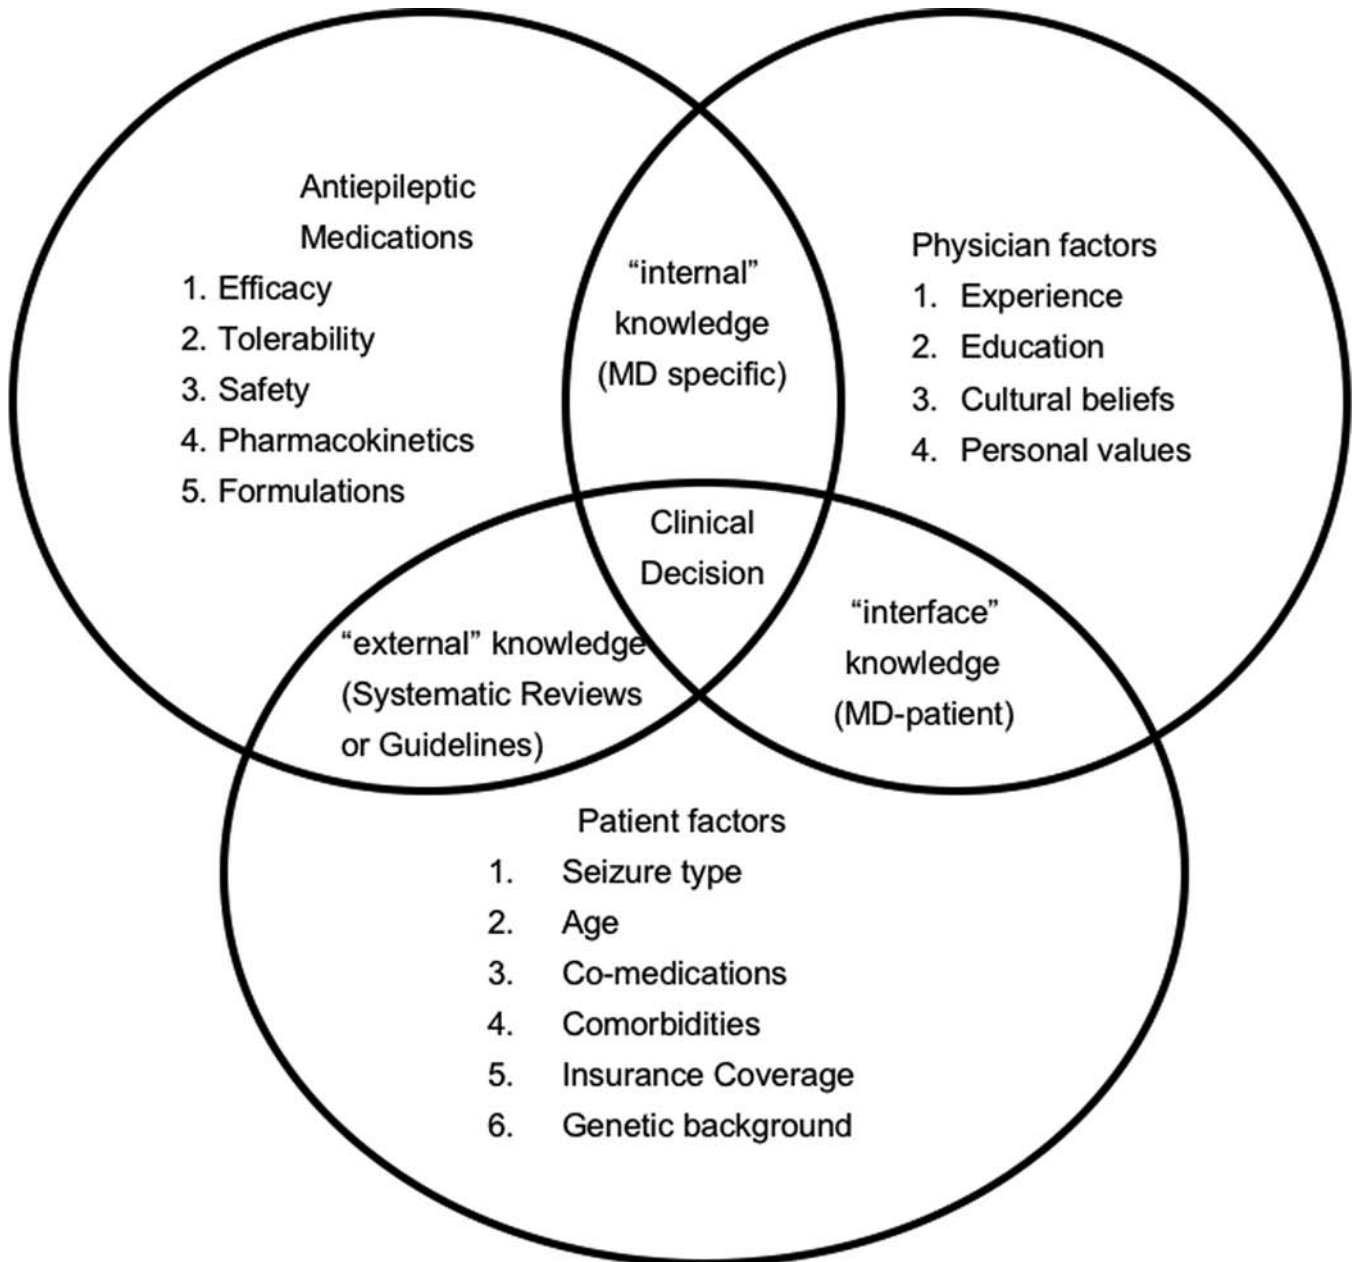

FIGURE 31-1

Factors involved with making drug selection for patients with epilepsy (clinical decision tripod) (adapted from Mulrow CD, Cook DJ, Davidoff F. Systematic reviews: critical links in the great chain of evidence. *Ann Intern Med* 1997; 126[5]:389–391.)

has been shown to be effective (5). Professor Cochrane felt the focus should be on randomized, controlled trials (RCTs) as the most reliable source of information. This approach gained widespread acceptance and led to the development during the 1980s of an international collaboration that developed a database of perinatal trials. After his death in 1988 the movement continued, and in 1992 the first Cochrane center opened in Oxford, UK. The next year, The Cochrane Collaboration was founded.

“The Cochrane Collaboration is an international not-for-profit and independent organization, dedicated to making up-to-date, accurate information about the effects of healthcare readily available worldwide. It produces and disseminates systematic reviews of healthcare interventions and promotes the search for evidence in the form of clinical trials and other studies of interventions” (6).

The major output of the Cochrane Collaboration is the Cochrane Database of Systematic Reviews. These

reviews are part of the Cochrane Library, which is a collection of databases for clinicians including the Cochrane Database of Systematic Reviews, the Database of Abstracts of Reviews of Effects, the Cochrane Central Register of Controlled Trials (CENTRAL), the Cochrane Methodology Register, the NHS Economic Evaluation Database, Health Technology Assessment Database, and the Cochrane Database of Methodology Reviews (CDMR) (7). The Library is published on CD-ROM and the Internet and updated quarterly (7).

A second major contribution was by the clinical epidemiologist Dr. David Sackett (1934–present). His background was as a physician (MD from the University of Illinois) and epidemiologist (MS in epidemiology from Harvard University). He founded the first department of clinical epidemiology in Canada at McMaster University and played a major role in the development and implementation of problem-based learning for the medical students at McMaster Medical School. He incorporated EBM as an important part of the learning process. In 1994, he left McMaster University for Oxford University in England and the Oxford Centre for Evidence-Based Medicine. His passion for EBM, coupled with his articles (8–16) and books (17, 18) on the need, benefits, and methods of EBM, helped to solidify EBM's place in the medical community (19).

The last major contribution occurred in the United States in the late 1980s. As a result of the skyrocketing cost of health care and the high rate of Americans without health insurance, in 1989 dramatic changes in federally funded health care programs were being proposed, including a cap to total federal health care spending (20). Medical organizations strongly opposed these expenditure targets and argued that a better approach would be to encourage outcome assessment and practice guidelines as cost-effective alternatives (20). In 1989 the final budget reconciliation included legislation that replaced these expenditure targets with Voluntary Performance Standards (20). The goal then was to develop scientifically sound practice parameters that would improve clinical practice and therefore be cost efficient and reduce wasteful spending.

The Agency for Health Care Policy and Research (AHCPR) was established with the goal to develop practice guidelines (20). The Omnibus Budget Reconciliation Act of 1989 also established a National Advisory Council for Health Care Policy Research and Evaluation whose responsibility it was to advise the Administrator of AHCPR and the Secretary of the Department of Health and Human Services on developing, reviewing, and updating guidelines (20). The Institute of Medicine of the National Academy of Sciences was awarded a contract to develop priorities for guidelines along with developing definitions to be used (20). Over the past two decades, multiple professional organizations,

nonprofit organizations, and government agencies have developed hundreds of guidelines for a wide variety of diseases (21).

## EBM DEFINITIONS

EBM, a term formally introduced in 1992 (22, 23), has been defined as “the conscientious, explicit, and judicious use of current best evidence in making decisions about the care of individualized patients. The practice of evidence-based medicine means integrating individual clinical expertise with the best available external clinical evidence from systematic research” (8).

The two most commonly used EBM tools are the systematic review and the practice guideline.

A systematic review is “A review of a clearly formulated question that uses systematic and explicit methods to identify, select, and critically appraise relevant research, and to collect and analyse data from the studies that are included in the review. Statistical methods (meta-analysis) may or may not be used to analyse and summarise the results of the included studies” (7).

Practice guidelines are “Systematically developed statements to assist practitioner and patient decisions about appropriate health care for specific clinical circumstances” (24).

The American Medical Association (AMA) felt that negative connotations from terminology might limit physicians' acceptance of these policies, standards, and guidelines. As such the AMA preferred to use the term “parameter.” The AMA defined “practice parameters” as “strategies for patient management, developed to assist physicians in clinical decision making . . . including standards, guidelines, and other patient management strategies” (20).

## EBM TOOLS

### Systematic Review

*Overview.* The most refined example of a systematic review is the Cochrane Review. The development of a Cochrane Review is a multistep collaborative process between the investigators and the Cochrane Review Group's editorial team. After extensive discussions with the editorial team about the topic or title of the review, authors usually attend a protocol workshop to help them understand how to carry out the highly structured review. The next step is to develop and publish a protocol describing how the review will be conducted. All Cochrane Reviews are prepared using a software program called Review Manager (RevMan). The review follows the format described in the *Cochrane Handbook for*

*Systematic Reviews of Interventions.* As the review is being constructed, additional methodological, statistical, and editorial input is given as needed by the Cochrane Review editorial team. Prior to publication, the review is evaluated by impartial external referees. Once published, authors update the reviews yearly if new relevant information becomes available (25).

*Structure.* A Cochrane Review is a highly structured document containing well-defined sections. The review begins with a short summary written in plain language for lay people. A structured abstract of the entire review follows. Then relevant background information, objectives of the review, and selection criteria (e.g., types of studies, types of participants, types of interventions, and types of outcome measures) are described, followed by the search strategy for identifying potentially eligible studies. Methods is the next section; the inclusion/exclusion criteria for eligible studies are described, the approach to assessing study quality is presented, how data were extracted and analyzed is depicted, and details about whether any subgroups were studied are presented. The results section describes the type and number of studies identified, along with a detailed assessment of each study's methodologies, and a summary of the data (potentially including a meta-analysis). The interpretation and assessment of the results is contained in the discussion section. Last, the authors provide their own conclusions along with the data's implications for practice for research (25).

*Examples.* To date, there are 33 epilepsy Cochrane Reviews. Seven systematic reviews have examined AED use in monotherapy (26–32): carbamazepine vs. valproic acid (26), phenytoin vs. valproic acid (28), carbamazepine vs. phenytoin (29), phenytoin vs. phenobarbital (27), carbamazepine vs. phenobarbital (30), oxcarbazepine vs. phenytoin (31), and lamotrigine vs. carbamazepine (32). The outcome focus was on three end points: time to withdrawal, number of patients achieving 12-month seizure freedom, and time to first seizure. Because of the paucity of high-quality studies (class I and class II, as defined in Tables 31-1 and 31-2), the overwhelming majority of data used in these reviews was from class III studies. Many times the reviews found no significant differences for the outcomes examined.

Nine Cochrane Reviews have examined AEDs' use as add-on therapy in drug-resistant partial epilepsy (33–44). These reviews examined topiramate (33), lamotrigine (39), levetiracetam (41), oxcarbazepine (42), zonisamide (34, 37), tiagabine (36), gabapentin (43, 44), calcium antagonists (38), and remacemide (35).

Other Cochrane Reviews have been published for absence seizures (45), infantile spasms (46), Lennox-Gastaut syndrome (47), neonatal seizures (48), corticosteroid use for childhood epilepsy (49), status epilepticus (50, 51),

neuropsychological outcomes in children with epilepsy (52), and the ketogenic diet (53).

Non-Cochrane systematic epilepsy reviews have also been published, covering topics such as management of newly diagnosed epilepsy (54–57), tonic-clonic seizures (58), adults with epilepsy and intellectual disability (59), childhood epilepsies (60), AED clinical trials (61), AEDs and cognitive function (62), ketogenic diet (63, 64), quality of life (65), and AED economic issues (66, 67).

## Practice Guideline

*Overview.* The evolution of the systematic review was relatively straightforward compared to the developments leading up to practice guidelines. Guidelines have evolved through multiple stages including individual expert opinion, informal consensus guidelines, formal consensus guidelines, and evidence-based guidelines (68).

*Non-evidence-based Guidelines.* Over the past hundred years, 36 AEDs have been released worldwide resulting in multiple medical treatment options for people with epilepsy (1). The first wave of AEDs was in the first half of the twentieth century and included phenobarbital, phenytoin, and structurally similar AEDs. In the 1970s a second wave of AEDs included carbamazepine and valproic acid. The latest wave began in the early 1990s and contained 10 new AEDs.

The early growth in AEDs was not accompanied by a concomitant growth in the amount of available scientific evidence regarding each drug's efficacy, safety, and tolerability. Clinicians relied on their own clinical experience coupled with the advice of a few trusted colleagues when selecting a medication for patients with epilepsy. This "individual expert opinion" approach led to diverse (and often strongly held) opinions about the appropriate choice and sequencing of medications for specific groups of patients. During this time, the lack of widely accepted methodology for conducting epilepsy clinical trials and the frequent reporting of treatment outcomes in small groups of patients impaired practitioners from assessing which treatment approaches were superior.

The next evolution was to bring experts together and let them come to a consensus about the appropriate medication or sequencing of medications for particular groups of patients. This approach has been called the "informal consensus development" (68) approach or the "global subjective judgment" approach (69). The methodology involved in developing the conclusions and recommendations for this type of guideline is usually poorly described and poorly implemented. There is frequently little mention of how studies are selected for inclusion, how the recommendations relate to the evidence, or, in general, how the bias of the experts was minimized. Unfortunately this type of guideline remains a commonly

used approach because it is easy to construct, fast to develop, and needs little formal statistical analysis (68). Even today, there are multiple examples of this flawed approach in the epilepsy literature; the resulting conclusions must be viewed with a jaundiced eye.

In the late 1970s a new approach was developed called the “formal consensus” (68) or the “expert consensus” approach. This approach is used by the Consensus Development Program sponsored by the National Institutes of Health (NIH) (70–72). Since 1977, these structured two-and-a-half-day conferences have focused on medical technologies and practices in which there is a difference of opinion about best practices (20). These conferences produce evidence-based consensus statements that address controversial issues in medicine that have significant importance to patients, providers, and the general public. From 1977 through 1990, 84 conferences have been held. Only two have focused on seizures or epilepsy: one related to the surgical treatment of epilepsy (73), and one focused on febrile seizures (74, 75). Evidence, including a systematic literature review prepared by the Agency for Healthcare Research and Quality, is presented to an impartial panel. The panel is then sequestered and then renders its recommendations in its statement. Each consensus statement answers approximately four to six

questions; the final document is not a policy statement of the NIH or the federal government.

The expert consensus guideline with the largest national impact was the 1993 expert consensus panel sponsored by the Epilepsy Foundation for the management of convulsive seizures and status epilepticus, published in *Journal of the American Medical Association* (76).

*Evidence-based Guidelines.* Over the last 20 years each medical specialty, nonprofit organization, and government agency that has developed evidence-based guidelines has used the same general approach but slightly different specific methodology. A common backbone for the development of evidence-based guidelines is shown in Figure 31-2. The process starts with selecting a topic and then a panel of experts; these experts develop clinical questions based on the topic. A comprehensive review of the literature is then performed, and identified articles are abstracted according to a stylized format. The abstracted data are placed in evidence tables and the articles are rated. Based upon the identified evidence and a predetermined methodologic approach to interpretation, the panel of experts then develops recommendations and algorithms. The algorithms are distributed for extensive peer review and undergo external validation.

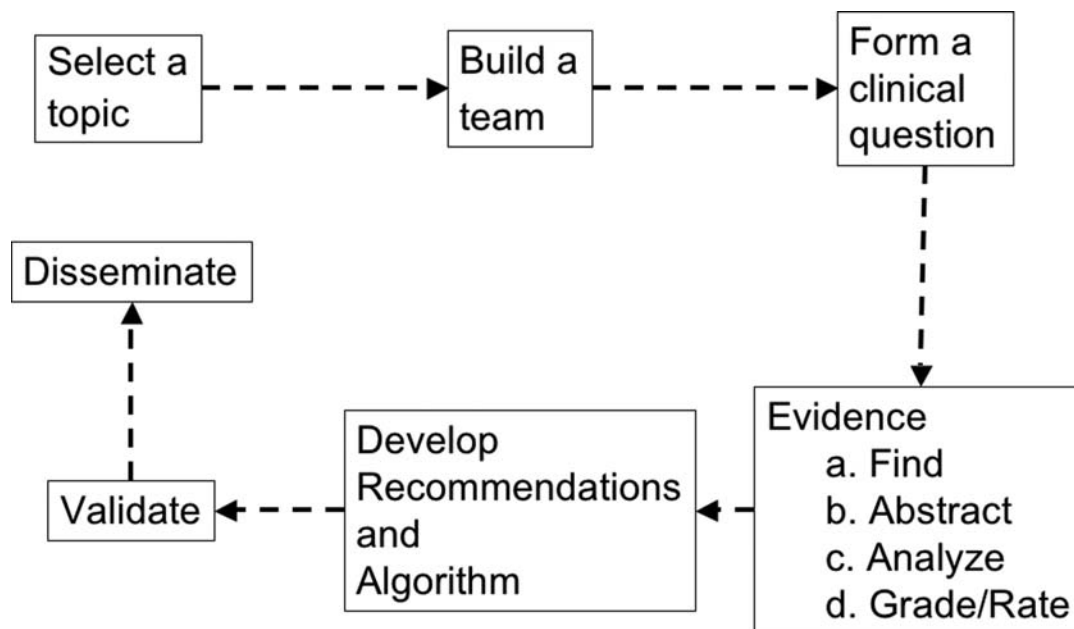

FIGURE 31-2

Sequence of steps involved with developing an evidence-based guideline.

After feedback is received and incorporated, the guidelines are disseminated into the community.

*Examples of Evidence-based Guidelines.* Since 1996, the American Academy of Neurology (AAN) has produced 14 evidenced-based guidelines focused on some aspect of epilepsy and its evaluation or treatment. There have been treatment guidelines addressing the use of the newer AEDs in new-onset epilepsy (77, 78), the use of the newer AEDs (and felbamate) in refractory epilepsy (79–81), and the treatment of infantile spasms (82). The International League Against Epilepsy (ILAE) published an evidence-based guideline on the treatment of new-onset epilepsy of all seizure types and all ages (1). Other important epilepsy guidelines have been published by the Scottish Intercollegiate Guidelines Network (SIGN; <http://www.sign.ac.uk/>) (83) and the National Institute for Clinical Excellence (NICE; <http://www.nice.org.uk/>).

### Limitations of Evidence-Based Medicine

*Problems with Evidence-based Guidelines.* The above approach is a thumbnail sketch of the process. When viewed in detail, many issues arise that impact on the practical application of evidence-based guidelines to clinical care. These issues involve topic selection, conflict of interest, question formation, grading criteria for studies, and criteria for assessing strengths of recommendation.

The process begins with a sponsoring organization picking a topic. The topic must have significance (e.g., there is a gap or controversy between current practice and the existing evidence) and feasibility (there is sufficient medical evidence to try to answer the question). Epilepsy topics often have the former but not the latter. As such, epilepsy guidelines may end up with no clinically relevant conclusion because of lack of evidence. This outcome is frustrating for clinicians seeking guidance for a clinical problem in a specific patient.

The multidisciplinary team of experts can include physicians, nurses, doctors of pharmacy, clinical pharmacologist, statisticians, epidemiologists, health care economists, consumers, and patient representatives. Not every team needs to have all members from each of these constituencies, but the greater the variety of constituencies involved, the more comprehensive and wide ranging the impact of the guideline may be. One problem these teams face are real or perceived conflicts of interest. It is easy to allow bias to subtly affect selection criteria or study interpretation. A guideline's credibility is only as good as the credibility of its authors. Panel members need to declare these real or perceived conflicts of interest in order not to jeopardize the project's credibility. Different guidelines set different time frames. For example, for the AAN, conflicts must be declared for the past 5 years.

Once the topic has been selected and a team assembled, clinical questions must be formed. The clinical question is often formulated as a five-part PECOT-structured question. These letters stand for Patient/Participants/Population, Exposure/Interventions, Comparison, Outcomes, and Time. For example a typical PECOT-structured question would be: "For children with partial onset seizures (P), which antiepileptic drug (E) compared to an adequate comparator (C) provides the highest efficacy (O) over the first year of exposure (T)?" Formulation of this specific clinical question is one of the key aspects of the guideline. Two separate guidelines formulating clinical questions on the same topic can produce different conclusions if their PECOT questions are framed differently. It is critical to understand the question asked by the guideline when assessing the guideline's clinical utility for any particular patient.

Different organizations (and their guidelines) have different strategies on how to score, grade, and rate the evidence found, along with the studies generating it. In general, most scoring systems rank studies according to the number of "major" or "minor" variables present or absent in a study; these variables are factors that impact on the reliability, verifiability, and objectivity of the outcome. For example, major variables include the use of randomization, the use of control groups, the use of masked outcome assessments (blinding), the use of adequate comparators, and adequate enrollment to detect differences (if they exist) between treatment groups. Minor variables include a clearly defined primary outcome variable, clearly stated inclusion and exclusion criteria, addressing of baseline differences between treatment groups, adequate duration of assessment (e.g., in the case of infrequent seizure activity at baseline), and adequate handling of patients who drop out of the study.

In general, studies receiving the top grade are RCTs with the best evidence that meets all major and minor criteria. Studies receiving the next best grade are RCTs that are missing some minor criterion. Trials in the third ranking are those missing some major criterion. The lowest ranked studies are missing most or all major criteria or are only expert opinion. There is significant variability in these grading and rating scales across different guidelines. The AAN and ILAE methods of grading clinical trials are shown in Tables 31-1 and 31-2.

Last, after all the relevant studies have been abstracted, analyzed, and graded, the panel of experts must translate the evidence into recommendations. The strength of these recommendations is determined using a predetermined scoring system, which can vary between organizations (AAN's scoring for strength of recommendations is shown in Table 31-1; ILAE's scoring system is shown in Table 31-3). There are usually four to five levels of recommendations and usually at least one recommendation per question.

TABLE 31-1

*Relationship Between Clinical Trial Ratings, Level of Evidence, and Conclusions for AAN Guidelines (77, 78)*

CONCLUSION AND RECOMMENDATION	TRANSLATION OF EVIDENCE TO RECOMMENDATION	RATING OF ARTICLE
<p>Conclusion: Level A: Established as effective, ineffective or harmful for the given condition in the specified population</p> <p>Recommendation: Should be done or should not be done</p>	<p>Level A rating: Two or more consistent Class I studies</p>	<p>Class I: Prospective, randomized, controlled clinical trial with masked outcome assessment, in a representative population. The following are required:</p> <ol style="list-style-type: none"> <li>Primary outcome(s) is/are clearly defined,</li> <li>exclusion/inclusion criteria are clearly defined,</li> <li>adequate accounting for dropouts and crossovers with numbers sufficiently low to have minimal potential for bias</li> <li>relevant baseline characteristics are presented and substantially equivalent among treatment groups or there is appropriate statistical adjustment for differences.</li> </ol>
<p>Conclusion: Level B: Probably effective, ineffective or harmful for the given condition in the specified population</p> <p>Recommendation: Should be considered or should not be considered</p>	<p>Level B rating: At least one Class I study OR Two consistent Class II studies</p>	<p>Class II: Prospective matched group cohort study in a representative population with masked outcome assessment that meets criteria a–d. above OR an RCT in a representative population that lacks one criteria of a–d.</p>
<p>Conclusion: Level C: Possibly effective, ineffective or harmful for the given condition in the specified population</p> <p>Recommendation: May be considered or may not be considered</p>	<p>Level C rating: At least one Class II study OR Two consistent Class III studies</p>	<p>Class III: All other controlled trials (including well-defined natural history controls or patients serving as own controls) in a representative population, where outcome is independently assessed, or independently derived by objective outcome measurements.</p>
<p>Conclusion: Level U: Data inadequate or conflicting. Given current knowledge, treatment is unproven.</p> <p>Recommendation: None</p>	<p>Level U: Studies not meeting criteria for Class I–Class III</p>	<p>Class IV: Evidence from uncontrolled studies, case series, case reports, or expert opinion.</p>

Although guidelines use a common methodologic backbone, it is hard to compare guidelines from different organizations for the same topic because different PECOT questions are asked, variability in rating and grading scales occurs, and strength of recommendation criteria frequently differ between organizations. Both the ILAE and the AAN/American Epilepsy Society (AES) guidelines use appropriate methodology to provide evidence-based recommendations to specifically address clinically relevant questions. A comparison of the AAN/AES and the ILAE

guidelines for the initial monotherapy treatment of epilepsy is shown in Figure 31-3. Although both guidelines dealt with pediatric epilepsy in some form, there were significant differences between the guidelines in terms of drugs examined, scoring system used, and key variables assessed. In addition, cost was never factored into either guideline. This is just one example of how two guidelines addressing the same topic can be dramatically different based on specific aspects of their methodology. These differences in guideline methodology lead to clear differences

**TABLE 31-2**  
**Rating Scale of Evidence for Potentially Relevant Studies for ILAE Guideline on Initial Monotherapy for Adults and Children with Epilepsy (1)**

CLASS	CRITERIA
I	<p>A prospective, randomized, controlled clinical trial (RCT) or meta-analysis of RCTs, in a representative population that meets all 6 criteria:</p> <ol style="list-style-type: none"> <li>1. Primary outcome variable: efficacy or effectiveness</li> <li>2. Treatment duration: <math>\geq 48</math> weeks</li> <li>3. Study design: Double blind</li> <li>4. Superiority demonstrated or if no superiority demonstrated the study's actual sample size was sufficient to show non-inferiority of no worse than a 20% relative difference in effectiveness/efficacy (see text for detailed explanation of this detectable noninferiority boundary)</li> <li>5. Study exit: Not forced by a predetermined number of treatment emergent seizures</li> <li>6. Appropriate statistical analysis</li> </ol>
II	<p>An RCT or meta-analysis meeting all the Class I criteria except that</p> <ol style="list-style-type: none"> <li>1. No superiority was demonstrated and the study's actual sample size was sufficient only to show non-inferiority at a 21% to 30% relative difference in effectiveness/efficacy</li> </ol> <p>OR</p> <ol style="list-style-type: none"> <li>2. Treatment duration: <math>\geq 24</math> weeks but <math>&lt; 48</math> weeks</li> </ol>
III	<p>An RCT or meta-analysis not meeting the criteria for any Class I or Class II category (e.g., an open label study or a double blind study with either a detectable noninferiority boundary of <math>&gt; 30\%</math> or forced exit criteria)</p>
IV	<p>Evidence from nonrandomized, prospective, controlled or uncontrolled studies, case series, or expert reports.</p>

in guideline conclusions and recommendations. Table 31-4 compares treatment recommendations for pediatric seizure types and epilepsy syndrome for three evidence-based guidelines (ILAE guidelines [1], SIGN [83], and the NICE), two national surveys (Pediatric Expert Consensus survey [84] and a French national survey [85]), and the United States Food and Drug Administration (FDA). Although trends are noted for some AEDs for certain seizure or epilepsy types, there are clear disagreements. It is critical to understand a guideline's questions and methodology before incorporating its recommendations into the evidence-based medicine decision-making process.

*Problems with EBM Itself.* EBM relies heavily on the power of RCTs. There are many benefits to this: RCTs tend to minimize bias that can affect the trial's outcome, they minimize the impact of variability, and they give better information than anecdotal medicine. In short, RCTs improve the chances of getting the "right answer." However, there are significant limitations with RCTs. The RCT trial may not ask the "right question," may not pick a clinically significant treatment effect, and does not explain the factors underlying intersubject variability in response to therapy. RCTs look for population effects. The study population size in most RCTs is selected to answer only one specific question; any alternative questions and analyses may not show any treatment effect because they are underpowered.

There are critics of the EBM approach in general. Some believe that:

1. Knowledge gained from clinical research and clinical reviews is not directly applicable to the care of individualized patients (23).
2. EBM will be used as an objective (yet incomplete) method by which insurers could approve or deny payment for care (86, 87).
3. EBM is impossible to practice because of the time demands, financial issues, and patient variability seen outside academic centers (8).
4. EBM is "cookbook" medicine (8).
5. EBM is limited because it relies primarily on randomized trials and meta-analyses (8).

Many convincing arguments exist rebutting these concerns. However, EBM is still a young discipline, and much work still must be done before it becomes the standard approach for medical care for patients with epilepsy.

## CONCLUSION

Evidence-based medicine is a powerful approach that can help clinicians reach personalized clinical decisions for their patients with epilepsy. Systematic reviews, evidence-based

**TABLE 31-3**  
**Relationship Between Clinical Trial Ratings, Level of Evidence and Conclusions for ILAE Guideline on Initial Monotherapy for Adults and Children with Epilepsy (1)**

COMBINATION(S) OF CLINICAL TRIAL RATINGS	LEVEL OF EVIDENCE	CONCLUSIONS	RECOMMENDATION (BASED ON EFFICACY AND EFFECTIVENESS DATA ONLY)
≥1 Class I studies or meta-analysis meeting Class I criteria sources OR ≥ 2 Class II studies	A	AED established as efficacious or effective as initial monotherapy	AED should be considered for initial monotherapy—First-line monotherapy candidate
1 Class II study or meta-analysis meeting Class II criteria	B	AED probably efficacious or effective as initial monotherapy	
≥2 Class III double-blind or open label studies	C	AED possibly efficacious or effective as initial monotherapy	AED may be considered for initial monotherapy—Alternative first-line monotherapy candidates
1 Class III double blind or open label study OR ≥1 Class IV clinical studies OR Data from expert committee reports, opinions from experienced clinicians	D	AED potentially efficacious or effective as initial monotherapy	Weak efficacy or effectiveness data available to support the use of the AED for initial monotherapy
Absence of directly applicable clinical evidence upon which to base a recommendation	E	No data available to assess if AED is effective as initial monotherapy	Either no data or inadequate efficacy or effectiveness data available to decide whether AED could be considered for initial monotherapy
Positive evidence of lack of efficacy or effectiveness based on Class I to IV studies OR Significant risk of seizure aggravation based on Class I to IV studies	F	AED established as ineffective or significant risk of seizure aggravation	AED <i>should not</i> be used for initial monotherapy

Variable	 <b>ILAE</b>	 <b>AAN/AES</b>
Team	N = 10, 6 countries	N = 24, 1 country
AEDs examined	31 AEDs	7 newer US AEDs
Study years	1940-present	1987-2003
Scoring system	ILAE system	AAN system
Data reanalysis	Yes, used to rank	No
Key variables	Randomization, blinding, adequate power	Control group
Effective dose	Not discussed	Discussed
Costs	Not considered	Not considered

Lennox-Gastaut syndrome	VPA, TPM, LTG	not reviewed	not specifically mentioned	LTG, VPA, TPM	not surveyed	FLB, TPM, LTG
Infantile spasms	VGB, ACTH	not reviewed	not specifically mentioned	VGB, corticosteroids	not surveyed	none

ACTH, adrenocorticotropin; CBZ, carbamazepine; CLB, clobazam; ESM, ethosuximide; FLB, felbamate; LTG, lamotrigine; OXC, oxcarbazepine; PB, phenobarbital; PHT, phenytoin; TPM, topiramate; VGB, vigabatrin; VPA, valproic acid.

guidelines, and practice parameters are critical tools for practicing evidence-based medicine. However, these “external” knowledge sources should not be used alone; they need to be integrated with a clinician’s experience and background, with both AED-specific factors (“internal” knowledge) and patient-specific variables (“interface” knowledge) to select the appropriate antiepileptic medication for a patient.

Clinical decisions should not be driven by only one type of knowledge. For example, ignoring evidence-based guidelines and practice parameters can lead to practicing anecdotal medicine. In contrast, ignoring one’s own clinical

experience in favor of solely relying on guidelines and practice parameters can lead to a cookbook approach. The physician’s background, the patient’s characteristics, each AED’s characteristics, and evidence-based evaluations are all important components of making the best patient care decisions.

Through better understanding of guidelines and practice parameter methodology, clinicians should feel more comfortable integrating these evidence-based assessments into their clinical decision-making process. Practicing evidence-based medicine should lead to better personalized and comprehensive care of our patients.

## Combination Drug Therapy: Monotherapy Versus Polytherapy

*Blaise F. D. Bourgeois*

The trends of predominant combination therapy versus predominant monotherapy in the medical treatment of epilepsy can be historically divided into three sequential currents. Following the introduction of phenytoin in 1938, several additional antiepileptic drugs (AEDs) became available, and patients whose seizures were not controlled by one drug were commonly prescribed multiple drugs. It is likely that the rationale for this approach was mostly based on the assumption that AEDs interact synergistically and that multiple drugs can provide more seizure protection together than one drug alone. This reasoning does not take into account the undesirable other side of this equation—namely, that multiple drugs can provide more side effects together than one drug alone. Therefore, the concept of monotherapy and sequential monotherapy gained wide acceptance in the late 1970s and early 1980s, because the frequent negative impact of polytherapy on the number and intensity of side effects was increasingly recognized. Recommendations for monotherapy were based on repeated observations that the severity or number of side effects often diminished following a reduction in the number of AEDs, in

most cases without appreciable loss in seizure control (1–6), and that the beneficial effect of adding a second drug after the failure of a first drug was modest (7). Patients who had undergone a temporal lobe resection were randomized to ongoing polytherapy or to reduction to carbamazepine monotherapy (8). The seizure recurrence rate was the same in both groups, but drug-related side effects were less common in the monotherapy group (10%) than in the polytherapy group (30%). The concept of monotherapy was extended to the practice of “high-dose monotherapy” (9). However, two main factors prompted the transition to a third era: (1) the realization that about one-third of patients still remained refractory even to high-dose monotherapy, and (2) the release of several newer AEDs after 1993 with fewer or no pharmacokinetic interactions. In the 1990s, the concept of “rational polytherapy” was promoted, with intense discussion and speculation but few rigorous clinical studies. When single-drug therapy fails to render patients seizure free, the temptation to combine AEDs will endure. Because of this, it will always remain important to evaluate and identify potentially beneficial specific drug combinations and to carefully assess the advantages and disadvantages of AED combinations.

## DISADVANTAGES OF COMBINATION DRUG THERAPY

### Pharmacokinetic Interactions

Adding or removing a drug from the treatment regimen may alter the established relationship between dose and blood level of drugs already in use, either AEDs or other drugs. In general, pharmacokinetic interactions make more frequent drug level determinations and dosage readjustments necessary, and they also increase the probability of the occurrence of a drug level that is either too low or too high. It is more likely that an interaction will be overlooked when a drug causing an interaction is removed than when it is added. It should also be noted that enzyme-inducing drugs cause interactions that reach their maximum only after days to weeks and are only slowly reversible, whereas enzyme inhibitors cause reactions that reach their full impacts within hours to a few days and are rapidly reversible. Most newer AEDs have a lower potential for interactions, in particular for enzyme induction, and some have practically no interactions. Pharmacokinetic interactions are reviewed in detail in Chapter 39. Pharmacokinetic interactions are only rarely beneficial. For instance, the inhibitory effect of valproate on lamotrigine kinetics can have the theoretical advantages of reducing the fluctuations of the levels of lamotrigine by prolonging its elimination half-life and of reducing the dosage requirements of lamotrigine for a desired blood level. In most instances, however, pharmacokinetic interactions are at best harmless and only if they are anticipated or recognized early. Valproate levels are particularly sensitive to comedication with enzyme-inducing drugs, especially in children. Even at very high doses of more than 100 mg/kg/day, some children cannot achieve therapeutic levels of valproate when in combination therapy with enzyme-inducing drugs (10). The carbamazepine dose-to-level ratio can also be markedly affected by inducing drugs, and the increased dose requirement is associated with an increase in the concentration of the active metabolite carbamazepine-10,11-epoxide. The accelerated biotransformation of such drugs as valproate and carbamazepine usually shortens their half-life and lowers their concentration, causing larger fluctuations in blood levels between doses. Larger fluctuations may increase the risk of seizures just before the dose or increase the risk of toxic side effects at the time of the peak level. Inversely, the inhibition of lamotrigine elimination by valproate increases the level-to-dose ratio of lamotrigine and is likely to be responsible for the observed increase in the incidence of rashes associated with lamotrigine (11), an observation that led to a downward readjustment of the titration rate of lamotrigine dosage in these patients.

### Cumulative Toxicity

Experimental data on the pharmacodynamic interactions of AEDs suggest that neurological toxicity is often additive, although it can be at times infra-additive or supra-additive (12) (Table 32-1). This finding implies that two drugs with a concentration in the recommended therapeutic range are more likely to cause side effects than each drug alone at the same concentration. Correspondingly, in several clinical studies in which polypharmacy was reduced, there was an associated decrease in side effects, especially a reduction in sedation (2, 3, 5, 6). This increased alertness was especially apparent after withdrawal of barbiturates or benzodiazepines (4). Controlled monotherapy trials with some of the newer AEDs have demonstrated a lower incidence of side effects than in the corresponding add-on trials with the same drug. The notion of cumulative toxicity becomes particularly important if one considers the fact that toxicity is often subtle and can be associated with chronic impairment of cognitive function (13).

In addition to cumulative toxicity, when two or more drugs are prescribed together, there is a greater likelihood that one of the drug concentrations will eventually be in the toxic range. In a longitudinal study of children with epilepsy, the number of children with one or more drug levels in the toxic range increased with the numbers of drugs prescribed (14). Toxic levels occurred in 14% of those taking one drug, 50% of those taking two drugs, and 100% of those taking three or more drugs. Therefore, polytherapy is likely to increase the frequency of dose-related side effects. It also increases the probability of idiosyncratic adverse effects and organ toxicity. Deckers and coworkers (15) reviewed the literature to reassess the relationship between AED polytherapy and adverse effects. They found some evidence suggesting that the toxicity of polytherapy may be related to total drug load (that is, total dose of all drugs) rather than to the number of drugs. In other words, one drug at a relatively high dose may cause more adverse effects than two drugs at low doses. Combination therapy may result not only in stronger side effects but also in more side effects of different types. For example, a given patient could have thrombocytopenia from valproate, nephrolithiasis from topiramate, and gingival hyperplasia from phenytoin. However, one could also observe cancellation of opposite side effects of different drugs, as for instance a normalization of excessive weight on valproate after the introduction of topiramate, the latter being known to potentially cause excessive weight loss.

### Differences in Therapeutic Range

The therapeutic range is a statistical compromise based on studies of groups of patients. It provides loose guidelines

CBZ, carbamazepine; CBZ-E, carbamazepine epoxide; CZP, clonazepam; ESM, ethosuximide;  
FBM, felbamate; GBP, gabapentin; LEV, levetiracetam; LTG, lamotrigine; OXC, oxcarbazepine; PB,  
phenobarbital; PEMA, pheno-ethyl-malonamide (primidone metabolite); PHT, phenytoin; PRM,  
primidone; TGB, tiagabine; TPM, topiramate; VPA, valproate.

with regard to the minimal effective concentration and the concentration at which side effects become frequent. Based on the experimental evidence for additive interactions between AEDs, it is unlikely that the therapeutic range of a drug will be the same when it is taken alone as when it is taken in combination with other drugs. Polytherapy is more likely to be associated with toxicity when drug levels are within the therapeutic range. Clinical observations indeed suggest that toxic side effects from carbamazepine or phenytoin (9) and from valproate (16) appear at higher levels when these drugs are taken alone. Therefore, when side effects occur at a certain level of a drug during combination therapy, this finding does

not necessarily imply that the side effects will recur at similar levels in monotherapy in the same patient.

### Interpretation of Drug Effect

In patients on AED polytherapy, it may be difficult to determine which drug has caused a reduction in seizure frequency and which drug is responsible for side effects, unless the adverse reaction is unique to one of the drugs. Idiosyncratic toxic reactions, such as an allergic rash, do not necessarily appear promptly after the introduction of a new drug; therefore, they may not necessarily be caused by the last drug added to the regimen. This can

create a dilemma, especially when two drugs known for their potential for allergic reactions have been introduced within a relatively short time interval. These problems are compounded by frequent dose changes and short periods of observation. A carry-over effect or delayed maximal efficacy of a drug contributes to confusion when several drugs are prescribed simultaneously.

### Idiosyncratic Toxic Reactions

Idiosyncratic adverse side effects of drugs are not dose related. Certain idiosyncratic reactions are more likely to occur when two drugs are taken in combination. As mentioned earlier, valproate can increase the incidence of rashes associated with lamotrigine (11). Also, the combination of valproate with other AEDs, more often than valproate monotherapy, can result in a dramatic encephalopathic state that does not result from toxic drug levels or from a pharmacokinetic interaction (16, 17). This is characterized by alteration of consciousness, usually a stuporous state, and by sudden and pronounced slowing of the background activity in the electroencephalogram. It is important to recognize the cause of these stuporous episodes because they are rapidly reversible upon discontinuation of valproate or of the last introduced drug. The mechanism of this encephalopathy has not been elucidated, but it does not appear to be related to hyperammonemia. Finally, one of the disadvantages of taking two or more drugs is the higher cost. For patients who are prescribed multiple drugs for several years, this is a tangible factor and there must be some evidence that the higher cost is associated with an increased benefit.

There can also be an exacerbation of the dose-related side effects of one AED by another. In two reports, an increase in the known tremor associated with valproate therapy was described following the addition of lamotrigine (18, 19). Also, an increase in side effects characteristic of carbamazepine, but not of levetiracetam, was noted in four patients after the addition of levetiracetam to carbamazepine (20), and after the addition of lamotrigine to carbamazepine (21). Finally, three patients experienced chorea while taking phenytoin and lamotrigine in combination only, with resolution when either one of the medications was withdrawn (22).

### POTENTIAL ADVANTAGES OF COMBINATION DRUG THERAPY

Compared with single-drug therapy there are two potential advantages of combination drug therapy: better seizure control or a similar degree of seizure control with fewer dose-related side effects. For any combination of AEDs to meet either of these criteria, the particular combination must have either a wider antiepileptic spectrum

or a better therapeutic index than either drug alone. For example, a patient with both primarily generalized tonic-clonic seizures and myoclonic seizures who failed to have both seizure types controlled by lamotrigine alone or by clonazepam alone might do well on both drugs. Although lamotrigine may not have controlled the myoclonic seizures and clonazepam may not have controlled the generalized tonic-clonic seizures, together they may complement each other and have a wider antiepileptic spectrum than either one alone. In another hypothetical case, consider a patient whose partial seizures were not controlled by the maximal tolerated doses of either levetiracetam alone or oxcarbazepine alone, leading to both drugs being prescribed together. If the seizures can be controlled by the combination of levetiracetam and oxcarbazepine at doses tolerated by the patient, a superior therapeutic index for the combination of levetiracetam and carbamazepine would have been demonstrated. Unfortunately, there are very few data in the clinical literature demonstrating for any combination of AEDs a better effectiveness than for either drug alone. Furthermore, although a great deal of information is available on the pharmacokinetic interactions between AEDs, less is known about pharmacodynamic interactions—interactions that occur in the central nervous system—because they are more difficult to quantify. However, increasing attention is being paid to the theoretical, experimental, and clinical background for the practice of combining AEDs.

A supra-additive pharmacodynamic interaction (potentiation or synergism) between two drugs with regard to their protective effect against seizures has often been used as supportive evidence that these two drugs represent a superior combination. However, this antiepileptic interaction in itself has little meaning unless the neurotoxic effects are also evaluated. If toxicity is also supra-additive to a same or greater extent as the antiepileptic effect, the therapeutic index of the combination is equal to or inferior to the therapeutic index of each drug alone. In other words, at the same level of neurotoxicity, the drug combination does not provide more seizure protection than either of the two drugs alone. Clinically, it is very difficult to study the individual and combined therapeutic index of AEDs, because both seizure protection and neurotoxic side effects of single drugs and of combinations of drugs must be assessed quantitatively in a homogeneous population of patients with epilepsy. Therefore, most of the available information on the pharmacodynamic effect of combining AEDs has been obtained from animal experiments.

### Experimental Studies

Table 32-1 summarizes the results of studies on antiepileptic and neurotoxic interactions between many of

the established and newer AEDs, including interactions between drugs and their active metabolites (12, 23–37). All results in these studies are based on the analysis of brain drug concentrations in mice. Seizure protection was assessed by standardized experimental seizure models. Neurotoxicity was assessed by various standardized models of motor incoordination in animals. Although this is a rough assessment of dose-related neurotoxicity, there is no reliable animal model that reflects the scope of dose-related neurotoxicity of AEDs in humans. The methods used for the quantitative assessment of the pharmacodynamic drug interactions were either the isobolographic analysis, the fractional effective concentration index, or both (23, 25, 27).

The majority of the neurotoxic interactions are additive or infra-additive, less commonly supra-additive. Thus, in most instances, neurotoxicity of AEDs is not potentiated when they are combined. Inversely, antiepileptic interactions are mostly additive or supra-additive, less commonly infra-additive. Drug pairs with supra-additive antiepileptic interactions can be advantageous even when the neurotoxic interaction is additive. When the antiepileptic interaction is additive, only combinations with an infra-additive neurotoxic interaction can have a better protective index than the single drug. According to Table 32-1, several pairs of drugs appear to meet these criteria for an advantageous combination in this animal model. When carrying out such studies of pharmacodynamic interactions, drug concentrations and not doses must be used because of the effect of possible pharmacokinetic interactions. For example, earlier studies of the antiepileptic interaction between phenytoin and phenobarbital, based on the analysis of doses administered, suggested a supra-additive interaction. A purely additive interaction was found when brain levels were measured in two independent studies (23, 38). Indeed, an acute elevation of the phenytoin level-to-dose ratio in the presence of phenobarbital could be demonstrated (23).

The combinations of clonazepam with valproate and clonazepam with ethosuximide were also tested in mice (29). Nonprotective and nontoxic doses of clonazepam increased the protective effect and the neurotoxicity of valproate and ethosuximide, indicating supra-additive effects. The two drug combinations had a better protective index than each drug alone despite supra-additive neurotoxicity. Using a similar model, Gordon and coworkers (39) studied pharmacodynamic interactions between felbamate and phenytoin, carbamazepine, valproate, and phenobarbital. They found that nonprotective doses of the latter four drugs decreased the median effective dose ( $ED_{50}$ ) values of felbamate against maximal electroshock seizures. However, neurotoxicity was not potentiated, and the protective index of felbamate was more than doubled by the addition of any one of the four drugs. Although the analysis was based on doses, the authors

did measure plasma drug levels and demonstrated the absence of pharmacokinetic interaction.

### Clinical Studies

The results of the above studies in animals cannot be extrapolated to patients. There have been very few clinical studies of AED combinations based on systematic comparisons between the effect of two drugs administered both in monotherapy and their effect in combination. Comparing the effect of adding a second drug with the result of monotherapy with the first drug is not sufficient to demonstrate the superiority of the combination. Success with add-on therapy should be considered as success of alternative therapy until proven otherwise. In 30 adult patients who had failed to respond to the maximal tolerated dose of carbamazepine, phenytoin, phenobarbital, or primidone, a second drug (carbamazepine, phenytoin, phenobarbital, primidone, valproic acid, clonazepam, or clobazam) was added, if necessary up to the maximum tolerated dose (7). A reduction in seizure frequency by 75% or more was observed in 4 patients (13%). However, no patient became seizure free, and 3 patients (10%) experienced an increase in seizure frequency by more than 100%. In a study of 157 patients whose seizures were not controlled on a monotherapy, their treatment was randomized to alternative monotherapy or to adjunctive therapy (40). The outcome in the two groups in terms of seizure control and adverse effects did not differ. Schapel and coworkers (41) evaluated the combination of vigabatrin with lamotrigine in 42 patients with intractable epilepsy. On the combination, the median seizure frequency was reduced by 18% when vigabatrin was added to lamotrigine ( $n = 27$ ) and by 24% when lamotrigine was added to vigabatrin ( $n = 15$ ). However, this study does not document superiority of the combination. Because patients did not receive both drugs in monotherapy before the combination, the results may just reflect the effect of the second drug added, not of the combination.

In a sequential study, some patients whose seizures were not controlled by valproate alone and by carbamazepine alone had a response to the combination of these two drugs (42). The combination of carbamazepine and phenytoin was assessed in a well-designed study, which was published only as an abstract (43). Initial treatment in 100 newly diagnosed patients was monotherapy with either carbamazepine or with phenytoin, in a randomized design. Fifty patients were not seizure free after 1 year and were switched to the other drug; 17 (34%) became seizure free. The remaining 33 patients received both medications, and only 5 (15%) were fully controlled. The potential benefit of the combination of carbamazepine with vigabatrin was assessed in newly diagnosed patients whose treatment was randomized to monotherapy with

either one of these two drugs (44). Seizure control was not achieved in 25 patients, but 11 of them (44%) became seizure free when switched to the other drug. The remaining still refractory 14 patients were treated with the two drugs in combination, and 5 (36%) achieved full seizure control.

At least two clinical studies provided evidence suggestive of a synergism between valproate and lamotrigine. Brodie and Yuen (45) found evidence suggestive of a synergism between lamotrigine and valproate in a lamotrigine substitution study. In 347 uncontrolled patients on monotherapy with valproate, carbamazepine, phenytoin, or phenobarbital, lamotrigine was added. An attempt was made to withdraw the first drug in patients with a 50% or greater seizure reduction. A synergism between lamotrigine and valproate was suggested on the basis of two observations: (1) a significantly better response after adding lamotrigine to valproate than to carbamazepine or phenytoin ( $P < 0.001$ ), both for partial seizures ( $P < 0.02$ ) and for generalized tonic-clonic seizures (not statistically significant), and (2) a poorer response after valproate was withdrawn. A smaller, but very systematic, study addressed the same combination (18). Valproate was added to a pre-existing drug regimen in 20 patients with refractory complex partial seizures. Only three experienced a  $>50\%$  reduction in seizure frequency. Valproate was replaced by lamotrigine (added to the same pre-existing regimen) in the remaining 17 patients. A  $>50\%$  seizure reduction was observed in 4 of the 17 patients. When valproate was reintroduced in addition to the lamotrigine in the remaining 13 patients, 8 of the patients had a favorable response, 4 had a  $>50\%$  seizure reduction, and 4 became seizure free.

Among the drugs used in the treatment of absence seizures, one clinical study suggests that the combination of valproate and ethosuximide is possibly beneficial. Five patients with absence seizures that had remained refractory to ethosuximide or to sodium valproate alone (or to both) became seizure free when the two drugs were combined (46). The experimental evidence discussed earlier also suggests that valproate with ethosuximide is one of the combinations with a favorable protective index.

### HOW SHOULD ANTIPILEPTIC DRUG COMBINATIONS BE SELECTED?

Considering the fact that there are no definitive clinical studies documenting the superiority of any specific drug combination, selecting a combination of two AEDs remains at the present time an educated guess at best. The choice may be based on several considerations that include the mechanisms of action, the clinical spectrum of activity, side effects, and pharmacokinetic interactions.

The mechanism of action of AEDs has been suggested as a consideration for rational combinations (47, 48) based on the concept that drugs to be combined should have different mechanisms of action that could be complementary. This is an elegant hypothesis, which has never been proved experimentally or clinically. For the time being, choosing a drug combination based on the mechanisms of action remains purely hypothetical, and no specific drug pair can be recommended.

When a patient has two or more seizure types that cannot be controlled by one drug alone, two drugs can be selected according to their spectrum of efficacy. For each seizure type, the most effective and best tolerated drug should be selected. An example of epilepsy with multiple seizure types is Lennox-Gastaut syndrome. Valproate has long been a preferred drug in patients with Lennox-Gastaut syndrome, but three drugs have now been shown in double-blind studies to be effective: felbamate (49), lamotrigine (50), and topiramate (51). Combinations between these four drugs might be more effective in reducing drop attacks as well as atypical absences and tonic seizures than only one drug alone. On the other hand, phenytoin and carbamazepine usually are not effective and can even exacerbate certain seizures in these patients (52).

The absence of pharmacokinetic interactions between two drugs certainly makes it easier to use them together. However, pharmacokinetic interactions are known and predictable, and it is the physician's responsibility to make appropriate dosage adjustments, either as a corrective measure or preferably as a preventive measure. Therefore, pharmacokinetic interactions should not be a reason to avoid a drug combination that could be beneficial to the patient. Combinations to be avoided are those between drugs with similar side effects, such as barbiturates and benzodiazepines or barbiturates and topiramate (sedation, cognitive effects), topiramate with zonisamide or acetazolamide (nephrolithiasis, acidosis, weight loss), or carbamazepine with oxcarbazepine (hyponatremia), valproate and gabapentin (weight gain).

As opposed to the classic concept of "high-dose monotherapy" (9), a concept of "low-dose polytherapy" could be advocated. The rationale would be that AEDs share their antiepileptic effect but do not always share their adverse effects. Therefore, if a patient has a good seizure response to two drugs in monotherapy, but with side effects, the two drugs might achieve the same seizure reduction together, at lower doses that could be below the clinical threshold for their side effects. An example would be a child with absence seizures who has thrombocytopenia or tremor at effective doses of valproate and persisting gastrointestinal side effects at effective doses of ethosuximide. The same seizure control without the side effects might be achieved with the two drugs at lower doses. Any two drugs with different side effects, but efficacy against the same seizure type, could be combined

according to this concept. This concept is supported by the experimental pharmacodynamic interaction studies described earlier. These studies have demonstrated that the neurotoxic pharmacodynamic interaction often does not parallel the antiepileptic pharmacodynamic interaction (Table 32-1).

In conclusion, in view of the known disadvantages of combination therapy, the benefit of a given drug combination must be well documented in every patient if the combination is to be maintained. To quote Meinardi (53), "at present, however, there are too many gaps in our knowledge to make theoretical planning of [combination] drug therapy more promising than an empirical approach." Drug combinations are best chosen by selecting the best drugs known to be effective against the patient's seizure type or seizure types. Rational polytherapy cannot be predicted and must be documented for every

patient according to the following definition: whether the patient does better in terms of seizure control versus side effects while taking drugs A and B together (at any dose) than the patient had done on drug A alone and on drug B alone at their respective optimal doses. However, there may be instances in which it would be appropriate to maintain a drug combination even when the above definition is not met. For instance, a patient may respond partially to a first drug and experience further improvement after addition of the second drug, or the patient may become seizure free after addition of the second drug, despite lack of response to the first drug. In such cases, it is understandable that one may be reluctant to make any change. Finally, in clinical practice, the need to reduce overtreatment of patients with epilepsy may be at least as common as the need to find an appropriate drug combination (54).

## Adverse Effects of Antiepileptic Drugs

*L. James Willmore  
James W. Wheless  
John M. Pellock*

**C**hildren with seizures and epilepsy commonly are treated with an antiepileptic drug. Although efficacy for some specific seizure types sometimes drives drug selection, the side effect profile of drugs and the potential for toxicity are important considerations. Parents and patients must receive adequate data so that they can participate in treatment decisions and provide informed consent. Treatment must balance the goal of complete seizure control with drug toxicity during both acute and chronic treatment (1). Antiepileptic drugs cause nonspecific dose-related responses, unique effects specific to a given drug, or rare but potentially dangerous idiosyncratic reactions. Drug treatment, in the absence of a specific history of allergy, is a task of trial and error. However, specific cellular mechanisms or metabolic abnormalities may account for some adverse drug effects.

Treatment requires accurate diagnosis followed by knowledgeable use of drugs based on pharmacokinetics and pharmacodynamics. Although the commonly used antiepileptic drugs are effective in many patients, efficacy of any selected drug for a specific patient cannot be predicted. Therefore, sequencing of treatment using several drugs often is required. Plasma levels guide treatment in some cases, but titration of dose, using development of dose-related symptoms as an endpoint, should be completed before a drug is declared ineffective.

Common problems can be anticipated, but dangerous, unexpected, and rare individual responses and reactions require physicians to provide detailed information during the process of informed consent. Thus, all persons involved in the care of a patient must be informed in explicit terms about the potential for serious or even fatal reactions to drugs.

Adverse drug reactions (ADRs) are noxious effects occurring at dosages of drugs used appropriately in humans for prophylaxis, diagnosis, or therapy (2). Some of these reactions depend on pharmacokinetic effects, with dose-dependent responses that correlate with plasma blood levels of a drug.

Pharmacodynamic effects occur when target organ responses are altered in a way that is independent of plasma concentration; such effects may be unique to a drug or to an individual patient. Serious non-dose-related ADRs cause drug-induced disease that may be acute or may occur following chronic treatment. Potentially fatal idiosyncratic reactions are listed in Table 33-1 (4).

Neurotoxicity, either dependent on dose or pharmacodynamic in nature, may occur at the time of drug initiation, during dose escalation, or at the time of the peak in plasma levels. These mild and reversible effects include sedation, changes in behavior, tremor, vertigo, diplopia, nystagmus, ataxia, or even dysarthria (1, 5).

Dose-related neurotoxicity becomes a more commonly encountered problem if two or more antiepileptic drugs (AEDs) are used in combination. Monotherapy improves compliance, reduces total cost of medication, and may eliminate interactions that could cause additive adverse effects (6, 7). Monotherapy use of the commonly available AEDs results in seizure control in 50% to 80% of patients with epilepsy (8, 9).

Almost all AEDs have caused idiosyncratic reactions or drug allergy. Such reactions may be severe, unpredictable, and although rare, may be life-threatening (3). Idiosyncratic responses to AEDs in a given patient are associated with cellular, immunologic, or enzymatic characteristics that are unique to that patient. Drug clearance by oxidation requires catalyzed effects of the microsomal membrane-bound mixed function oxidases that contain cytochrome P450 (10). The P450 terminal oxidases receive electrons from reduced nicotinamide adenine dinucleotide phosphate (NADPH) and reduced nicotinamide adenine dinucleotide (NADH). The heterogeneity of the P-450 system causes apparent specificity, with isozyme families produced by the same gene family. Some AEDs are metabolized through such mixed-function oxidases, yielding either stable, unstable, or potentially reactive molecular species. The accumulation of reactive and toxic intermediates as a result of drug treatment is determined by genetically derived enzyme activities. Thus, metabolism of a ring compounds via arene oxidase with impairment of metabolism of the arene oxide product could occur with deficiency of the enzyme epoxide hydrolase. The arene form of phenytoin has been implicated as a cause of hepatotoxicity, teratogenicity, bone marrow toxicity, and allergic skin reactions (11, 12).

AED hypersensitivity syndrome occurs early in the treatment with aromatic antiepileptic compounds. Components include rash, fever, and eosinophilia and may include lymphadenopathy and life-threatening hepatic necrosis (13). Skin rash may or may not be pruritic and is in the form of an exanthema. More severe reactions include exfoliative dermatitis, erythema multiforme, Stevens-Johnson syndrome, or even toxic epidermal necrolysis (14). Adverse reactions of the idiosyncratic type tend to be immune-mediated effects in a susceptible individual (15).

Mechanisms are not completely understood, but most rash and hypersensitivity syndromes probably are related to pharmacogenetic variation in drug biotransformation (16). Immune involvement is suggested by the occurrence of a sensitization interval of 7–10 days after first exposure to a drug (17). In fact, T lymphocytes have been found in the perivascular infiltrate and epidermis (CD8C and CD4C) of patients with carbamazepine-induced toxic epidermal necrolysis (17). Reactive metabolites produced by bioactivation are cytotoxic by binding to microsomal proteins. Such covalent adducts are formed in hepatic cytochrome P-450-mediated reactions (15).

Antibodies to P450 enzymes, with epitopes such as anti-CYP2D6 and anti-CYP3A, have amino acid sequences similar to those of viral or fungal origin that suggest prior host-dependent immune responses to infection that are unique to a person's human lymphocyte antigen (HLA) genotype (15). With exposure to a bioactivated AED, a chemical modification of the P450 enzyme occurs. These effects may be from formation of reactive drug metabolites, free radical species, or impairment of detoxification enzymes. These changes in enzyme function yield altered peptide structures that result in the immune response (15).

TABLE 33-1

REACTION	CBZ	ETH	FBM	GBP	LEV	LTG	OXC	PB	PHT	TPM	TGB	VPA	ZNS

Hepatic failure	X		X					X	X			X	
Allergic dermatitis	X	X	X	X		X	X	X	X	X	X	X	X
Serum sickness	X	X						X	X			X	
Pancreatitis	X												
Nephrolithiasis										X			X
Bone metabolism	X								X				

Abbreviations: CBZ, carbamazepine; ETH, ethosuximide; FBM, felbamate; GBP, gabapentin; LEV, levetiracetam; LTG, lamotrigine; OXC, oxcarbazepine; PB, phenobarbital; PHT, phenytoin; TPM, topiramate; TGB, tiagabine; VPA, valproate; ZNS, zonisamide

Impact of enzyme-inducing drugs on bone health must be considered in all patients. Although most institutionalized patients in the modern era are given calcium supplementation and vitamin D, these simple interventions and the need for assessment of bone density in those patients on long-term drug use must be kept in mind (18).

## SPECIFIC DRUGS

### Phenobarbital

Phenobarbital (see Chapter 48) has been in continual use for at least 95 years. Common side effects in children include behavioral changes with hyperactivity and irritability; adults experience drowsiness. Altered attention, effects on cognition, and even depression may be dose related or occur in specific patients without relationship to plasma level (19–21). Dose-related neurotoxicity includes nystagmus, ataxia, incoordination, dyskinesia, and altered sleep patterns. Idiosyncratic reactions include allergic dermatitis, Stevens-Johnson syndrome, serum sickness, and hepatic failure. Agranulocytosis and aplastic anemia have been reported (3, 4). Folate deficiency in patients treated with AEDs is claimed to be associated with behavioral changes (22). Phenobarbital is known to exacerbate acute intermittent porphyria (23).

Induction of hepatic oxidative metabolism by phenobarbital is a fundamental mechanism for drug interactions. Vitamin D metabolism is induced by phenobarbital; thus, multihandicapped and bedridden children receiving this drug or other AEDs may develop osteoporosis; vitamin D supplementation is important in these children (24). Phenobarbital alters absorption and induces metabolism of vitamin K. Neonates of mothers treated with phenobarbital or other barbiturates need vitamin K supplementation to prevent neonatal hemorrhagic disease. Prophylactic vitamin K must be given during the last month of gestation, at the beginning of labor, and to the infant at birth.

Chronic phenobarbital treatment may cause connective tissue changes, with coarsened facial feature, Dupuytren's contracture, Ledderhose syndrome (plantar fibromas), and frozen shoulder (25). Sedative effects of phenobarbital may cause exacerbation of absence, atonic, and myoclonic seizures, although other mechanisms may be operant (6). Sudden withholding of doses of short-acting barbiturates may precipitate drug withdrawal seizures or even status epilepticus. Given the slow rate of clearance of phenobarbital, such acute withdrawal seizures are less problematic, but it is wise to taper the dose of phenobarbital if the drug is to be discontinued. Some children, and even adults, may experience mild withdrawal symptoms that include tremor, sweating, restlessness, irritability, weight loss, disturbance of sleep, and even psychiatric symptoms. Mothers treated with

phenobarbital may deliver infants that have withdrawal, including irritability, hypotonia, and vomiting, for several days after delivery (26).

### Phenytoin

Phenytoin is metabolized by hepatic enzymes that are capacity limited (see Chapter 49). This system is commonly saturated at serum concentrations of 8–10 µg/mL. Because of the saturation kinetics of phenytoin, small changes in the maintenance dose will produce large changes in serum concentration (27). Thus the half-life of the drug increases with higher plasma concentrations. Because of saturation kinetics, dose changes must be made with care. One challenge to phenytoin use is alteration of steady state by interaction with other drugs (28).

Dose-related effects of phenytoin include nystagmus, ataxia, altered coordination, cognitive changes, and dyskinesia (3). Infrequently, children may become irritable or hyperactive (29). Children seldom develop nystagmus even when they are overtly ataxic and have elevated serum levels of phenytoin. A constellation of anorexia, weight loss, and vomiting in a child should suggest phenytoin toxicity (29). Although not strictly a pharmacologic problem, phenytoin causes some drug-specific effects that do not appear to be related to dose. Facial features may coarsen, and body hair will change in texture and become dark in color. Acne may worsen, and gingival hypertrophy is common. Other effects of chronic phenytoin use are osteoporosis and lymphadenopathy (30). Folate deficiency may be severe enough to cause megaloblastic anemia; a transient encephalopathy is said to occur by a similar mechanism (22). Prolonged exposure to high plasma levels of phenytoin has been associated with cerebellar atrophy (29, 31). Idiosyncratic reactions that may be fatal include allergic dermatitis, hepatotoxicity (32), serum sickness reaction, and aplastic anemia (3, 30). Drug-induced lupus erythematosus reactions have been observed (33).

### Ethosuximide

Ethosuximide (see Chapter 43) has a half-life that would be compatible with single daily dosing, but such large doses of the drug causes nausea, gastric distress, and abdominal pain unless the drug is given with meals and in divided doses. Rash and headaches, and on rare occasion leukopenia, pancytopenia, and aplastic anemia, have occurred (4). Neurologic effects include headache that may be severe, lethargy, agitation, aggressiveness, depression, and memory problems. Psychiatric disorders were attributed to normalization of the electroencephalogram (EEG) by this drug, but such reactions have been described with other drugs as well, making this hypothesis less tenable (34, 35). Drug-induced lupus has been reported to occur in children (36).

### Carbamazepine

Carbamazepine (CBZ) (see Chapter 42) is insoluble in aqueous solutions, behaving as a neutral lipophilic substance (37). Carbamazepine is biotransformed, forming CBZ-10,11-epoxide (38). This epoxide is formed at the 10,11-double bond of the azepine ring when CBZ is catalyzed by the hepatic monooxygenases (39). Inhibition of the activity of epoxide hydrolase, as occurs with concomitant administration of valproic acid (VPA), will increase the quantity of the epoxide (40). Carbamazepine causes mild dose-related neurotoxic effects. Most are concentration dependent. Transient effects include nausea, drowsiness, vertigo, ataxia, and speech slurring. Diplopia is a common concentration-dependent effect that is useful for clinical titration (5). Tremor and headache have been reported. Nausea, vomiting, diarrhea, and abdominal pain occur, but infrequently. Hyponatremia is common but rarely of clinical consequence (41). These transient adverse effects may be limited by administering one of the extended release formulations that result in less peak-to-trough variations in blood levels.

Severe reactions to CBZ cause alteration of hematopoietic, skin, hepatic, and cardiovascular systems (5). Rash occurs in 5% to 8% of patients and rarely may progress to exfoliative dermatitis or even a bullous reaction such as Stevens-Johnson syndrome (42). Hematologic changes are common, with leukopenia observed in 10% to 12% of patients treated with CBZ. However, fatal reactions such as aplastic anemia, are rare, with death in 1.1 per 500,000 treated patients per year (43). Patients and parents must be informed about these serious reactions and reassured that frequent monitoring of blood cell counts and liver studies are unnecessary. Communication with the patient and informed consent are the best methods for long-term monitoring (44).

### Valproate

Gastrointestinal effects commonly accompanying initiation of VPA (see Chapter 53) treatment include nausea, diarrhea, abdominal pain, and even vomiting (45). Use at meal time, or administration of a slow-release form of the drug, will cause abatement of these symptoms in most patients. Three dose-related effects occur commonly. Tremor with sustention and at rest is age and dose related because this symptom is found less in children (46). Body weight gain is another common side effect, with 20% to 54% of patients reporting this problem (47). Patients report appetite stimulation. Weight change may require discontinuation of this drug. Hair loss is common and transient. Hair appears to be fragile; regrowth of the broken hair results in a curlier shaft (48). Supplementation with multivitamins containing zinc may protect hair.

Thrombocytopenia occurs in a pattern that suggests it is dose related. Platelet counts vary without dose changes necessarily and are commonly asymptomatic. Petechial hemorrhage and ecchymoses do occur, necessitating lowering the dose or even discontinuing the drug (49, 50).

Other less frequently encountered effects include sedation or encephalopathy (51, 52). Acute encephalopathy and even coma may develop on initial exposure to VPA (51). Upon investigation, these patients may be severely acidotic and have elevated urinary organic acid excretion. Because VPA is known to sequester coenzyme A (53), such patients are suspect of having a partially compensated defect in the mitochondrial beta-oxidation enzymes (52, 54). Dermatologic abnormalities are unusual, but may be severe (55).

Acute hemorrhage pancreatitis may develop in younger patients. Fatal outcome has been reported. Abdominal pain reported by patients receiving VPA should lead to measurement of lipase and amylase levels (56).

Age-related changes in pharmacokinetics of VPA should be anticipated because of the high percentage of drug that is protein bound (57). Valproic acid is a branched-chain carboxylic acid that may be metabolized either through mitochondrial mechanisms or via cytoplasmic enzymes. Dehydrogenation of VPA results in the accumulation of 2-en-, 3-en-, and 4-en-VPA compounds. The 4-en metabolites are highest in infants and decline with age. The 2-en compound has anticonvulsant potency (58). Valproic acid binds to albumin at high- and low-affinity sites. This binding is saturable, causing the free fraction to increase with dose.

Assessment of patients developing hepatotoxicity from treatment with VPA suggests that the highest risk is in children younger than 2 years of age being treated with several AEDs. Additional risk characteristics include presumed metabolic disorders or severe epilepsy complicating mental retardation and organic brain disease (59–62). Although this pattern of incidence provides useful clinical guidelines, most clinicians consider them too restrictive or of insufficient detail to allow identification of patients at highest risk (63). Further complicating management strategies, routine laboratory monitoring does not predict the development of fulminant and irreversible hepatic failure (64). Some patients progressing to fatal hepatotoxicity never developed abnormalities of specific hepatic function tests. Conversely, abnormalities of serum ammonia, carnitine, fibrinogen, and hepatic function tests have been reported to occur without the presence of clinically significant hepatotoxicity (65, 66). Reporting clinical symptoms and identification of patients at greatest risk for fatal hepatotoxicity are more reliable means for monitoring. Vomiting was the most frequently reported initial symptom in fatal cases (59, 60). Combined symptoms of nausea, vomiting, and anorexia occurred in 82% of patients with VPA-associated

hepatotoxicity, whereas lethargy, drowsiness, and coma were reported in 40% (67, 68). Although some patients may have reversal of hepatotoxicity by early drug discontinuation, fatalities still result following such prompt action (69). No biochemical marker has been identified to differentiate those patients surviving from those with fatal outcome (69). Rescue of patients with hepatic failure by administration of carnitine has been reported (70). Obtain urinary organic acid measurement and metabolic evaluation in high risk patients, as indicated previously, or in any patient without an established reason for mental retardation and seizures (63).

Identifying high risk patients was reported by Dreiffuss et al (59, 60). Most fatalities occurred in the first 6 months of treatment, but some patients developed hepatotoxicity up to 2 years after VPA initiation. Children younger than 2 years of age receiving polytherapy had a 1 in 500 to 800 chance of developing fatal VPA hepatotoxicity. Negative predictors were documented. Patients at negligible risk are those older than the age of 10 years treated with VPA alone and free of indication of underlying metabolic or neurologic disorders. Children at intermediate risk were between age 2 and 10 years on monotherapy and all patients requiring polytherapy.

Patients reported with fatal hepatotoxicity, in the majority of cases, had neurologic abnormalities, including mental retardation, encephalopathy, and decline of neurologic function. In those reported patients older than 21 years of age, two of four had degenerative disease of the nervous system. One report stated that 9 of 16 hepatic fatalities were neurologically abnormal (71). In one series, all patients in the 11-to-20 age group were neurologically abnormal. In a recent review, only 7 of 26 adults reported with fatal hepatic failure from valproate were considered to be neurologically normal (72).

Specific biochemical disorders associated with VPA hepatotoxicity include urea cycle defects, organic acidurias, multiple carboxylase deficiency, mitochondrial or respiratory chain dysfunction, cytochrome aa3 deficiency in muscle, pyruvate carboxylase deficiency, and hepatic pyruvate dehydrogenase complex deficiency (brain) (63, 73, 74). Clinical disorders associated with VPA toxicity include GM1 gangliosidosis type 2, spinocerebellar degeneration, Friedreich's ataxia, Lafora body disease, Alpers disease, and MERRF syndrome (myoclonus epilepsy with ragged red fibers) (67). Patients with such disorders must be identified because of higher risk for VPA hepatotoxicity.

### Felbamate

Felbamate (FBM) causes headache, insomnia, and weight loss. Drug interactions with FBM are vigorous and may cause clinically significant toxicity or seizure exacerbation. When FBM is added to CBZ, levels of the parent

compound decline by 20% to 25%, but the metabolite CBZ-10,11-epoxide increases by as much as 50% (75, 76). These effects suggest induction of cytochrome P450 along with inhibition of some of the action of epoxide hydrolase. This interaction induces CBZ side effects; the combination also causes headache. Following the identification of aplastic anemia and hepatotoxicity and notification of physicians by the Food and Drug Administration (FDA) in August and September 1994, the number of persons being treated with FBM decreased drastically. Kaufman et al (77) reviewed cases of aplastic anemia reported in the United States and suggested an incidence of aplastic anemia of 27–209 per million in those receiving FBM versus 2–2.5 per million persons in the general population. The aplastic anemia risk with FBM treatment is perhaps up to 20 times greater than that for CBZ. Importantly, no case of aplastic anemia has been reported in children younger than 13 years old. The mean time to presentation is 154 days, with very few cases being reported after 6 months of exposure. Similarly, severe hepatotoxicity associated with FBM has been reported, but this risk seems to be similar to that from valproate. Although there is no predilection for age, children have been affected by severe, life-threatening hepatotoxicity associated with FBM.

Recommended guidelines for the use of FBM now stress that this agent should be used for adults and children with severe epilepsy refractory to other therapy, such as patients with Lennox-Gastaut syndrome. Before beginning treatment a careful history concerning past indications of hematologic toxicity, of hepatotoxicity, and of autoimmune diseases should be sought. Women with autoimmune disease account for the largest portion of those who developed aplastic anemia. Baseline routine hematologic and liver function tests should be performed, and patients and their families must be fully informed of the potential risks; in the United States written consent is recommended. Dose escalation should be made slowly, and dosages of adjunctive medication must be corrected for known interactions where possible. Monotherapy with FBM leads to fewer systemic side effects, but it is unknown whether the rare but potentially life-threatening side effects will be decreased by using FBM alone. Clinical monitoring and specific scheduled blood testing should be done frequently, and patients should be educated regarding symptoms that may possibly signify either hematologic toxicity or hepatotoxicity.

### Gabapentin

Structurally related to gamma-aminobutyric acid (GABA), gabapentin reaches peak plasma concentrations 2–3 hours after an oral dose. Unique for an AED, gabapentin is not bound to plasma proteins, nor is it metabolized. Its bland pharmacokinetic properties

include no hepatic enzyme induction and little effect on plasma levels of other AEDs. Adverse events were detected in treated patients and were typically neurotoxic, but withdrawal from studies was infrequent. Children have similar adverse events profiles as noted in adults. Patients may experience weight gain. Peripheral edema with normal plasma protein and albumin is observed rarely. There is an increase in the incidence of hyperactivity and aggressive behavior, particularly in mentally retarded children (78) (see Chapter 45).

### Lamotrigine

CNS-related side effects of lamotrigine include lethargy, fatigue, and mental confusion (79–84). Serious rashes have occurred; the rate of dose ascension appears to be correlated with this type of adverse event (85). Serious rash may be more common in children; current guidelines in the United States require this drug be discontinued if a rash develops (see Chapter 46).

Although erythematous rash with a morbilliform pattern or urticaria or patterns with a maculopapular component are most common (86–91), some patients can develop erythema multiforme and blistering reactions such as the Stevens-Johnson syndrome or toxic epidermal necrolysis. Simple rashes require careful assessment to be sure a hypersensitivity syndrome is not developing. Sensitivity reactions include fever, lymphadenopathy, elevated liver enzymes, and altered numbers of circulating cellular elements of blood (89).

In drug trials in the United States rash was observed in about 10% of patients, with 3.8% having to discontinue and 0.3% being hospitalized (89). Most serious rashes developed within 6 weeks of beginning treatment with lamotrigine. In children treated in drug trials, rash was observed in 12.9% with serious rash in 1.1% with half of those with Stevens-Johnson syndrome (89). Of interest, more than 80% of patients with complete data developing serious rash were being treated with valproate or had been given doses at a rate higher than recommended (89). Rash was suspected to be a drug interaction with valproate, but that drug inhibits metabolism of lamotrigine, causing diminished clearance with resultant high blood levels (90). Apparently when specific treatment guidelines are followed, the incidence of serious rash may possibly be reduced (89, 91, 92). In the United States, if rash develops it is advised that the drug be discontinued. Table 46-1 (in Chapter 46) lists the suggested drug initiation treatment plan for lamotrigine.

### Pregabalin

This drug has impact on voltage-gated calcium channels with inhibition of transmembrane calcium flow through binding with the channel's high-affinity  $\alpha_2\delta$  sub-

unit (93, 94). Data from postmarketing are not available. Clinical trials revealed most common adverse effects were dizziness, somnolence, and ataxia; weight gain was reported as well (95, 96).

### Levetiracetam

Levetiracetam has an effect against partial onset seizures, primary generalized tonic-clonic seizures, juvenile myoclonic epilepsy, and photosensitivity-related epilepsy syndromes. Although a specific mechanism of action has not been reported, the drug does bind to synaptic vesicle protein and has actions on neuronal GABA and glycine-gated currents (97). Side effects reported from the clinical trials include somnolence, headache, anorexia, and nervousness (98). Behavioral changes in children, including psychosis, have been reported; exacerbation of a preexisting tendency has been suggested as a mechanism (99).

### Topiramate

Topiramate has a monosaccharide-type structure (see Chapter 52). Treatment emergent adverse effects with add-on studies showed ataxia, impaired concentration, confusion, dizziness, fatigue, paresthesias, somnolence, and abnormal thinking related to topiramate treatment (100). Nephrolithiasis and dose-related weight loss are potential problems that require discussion with patients. Serious rashes have occurred. Reports of development of acute secondary angle closure glaucoma in patients treated with this drug require informing patients and cautioning them to report development of ocular pain or altered visual acuity immediately (101–103). As with other drugs that alter carbonic anhydrase, oligohydrosis with hyperthermia has been reported and children must be monitored for this problem especially in hot weather (104, 105). Many side effects detected in the studies were caused by forced titration to high doses. Adverse cognitive effects occur at higher doses in adults (100). Slowing the pace of dose ascension reduces the impact on cognitive function.

### Tiagabine

Most commonly identified side effects in the pivotal trials of tiagabine included dizziness, asthenia, muscle weakness, nervousness, tremor, impaired concentration, lethargy, and depression (106). These occurred during dose titration. Reasons for withdrawal from the trials included occurrence of confusion, somnolence, ataxia, and dizziness (107). Hepatic clearance signals the need to reduce the dose in patients with liver disease (108).

### Oxcarbazepine

Oxcarbazepine is a keto analog of CBZ that is rapidly converted to 10,11-dihydro-10-hydroxycarbazepine, a monohydroxy active metabolite. Dizziness, sedation, and fatigue were side effects that may be dose related. Hyponatremia has occurred with this drug and some vigilance may be required (109). Rash occurs infrequently, and Stevens-Johnson syndrome and toxic epidermal necrolysis are rare (110).

### Vigabatrin

Vigabatrin, also known as gamma-vinyl GABA, is an analog of GABA that acts to increase tissue concentration of that inhibitory transmitter by irreversible inhibition of GABA transaminase, the enzyme that degrades GABA. This effect on a specific enzyme makes traditional pharmacokinetics less relevant.

Adverse effects, in general, are those expected with an AED; drowsiness, irritability, ataxia, and headache have been observed. Of concern are severe changes in behavior with agitation, hallucinations, and altered thinking, effects that are thought to be dose related (35). Depression is an important potential problem in treating all patients (111). Loss of peripheral retinal visual function is of concern (112, 113). One report compared 32 adults treated with vigabatrin with 18 patients treated with CBZ. Up to 40% of the vigabatrin-treated patients had concentrically constricted visual fields (113, 114). Because of robust efficacy in children with infantile spasms trials are under way and screening methods for visual change are being developed (115).

### Zonisamide

Zonisamide is a sulfonamide drug widely available in Japan and in the United States. Zonisamide is rapidly absorbed by oral intake; protein binding is about 50%, but drug accumulates in erythrocytes. Plasma half-life is prolonged, at around 55 hours, but is reduced to about 30 hours in patients being treated with enzyme-inducing drugs. This drug is extensively metabolized (108).

Adverse effects of drowsiness and altered thinking in clinical trials were associated as well with anorexia, dizziness, ataxia, fatigue, somnolence, confusion, and poor concentration. Zonisamide has been associated with nephrolithiasis (116). Children may develop oligohydrosis and hyperthermia (117). Parents must be taught to be vigilant when a child is exposed to a hot environment and provide skin moisture to aid in convection cooling.

### MECHANISMS AND MONITORING

Hypersensitivity reactions may cause cellular changes that resemble the cytotoxic effects of viral hepatitis. This type of hepatic injury is a common component of systemic reactions involving rash, lymphadenopathy, and eosinophilia. Toxic injury at the cellular level may be related to the formation of arene oxide (118).

Even though routine monitoring may detect alterations in liver function, clinical problems are often not apparent (64). Such findings, however, create a dilemma for the physician regarding plans for ongoing assessment and the need for specific action. Biochemical changes observed in patients being treated with valproate seldom herald the development of a fatal reaction. The first detailed report of valproate-induced hepatotoxicity included one patient with symptomatic hepatic dysfunction and three patients with isolated biochemical changes (64). The observation of transient dose-related hepatotoxicity was followed in 1979 by reports of fatalities associated with valproate treatment (119, 120). Unfortunately, although metabolic abnormalities are occasionally uncovered by valproate administration (52, 121, 122), most patients with mild to moderate symptoms caused by a dose-related side effect cannot be differentiated from those with serious idiosyncratic responses in any way other than by outcome. The idiosyncratic effects upon liver function include hyperammonemia (123–125), severe hepatic dysfunction with recovery, and fulminant hepatic failure (60, 122, 126).

Valproic acid occasionally causes stupor or coma (51). Valproate is known to affect mitochondrial function, causing elevations in serum levels of some branched-chain fatty acids (127). Decreased serum carnitine levels observed with valproate administration (53, 127) are accompanied by increased excretion of acetylcarnitine (128). Valproate reduces levels of both free coenzyme A (CoASH) and acetyl-CoA in rat liver (129, 130). This reduction in CoASH is accompanied by an increase in the intrahepatic medium chain acyl-CoA fraction, identified as valproyl-CoA (129). Although valproate increases activity of the medium chain fraction of acyl-CoA hydrolase, valproyl-CoA itself is hydrolyzed poorly (131). Because valproate-induced inhibition of in-vitro fatty acid oxidation is reversed by addition of CoASH and carnitine to the reactants (132), it would appear that VPA causes sequestration of CoASH.

Sequestration of CoASH and formation of valproyl-CoA could impair or block several steps in fatty acid oxidation. Because fatty acid is esterified to acyl-CoA in the cytosol prior to carnitine-mediated transport across the mitochondrial membrane, decreased CoASH would impair formation of acyl-CoA, or conversion of acyl-carnitine to acyl-CoA, favoring omega oxidation with resultant dicarboxylic aciduria. Coenzyme A deficiency also could impair cleavage of 3-ketoacyl-CoA by thiolase activity,

causing accumulation of acetoacetyl-CoA, butyryl-CoA, and hexanoyl-CoA, producing ketosis with excretion of ethylmalonic and adipic acids. Because butyryl-CoA and hexanoyl-CoA dehydrogenases are inhibited by an acyl-CoA metabolite of hypoglycin (133), valproyl-CoA may inhibit these dehydrogenases (52, 54, 63).

Drug-induced effects on the hematopoietic system may be caused by hypersensitivity reactions with antibody-mediated peripheral destruction, by secondary effects such as occurs in a lupus-like syndrome, or by toxic marrow inhibition (134–136). Hypersensitivity reactions may be associated with the drug acting as a hapten with a protein. The net result is that IgE is produced. Another possibility is that there may be a direct drug effect by activation of the complement cascade or by a change in the function of lymphocytes. Direct cellular effects may alter lymphocyte populations or reactivity. For example, it has been postulated that phenytoin may alter lymphocytes, because 21% to 25% of patients chronically treated with this drug will have decreased circulating levels of IgA along with depressed lymphocyte phytohemagglutinin transformation (137, 138). Phenytoin hypersensitivity includes characteristic hepatic involvement and lymphadenopathy (139–142). Potential mechanisms include hapten formation, formation of an arene compounds (118), conversion of the aromatic ring by oxidation to phenol metabolites, or chlorination of nitrogen components on the hydantoin ring (136). Indeed, a metabolite of phenytoin from hepatic microsomes appears to be toxic to lymphocytes. A similar mechanism has been proposed for CBZ. Indeed, CBZ is oxidized to several metabolites that may cause toxic effects on granulocytes (143). Lymphocytes from a patient with sequential aplastic anemia had challenge of those cells with metabolites derived from murine hepatocytes; the sensitivity of the lymphocytes suggested an arene oxide metabolite formation as a mechanism (144).

Serious toxic effects that result from the use of AEDs are usually discovered during the course of treatment. Hence, patients must be informed and freely communicate with their physician. It takes a joint effort to use medications to control seizures. Good therapeutic alliances between patient and physician will serve until such time that screening assays are developed to identify patients likely to develop serious adverse drug effects (44).

### Clinical Monitoring

Clinical monitoring is adequate especially within the context of incidence of serious adverse reactions. Although routine monitoring of hepatic function revealed elevation of values in 5% to 15% of patients treated with CBZ, fewer than 20 patients with significant hepatic complications were reported in the United States from 1978 to

1989 (145). Fewer cases of pancreatitis were reported. Transient leukopenia occurs in up to 12% of adults and children treated with CBZ (5, 143). Aplastic anemia or agranulocytosis, unrelated to benign leukopenia, occurs in 2 per 575,000 with a mortality rate of approximately 1 in 575,000 treated patients per year (145). Only 4 of the 65 cases of agranulocytosis or aplastic anemia occurred in children.

Of patients developing exfoliative dermatitis alone or as part of systemic hypersensitivity, blood test abnormalities were not found until patients developed clinical symptoms. Presymptomatic blood studies fail to predict disease development. Test abnormalities such as benign leukopenia or transient hepatic enzyme elevations do not predict the occurrence of life-threatening reactions. A genetic abnormality in arene oxide metabolism may occur in those patients at higher risk for some types of adverse responses such as hepatitis (118). A screening test for such defects is not available. The data show that routine monitoring, as practiced commonly, does not allow anticipation of life-threatening effects associated with CBZ treatment. Findings for phenytoin and phenobarbital are similar (4).

As new drugs are developed and added to the regimen available for treating children with epilepsy, physicians should review source documents about those medications and devise a strategy for treatment and monitoring. Because data tend to be limited, initiation of treatment with a newly available drug requires special caution. Although the process of informed consent remains informal, patients and parents should be given as much information as possible. Although industry-produced materials may prove useful, in our opinion the physician should provide copies of package inserts coupled with material they prepare describing how the drug is to be used and any monitoring strategy planned. Although the guiding principle about monitoring of patients being treated with established drugs is parsimony in terms of obtaining routine chemical and hematologic studies, based on the knowledge that such monitoring is ineffective in detecting the occurrence of serious adverse events, such is not necessarily the case with a newly introduced drug. As with the established drugs, baseline hematologic and hepatic screening data should be obtained. Communication is still key; the patient must be prepared to contact the physician and the physician must facilitate that communication. Chemical and hematologic monitoring with use of a new drug may be recommended in the materials a company develops in concert with regulatory functions of the FDA. Although recommendations may seem excessively conservative, it may be wise to follow those guidelines until a larger experience is obtained and data become available.

### Recommendations for Monitoring

1. Obtain screening laboratory studies before initiation of AED treatment. Data are unavailable regarding the yield of such testing, but baseline studies provide a benchmark and could identify patients with special risk factors that could influence drug selection.
2. Blood and urine monitoring in otherwise healthy and asymptomatic patients treated with AEDs is not necessary.
3. Identify high risk patients before beginning treatment. These patients include those with presumptive biochemical disorders, altered systemic health, neurodegenerative disease, or a history of significant

adverse drug reactions. Monitoring must be designed based on the specifics of the clinical situation.

4. Patients without an advocate, or those unable to communicate, require a different strategy. Although data are unavailable, blood monitoring should be obtained for patients with multiple handicaps who are institutionalized. Monitoring should include basic hematology and chemistry with additional studies based upon the patient's clinical situation.
5. For newly introduced drugs, follow recommended guidelines for blood monitoring until the numbers of patients treated in this country increase and data become available.

## Status Epilepticus and Acute Seizures

**David J. Leszczyszyn**  
**John M. Pellock**

**S**tatus epilepticus (SE) is a true neurologic emergency (1). Both convulsive and nonconvulsive SE affect people of all ages, being more common and carrying greater morbidity and mortality in infants and the elderly (2–5). Recent large population studies have revealed an incidence 2 to 2.5 times greater than previously recognized (6). Large, hospital-based studies have disclosed that SE is underrecognized and is the cause of coma in a significant number of patients who demonstrate no overt seizure activity (7, 8). In addition, the economic burden of SE has recently been estimated at 4 billion dollars. The direct patient care costs are quite high compared with the direct costs of other major health conditions such as acute myocardial infarction and congestive heart failure (9). Prompt recognition and management certainly lead to the best chance for successful outcome. Supported by the refractory nature of seizures lasting longer than 7 minutes and because of the potentially significant morbidity and mortality, there are strong arguments to shorten the functional definition of SE so as to encourage earlier intervention in this important public health issue (10). Several recent advances in treatment have occurred, including improved prehospital care for acute and acute repetitive seizures, new anticonvulsant formulations, use of emergency electroencephalography (EEG), and improved emergency room and intensive care

management. These approaches with a particular focus on the treatment of acute seizures as well as a deeper understanding of the pathophysiology and prognosis of SE are discussed.

### DEFINITION AND CLASSIFICATION

Although the malady had been recognized for centuries, in 1824 Calmeil first used the term *état de mal* (status epilepticus) to describe the state in which grand mal (generalized tonic-clonic) seizures occurred in rapid succession without recovery between convulsions (11). The International League Against Epilepsy (ILAE) and the World Health Organization currently define SE as a “condition characterized by an epileptic seizure that is so frequently repeated or so prolonged as to create a fixed and lasting condition” (12). The lack of recovery for a fixed period, possible frequent repetition, prolongation, and possible propagation of further seizures are inherent in the definition. Status epilepticus is defined functionally as a seizure lasting more than 30 minutes or recurrent seizures lasting more than 30 minutes from which the patient does not regain consciousness (13). The classification of individual episodes of SE should be based on observation of clinical events combined with electrographic information when possible (Table 34-1). Clinical care requires

**Proposed Classification of Status Epilepticus (SE)**

<b>Partial</b>	
Convulsive	
• Tonic	Hemiclonic status epilepticus,
• Clonic	hemiconvulsion-hemiplegia- epilepsy, hemi-grand mal status epilepticus, grand mal
Nonconvulsive	
Simple	Focal motor status, focal sensory, epilepsia partialis continuans, adversive status epilepticus
Complex partial	Epileptic fugue state, prolonged epileptic stupor, prolonged epileptic confusional state, temporal lobe status epilepti- cus, psychomotor status epi- lepticus, continuous epileptic twilight state
<b>Generalized</b>	
Convulsive	
Tonic-clonic	Grand mal, epilepticus convulsivus
Tonic	
Clonic	
Myoclonic	Myoclonic SE
Nonconvulsive	
Absence	Spike and wave stupor, spike and slow wave or 3-Hz spike-and- wave status epilepticus, petit mal, epileptic fugue, epilepsia minora continua, epileptic twilight state, minor status epi- lepticus
<b>Undetermined</b>	
Subtle	Epileptic coma
Neonatal	Erratic status epilepticus

intervention for seizures lasting longer than 5 minutes, recognizing that any type of seizure can develop into SE (Table 34-2). The current definition of 30 minutes is not, as described earlier, universally accepted, and several clinical studies have been published using durations of 10 or 20 minutes. Shinnar and colleagues demonstrated that the majority of pediatric seizures lasting 7 minutes or more had not stopped without active treatment by 30 minutes (14). DeLorenzo et al confirmed a nearly 10-fold greater mortality for seizures lasting 30 minutes or greater compared with those lasting 10 to 29 minutes (15). More information is needed to clarify and allow acceptance of a standard operational definition for SE.

This chapter deals primarily with convulsive tonic-clonic SE that is primarily or secondarily generalized using the 30-minute operational definition. This is the most commonly recognized form of SE in children. Partial seizures that evolve to SE most commonly are secondarily

generalized convulsive seizures and may occur at any age but probably account for the overwhelming majority of adult cases. Status epilepticus also encompasses several nonconvulsive entities, including complex partial, simple partial, and absence seizures. Complex partial SE usually is characterized by an epileptic twilight state in which there is a cyclical variation between periods of partial responsiveness and episodes of motionless staring and complete unresponsiveness accompanied, at times, by automatic behavior (7, 16, 17). Simple partial SE is characterized by focal seizures that may persist or be repetitive. When this condition lasts for hours or days, it is termed *epilepsia partialis continua*. Absence, or petit mal, status has also been referred to as spike-wave stupor. This type of nonconvulsive SE may be extremely difficult to differentiate from complex partial SE without the aid of an EEG evaluation. Classically, in absence status there is a continuous alteration of consciousness without cyclical variations seen with complex partial SE. The EEG recording exhibits prolonged, sometimes continuous, generalized synchronous 3-Hz spike and wave complexes rather than focal ictal discharges that characterize partial SE (7, 18). The child presenting with a

prolonged confused state, fluctuating level of consciousness, or prolonged unconsciousness needs both clinical and EEG evaluations in addition to other studies.

Myoclonic, generalized clonic, and generalized tonic SE are seen primarily in children. Such children usually are those with encephalopathic epilepsies (3, 7, 19), and their consciousness seems to be preserved throughout the attacks. The EEG pattern is bilaterally symmetric with polyspike discharges coinciding with the myoclonic jerks. The term myoclonic SE should not be used when children with severe encephalopathy exhibit repetitive myoclonic jerks not accompanied by ictal discharges on EEG. These patients have subtle, generalized, convulsive SE as defined by Treiman (7). About one-half of the cases of generalized clonic SE occur in normal children and are associated with prolonged febrile seizures; the other half are distributed among those with acute and chronic encephalopathies (20). Generalized tonic SE appears most frequently in children, particularly those with Lennox-Gastaut syndrome. Prolonged generalized tonic convulsions have been precipitated by benzodiazepine administration.

## EPIDEMIOLOGY

Status epilepticus is usually a manifestation of symptomatic epilepsy with preexisting neurologic dysfunction or a manifestation of acute disease primarily or secondarily affecting the central nervous system (CNS). In infants and young children, it is uncommon for SE to occur in the unstressed patient with idiopathic epilepsy. A child who has prolonged resistant seizures should receive a full diagnostic evaluation for all etiologies of seizures, along with a search for those precipitating events listed in Table 34-2. Interestingly, there also is evidence for a genetic predisposition for SE (21, 22). The major causes vary with age, such as febrile SE in children 1 to 2 years of age and remote symptomatic etiologies in the 5- to 10-year range (23). Acute symptomatic etiologies most commonly lead to prolonged SE lasting over 1 hour (24, 25). Similarly, recurrent SE is more frequent in children with remote symptomatic etiologies or progressive degenerative disease (23, 26).

A recent prospective population-based study of SE revealed the incidence of SE to be 41 patients per year per 100,000 population, resulting in a total of 50 episodes of SE per year per 100,000. It is projected that between 102,000 and 152,000 events occur in the United States annually, an incidence 2 to 2.5 times greater than that previously proposed by DeLorenzo et al (6) and Hauser et al (27). Approximately one-third of the cases present as the initial seizure of epilepsy, one-third occur in patients with previously established epilepsy, and one-third occur as the result of an acute isolated brain insult. Among those previously diagnosed as having epilepsy,

estimates of SE occurrence range from 0.5% to 6.6%. Hauser reported that up to 70% of children who have epilepsy that begins before the age of 1 year experience an episode of SE. Also, within 5 years of the initial diagnosis of epilepsy, 20% of all patients experience an episode of SE. A greater incidence of SE was reported by Shinnar from a cohort of patients with childhood-onset epilepsy. One-third of the patients experienced SE over a 30-year period, 50% presenting as the first seizure and an additional 22% occurring within 12 months of onset of epilepsy. In this group, SE occurred in 44% of those with remote symptomatic epilepsy and 20% of those with idiopathic or cryptogenic epilepsy (28).

Although adults with SE as their first unprovoked seizure are likely to develop subsequent epilepsy (27), a prospective study of children with SE found that only 30% of those initially presenting with SE later developed epilepsy (24). Hesdorffer et al have presented more recent data indicating a greater likelihood of epilepsy following SE in a group of 95 people, one-third of whom were children. Over the ensuing 10-year period following a symptomatic bout of SE, there was a 41% risk of an unprovoked seizure (29).

Among children, SE is most common in infants and young toddlers, with more than 50% of cases of SE occurring in those younger than 3 years of age (30). In the Richmond, Virginia, study, total SE events and incidence per 100,000 individuals per year showed a bimodal distribution with the highest values during the first year of life and after 60 years of age (6, 20, 31). Infants younger than 1 year of age represent a subgroup of children with the highest incidence of SE whether events, total incidents, or recurrence is counted. The recurrence rate of SE in the Richmond study was 10.8% (6), but 38% of patients younger than 4 years old had repeat episodes, findings supported by the Finnish study (28). In another cohort of pediatric epilepsy patients followed by Berg and coworkers for 5 years, only 4.3% had their first episode of SE, whereas 19.6% of those who presented with status had one or more episodes of SE (32). More recently, but again from the prospective pediatric epilepsy cohort in Connecticut, Berg and Shinnar reported on factors influencing SE following a diagnosis of epilepsy. In this study only 10% of the children experienced SE over a median 8-year follow-up period, compared with 20% in the report of Hauser et al and the 22% incidence in the previously described Finnish study. SE occurring prior to the epilepsy diagnosis, younger age, and symptomatic etiology influenced the risk of later SE (33).

Extrapolating these figures worldwide, more than one million cases of SE occur annually. Because SE is a neurologic emergency that requires immediate, effective treatment to prevent residual neurologic complications or death, SE poses a substantial health risk. Mortality rates as high as 30% have been reported in overall studies.

Children have a far lower mortality rate than do adults, with the exception of those in the first year of life (34). Age, etiology, and duration correlate directly with mortality (4, 6, 35). Multiple studies confirm the lower mortality rate in most children following adequate emergency treatment (24, 30, 36–38).

### PATHOPHYSIOLOGY

The cellular physiology and neuropathology of SE has been reviewed recently (39, 40) and is discussed in earlier chapters of this book. The mechanisms by which chronic seizures evolve to SE remain unclear (3). There seems to be a loss of inhibitory mechanisms, and neuronal metabolism is not able to keep up with the demand of continuing ictal activity. The pathophysiologic changes that accompany SE can be divided into neuronal (cerebral) and systemic effects. Continuing seizures lead to both biochemical changes within the brain and systemic derangements that further complicate these cerebral changes.

Prolonged convulsive seizures can lead to excitotoxic brain injury. Glutamate, the primary excitatory amino acid neurotransmitter, binds to several neuronal receptors, including the N-methyl-D-aspartate (NMDA) receptor, which is activated by depolarization. The resulting calcium influx causes further depolarization and perpetuates seizures. Glutamate also activates receptors that open channels that conduct sodium and calcium into the cell. Further neuronal damage results through this excessive excitatory neurotransmission. Although gamma-aminobutyric acid (GABA) is the most prevalent inhibitory neurotransmitter in the brain, excessive GABA may in fact increase activity on both GABA<sub>A</sub> and GABA<sub>B</sub> receptors. Activation of the presynaptic GABA<sub>B</sub> receptors can provide feedback inhibition of GABA<sub>A</sub> receptors and paradoxically exacerbate seizures. Other neurotransmitters that may be important in the initiation and maintenance of SE include acetylcholine, adenosine, and nitric oxide (39). Neuropeptides such as dynorphin, substance P, and galanin are potent modulators of the process and may affect the maintenance phase of SE (39).

Neuronal injury and cell death from SE are most prominent in areas that are rich in NMDA glutamate receptors, including the limbic region. The increase in intracellular calcium concentration is critical to cell death. Calcium activates proteases and lipases that degrade intracellular elements, leading to mitochondrial dysfunction and cellular necrosis. Laminar necrosis and neuronal damage after prolonged seizures are similar to those following cerebral hypoxia. Although young animals may be less likely to develop brain damage from SE (41, 42), studies using alternative models demonstrate hippocampal cellular injury even in immature rodents (43). It is

believed that the glutamate-initiated calcium-dependent cascade is similar to the mechanism of NMDA receptor-mediated cell death during cerebral ischemia. Absence SE associated with excessive inhibitory influences generated by GABA<sub>B</sub>-mediated hyperpolarization and activation of folinic T-type calcium channels does not cause cerebral injury (44). Furthermore, recent evidence suggests that acute and long-term changes in gene expression may occur following prolonged seizures and may contribute directly to hyperexcitability (45).

Systemic metabolic abnormalities increase the risk of brain damage in convulsive SE. These include alterations of blood pressure, heart rate, acidosis, hypoxia, changes in respiratory function, body temperature, leukocytosis, rhabdomyolysis, and heightened demands on cerebral oxygen and glucose utilization (46). Circulating catecholamine concentrations increase during the initial 30 minutes of SE, resulting in a hypersympathetic state. In some patients there is truly massive catecholamine release, resulting in the formation of cardiac contraction bands, ultimately representing the real cause of death (47). Tachycardia, sometimes associated with severe cardiac dysrhythmias, occurs and (rarely) also may be fatal (48). Furthermore, cardiac output diminishes and total peripheral resistance increases along with mean arterial blood pressure, perhaps because of the sympathetic overload. Hyperpyrexia may become significant during the course of SE, even without prior febrile illness, in both children and adults and may contribute to neuronal injury (49).

Hypoventilation leads to hypoxia and respiratory acidosis. In addition, serum pH and glucose levels are frequently abnormal as lactic acidosis develops following increased anaerobic metabolism. A leukemoid reaction of peripheral blood frequently occurs in the absence of infection. Rhabdomyolysis, which is not uncommonly seen, may compromise renal function. Recovery from this complicated derangement of metabolism is time dependent. More prolonged seizures produce further neuronal injury and death.

### PROGNOSIS

The morbidity and mortality of SE are direct consequences of its basic pathophysiology and the efficiency of treatment. Previously, overall mortality figures for SE were quoted as 10% to 30% (35, 50, 51). The mortality rate for the Richmond, Virginia, population was 22% overall. Based on this study, which includes all age groups, there are approximately 126,000 to 195,000 SE events with 22,000 to 42,000 deaths per year in the United States. However, the mortality rate in children was only 3%, and most of the pediatric deaths occurred between the ages of 1 and 4 years (Table 34-3). The pediatric and aged

**TABLE 34-3**  
*Childhood Status Epilepticus Prognosis*

Morbidity (%)	>50	23	9.1	11–15
Mortality (%)	11	8	3.6	3

populations had an increased number of recurrences of SE following a single episode. In general, children had chronic neurologic disabilities but rarely went on to die. Among those patients who died, death rarely occurred during the acute episode of SE. Rather, most patients succumbed 15 to 30 days later. Children with chronic epilepsy and low levels of anticonvulsant drugs have the lowest mortality rate overall. This latter finding as well as additional confirmation of a 3% SE-related mortality was reported by Chin et al from the prospective North London Status Epilepticus in Childhood Surveillance Study. This study did not contain morbidity data but did reveal the highest yet reported early SE recurrence—16% within 1 year of the initial episode (52).

The morbidity of SE in children was examined in the same database from Virginia. Before their SE event, 81% of children with no prior history of seizures were neurologically normal, in contrast to only 31% of children with seizure histories. Of the neurologically normal children with no prior seizures, more than 25% deteriorated after their first SE event, in comparison with less than 15% of neurologically normal children with a seizure history. Children who were neurologically abnormal without prior seizure deteriorated further in 6.7%, compared with 11.3% of the abnormal children with a seizure history. Morbidity was determined at the time of hospital discharge, and in some children the abnormalities certainly improve as minor degrees of ataxia, incoordination, or motor deficits can be attributed to the acute therapies or clinical changes after prolonged seizures and may not persist. Determining whether language deficits and school performance difficulties were transient or more permanent was much more difficult. In the prospective study, 11% to 15% had significant morbidity after an episode of SE (Table 34-3). These findings suggest a neurologic morbidity substantially lower than the “greater than 50 percent” rate previously reported in children having SE (50), but the morbidity and mortality of very sick infants is higher than in older children (34).

Hesdorffer and colleagues in Rochester, Minnesota, have recently demonstrated a 41% 10-year risk of having an unprovoked seizure following an acute seizure with SE.

This 95-person cohort included 17 individuals younger than 1 year of age and 17 individuals from 1 to 19 years of age. This risk was increased 18.8-fold for SE as a result of anoxic encephalopathy, 7.1-fold for structural causes, and 3.6-fold for metabolic causes over the risk in a population of patients who experienced a less prolonged acute symptomatic seizure (29). Electrographic and biochemical markers for increased morbidity and mortality in SE exist. The duration of the individual seizure, especially if it evolves to nonconvulsive SE (NCSE), has been directly correlated with death or poor outcome as defined by inability to return to prehospital level of function (53). Serum and CSF levels of neuron-specific enolase (NSE) rise above normal after both brief and prolonged seizures. Serum levels following SE are significantly higher and are at their highest in patients following NCSE, where levels higher than 37 ng/mL correlate with poor outcome (54). CSF lactate is certainly elevated following SE, and levels three times greater than the accepted normal have been associated with poor outcome, whereas those elevated 2-fold or less had better outcomes. Elevated CDF pro-inflammatory cytokines such as tumor necrosis factor- $\alpha$  and interleukin-6 have been documented following SE (55). CSF lactate dehydrogenase (LDH) and creatine kinase do not appear to be valid indicators of prognosis in SE (56). CSF pleocytosis also does not appear to be a valid indicator of prognosis in SE. In all ages it is typically related to the acute illness or injury precipitating the seizure. More than 6 white blood cells (WBCs)/mm<sup>3</sup> or any polymorphonuclear lymphocytes (PMNs) in the adults or more than 8 WBCs/mm<sup>3</sup> (and greater than 4 PMNs/mm<sup>3</sup>) in children should prompt a search for an etiology other than the seizure itself (57, 58).

Radiographic findings following SE, typically reversible focal magnetic resonance imaging (MRI) T2-weighted abnormalities, have been recognized for years (59). It had been assumed these findings were benign. The variations in peri- and postictal changes on anatomical and functional imaging examinations have been recently reviewed (60). However, there is a growing collection of case reports suggesting that there is brain injury despite radiographic normalization, as evidenced by persistent EEG abnormalities

and proton MR spectroscopy abnormalities (61, 62). One report describing hyperintensities in anterior cerebral white matter suggests that a biphasic clinical course of SE, followed by clinical improvement and then early seizure recurrence, increases the odds for neurologic sequelae (55). Similar changes, particularly evolving mesial temporal sclerosis, are being carefully explored in febrile SE, which represents the single largest etiologic subgroup (63, 64). There is also strong evidence that structural brain injury in the form of ischemic stroke has a synergistic effect with SE, leading to increased mortality (65).

## THERAPY

Extrapolating the statistical figures worldwide, more than one million cases of SE occur annually. As a true neurologic emergency, it requires mobilization of significant personal and medical resources and certainly qualifies as a substantial public health concern. With mortality rates as high as 30% reported in all-age-inclusive studies, immediate effective treatment is necessary to prevent residual neurologic complications or death. Age, etiology, and duration correlate directly with mortality (4, 6). The highest mortality is seen in the elderly; fortunately, children have a far lower mortality rate than do adults (4, 24, 27, 35). Some of this improved prognosis is probably a result of fewer coexisting medical conditions. That said, multiple studies confirm a lower mortality rate in children following adequate emergency treatment (24, 30, 36–38).

### Acute Seizure Management

SE begins as either a prolonged seizure or continuing acute-repetitive seizures. These usually occur away from a medical center, and our approach for acute seizures is presented. The blurring of the previously clear timeline when long or recurrent seizures become SE has been previously discussed. In an attempt to prevent this progression, medical intervention is suggested when the seizure duration is 5 minutes or more. As such, it is paramount that families become educated on seizure first aid, and they must have an action plan. They or the first responders must note the time of seizure onset as part of their providing support to the child. Many times this support will include at-home benzodiazepine administration, usually in the form of rectal diazepam, but sometimes oral lorazepam or diazepam if consciousness is retained and the patient can safely swallow liquids. Appropriate first-aid recommendations are discussed here for completeness. The Epilepsy Foundation of America (EFA) recommends that the first responders:

- Look for medical identification.
- Protect the person from nearby hazards.

- Loosen ties or shirt collars.
- Protect the head from injury.
- Turn the person on his side to keep the airway clear.
- Reassure when consciousness returns.
- If a single seizure lasts more than 5 minutes, ask whether hospital evaluation is wanted. If multiple seizures, or if one seizure lasts longer than 5 minutes, call an ambulance. If the person is pregnant, injured, or diabetic, call aid at once.

The EFA also recommends that first responders:

- Do not put any hard implement in the mouth.
- Do not try to hold the tongue. It cannot be swallowed.
- Do not try to give liquids during or just after the seizure.
- Do not use artificial respiration unless breathing is absent after muscle jerks subside, or unless water has been inhaled.
- Do not restrain the person.
- The person should be transferred to a medical center as soon as possible if their seizure continues beyond 5 minutes or, if after ceasing, it begins again (66).

The neurologic emergency of SE requires maintenance of respiration, general medical support, and specific treatment of seizures while the etiology is sought (1, 67, 68). One typical and unfortunately frequent mistake made in the treatment of SE is that inadequate doses of drugs are given initially, and physicians wait for more seizures to occur before administering the necessary total dose (67, 69). Additionally, given that febrile seizures are common and such patients regularly present to emergency rooms for evaluation, the progression from prolonged simple febrile seizure to febrile SE is often missed (70). The ideal antiepileptic drug (AED) for the treatment of SE should have the following properties: rapid onset of action, broad spectrum of activity, ease of administration including intravenous (IV) and intramuscular (IM) preparations, minimal redistribution from the CNS, and wide therapeutic safety margin. With confirmed safety and efficacy data (71) and particularly because it is longer acting, lorazepam (LZP) has become more popular in many centers as the initial agent, thus replacing diazepam (DZP). Recent studies in both children and adults also support the use of midazolam (MDZ). Its rapid absorption from varied sites of administration and rapid onset of anticonvulsant activity make MDZ a very attractive agent for use in multiple settings. If, however, SE continues after the initial dosing of a benzodiazepine and persists after a primary AED such as phenytoin (PHT) (as fosphenytoin, FOS) or phenobarbital (PB) is given, a second dose of the same AED should be administered before switching to alternative medications. SE refractory to these established

**TABLE 34-4**  
*The Steps of Status Epilepticus Emergency Management*

1. Ensure adequate brain oxygenation and cardiorespiratory function
2. Terminate clinical and electrical seizure activity as rapidly as possible
3. Prevent seizure recurrence
4. Identify precipitating factors such as hypoglycemia, electrolyte imbalance, lowered drug levels, infection, and fever
5. Correct metabolic imbalance
6. Prevent systemic complications
7. Further evaluate and treat the etiology of SE

agents carries a graver prognosis (68). Numerous studies suggest that additional bolus administration followed by titrated IV infusions of DZP, MDZ, pentobarbital, or the anesthetic agents lidocaine or propofol, may break these seizures. The use of IV valproic acid (VPA) in the treatment of SE has expanded greatly in the past few years. There are reports, as well, supporting the safety and efficacy of topiramate and levetiracetam in the treatment of refractory SE.

The primary goal of treatment is to stop the convulsive discharges in the brain. Table 34-4 lists the steps of the emergency management of SE (67, 72). The child presenting in SE must have cardiorespiratory function assessed immediately by vital sign determination, auscultation, airway inspection, arterial blood gas determination, and suction if necessary. Although spontaneously breathing on presentation, children may already be hypoxic with respiratory or metabolic acidosis from apnea, aspiration, or central respiratory depression (1). The need for ventilator support depends not only on respiratory status at the time of presentation but also on the conditions before arrival and the ability to maintain adequate oxygenation throughout ongoing seizures and during the IV administration of drugs, all of which cause some amount of respiratory depression. Elective intubation and respiratory support are urged in the neurologically depressed patient. In most patients with placement of an oral airway or nasal canula or both, oxygen is insufficient as respiratory drive is depressed. Significant hypoxia is a principal factor determining morbidity and mortality (6). Rapid assessment of vital signs and general neurologic examination give clues to the etiology of SE. Blood drawn to determine blood gases, glucose, calcium, electrolytes, complete blood count, AED levels, culture, and virologic and toxicologic studies help with the overall determination of etiology. Similarly, urine for drug and metabolic screens should be collected. The roles of CSF NSE, cytokines, and lactate, as well as serum NSE, in

the prognostication of outcomes in SE were discussed previously.

Intravenous fluids should be administered judiciously, with appropriate corrections for fever, suction, and chemical abnormality. Fluid restriction is rarely necessary. Immediately following placement of the IV line, 25% glucose (2–4 mL/kg) should be given by bolus. In the case in which IV access cannot be established, the intraosseous route has been shown efficient for both fluid and medication administration (73). Because of the high incidence of febrile SE resulting from CNS infection in infants, a lumbar puncture should be done early in the course of management but not necessarily during the initial phase of stabilization. It is rarely necessary to wait for imaging studies to be performed in this group. If lumbar puncture is deferred for any reason, appropriate antimicrobial coverage for possible meningitis or encephalitis should be considered. Electrocardiographic (ECG) and EEG monitoring is desirable when available (68).

EEG monitoring is extremely useful in both the initial and the subsequent management of SE (72, 74–76). The classification of SE, clues to etiology, and prognosis may be suggested from the EEG and its response to therapy. This includes patients with completely hysterical attacks and those presenting with an overdose of drugs or focal pathology. Definition of seizures as being mainly partial versus primarily or secondarily generalized is easily recognized; in nonconvulsive cases the EEG easily establishes the diagnosis as complex partial or absence. The use of EEG is mandatory in the presence of neuromuscular blockade or whenever recurrence of seizures cannot be documented on a clinical basis (1, 72).

An electroclinical dissociation may exist after large doses of AEDs have been given, so that the clinical manifestations are absent while electrographic seizures continue. The recognition of EEG patterns, such as paroxysmal lateralized epileptiform discharges (PLEDs), periodic epileptiform discharges (PEDs), and evidence of continued post-SE ictal discharges without clinical correlation while the patient remains in a coma, requires ongoing therapy and may be helpful in establishing the etiologic diagnosis and prognosis (8). One recent study of 50 patients with SE reported poor outcomes, including death or persistent vegetative states, in 44% of those whose records demonstrated PEDs, compared with 19% without PEDs (77). ECG alterations seen in adults during and after SE range from ischemic changes to tachyarrhythmias. These changes must be promptly and appropriately treated (46, 78). These relatively new findings suggest that EEG be more aggressively used in the evaluation and treatment of SE. Practical limitations must be realized, however, because many treatment sites do not have EEG readily available. Nevertheless, urgent use of this monitoring must be considered when patients do not regain consciousness or when seizures are continuous or recurrent.

## DRUG THERAPY OF STATUS EPILEPTICUS

There are multiple regimens for treating SE successfully. Benzodiazepines and FOS (PHT equivalent) as initial therapy are preferred by our group at the Medical College of Virginia of Virginia Commonwealth University (MCV/VCU), but others may wish to continue alternative agents if the patient is known to be on maintenance therapy or has already received smaller doses of PHT or PB (79, 80). LZP, DZP, FOS, and PB are accepted agents for initial and continued therapy of SE. The large SE treatment study done in adults and sponsored by the U.S. Veterans Administration suggests that there is no significant difference between three IV drug regimens: (1) DZP, 0.15 mg/kg, and PHT, 18 mg/kg; (2) LZP, 0.1 mg/kg; or (3) PB, 15 mg/kg, for initial management of generalized convulsive SE when results were measured at 20 minutes (81). Each was superior to PHT, 18 mg/kg, used alone. It is important to note that the rate of PHT administration probably biased the study. The much more rapid speed at which FOS can be administered may significantly change these results. The choice of an initial agent may depend on individual patient characteristics, prior AED therapy, and physician preference. Recommended doses of commonly used drugs for the treatment of convulsive SE are listed in Table 34-5. Protocols presently used by our group at MCV/VCU for the management of SE in children, adolescents, and adults are given in Tables 34-6 and 34-7 (79).

### Benzodiazepines

As a group the benzodiazepines are the most potent and efficacious drugs in the treatment of SE (82). Lasting control of SE is achieved in approximately 80% of patients treated with LZP, DZP, or clonazepam (81). Because the IV preparation of clonazepam is not available in the United States, lorazepam and diazepam are

most frequently used. A prospective, randomized study determined that IM MDZ is as effective as DZP in stopping seizures and is faster than DZP because it avoids the requirement of starting an IV line (83). Nasal and buccal administration of benzodiazepines have demonstrated efficacy in aborting acute seizures, but no prospective studies support these routes in treating SE (84, 85).

### Lorazepam

Lorazepam is a potent benzodiazepine with rapid onset and more prolonged duration of anticonvulsant action than those of DZP. With a half-life of approximately 10 to 15 hours in adults and children, LZP continues to have an effective brain level for 8 to 24 hours. A favorable lipid partition coefficient allows LZP to remain in the brain longer than DZP, which redistributes more rapidly. The recommended IV bolus LZP dose is 0.1 mg/kg up to a total of 5 to 8 mg. Tachyphylaxis develops, making repeated doses less effective (86, 87). LZP is also less useful in patients receiving chronic benzodiazepine therapy.

The efficacy of LZP equals that of DZP in neonates, children, and adults (87–94). Adverse effects include hypoventilation, ataxia, vomiting, amnesia, lethargy, respiratory depression, and hypotension. These symptoms are exacerbated when barbiturates, paraldehyde, or other depressant drugs are administered before LZP. Following rectal administration, LZP has a more delayed onset of action than DZP (93). Sedation that follows IV administration of LZP is longer lasting than that following DZP. Significant sedation is a disadvantage of both drugs when continued observation of level of consciousness is necessary.

### Diazepam

Diazepam enters the brain within seconds following IV administration and successfully stops convulsive and

**Medical College of Virginia Hospitals Status Epilepticus Protocol for Children and Adults**

**CHILDREN<sup>a</sup>**

STEP	TIME FROM START OF INTERVENTION	PROCEDURE
1	0–5 min	Determination of SE. As soon as the diagnosis is made, institute monitoring of temperature, blood pressure, pulse, respirations, ECG, and EEG. Insert oral airway and administer O <sub>2</sub> if necessary. Insert an IV catheter and draw venous blood levels of anticonvulsants, glucose, electrolytes, calcium, BUN, and CBC. Draw arterial blood for antipyretics (acetaminophen). Perform frequent suctioning.
2	6–9 min	Place an IV line with normal saline. Administer a bolus of 2 mL/kg 50% glucose.
3	10–30 min	Initial treatment consists of an infusion by IV lorazepam given at a rate of 1–2 mg/min (0.1 mg/kg) to a maximal dose of 8 mg. This is followed by IV fosphenytoin (FOS) infused at 150 mg/min (or phenytoin [PHT] infused at a rate not to exceed 1 mg/kg/min or 50 mg/min). Monitor ECG and blood pressure. May repeat FOS (PHT) 10 mg/kg before proceeding to next step.
4	31–59 min	If seizures persist, administer a bolus infusion of phenobarbital at a rate not to exceed 50 mg/min until seizures stop or to a loading dose of 20 mg/kg.
5	60 min	If control is not achieved, other options include: <ul style="list-style-type: none"> <li>• Diazepam (50 mg) is diluted in a solution of 250 mL 0.9% NaCl or D5W and run as a continuous infusion at 1 mL/kg/hr (2 mg/kg/hr) to achieve blood levels of 0.2–8.0 mg/mL. The IV solution is changed every 6 h, as advised by certain authors, and short-length tubing is used.</li> <li>• Pentobarbital with an initial IV loading dose of 5 mg/kg with additional amounts given to produce a “burst suppression” pattern on EEG. Maintenance of pentobarbital anesthesia is continued for approximately 4 h by an infusion of 1–3 mg/kg/hr. The patient is then checked for the reappearance of seizure activity by decreasing the infusion rate. If clinical seizures and/or generalized discharges persist on EEG, the procedure is repeated; if not, the pentobarbital is tapered over 12–24 hours.</li> </ul>
6	61–80 min	If seizures are still not controlled, call anesthesia department to begin general anesthesia with halothane and neuromuscular blockade.

Abbreviations: ECG, electrocardiogram; EEG, electroencephalogram; IV, intravenous; BUN, blood urea nitrogen; CBC, complete blood count; D5W, 5% dextrose in water.

<sup>a</sup>Continuous monitoring of EEG is recommended in an obtunded patient to ensure that SE has not recurred. In the management of intractable status, a neurologist who has expertise in SE should be consulted, and advice from a regional epilepsy center should be sought. Lumbar puncture should be performed as soon as possible, especially in a febrile child or infant <1 year old. For infants with a history of neonatal seizures, infantile spasms, or early-onset seizures, pyridoxine 100 mg IV should be administered while EEG monitoring is being performed to diagnose and treat the rare patient with seizures and a vitamin B<sub>6</sub> deficiency.

nonconvulsive seizures in the majority of adults and children (82). Its primary disadvantages are similar to those of LZP. In addition, because of rapid redistribution, seizures frequently reoccur after 15 to 20 minutes after IV administration, requiring that a second, longer-acting drug be given or a second dose of DZP be administered. Respiratory support should be available when DZP is used to treat SE. Recommended dose estimates by age are given in Table 34-4 based on 10 to 15 mg/m<sup>2</sup>, or 0.3 mg/kg. An initial estimate of dose may be made by taking the patient's age and giving 1 mg per year plus

1 mg (1). Diazepam may be given by intraosseous or rectal route or by a continuous IV infusion (95). In addition to respiratory depression, laryngospasm may develop during the administration of diazepam.

As LZP is supplanting DZP in many hospital emergency situations, DZP has taken on another important role—that of prehospital treatment by family or other caregivers for prolonged or acute repetitive seizures. The viscous solution of 5 mg/mL DZP was developed specifically for rectal administration. Its safety and efficacy have been established in two U.S. trials, and considerably

fewer of the DZP gel-treated patients required subsequent emergency medical attention for continued seizures following the treatment of their episode (96, 97). This leads to a reduced cost of care and, in the future, may decrease the prolongation of some seizures to SE (98). Since 2005, and in an effort to improve compliance and enhance safety, the delivery system for branded rectal DZP, Diastat, was changed to the AcuDial system. The dose delivered via the rectal syringe is preset by the pharmacist and can be better tailored to meet the child's need based on age and weight.

### Midazolam

Midazolam has been used successfully as a first-line treatment for convulsive SE and for refractory convulsive SE.

Clinical evidence supports that IM MDZ is more effective than IM DZP and as effective as IV DZP in abolishing interictal spikes on EEG recordings. At doses from 0.15 to 0.3 mg/kg it effectively terminated convulsive seizure activity (99). More than 100 children with SE are described in the literature as being successfully treated primarily with MDZ, without drug-related cardiac side effects or urgent intubation for ventilatory support (100–102). The dosing of MDZ for SE in children is not established. Suggested values are found in Table 34-5. Although LZP, DZP, and now MDZ are usually considered as the initial drugs of choice, they sometimes are useful as the second or third agent when seizures continue. Respiratory support should be available when any of the benzodiazepines are used because of the cumulative blunting of the respiratory drive centers. Additional intensive monitoring should also be performed to guard against hypotension.

Midazolam undergoes rapid hepatic breakdown, leaving no active metabolites. The elimination half-life of MDZ in children aged 6 months to 10 years ranges from 1.17 to 4 hours, in contrast to longer values in adults (1.8–6.4 hours) and elderly men (5–6 hours) (103). Recall that the active desmethyl metabolite of DZP has a physiologic half-life of 46 to 78 hours. When MDZ is administered as a continuous IV drip, dosing needs to be adjusted upward to achieve continued anticonvulsant or sedative action because of marked tachyphylaxis.

### Phenobarbital

Phenobarbital remains the initial drug of choice in some institutions for the treatment of childhood SE (104, 105). Its time to onset of action is longer than that of LZP and DZP, with peak brain levels being reached in 20 to 60 minutes. Slow IV bolus infusion of 20 to 25 mg/kg is suggested initially. Repeated 10 to 20 mg/kg doses may be necessary to be successful (1, 105). Principal side effects are hypotension and respiratory and sensorial depression. PB should be administered by IV infusion no faster than 100 mg/min. In the VA Cooperative Study PB was just as efficacious in treating SE as LZP and LZP plus PHT, and a better first drug (regimen) than PHT alone (81).

### Fosphenytoin (Phenytoin Prodrug Equivalent)

Fosphenytoin has replaced injectable PHT at our institution because of its safety advantages. This prodrug is nearly 100% bioavailable and, unlike its product (PHT), is freely soluble in aqueous solutions (106). Given IV, FOS is rapidly converted to PHT by phosphatases in the bloodstream. The PHT then enters the brain, reaching peak brain levels at 15 minutes (107, 108). FOS is an excellent agent for the treatment of convulsive SE, both partial and generalized, but it is ineffective in the treatment of absence status (1). A marked advantage is

that it does not depress respiration as other drugs do in this situation (1). The dose is prescribed as milligrams of PHT equivalents (PE). In young children, the initial IV FOS dose should be 15 to 25 mg PE/kg (109). In adolescents and adults, a dose of 18 mg PE/kg provides initial serum PHT levels greater than 25 µg/mL and is effective in maintaining serum levels of 10 µg/mL for 24 hours (110). Cardiac conduction disturbances have not been seen, and hypotension is rare with infusion rates up to 150 mg PE/min (111). According to data from animal and human studies, most systemic adverse effects are due to the derived PHT, so the most common CNS effects include nystagmus, headache, ataxia, and somnolence. Intramuscular administration of FOS at doses from 10 to 20 mg PE/kg may allow for treatment in the field or when no IV access is present, potentially allowing for more rapid seizure control. Therapeutic blood levels can be attained in 20 to 30 minutes following IM injection (112).

Although FOS has many advantages over PHT (IM route, safe when IV site infiltrates, faster rates of administration, and lack of solvent, cardiosuppressive effects), it is not available in all facilities and frequently is not available outside the United States. FOS is significantly more expensive than PHT, but pharmacokinetics studies in patients can demonstrate its overall advantage.

### Phenytoin

Phenytoin is an excellent agent for the treatment of convulsive SE, both partial and generalized, but it is not indicated in the treatment of absence status (1). After IV administration PHT reaches peak brain levels at 15 minutes (107, 108). A marked advantage of PHT is that it does not cause significant respiratory depression (1). As demonstrated by the VA study, it is best administered in combination with a benzodiazepine to ensure a rapid anticonvulsant effect, followed by the long-lasting efficacy of PHT (81). The ECG should be monitored during administration because of hypotension and cardiac conduction disturbances, primarily in adults or children with preexisting cardiac disease (1). The rate of infusion should be less than 50 mg/min in adults or 25 mg/min in children. Intravenous injection should be directly into the vein or IV line close to venous access because precipitation is likely to occur in most IV solutions. Intramuscular administration of PHT is discouraged because of crystallization, muscle destruction, and unpredictable absorption (113).

### Pentobarbital

Pentobarbital is used at many institutions for refractory SE. Following a loading dose of 20 mg/kg,

1 to 2 mg/kg/hr is given IV to keep the serum level at 20 to 40 µg/mL to produce electrographic suppression or burst-suppression pattern. Pentobarbital's half-life is approximately 20 hours. Most authorities stop pentobarbital coma at 24 to 48 hours to determine whether SE subsides (114). Cardiac output and blood pressure are compromised at levels higher than 40 g/mL. Unfortunately, refractory SE requiring coma with pentobarbital or other anesthetic agents to produce EEG suppression is associated with a higher rate of morbidity and mortality (69).

### Other Agents

When SE is resistant to benzodiazepines, PB, and PHT, paraldehyde was previously used (1). Paraldehyde IV solution is no longer commercially available in the United States, but rectal solution is sometimes still used. For rectal administration a 2:1 paraldehyde oil (vegetable or peanut) mixture is administered at 0.3 mL/kg per dose with doses repeated every 2 to 4 hours (115). Intravenous lidocaine may alternatively be used for the treatment of SE. There are no large, double-blind, placebo-controlled studies of the efficacy of lidocaine, but numerous case reports and case series suggest an initial bolus of 1 to 3 mg/kg followed by slow infusion of 4 to 10 mg/kg/hr (107, 116). The principal side effect is cardiovascular dysfunction. Paradoxical convulsions may occur as levels of lidocaine elevate.

In addition to lidocaine, other anesthetic agents have been used for seizure and EEG suppression (1). The foremost of these is propofol, and its use in the treatment of refractory SE has recently been reviewed (117). Based on case reports and two small, open, uncontrolled studies, propofol is no better than other second-line agents for ultimate control of prolonged seizures, but compared with high-dose barbiturate therapy, the time to attain seizure control appears markedly reduced (118). This promising property of propofol is, however, offset in the pediatric population by two drawbacks. The metabolism of this drug is exceedingly rapid, and escalating doses are required to maintain adequate blood levels, without which breakthrough seizures and SE are common. Several cases of severe metabolic acidosis and rhabdomyolysis have also been reported (119). The propofol infusion syndrome in children has been reviewed (120), and there are now clear guidelines for safe use and wide recognition of the need to limit the total dose received.

Intravenous VPA may be given to patients with epilepsy when it is not possible to maintain concentrations by the oral route. Although there still have been no multicenter, controlled trials of IV valproate in SE, there are multiple reports of improvement in patients with

refractory SE (121–124). Doses in these studies of seizures and SE were usually an IV bolus of 15 to 30 mg/kg followed by continuous or intermittent infusions at rates of 0.5 to 1.0 mg/kg/hr. We presently recommend administering the available VPA for IV use diluted 1:1 at a rate of 6 mg/kg/min for rapid replacement or when seizures are refractory to other therapies (125). Steady-state concentrations greater than 50 mg/L have been reported after administration of IV VPA 15 mg/kg followed 1 to 3 hours later by either IV VPA or sustained-release oral divalproex sodium 7.0 mg/kg every 8 hours or 4 mg/kg every 6 hours. When VPA concentrations must be maintained above 100 mg/L, the drug may need to be infused every 4 hours (126).

Research efforts concerning the optimal or first-choice drug therapy of SE examine morbidity and mortality, along with the practical issues of drug administration and adverse effects. What Holmes (80) concluded almost 20 years ago is still true today, no one drug of choice may be acceptable to all clinicians. Certainly LZP, DZP, MDZ, PHT, and PB are all useful agents for both the initial and continued therapy of SE (127–129). Thus, one's choice of the initial and subsequent medications for the treatment of SE may depend on the individual patient characteristics, prior AED therapy, and physician preference. Most important, a protocol should be established so that prompt and appropriate emergency treatment can be given in an efficient manner (130). The use of IV VPA in SE is currently being defined. There are also an increasing number of reports supporting agents such as topiramate and levetiracetam in SE (131–133), and ongoing studies are exploring the roles of alternative forms of administering benzodiazepines.

### MEDICAL COMPLICATIONS OF STATUS EPILEPTICUS

The treatment of SE requires close monitoring of physiologic variables and excellent nursing to prevent secondary complications (3, 7, 74). Besides the underlying or precipitating disease states associated with SE, subsequent medical complications are quite common. Pulmonary care, proper positioning, and careful observation of seizures, noting the possible changes in seizure pattern, are mandatory. Frequent surveillance and normalization of glucose and electrolytes, particularly in neonates and small infants, is mandatory. Optimal oxygenation and expectant observation and treatment for hyperthermia and other medical complications lead directly to a lessening of morbidity and mortality. Cardiovascular, respiratory, and renal effects may be severe. Medical complications of SE, which may occur in both infants and older children, are listed in Table 34-7.

When hyperthermia is resistant to rectally administered antipyretics and cooling blankets, muscular blockade may be necessary. EEG monitoring is a necessity when this is performed. A rise in blood pressure consistently accompanies seizures but rarely requires antihypertensive medication unless the child is at risk for malignant hypertension. Unfortunately, treatment may result in hypotension and reduce cerebral perfusion pressure. Very infrequently does cerebral edema or increased intracranial pressure become problematic during most cases of SE not associated with an intracranial mass. The use of osmotic diuretics and steroids are therefore rarely indicated in the routine treatment of SE.

### NONCONVULSIVE STATUS EPILEPTICUS (NCSE)

Convulsive generalized tonic-clonic SE may evolve into nonconvulsive or subtle SE either without treatment as part of its natural history or because of partially successful drug treatment. The incidence of posttreatment subtle SE has been placed as high as 48% in patients requiring intensive care management (8). NCSE has also been reported as an unrecognized cause of coma in intensive care unit (ICU) patients, with up to 8% of adults and 33% of pediatric patients having EEGs that met criteria for this diagnosis (134, 135). The mortality in such cases has been difficult to isolate from the associated acute medical illnesses, but ranges from 33% to 52%, rising well above that for the SE population as a whole. Multifactorial analysis does suggest, however, that the morbidity and mortality in this group are most closely correlated with the delay in time to diagnosis (duration of seizure) and serum levels of NSE (53, 54). Shnecker and Fountain reviewed the records of 100 consecutive NCSE patients, confirming a similarly high mortality rate of 39% in one subgroup and suggesting that, in addition, severe mental status impairment and acute medical complications influence outcome, but the nature of their EEG discharges do not (136). Treatment of subtle SE is identical to that of refractory SE, and the central theme to improving outcome is early recognition and intensive EEG monitoring.

In addition to postconvulsive subtle seizures, NCSE also presents as prolonged complex partial, absence, myoclonic, or atonic seizures. These confusional or fugue states are a separate entity from the previously described subtle SE. Childhood conditions with periods of frequently occurring seizures that meet the definition of SE include the syndromes of West (infantile spasms/hypsarrhythmia), Lennox-Gastaut, Landau-Kleffner, childhood absence (pyknolepsy), continuous spike-wave during sleep, and continuous occipital spike-wave during sleep (90). Furthermore, neonatal seizures, with their various subtle and sometimes variable symptomatology,

may sometimes represent SE. Specific etiologies should always be considered in these cases.

EEG monitoring reveals continuous or noncontinuous generalized, symmetric or diffuse, and irregular 1.5- to 4-Hz multispikes-and-wave complexes in absence status, as opposed to the partial discharges seen in SE because of complex partial seizures (60). Clinically, a child in absence status usually demonstrates partial responsiveness with confusion, disorientation, speech arrest, amnesia, and sometimes automatisms (137). Total unresponsiveness with stereotyped automatisms is usually lacking in absence status (137). Complex partial SE is more likely to be fluctuating, sometimes with nearly cyclical impairment of consciousness, including total unresponsiveness and more complex stereotyped automatisms, with wandering eye movements or eye deviations (138, 139).

The therapy of complex partial SE is similar therapy for convulsive SE. For absence status, IV LZP or DZP is excellent. This medication should then be followed quickly by IV VPA or oral, nasogastric, or rectal doses of ethosuximide or clonazepam. Rarely, combined administration of VPA and clonazepam may produce absence status. Some children with Lennox-Gastaut syndrome have seizures exacerbated by benzodiazepines (127). Case reports demonstrate the response of refractory partial

SE to clobazam (140) and refractory absence SE to propofol or IV VPA (141, 142). Respiratory support is less problematic in NCSE than in convulsive forms; however, some patients have difficulty handling secretions in their "twilight state" or spike wave stupor.

## CONCLUSIONS

Similar to other seizure types, SE represents a symptom of CNS dysfunction. However, it signifies severe malfunction. The etiology of SE must be sought out, because the highest percentage of SE is symptomatic, particularly in young children. Judicious use of routine laboratory tests coupled with neuroradiologic studies and lumbar puncture should be used in almost every patient. Those patients who remain in prolonged coma may harbor a disease such as intracranial hemorrhage, meningitis, or encephalitis, and in general have a poorer prognosis, as do all patients with prolonged or uncontrollable SE. Recent studies dispute the prior morbidity and mortality figures for SE at approximately two-thirds. A better prognosis seems possible if seizures are controlled more rapidly while optimal support is given. Promptly recognizing medical complications and treating concomitant diseases further improve outcome in all children.

## The Female Patient and Epilepsy

Mark S. Yerby

**H**ippocrates noted that while epilepsy at birth tended to be resistant to cure, seizures whose origin was in later childhood tended to cease at puberty. In fact, some early Greek physicians suggested early sexual intercourse for such children in an attempt to provoke a cure. Though many seizure disorders improve during puberty, many worsen. In primarily generalized absence seizure, improvement is common, but a small proportion go on to develop generalized convulsive seizures at puberty (1). Benign focal epilepsy remits during puberty (2). Photic-sensitive epilepsies generally begin during puberty, as do generalized tonic-clonic seizures on awakening (3, 4). Juvenile myoclonic epilepsy also begins at puberty and is more common in girls, and seizures often are more frequent during menses (5). Lennox-Gastaut syndrome often worsens during puberty (6).

### PHYSIOLOGY OF SEXUAL MATURATION

At puberty the hypothalamus begins to secrete gonadotropin-releasing hormone (GnRH). This is carried in the portal circulation to the anterior pituitary, which, in turn, releases follicle-stimulating hormone (FSH). Follicle-stimulating hormone promotes the development of ovarian follicles. The ovarian follicles secrete estradiol.

Lutenizing hormone (LH) is also secreted by the pituitary, but, unlike FSH, it has a pulsatile secretory pattern. It promotes maturation of the ovarian follicle and ovulation. The remaining follicular cells then become the corpus luteum, which secretes progesterins. At the point at which the corpus luteum is developed, the follicular phase ends and the luteal phase of the menstrual cycle begins. Progesterone inhibits secretion of GnRH, FSH, and LH. If there is no fertilization, the corpus luteum regresses, and estrogen and progesterin levels decline. With this decline the GnRH secretion resumes and the cycle repeats.

There are direct connections from the temporal lobe to the hypothalamus. Aberrant discharges from the temporal lobe may therefore impact hypothalamic activity and thus pituitary hormone secretion. Direct stimulation of the amygdala's corticomедial zone increases GnRH (7) and stimulation of the basolateral region reduces GnRH (8).

### ASSOCIATION OF MENSES WITH EPILEPSY

The term *catamenial epilepsy* (from the Greek *kata*, by; *men*, month) epilepsy refers to seizure exacerbation in relation to the menstrual cycle. Traditionally, the term has been used to refer to seizure exacerbation at the time of menstruation. It has long been a recognized phenomenon. Gowers was the first of the "modern" epileptologists

**TABLE 35-1**  
*Rates of Catamenial Epilepsy*

to recognize an association of increased seizures with menstruation (9). In 1904 Spratling reported that 25% of women had their seizures during menstruation (10). Turner reported in 1907 “The relationship between fits and menstruation has been well established” (11). Lennox and Cobb (12) wrote that “it is a well known fact that many female patients frequently have seizures near their menstrual period.” Subsequent reports were primarily brief case series, and they show significant differences as to whether and to what degree catamenial epilepsy occurred. Although the phenomenon is well described and appreciated, a precise definition of catamenial epilepsy has been elusive. In addition to a lack of precise definition, the length of observation required to make the diagnosis varies widely, and in many studies documentation has been merely the recollection of seizures by patients. Table 35-1 (13–23) gives one an idea of the range of observations.

Using a function definition and a prospective questionnaire, Duncan and colleagues (19) studied forty women of childbearing age with refractory epilepsy. They were asked to record their seizures and the first and last days of their menstrual periods. By defining catamenial epilepsy as the occurrence of at least 75% of seizures each month in the 10-day time frame that included the 4 days preceding menstruation and the 6 days after its onset, only 12.5% were identified who fulfilled the criterion. Nevertheless, after the study was completed, 78% of these patients claimed that most of their seizures occurred near the time of and were exacerbated by menstruation.

Thus, one can see that the notion of what represents an association with menses has a large subjective component. If seizures are random events, then by chance alone many will occur during the menstrual period. That is not

**TABLE 35-2**  
*Patterns of Catamenial Epilepsy*

SEIZURE FREQUENCY DURING THE MENSTRUAL CYCLE			
PHASE		OVULATION	ANOVLUTION
Menstrual	–3 to +3	0.59*	0.78
Follicular	+4 to +9	0.41	0.49
Ovulation	+10 to –13	0.50*	0.74
Luteal	–12 to –4	0.40	0.74

*P* < 0.001. Source: Herzog et al, 1997 (25).

to say that the phenomenon does not exist but that its frequency is unclear.

More recent concepts of catamenial epilepsy have been established by prospective observation. Herkes and colleagues (24) followed 12 women for almost four years and found two peaks in seizure occurrence: one just prior to and during menstrual flow, and the other at midcycle. In addition they determined that anovulatory cycles were not associated with an increase in seizures.

Herzog and colleagues (25) have determined that catamenial epilepsies are a heterogenous group. They describe three patterns (Table 35-2). The least frequent are seizures occurring around ovulation. The most common are perimenstrual. There is yet a third group whose cycles tend to be anovulatory, and the exacerbation of seizures occurs throughout the entire luteal phase.

It is interesting to note that the first anticonvulsant drug, potassium bromide, was introduced to treat “hysterical epilepsy” in women. This term was previously used to describe seizures occurring during menstruation. During a presentation by Dr. Sieveking to the Royal Medical and Chirurgical Society of London on May 11, 1857, Sir Charles Locock commented that he had tried bromide for women with (hysterical or catamenial) epilepsy and had successfully prevented seizures in 13 of 14 patents treated (26).

### Hormonal Changes in Catamenial Epilepsy

A number of investigators have noted a decrease in progesterone concentrations, particularly during the luteal phase (27–29). It appears as though estrogens potentiate epileptiform discharges on EEG recording (30). Conversely, intravenous progestins reduce epileptiform spikes in women with epilepsy (WWE) (31). A number of investigators have demonstrated a protective effect of progesterone in animal models of epilepsy (32–34). Allopregnanolone, a metabolite of progesterone, has anti-seizure activity. It acts as a modulator of GABA<sub>A</sub> receptors, thus increasing seizure threshold (35). Cortisol levels are higher and dehydroepiandrosterone sulfate (DHEAS)

levels lower in WWE, and these changes are even more pronounced in women whose seizures are poorly controlled (36).

Attempts to use hormonal supplementation for women with catamenial epilepsy has met with mixed results. The use of medroxyprogesterone resulted in seizure reduction in 7 of 14 treated women; however, 11 of them developed amenorrhea (37). A double-blind placebo-controlled trial of the progestin norethisterone (norethindrone) was not effective (38). The use of intermittent progesterone by Herzog and colleagues (39) resulted in a 68% decline in complex partial seizures. Intravaginal progesterone lozenges (200 mg), 3 times daily, were given from days 23 to 25 in women with perimenstrual catamenial epilepsy and from days 15 to 25 for those with exacerbation in the luteal phase. Seventy-two percent of women had a reduction of seizure frequency (40). Unfortunately the lozenges require the patient to remain supine following insertion, and vaginal spotting, breast tenderness, and depression may be seen with progesterone supplementation. It is felt that natural progesterone may be more effective than the synthetic hormone in reducing seizure frequency, and investigations in this area are under way (35).

### Management of Catamenial Epilepsy

The effective management of catamenial epilepsy requires a precise diagnosis. Antiepileptic drugs (AEDs) are the first line of defense, and their use should be maximized before alternative therapies are considered. A careful compilation of a woman's seizures and menstrual cycle on a calendar will demonstrate an association if it exists. The present author suggests doing so for at least three cycles in order to confirm the diagnosis.

Once a diagnosis of catamenial epilepsy has been established, one needs to demonstrate a progesterone deficiency prior to supplementing a patient. Differentiating inadequate luteal phase and anovulatory cycles is important in planning further investigations. A progesterone level measured during the midluteal phase (day 20–22 of a 28-day cycle) should be higher than 5.0 ng/mL. Failure to attain this level implies inadequate progesterone production and suggests that supplementation with progesterone may be helpful.

Determining ovulation is a bit more tedious. The failure of the basal body temperature to rise by 0.7°F for at least 10 days during the second half of the cycle implies failure of ovulation. If this occurs, further investigation is required to rule out polycystic ovarian disorder with ultrasound. There are now available a number of "ovulation kits" a woman can purchase over the counter that are quite accurate.

Once the preliminary studies are complete, one can categorize the patient into two groups: one with low

progesterone and one with normal progesterone levels. Low-progesterone patients may benefit from progesterone supplementation. A variety of approaches are available. Progesterone creams may be useful, but their concentration and absorption are quite variable, and so is their effectiveness. A natural progesterone creams or lozenge can be prepared by a compounding pharmacist. Herzog (39) recommends 100 to 200 mg three to four times a day. The target progesterone levels are 5–25 ng/mL. Synthetic progestational agents such as medroxyprogesterone may be administered intramuscularly 120–150 mg every 6–12 weeks. Cessation of menses can occur, as can hot flashes, vaginal bleeding, and breast tenderness. Such an approach limits one's ability to adjust the dosage quickly (41, 40). Most authors have not found oral synthetic progesterone effective (42, 43). Many women, unfortunately, suffer from side effects of progesterone, limiting its utility. Sedation, depression, breast tenderness, weight gain, and vaginal spotting have frequently been reported.

For women with normal progesterone levels, one must determine whether they are ovulating or having anovulatory cycles. In ovulatory patients the present author has had some success with the continuous use of oral contraceptives such as Nordette® (levonorgestrel 0.15 mg, ethinyl estradiol 0.03 mg).

In anovulatory patients one must first rule out ovarian dysfunction, particularly polycystic ovaries. If otherwise normal, a short course of clomiphene to restore ovulation may be effective.

Catamenial epilepsy represents a challenge for epileptologists. It is hoped that with more research into the mechanisms by which hormones effect seizures, better therapies may result.

## INFERTILITY IN WWE

### Infertility and Reproductive Abnormalities

Epidemiologic studies have demonstrated that women with epilepsy have only one-fourth to one-third as many children as women in the general population (44, 45). A variety of hypotheses have been developed to explain this phenomenon. A direct effect of seizures or epileptiform discharges on pituitary and hypothalamus could disrupt ovulation. Electroconvulsive therapy increases prolactin concentrations over 5-fold within 15 to 20 minutes, and in premenopausal women there is an acute increase in LH and FSH. Generalized seizures also increase prolactin serum concentrations within 15 to 20 minutes by a factor 3-fold. This fact has been used to assist physicians in differentiating epileptic from nonepileptic seizures (46).

WWE have higher rates of reproductive and endocrine disorders (RED) than expected. In a large clinical center 50% of WWE were found to have menstrual

abnormalities, 20% amenorrheic and 35% anovulatory (47). Herzog and co-workers (48) was among the first to demonstrate RED in women with temporal lobe epilepsy. Women with primary generalized epilepsies also have RED. Five of 20 women studied by Bilo and colleagues (44) had RED: 3 with polycystic ovarian disease and 2 with hypogonadotropic hypogonadism.

AEDs may also interfere with the hypothalamic-pituitary axis. Amenorrhea, oligomenorrhea, and prolonged or irregular cycles have been described in WWE by Isojarvi and colleagues (45). WWE taking valproate were overrepresented; 45% of those on valproate monotherapy and 25% on valproate polytherapy had menstrual disturbances. Polycystic ovaries were found in 4% of valproate-treated women and 80% of women treated with valproate before the age of 29 had polycystic ovaries.

Women with epilepsy have more variation in luteinizing hormone (LH) pulse frequency and lower LH concentrations than controls (46). In addition, women with left-sided ictal epileptiform foci had polycystic ovarian disease, and those with right-sided foci had hypogonadotropic hypogonadism.

Libido is significantly reduced in one-third of men and women with epilepsy (49). Increasing seizure frequency appears to decrease sexual desire, while there is no difference in libido between treated and untreated WWE. Hyposexuality and orgasmic dysfunction has been reported in 8% to 68% of WWE (50). Persons with localization-related epilepsies appear to have higher rates of sexual dysfunction than those with primarily generalized epilepsies. Shukla and colleagues (51) demonstrated 64% of women with partial, compared to 8% of generalized, epilepsies report hyposexuality and sexual dysfunction.

The problem of infertility in WWE is therefore complex. There are multiple factors—seizure type, frequency, and the site of ictal onset, as well as AEDs—that may affect an individual patient. Infertility in a couple deserves a careful evaluation of both partners. For WWE, ultrasonography (to rule out polycystic ovarian disease), serum LH and FSH concentrations, and an evaluation of AED use will help the clinician narrow the focus of treatment. As described previously, there is evidence that valproate may adversely impact the fertility of some women. If the patient's seizures are controlled, discontinuation of valproate is not warranted unless polycystic ovarian disease or hypogonadotropic hypogonadism is found.

### ANTIPILEPTIC DRUGS AND HORMONAL CONTRACEPTIVES

A discussion of pregnancy needs to be preceded by reviewing the problems of contraception. Oral contraceptives have not been associated with exacerbation of epilepsy (43). The effectiveness of hormonal contraceptives

can, however, be reduced by enzyme-inducing AEDs (carbamazepine, phenytoin, phenobarbital, felbamate, topiramate). Hormonal contraceptives come in three formulations: oral (estrogen-progesterone combinations, or progesterone only); subcutaneous (levonorgestrel) or intrauterine (Progestasert®) implants; and injectable (Depo-Provera®). All three forms can be adversely impacted by enzyme-inducing AEDs.

AEDs may lower concentrations of estrogens by 40% to 50%. They also increase sex hormone-binding globulin (SHBG), which increases the binding of progesterone and reducing the unbound fraction. The result is that hormonal contraception is less reliable with enzyme-inducing AEDs.

The low- or mini-dose oral contraceptives are therefore to be used with caution. Because it is the progesterone, not the estrogen, that inhibits ovulation, using higher doses of estrogens alone may not be effective. The more rapid clearance of the oral contraceptive, when used in conjunction with an enzyme-inducing AED, will reduce the likelihood of unwanted side effects from higher-dose tablets.

Failures of implantable hormonal contraceptives have also occurred (52). Midcycle spotting or bleeding is a sign that ovulation is not suppressed. If this occurs, alternative or supplementary methods of contraception are required. Contraceptive failure may not always be predictable, even when midcycle spotting does not occur. Failure of basal body temperature to rise at midcycle can be used to document ovulatory suppression.

Medroxyprogesterone injections should be given every 10 instead of 12 weeks to women on enzyme-inducing AEDs. This shorter cycle is less likely to result in unintended pregnancy (53).

For multiparous women with epilepsy, intrauterine devices may be an excellent birth prevention choice. Alternatively, non-enzyme-inducing AEDs may need to be considered (valproate, lamotrigine, gabapentine, or zonisamide). A recent report suggests that topiramate at doses of less than 200 mg/day lacks enough enzyme induction to affect hormonal contraceptives. Higher doses, however, do reduce ethinyl estradiol concentrations by 18% on 200 mg, 21% with 400 mg, and 30% with 800 mg of topiramate a day (54).

The importance of the potential impact of enzyme-inducing AEDs cannot be underestimated. In a survey of 294 general practices in the General Practice Research Database, 16.7% of women with epilepsy aged 15 to 45 were taking an oral contraceptive. Two hundred were on an enzyme-inducing AED, and 56% on low-estrogen (<50 µg) hormonal contraceptives (55).

There has been at least one circumstance in which oral contraceptives affect AED concentration. Sabers and colleagues (56) have demonstrated a marked reduction in lamotrigine concentrations when oral contraceptives are also taken. The average plasma concentration in

22 women on lamotrigine monotherapy and an oral contraceptive was 13  $\mu\text{mol/L}$ . In a similar group of women on lamotrigine monotherapy with no oral contraceptive use the plasma concentrations averaged 28  $\mu\text{mol/L}$ ; that is, the contraceptive was correlated with a significant reduction in AED concentration of over 50%. It has been suggested that oral contraceptives may induce the metabolism of glucuronidated drugs such as lamotrigine.

## PREGNANCY

The majority of WVE can conceive and bear normal, healthy children. The pregnancies of WVE do present a greater risk for complications of pregnancy; they are more likely to have difficulties during labor, and there is a higher risk of adverse pregnancy outcomes.

### Increased Seizure Frequency

One-quarter to one-third of WVE will have an increase in seizure frequency during pregnancy. This increase is unrelated to seizure type, duration of epilepsy, or seizure frequency in a previous pregnancy. Although most studies have demonstrated that the increase tends to occur toward the end of pregnancy, recent reports find that a substantial number (31%) have their increase in the first trimester (57).

Plasma concentrations of anticonvulsant drugs decline as pregnancy progresses, even in the face of constant and, in some instances, increasing doses (58–61). Plasma concentrations tend to rise postpartum (62, 63). Although reduction of plasma drug concentration is not always accompanied by an increase in seizure frequency, virtually all women with increased seizures in pregnancy have subtherapeutic drug levels (64–67). The decline of anticonvulsant levels during pregnancy is largely a consequence of decreased plasma protein binding (59, 68, 69), reduced concentration of albumin, and increased drug clearance (58, 65, 70, 71). The clearance rates are greatest during the third trimester.

Seizures during pregnancy increase the risk of adverse pregnancy outcomes. Generalized, tonic-clonic seizures increase the risk for hypoxia and acidosis (72) as well as injury from blunt trauma. Canadian researchers have found that maternal seizures during gestation increase the risk of developmental delay (73). Although rare, stillbirths have occurred following a single generalized convulsion (74, 75), or series of seizures (76, 77).

Generalized (though not partial) convulsions occurring during labor can have a profound effect on fetal heart rate (78). The increased rate of neonatal hypoxia and low Apgar scores may be related to such events (69). Partial seizures may also have similar effects, if less often (79).

## COMPLICATIONS IN THE OFFSPRING

Infants of mothers with epilepsy (IME) are at greater risk for a variety of adverse pregnancy outcomes. These include fetal death, congenital malformations, neonatal hemorrhage, low birth weight, developmental delay, feeding difficulties, and childhood epilepsy.

### Infant Mortality

Fetal death (defined as fetal loss after 20 weeks gestation) appears to be as common and perhaps as great a problem as congenital malformations and anomalies. Studies comparing stillbirth rates found higher rates in IME (1.3–14.0%) than in infants of mothers without epilepsy (1.2–7.8%).

Spontaneous abortions, defined as fetal loss prior to 20 weeks of gestation, do appear to occur more commonly in infants of mothers with epilepsy (80). Women with localization-related epilepsies appear to be at greater risk for spontaneous abortions than those with other seizure types (81). Other studies have demonstrated increased rates of neonatal and perinatal death. Perinatal death rates range from 1.3% to 7.8%, compared to 1.0% to 3.9% for controls.

### Malformations

Fetal malformations have been associated with in-utero exposure to AED. Congenital malformations are defined as a physical defect requiring medical or surgical intervention and resulting in a major functional disturbance.

IME, exposed to anticonvulsant drugs in utero, are twice as likely to develop birth defects as infants not exposed to these drugs. Malformation rates in the general population range from 2% to 3%. Reports of malformation rates in various populations of exposed infants range from 1.25% to 12.5% (71, 82–92). These combined estimates yield a risk of malformations in a pregnancy of a WVE of 4% to 6%. Cleft lip, cleft palate, or both, and congenital heart disease account for many of the reported cases. Orofacial clefts are responsible for 30% of the increased risk of malformations in these infants (93–95).

A wide variety of congenital malformations have been reported, and every anticonvulsant drug has been implicated as a cause. No anticonvulsant drug can be considered absolutely safe in pregnancy, yet most of these drugs do not produce any specific pattern of major malformations.

An exception to the latter statement is the association of sodium valproate with neural tube defects (NTD). Methodologic problems make frequency estimates imprecise since most published data are case reports, case series, or very small cohorts from registries that were not designed to evaluate pregnancy outcomes. The prevalence of spina

bifida (SB) with valproate exposure is approximately 1% to 2% (96), and with carbamazepine 0.5% (97, 98). However, a prospective study in the Netherlands found that IME exposed to valproate had a 5.4% prevalence rate of SB. Average daily valproate doses were higher in the IME with SB ( $1,640 \pm 136$  mg/day) than in the unaffected IME ( $941 \pm 48$  mg/day) (99). Another group of investigators has found that valproate doses of 1,000 mg/day or less or plasma concentrations of less than 70  $\mu$ g/mL or less are unlikely to cause malformations (87, 90).

WWE, like all women of childbearing age, should take folate supplementation. The dose recommended by the Centers for Disease Control of 400  $\mu$ g/day may not be high enough for many women who do not metabolize folate effectively. Even with folate supplementation, women taking valproate or carbamazepine should avail themselves of prenatal diagnostic ultrasound to rule out NTD.

### Neonatal Hemorrhage

For many years it has been reported that IME are at greater risk for a unique form of neonatal hemorrhage, first described by Van Creveld (100), who suggested that vitamin K deficiency might be the cause. It was first delineated as a syndrome by Mountain (101), but there have been numerous reports of in-utero AED exposure associated with neonatal hemorrhage (102–109). It was initially associated with exposure to phenobarbital or primidone but has subsequently also been described in children exposed to phenytoin, carbamazepine, diazepam, mephobarbital, amobarbital, and ethosuximide.

This disorder has been differentiated from other hemorrhagic disorders in infancy in that the bleeding occurs internally, during the first 24 hours after birth. Accurate prevalence figures are lacking.

The hemorrhage appears to be a result of a deficiency of vitamin K-dependent clotting factors II, VII, IX, and X. Maternal coagulation parameters are invariably normal. The fetus, however, will demonstrate diminished clotting factors and prolonged prothrombin and partial thromboplastin times. A prothrombin precursor, protein induced by vitamin K absence (PIVKA), has been discovered in the serum of mothers taking anticonvulsants (110). Assays for PIVKA may permit prenatal identification of infants at risk for hemorrhage (111, 112).

The historical demonstration of an increased risk of neonatal hemorrhage, coupled with a demonstrated deficiency of vitamin K and the PIVKA, led clinicians to believe the relative lack of vitamin K and presence of PIVKA was the cause of this particular neonatal hemorrhage. Three studies demonstrated that oral maternal supplementation increased neonatal vitamin K and reduced hemorrhage (113–115).

The practice of maternal vitamin K supplementation has been challenged. Kaaja and colleagues (2002)

found no difference in the rates of neonatal hemorrhage in 667 infants of mothers with epilepsy (0.7%) and 1,334 control infants (0.4%). No mothers in either group were supplemented with vitamin K, but all infants received intramuscular vitamin K at delivery. They felt that on the basis of their experience no evidence of a difference in clinical bleeding could be found; hence, supplementation was not recommended. Hey (117) measured cord blood from 137 infants of mothers with epilepsy taking phenobarbital, phenytoin, or carbamazepine and found that 14 of 105 had prolonged prothrombin times but none had any clinical bleeding. He felt that the lack of clinical bleeding in his series made supplementation with vitamin K inappropriate.

Some background may help clarify the apparent differences in conclusions made by these observers. Vitamin K deficiency is common in a neonates. Maternal vitamin levels are not reflected in cord blood. When Shearer and colleagues (118) measured vitamin K in mothers, they found values ranging from 0.13 to 0.29 ng/mL, but none in the cord blood. Even after IV supplementation raised levels to 45–93 ng/mL, cord values rose only to 0–0.14 ng/mL. This discrepancy between maternal and neonatal vitamin K levels has led researchers to look for PIVKA as a proxy for vitamin K deficiency. PIVKA is formed as a result of incomplete carboxylation of protein precursors of vitamin K and so is present when vitamin K is absent or present in very small concentrations.

The problem is in part that there is a confusion between vitamin K deficiency, laboratory evidence of abnormal coagulation parameters, and clinical bleeding. Vitamin K deficiency is common, the presence of PIVKA less so, but clinical bleeding in neonatal life is rare. Shapiro et al (119) demonstrated that PIVKA presence is fairly uncommon in the general population of newborns (2.9%) and more common in premature infants. We have no good data on prevalence of neonatal hemorrhage in infants of mothers with epilepsy, but we do have reasonably accurate case reports.

We also have reasonable causation. Anticonvulsants can act like warfarin and can inhibit vitamin K transport across the placenta. These effects can be overcome by large concentrations of the vitamin. Despite lower coagulation factor levels, the fetus is generally able to obtain enough maternal vitamin K in utero. After birth it must rely on exogenous sources of vitamin K because the newborn gut is sterile. Routine administration of vitamin K at birth is not adequate to prevent hemorrhage if any two of the coagulation factors fall below 5% of normal values (108). Successful treatment requires fresh frozen plasma intravenously.

It is not so much that Kaaja and Hey are incorrect but that it is extremely difficult to measure the effects of infrequent clinical outcomes. Neonatal hemorrhage is also unlikely to be identified unless it is severe and the child

clinically ill in those first 24 hours. The marked increase in PIVKA in IME suggests that they are at increased risk for hemorrhage, and the increase in developmental delay and need for additional educational assistance seen so often in this population suggests that small degrees of hemorrhage may effect the development of these infants (73, 120, 121).

To make matters more interesting, Howe and colleagues (122) suggest that vitamin K deficiency in a developing embryo results in a failure of vitamin K-dependent carboxylation processes, resulting in an accumulation of compounds that affect embryonic cartilaginous development. Such children are at risk for midface hypoplasia. They base this hypothesis on the clinical similarities between the midface abnormalities seen in warfarin- and phenytoin-exposed children. Howe suggests that, because maternal supplementation with vitamin K reverses the deficiency, perhaps such supplementation should start prior to conception.

Therefore it is clear that one should offer maternal supplementation to pregnant women with epilepsy. The risk of neonatal hemorrhage, while low, clearly exists, as demonstrated by elevated PIVKA levels, particularly with enzyme-inducing AEDs. There is a lack of an effective intervention once a neonate bleeds. There is the additional possibility of small bleeds that, although not clinically detectable at birth, may have long-term effects. There is a hypothesized possibility of an association of decreased carboxylation secondary to decreased vitamin K and the development of some types of malformations. There is a lack of risk with the recommended vitamin K supplementation (10 mg/day). There is also a clear need for better prevalence data on the true risk of clinical bleeding in infants of mothers with epilepsy.

### Low Birth Weight

Low birth weight (less than 2,500 g) and prematurity have been described in infants of mothers with epilepsy. The average rates range from 7% to 10% for low birth weight and 4% to 11% for prematurity (123–127). These studies do not analyze the effect of specific seizure types, frequency, or AED on this aspect of fetal development.

A prospective study that pooled data from three countries (Canada, Japan, and Italy) on 870 infants of mothers with epilepsy found that 7.8% were below the 10th percentile in weight at birth (128). The risk was greater with polytherapy.

Body dimensions of IME have been studied by Wide and colleagues (128). Infants exposed to polytherapy not surprisingly, were shorter and smaller than those exposed to monotherapy. Exposure to monotherapy with carbamazepine revealed a tendency toward small birth weight and head circumference for gestational age, but it was not statistically significant.

### Developmental Delay

With epilepsy having a prevalence of 0.6% to 1%, it is estimated that there are 24,000 deliveries to women with epilepsy in the United States each year. If 75% to 95% of these mothers take AEDs, we can expect 18,000 to 22,800 infants exposed to AEDs in utero per year. It is estimated that half of all AED prescriptions are used for conditions other than epilepsy. Though these patient populations may have fewer women of childbearing years, the number of exposed children is substantial.

Most investigators have focused on congenital malformations as the primary adverse outcome for children of mothers with epilepsy. The rates are approximately double those in the general population. We would argue that the magnitude of developmental delay is similar.

Infants of mothers with epilepsy have been reported to have higher rates of mental retardation than controls. This risk is increased 2- to 7-fold according to various authors (130, 131). None of these early studies controlled for parental intelligence; although differences in IQ scores at age 7 between groups of children exposed (FSIQ = 91.7) or not exposed (FSIQ = 96.8) to phenytoin reached statistical significance, the clinical significance of such difference is unclear (132). In comparing 76 IME with 71 unexposed control children, Wide and colleagues (133) found no difference in scores on developmental tests but did find a tendency for phenytoin-exposed children to have a greater reduction in tests of motor coordination.

Leavitt and colleagues found that IME display lower scores in measures of verbal acquisition at both 2 and 3 years of age. Though there was no difference in physical growth parameters between IME and controls, IME scored significantly lower in the Bailey Scale of Infant Development's mental developmental index (MDI) at 2 and 3 years. They also performed significantly less well on the Bates Bretherton early language inventory ( $P < 0.02$ ) and in the Peabody Picture Vocabulary's scales of verbal reasoning ( $P < 0.001$ ) and composite IQ ( $P < 0.01$ ), and they displayed significantly shorter mean lengths of utterance ( $P < 0.001$ ) (134).

Polytherapy-exposed infants performed significantly less well on neuropsychometric testing than those exposed to monotherapy. Socioeconomic status had the strongest association with poor test scores, but maternal seizures during pregnancy were also a significant risk factor (135).

Leonard et al (74) have in part addressed the question of whether maternal seizures or in utero exposure to AEDs are responsible for the developmental delay seen. A group of children of mothers with epilepsy followed to school age were found to have a rate of intellectual deficiency of 8.6%. The Wechsler Intelligence Scale for Children revealed significantly lower scores for children

exposed to seizures during gestation (100.3) than for children whose mothers' seizures were controlled (104.1) or controls (112.9). All AEDs are clearly not created equal, and Koch and coworkers (136) have demonstrated that primidone, particularly when used in polytherapy, is associated with lower Wechsler score of intelligence.

Both maternal epilepsy and AED exposure in utero appear to affect development of offspring in a study by Koch et al. (136). Severity of outcomes increased from control, to maternal epilepsy with no AED exposure, to maternal epilepsy AED-exposed children.

An intensive retrospective analysis of 100 consecutive pregnancies seen at a tertiary epilepsy center found that 3.9% of the children were premature, 1.1% had congenital malformations, and 6.2% developmental delay, all despite the fact that 59% of the mothers were seizure free and 98% took folic acid during their pregnancy (137).

Another retrospective study demonstrated that 16% of 594 children of mothers with epilepsy exposed to AED in utero, compared to 11% of 176 children with no AED exposure, required additional educational assistance in school. This was felt to be a reasonable marker for developmental delay. In addition, differences between AEDs were found, with 30% of children exposed to valproate monotherapy, 24% of those exposed to valproate polytherapy, but only 3.2% of children exposed to carbamazepine monotherapy requiring additional educational assistance (120). Monotherapy with other AEDs had rates of 6%, and polytherapy without valproate 16%.

The same cohort of children was studied to determine their IQ scores. Of 251 children tested, the mean IQ for valproate-exposed children was 82, compared to 95 for carbamazepine-exposed and 92 for AED-unexposed children (138).

The authors followed up their initial cohort, eventually studying 249 children of mothers with epilepsy from ages 6 to 16. The numbers in monotherapy were modest: 41 exposed to valproate, 52 to carbamazepine, 21 to phenytoin. Forty-nine were exposed to polytherapy, and there were 80 unexposed children. The investigators used regression analysis to demonstrate that both exposure to valproate and frequent generalized tonic-clonic seizures in pregnancy increased the risk of low verbal IQ scores (139).

Three other studies have found increased rates of developmental delay in children exposed to carbamazepine, ranging from 8% to 20% (140–142). One of these studies used only a single standard deviation from the mean to qualify as developmentally delayed and thus overstates the risk (141).

A retrospective study of mothers with epilepsy delivering in Scotland between 1976 and 2000 used the nonexposed siblings as controls. Developmental delay was demonstrated in 19% of 293 AED-exposed children, compared to just 3% of their nonexposed siblings. The rate of delay in valproate-exposed children was particu-

larly high: 37%. Congenital malformations were found in 14% of exposed and 5% of nonexposed siblings. The investigators also state that facial dysmorphism was present in 52% of exposed and 25% of nonexposed siblings, which makes one wonder about the nature of this population (143).

Reinisch and colleagues conducted double-blind studies examining intelligence in adult men with in-utero exposure to phenobarbital (144). Their mothers by and large had not had epilepsy but took the drug for other indications. Unexposed members of the same birth cohort, matched on a large number of variables, were used as controls. The first study used the Wechsler Adult Intelligence Scale (Danish version); the second, the Danish Military Draft Board Intelligence Test. The authors concluded:

- Men exposed prenatally to phenobarbital had significantly lower verbal intelligence scores (approximately 0.5 SD or 7 IQ points) than predicted.
- Lower socioeconomic status and being the offspring of an “unwanted” pregnancy increased the magnitude of the negative effects to a mean of 20 IQ points less than controls.
- Exposure during the last trimester was the most detrimental.

In one of the best-designed prospective studies of outcomes of mothers with epilepsy, Gaily and colleagues (145) measured the intelligence of 182 children of mothers with epilepsy and 141 controls. The investigators performing the testing were blinded as to the child's exposure. Table 35-3 is from their report.

This study suggests that children exposed to valproate and polytherapy are at higher risk for developmental

delay than children exposed to carbamazepine or unexposed children.

### MANAGEMENT OF THE PREGNANT WOMAN WITH EPILEPSY

Those who care for WWE face a dilemma. Seizures need to be prevented; but fetal exposure to anticonvulsant drugs needs to be minimized. Just as important is the fact that maternal seizures increase the risk of injury, miscarriage, epilepsy in the offspring, and developmental delay.

The major organ systems have formed by late in the first trimester. The posterior neuropore closes by day 27, and the palate by the 47th day of gestation. By the time most women realize they are pregnant, malformations already may have developed. WWE of childbearing age need to be informed of the risks of pregnancy associated with anticonvulsant use, prior to conception if at all possible. They also need to know that seizures can be harmful to mother and fetus and that risks can be reduced with proper care.

Many people appear to be unaware that even healthy parents have a 2–3% risk of having a child with a malformation. Given the current state of the art, the best we can do is practice risk reduction. In general, risks can be minimized by the preconceptual use of multivitamins with folate, and using AED in monotherapy with the lowest effective dose and preventing maternal seizures. Monitoring free drug levels, both prior to and during pregnancy, will permit accurate assessment of concentrations in a situation where plasma protein binding is in flux. Dose adjustment, however, should be made on a clinical basis. Plasma anticonvulsant drug concentrations will fall in pregnant women, but only a quarter to one-third will have an increase in seizures. Keep dosage as low as possible during conception and organogenesis. Raising the dosage during the third trimester to reduce the risk of seizures during labor may be advisable.

Supplementation with at least 0.4 mg/day of folate is recommended by the Centers for Disease Control for all women of childbearing age, whether or not they have epilepsy.

Vitamin K<sub>1</sub>, 10 mg/day, should be initiated late in the third trimester to prevent neonatal hemorrhage.

Breastfeeding is generally safe in term infants, as they have been exposed to the AED for 9 months and have induced their hepatic microsomal enzyme systems. However, breastfeeding should be done cautiously by women receiving phenobarbital or primidone because of the risk of infant sedation.

Pregnant women taking valproate should avail themselves of prenatal diagnostic techniques: ultrasound and alpha fetoprotein measurement. Ultrasonography has become much more accurate and, in experienced hands, can identify the vast majority of structural defects. Current prenatal testing recommendations are as follows:

1. Anatomic ultrasound at 11–13 weeks (this can identify the most severe defects, such as anencephaly)
2. Maternal serum alpha fetoprotein
3. Repeat anatomic ultrasound at 16 weeks (this can identify abnormalities such as orofacial clefts, heart defects, and caudal neural tube defects)

When a WWE initially presents to her neurologist, pregnant, her gestational age (GA) needs to be established with reasonable accuracy. One cannot rely on last menstrual period (LMP) alone; an early ultrasound should be obtained to date the pregnancy. Once GA is established, a calendar can be planned with dates for monthly AED level checks, prenatal testing, and initiating Vitamin K supplementation determined ahead of time.

### CONCLUSION

Young women with epilepsy face multiple issues in addition to the seizures themselves. Epilepsy may affect their libido, ability to reproduce, and effectiveness of hormonal contraceptives. A subset of patients will find that there is a direct effect of their menstrual cycles on their epilepsy. Pregnancy is generally a positive experience, with the vast majority of patients having healthy children. These issues present challenges but can be managed, permitting most young women to enter adulthood with the same expectations as their peers without seizures.

## Teratogenic Effects of Antiepileptic Medications

*Torbjörn Tomson  
Dina Battino*

**N**ot so long ago, people with epilepsy were often denied the fundamental right to form a family, prevented by prejudiced legislation and public attitudes. This, fortunately, is no longer the case, thanks to changes in social attitudes as well as improvements in diagnosis and therapy of epilepsy. Today, more and more women with epilepsy become pregnant and have children, and it has been estimated that 0.3–0.4% of all children today are born to mothers with epilepsy (1, 2). The vast majority of these women will have uneventful pregnancies and give birth to perfectly normal children. However, there are specific risks associated pregnancies in women with epilepsy, and the medical management during gestation is a matter of special concern. The maternal and fetal risks associated with uncontrolled seizures generally necessitate continued drug treatment during pregnancy, but these seizure-related risks need to be weighed against the potential adverse outcomes in the offspring due to maternal use of antiepileptic drugs (AEDs). This chapter is dedicated to the latter part in this equation: the teratogenic effects of AEDs. The reader is referred to Chapter 35 for a discussion on how such effects are put into context for a rational management of women with epilepsy of childbearing potential.

The question whether AEDs may be harmful during pregnancy was first raised in a systematic way by Janz

and Fuchs in 1964 (3), and the first report of adverse fetal effects of AEDs was published a few years later (4). Since then, all of the major old-generation AEDs, such as phenobarbital, phenytoin, valproate, and carbamazepine, have been shown to be teratogenic. Less is known about the teratogenic potential of the newer-generation AEDs that have been introduced to the market during the last 15 years. Adverse outcomes reported in infants exposed to AEDs in utero include major congenital malformations, minor anomalies and dysmorphism, growth retardation, and impaired cognitive development. Although the pathogenesis is likely to be multifactorial, including genetic predisposition, socio-economic circumstances, seizures, and epilepsy, the available data strongly suggest that AEDs are the major cause for the increased risk of these adverse outcomes.

Other types of adverse pregnancy outcome (e.g., miscarriage, stillbirth, perinatal death, and neonatal haemorrhage) have also been associated with epilepsy. These aspects on pregnancy risks are, however, beyond the scope of this chapter and are dealt with elsewhere.

### METHODOLOGICAL ASPECTS

Different methods have been used to assess the fetal risks associated with exposure to AEDs. The most simple is

based on spontaneous reporting of pregnancy outcome to manufacturers of AEDs. Such reports may be useful to obtain signals, but they suffer from selective reporting of adverse outcomes and lack of information on the denominator and thus cannot be used for a proper risk assessment. Case-control designs have frequently been used, in which cases with, for example, specific malformations are compared to controls with respect to exposure to AEDs in utero. This design may be useful for uncommon outcomes, but it is associated with the risk of recall bias. Other studies utilize existing registries of, for example, drug prescriptions and cross-link those with registries of birth defects. Such registries can have the advantage of being population-based and sometimes even nationwide. They may thus be representative, but they generally lack information on other factors that could contribute to the outcome. Cohort studies are another common approach. The cohorts are generally identified through the epilepsy diagnosis of the mother. They are often hospital-based and can come from single hospitals, epilepsy centers, or from several collaborating clinics. Such studies can be retrospective or prospective. Retrospective identification of the cohort is associated with the risk of selection bias, whereas prospective studies ideally identify and enroll women with epilepsy before any information on pregnancy outcome is known, thus avoiding the risk of selection bias. A special type of cohort studies, AED and pregnancy registries, has been established lately. These registries are prospective observational studies enrolling women with epilepsy early in pregnancy, collecting information on drug exposure and other potential risk factors before outcome of the pregnancy is known. Women are followed throughout pregnancy, and the outcome, in terms of occurrence of birth defects in the offspring, is recorded. The advantage of such studies is that they may collect a high number of pregnancies, the type of drug exposure is recorded in an unbiased way without prior knowledge of teratogenic outcome, and detailed data on other relevant patient characteristics could be obtained. The internal validity of the risk assessments is therefore likely to be high whereas, the possibility to generalize from the results will depend on how pregnancies were enrolled.

However, even results of properly designed, prospective studies of teratogenic effects of AEDs may be difficult to interpret. The assessment of teratogenic effects is based on observational studies, and the women have not been randomized to different types of treatment. The selection of a particular drug or drug combination, the dosage, and the dosage schedule depend on individual environmental and genetic factors such as type of epilepsy and seizures, seizure frequency, comorbidity, and socioeconomic circumstances. These are factors that could be linked to the risk of malformations. An association between exposure to a certain AED and occurrence of adverse pregnancy

outcome is thus not evidence of a causal relationship. The impact of possible confounders, such as type of epilepsy, seizure frequency, family history of birth defects, and exposure to additional risk factors, needs to be assessed, which requires large sample sizes. It is thus important to pay attention to methodological issues such as statistical power, reliability of collected data, and attempts to control for appropriate confounding factors in the analyses, rather than to just compare rates of adverse pregnancy outcome in published studies.

## MAJOR CONGENITAL MALFORMATIONS

### Epilepsy and Other Potential Confounding Factors

A large number of studies have confirmed an increased frequency of major malformations in offspring of women treated with antiepileptic drugs. The incidence of major congenital malformations has ranged from 4% to 10%, corresponding to a 2- to 4-fold increase from that expected in the general population (Table 36-1) (2, 3, 5–68).

Differences in treatment strategy, study populations, controls, and criteria for malformations can account for the variation in outcome. Whether this increase is caused by the AED treatment or at least to some extent is linked to the underlying epilepsy disorder has been a matter of debate (2). Some studies of malformations in offspring of women with epilepsy have included also those who were untreated during pregnancy. The results of 66 cohort studies that include pregnancies of women with treated as well as untreated epilepsy are summarized in Table 36-1. The table includes retrospective studies that are population-based (5–16) and thus probably representative; retrospective hospital-based (2, 3, 55–68); prospective (22–54) and mixed prospective/retrospective (17–21) cohort studies. Irrespective of study methodology, these studies have consistently reported lower malformation rates among children of untreated mothers with epilepsy (on average 3.0%) than among those who have been exposed to AEDs in utero (6.6%). These observations have been confirmed in a recent meta-analysis of the evidence of epilepsy *per se* as a teratogenic risk (69). For this meta-analysis, ten studies reporting rates of congenital malformations in offspring of untreated women with epilepsy ( $n = 400$ ) were selected. The malformation rate in this group was not higher than among offspring of nonepileptic healthy controls ( $n = 2492$ ), odds ratio (OR) 1.92; 95% confidence interval (CI) 0.92–4.00. The OR was 0.99 (CI 0.49–2.01) after removal of some small studies likely to be affected by publication bias. The trend toward an increased risk of malformations among children of untreated women with epilepsy thus disappeared. The authors themselves, however, warned about the potential

**TABLE 36-1**  
**Malformation Rates in Offspring of Mothers with Epilepsy With or Without AED Treatment During Pregnancy**

	OFFSPRING OF TREATED MOTHERS WITH EPILEPSY			OFFSPRING OF UNTREATED MOTHERS WITH EPILEPSY

bias derived by incomplete reporting of the exact nature of the epilepsy and lack of information on clinical indications for treatment discontinuation (69). Although, obviously, untreated women with epilepsy are different in many respects from those who are under treatment during pregnancy, the available evidence strongly suggests that treatment is the major cause of increased risk of adverse pregnancy outcomes. Epilepsy-related factors nevertheless cannot be disregarded.

### Overall Malformation Rates

Since the 1960s, numerous studies have confirmed malformation rates of 4–10% in offspring of women treated for epilepsy during pregnancy. This is 2–3 times higher than expected in the general population and, as discussed above, also higher than among children of untreated mothers with epilepsy (Table 36-1). With slight variation, this 2–3-fold increase has been a consistent finding despite differences in populations, study design, and outcome criteria. A major limitation in most studies to date is the small sample size. Large cohorts are obviously needed to draw conclusions when the prevalence of birth defects (fortunately) is no more than 4–10%. In fact, surprisingly few studies comprise more than 500 pregnancies, which still, for the purpose of assessing the risk of birth defects, is a fairly small sample. The results of the existing 12 studies, each including at least 500 pregnancies, are summarized in Table 36-2 (7, 9, 16, 20, 31, 34, 42, 70–74). The overall malformation rate was 5.2% among the altogether 12,603 exposed to AEDs in these studies. For comparison, birth defects were reported in 2.7% of

1,820 epilepsy pregnancies without AED exposure from the same studies and 2.7% among offspring of nonepileptic controls (Table 36-2).

### Patterns of Malformations

The type of malformations and their frequency in pregnancies of women treated with AEDs, based on studies reporting specific birth defects, is presented in Figure 36-1 (2, 8, 15, 24, 25, 39, 44, 51, 52, 58). The pattern is mostly the same as seen in the general population. Congenital heart defects have been the most common, followed by facial clefts, hypospadias, limb reduction deficits, and neural tube defects. It appears that the pattern of malformations may vary with the type of AED, as indicated in Figure 36-2 (2, 6, 8, 11, 15, 17, 19, 23–25, 27, 28, 31, 32, 39, 40, 45, 51–55, 57, 58, 71–89). Whereas cardiac defects dominate among children exposed to barbiturates and, to a lesser extent, those exposed to phenytoin and carbamazepine, neural tube defects and hypospadias are more common among offspring of mothers who took valproic acid during pregnancy. The risk of neural tube defects in association with valproic acid has been estimated to be 1–2% of exposed infants (13, 90). Valproic acid has also been associated with skeletal abnormalities including radial aplasia (91, 92). An increased risk of neural tube defects of 0.5–1% has also been reported after carbamazepine exposure (93, 94). Changes in prescription patterns and drug selection for women of childbearing age with epilepsy can thus be expected to result in a shift in the pattern of malformations in the offspring of women with epilepsy.

FIGURE 36-1

Rates of different types of malformations in offspring of mothers with epilepsy and under treatment with antiepileptic drugs (“AED exposed”); without treatment during pregnancy (“not on AEDs”); and of nonepileptic control women (“controls”). The figure is based on data from 10 studies, each providing information on specific malformations for these three categories (2, 8, 15, 24, 25, 39, 44, 51, 52, 58).

### Risk Factors

Some of the studies summarized in Table 36-2 have applied multivariate analysis in an attempt to elucidate the role of the drug treatment and of other risk factors for the adverse pregnancy outcome. Nakane and coworkers thus identified familial epilepsy, previous miscarriage, partial epilepsy, and exposure to phenobarbital or primidone as risk factors for birth defects (20). Pooling data from five different prospective cohort studies, Samrén and coworkers observed an increased risk with carbamazepine and valproic acid monotherapy compared with unexposed control pregnancies, with phenobarbital in combination with caffeine, as well as with high doses of valproic acid (72). High doses of valproic acid, exposure to monotherapy with valproic acid or primidone, and malformations in siblings were associated with increased risks in the pooled prospective studies from Italy, Japan, and Canada (34). A prospective study from a single center in Finland reported monotherapy with carbamazepine, oxcarbazepine, or valproic acid, low maternal serum folate concentrations and low maternal education as significant risk factors (31). In a population-based nationwide Swedish

register study, polytherapy was associated with higher risks than monotherapy, and specifically monotherapy with valproic acid, as compared with carbamazepine (74). A Finnish nationwide study based on drug prescription registries identified polytherapy and monotherapy with valproic acid as associated with an increased risk for birth defects (75).

It is clear from these studies and from Table 36-2 that polytherapy with antiepileptic drugs is associated with a higher malformation rate, 7.6%, than monotherapy, 4.5%. This has been a consistent finding throughout most studies (95). Although, due to confounding factors, alternative interpretations are possible, this observation is supportive evidence for the contribution of the drug treatment to the increased risk of birth defects in children of women with epilepsy. A decreased malformation rate, in parallel with a shift in the therapeutic strategy from polytherapy to monotherapy during pregnancy, is an additional observation supporting a causal relationship between polytherapy and adverse pregnancy outcome (96). Some specific combinations of AEDs have

FIGURE 36-2

Rates of different types of malformations in offspring of mothers with epilepsy and under treatment with AEDs, by type of AED used in monotherapy. The graph is based on studies reporting specific malformations by type of monotherapy (2, 6, 8, 11, 15, 17, 19, 23–25, 27, 28, 31, 32, 39, 40, 45, 51–55, 57, 58, 71–89).

been associated with particularly high malformation rates. Among the old-generation anticonvulsants, this has been suggested for the combination of carbamazepine, phenobarbital, and valproic acid (41). More recent studies have also indicated a considerable risk in association with valproic acid in combination with lamotrigine. The International Lamotrigine Pregnancy Registry reported major malformations in 12.5% of children exposed to this specific combination, compared with 2.9% in lamotrigine monotherapy (76). Morrow and collaborators (42) found birth defects among 9.6% of the offspring of mothers treated with valproic acid and lamotrigine combined, versus 3.2% associated with lamotrigine monotherapy and 6.2% in monotherapy with valproic acid. Although interesting, these observations need to be interpreted with great caution, since factors such as differences in drug dosages and severity of the maternal seizure disorder may contribute and were not controlled for.

A dose-effect relationship would be expected with a pharmacologic effect such as the teratogenicity of AEDs. So far this has been shown most convincingly and consistently for valproic acid. Dosages above 800–1,000 mg/day have thus been associated with significantly higher risks for malformations than lower dosages (7, 19, 21, 34, 72, 73, 91, 97). A recent publication from the UK Epilepsy and Pregnancy Register reported a positive dose response

for major congenital malformations for lamotrigine as well; doses above 200 mg/day were associated with higher risks (42). This latter observation has, however, not yet been confirmed in other studies.

Genetic factors are obviously also of major importance to explain individual susceptibility to developmental toxicity of AEDs. For example, in some women treated with valproic acid during pregnancy, the history of a pregnancy resulting in a neural tube defect may predict a high risk of further birth defects in subsequent pregnancies (98, 99).

### Comparative Teratogenic Potential

Although all major old-generation AEDs have been shown to be teratogenic, the available information on the newer-generation antiepileptics, and, in particular, on potential differences between drugs in teratogenic potential, is more limited and less conclusive. Even in most of the largest cohort studies to date, the numbers on each individual drug as monotherapy have been too small to allow useful comparisons. Unfortunately, pooling of the data is hampered by differences between studies with respect to study populations, methodology, and outcome criteria. An internal comparison between different monotherapies within each of some major, fairly recent studies

FIGURE 36-3

Odds ratios and 95% confidence intervals for major malformations associated with prenatal exposure to different AEDs in monotherapy relative to the risk associated with exposure to carbamazepine monotherapy (risk = 1) in the same study. The figure presents data from seven recent comparatively large-scale studies.

is presented in Figure 36-3. Although most studies fail to reveal significant differences between drugs, there is a trend for valproic acid to be associated with a higher risk of malformations than carbamazepine. In three of the included studies, this difference is significant (7, 42, 74). In this, as well as many other attempts for comparison between drugs, no distinction is made between different types of major malformations. However, the concept “major malformations” can comprise a wide range of birth defects, some incapacitating, others of very limited consequences. A comparison between AEDs with respect to risks for specific malformations is thus desirable, not least since the types of birth defects are likely to differ (Figure 36-2). It is thus evident that larger studies are needed to obtain more information, in particular, on the new generation AEDs but also to permit multivariate analysis in which potentially contributing factors are included in addition to drug exposure. This will be necessary to advance from observed associations between exposure to a particular drug and pregnancy outcome to an assessment of causal relationships.

For these reasons, prospective AED and pregnancy registries have been set up in the late 1990s. The largest are The North American Antiepileptic Drugs and

Pregnancy Registry (NAREP), the United Kingdom Epilepsy and Pregnancy Register, and EURAP, an international registry enrolling pregnancies from 40 countries in Europe, Australia, Asia, Oceania, and South America. Using somewhat different methodologies, each of these registries had enrolled 5,000–8,000 pregnancies by early 2006, and two of them, NAREP and the UK registry, had published the first results on teratogenic outcome. NAREP discloses malformation rates associated with specific treatments as they are found to differ significantly from the background rate. Increased malformation rates in comparison with the general population have so far been identified with phenobarbital (relative risk [RR] 4.2; 95% CI: 1.5–9.4) (100) and valproic acid (RR 7.3; 4.4–12.2) (89). An internal comparison between different specific monotherapies from the same registry has not yet been presented, but the risk with phenobarbital was not significantly increased when compared to three other unspecified monotherapies taken together from the same registry (RR 2.0; 0.9–4.5), whereas the malformation rate with valproic acid was four times higher compared with all other monotherapies taken together (RR 4.0; 2.1–7.4). As yet, NAREP has not revealed any information in relation to the new-generation antiepileptic drugs. The UK

register recently published its first report based on 3,607 cases (42). Using multivariate analysis, monotherapy with valproic acid was found to be associated with a higher risk than carbamazepine. The rate of major congenital malformations for pregnancies exposed to valproate monotherapy was 6.2% (95% CI: 4.6–8.2%), compared with 2.2% (1.4–3.4%) for carbamazepine. The malformation rate with lamotrigine monotherapy was 3.2% (2.1–4.9%) based on 647 pregnancies. Interestingly, the malformation rate in offspring of 227 untreated women with epilepsy was 3.5% (1.8–6.8%), very similar to the 3.7% (3.0–4.5%) among the monotherapy exposures in general ( $n = 2,468$ ). The number of pregnancies with other new-generation antiepileptic drugs was too small for a meaningful assessment of the risks: 31 pregnancies on gabapentin (1 malformation), 28 on topiramate (2 malformations), and 22 on levetiracetam (no malformation).

With the exception of lamotrigine, the information on human teratogenicity of the new generation AEDs is thus particularly scarce and mainly based on case series or uncontrolled studies. In one case series from Argentina, all of 35 pregnancies with oxcarbazepine monotherapy, enrolled at any stage prior to birth, had normal outcome, while one of 20 pregnancies with oxcarbazepine as combination therapy resulted in a cardiac malformation (83). In the drug-prescription registry-based study from Finland, Artama et al (7) reported one urogenital malformation among 99 pregnancies with oxcarbazepine monotherapy. Of 16 retrospectively or prospectively enrolled women taking gabapentin as monotherapy from onset of pregnancy, one resulted in an infant born with one kidney (65). These studies are clearly far too small to allow any firm conclusions as to the teratogenic potential of oxcarbazepine or gabapentin.

Considerably more information is available on lamotrigine through the International Lamotrigine Pregnancy Registry (76), the manufacturer's voluntary reporting system. By March 2004, this registry had included 12 major malformations among 414 prospective lamotrigine monotherapy exposures, 2.9% (1.6–5.1%). Although systematically collected information on the outcome of pregnancies with a specific AED is of importance, the value is limited by possible selection bias and in particular of lack of comparator.

#### **MINOR ANOMALIES AND FETAL ANTIEPILEPTIC DRUG SYNDROMES**

Minor anomalies are structural variations that are visible at birth but without medical, surgical or cosmetic importance. Such anomalies frequently occur in normal unexposed infants, but combinations of several anomalies are less common and can form a pattern, or a dysmorphic

syndrome, that may indicate a more severe underlying dysfunction. Minor anomalies and dysmorphic syndromes have been reported to occur more frequently in infants of mothers treated for epilepsy during pregnancy. Facial features such as orbital hypertelorism, depressed nasal bridge, low-set ears, and micrognathia, along with distal digital hypoplasia, sometimes in combination with growth retardation and developmental delay, were first reported in association with exposure to phenytoin (101). Subsequently, however, similar patterns have been associated with exposure to carbamazepine (82). Valproate exposure has been claimed to cause a somewhat different dysmorphic syndrome, characterized by thin arched eyebrows with medial deficiency, broad nasal bridge, short anteverted nose, and a smooth long philtrum with thin upper lip (102). Such features have been suggested to be associated with, and indicative of, impaired cognitive development (57, 102). However, there is a considerable overlap in the various dysmorphisms, and their drug specificity has been questioned. A more general term, fetal or prenatal antiepileptic drug syndrome, has therefore been suggested (103). In addition, the pathogenesis is still somewhat controversial, and Gaily et al (104) attributed most of the minor anomalies to genetic factors rather than drug exposure. However, one study examined physical features of infants to women with a history of epilepsy but not taking antiepileptic drugs in pregnancy (105). No infants were found to have features of the fetal antiepileptic drug syndrome, suggesting that such features indeed are related to drug exposure. It should, however, be underlined that minor anomalies are much more difficult to assess objectively than major malformations and that the incidence of minor anomalies in exposed infants varies markedly between studies.

#### **GROWTH RETARDATION**

Several studies have reported that exposure to antiepileptic drugs is associated with an impaired intrauterine growth. Reduced birth weight, body length, and head circumference in the offspring of women treated with phenytoin was reported already in the 1970s (106). Reductions in body dimensions, in particular head circumference, have been confirmed in several subsequent studies of larger cohorts (51, 71, 80, 107–111). Most studies report a more pronounced effect in infants exposed to polytherapy (107–111). However, the association with specific antiepileptic drugs in monotherapy varies. Some investigators found an association to phenobarbital and primidone, whereas others report carbamazepine to be most strongly associated to a small head circumference. Wide et al (110) studied body dimensions in infants exposed to antiepileptic drugs in utero in a Swedish population over a period of 25 years, comparing data to the general population.

There was a clear trend toward normalization of the head circumference over the time period, in parallel with a shift from polytherapy toward monotherapy, despite an increasing use of carbamazepine. Other more recent studies also suggest that with present treatment strategies, where monotherapy prevails, microcephaly may no longer be more common among infants of mothers treated for epilepsy during pregnancy (44, 112), although smaller than expected head circumference is reported in some very recent studies (53). The reason for the particular interest in small head circumference, or microcephaly, is that it might signal a functional deficit. However, one study failed to find an association between a small head circumference in children exposed to antiepileptic drugs and cognitive functioning in adulthood (111).

### EFFECTS ON POSTNATAL COGNITIVE DEVELOPMENT

A particularly important additional issue is whether exposure to antiepileptic drugs in utero could adversely affect the development of the child after birth. Long-term follow-up studies of large cohorts of exposed individuals are necessary in order to address this issue. Such studies are difficult to perform and also complicated to interpret because of several confounding factors and since environmental factors become more important with increasing age of the child. Only few studies have been published, all with fairly small cohorts, and the results are conflicting. In a prospective population-based study, Gaily et al (113) found no influence on global IQ, and the observed cognitive dysfunction in children exposed to AEDs, mainly phenytoin and carbamazepine, was attributed to maternal seizures and educational level of the parents rather than to the treatment. Wide et al (114), in another population-based prospective study, found no difference in psychomotor development in children exposed to carbamazepine compared with control children of healthy mothers but a trend for phenytoin-exposed children to do slightly worse in some tests of motor coordination. Scolnik et al (115) reported lower global IQ in children exposed to phenytoin but not in those exposed to carbamazepine. Normal intellectual capacity was found in most of 170 individuals exposed to phenobarbital and phenytoin, but 12% of the exposed subjects, in contrast to 1% of unexposed controls, had persistent learning problems (111).

A recent Cochrane Review concluded that the majority of studies on developmental effects of antiepileptic drugs are of limited quality and that there is little evidence about which drugs carry more risks than others to the development of children exposed (116). Some studies in the last years, however, have suggested that exposure to valproic acid might be associated with a particular risk of adverse developmental effects (117, 118). A retrospective

survey from the UK found additional educational needs to be considerably more common among children that had been exposed to valproic acid monotherapy than in those exposed to carbamazepine or in unexposed children (117). A more thorough investigation of partly the same cohort of children revealed significantly lower verbal IQ in children exposed to valproic acid monotherapy (mean 83.6, 95% CI 78.2–89.0,  $n = 41$ ) than in unexposed children (90.9, 87.2–94.6,  $n = 80$ ) and children exposed to carbamazepine (94.1, 89.6–98.5,  $n = 52$ ) or phenytoin (98.5, 90.6–106.4,  $n = 21$ ) (118, 120). Multiple regression analysis identified exposure to valproic acid, five or more tonic-clonic seizures in pregnancy, and low maternal IQ to be associated with lower verbal IQ also after adjustment for confounding factors. Valproic acid doses above 800 mg/day were associated with lower verbal IQ than lower doses. Although efforts were made to control for confounding factors, these results should be interpreted with caution given the small numbers, the retrospective nature of the study, and the fact that only 40% of eligible mothers agreed to participate, which might introduce selection bias. The important signals from this report need to be confirmed or refuted in well-designed prospective studies. A recent small population-based prospective study from Finland found a lower verbal IQ in children exposed in utero to valproic acid and to polytherapy in general compared with nonexposed children or children exposed to carbamazepine (120). However, this study could not demonstrate an independent effect of valproic acid because of small numbers (13 children exposed to valproic acid monotherapy) and because the results were confounded by low maternal education and polytherapy. Another small, prospective, population-based Finnish study signals a similar trend for worse outcome in children exposed to valproic acid but also points to the problem of confounding factors, because the mothers using valproic acid in pregnancy scored lower on IQ than other groups (121).

Although conclusive evidence is lacking, the signals concerning potential adverse effects of, particularly, valproic acid on postnatal development need to be considered seriously and be explored in adequately sized prospective studies. However, considering the methodological shortcomings and inconsistencies in the outcome of the available sparse studies of developmental effects of antiepileptic drugs in general, it must be concluded that to date we lack definitive evidence that long-term adverse outcomes in children of epileptic mothers can be ascribed to AEDs.

### MECHANISMS OF TERATOGENICITY

A better understanding of the mechanisms behind the developmental toxicity of AEDs is essential for a more rational approach to the treatment of women with

epilepsy of childbearing potential. Such advancements might facilitate future development of new, nonteratogenic AEDs, give clues to other protective measures, or help identify individual patients at particular risk. Clinical and experimental data demonstrate an individual variability in the susceptibility to developmental toxicity of AEDs and also in the expression of teratogenic outcome, suggesting a genetic influence (122–128).

All the structural defects, and the retardation of growth and development observed in children exposed to AEDs in utero, have been reproduced after drug exposure to nonepileptic animals of various species (129) confirming the causal role of the antiepileptic drugs in the pathogenesis. As in humans, the pattern of malformations is to some extent different for different AEDs also in animal models, which suggests that multiple mechanisms are involved.

One of the earlier hypotheses suggests that the developmental toxicity of AEDs is related to their interference with folate metabolism. Foliates are cofactors involved in the biosynthesis of nucleic acids and in the remethylation of homocysteine to methionine. In experimental studies, a folate-deficient diet has resulted in an increased incidence of malformations in the offspring. Many AEDs, including phenobarbital, phenytoin, primidone, and carbamazepine, are known to reduce folate levels. Some clinical studies (130, 131) have reported an association between low maternal serum folate levels and adverse pregnancy outcome, including malformations. The latter observation, however, is controversial, because other studies have failed to confirm this finding. Pretreatment with folinic acid reduced valproic acid–induced malformations in mouse models (132). In humans, extra periconceptional supplementation with folate has been demonstrated to reduce the risk of neural tube defects (133) and, at higher doses, also the risk of recurrence in high-risk groups (134). These clinical studies, however, did not study prevention of neural tube defects in women with epilepsy or on AEDs.

Although phenytoin and phenobarbital are the antiepileptic drugs that decrease folate levels the most, these drugs have been linked to neural tube defects to a lesser extent than valproic acid and carbamazepine, which have less apparent effects on folate levels. Nevertheless, the available experimental data suggest that interference with embryonic folate metabolism may be involved in some aspects of, in particular, valproic acid teratogenesis, and genetic factors related to folate metabolism may explain differences in susceptibility observed between different strains (132).

The 5,10-methylene tetrahydrofolate reductase (MTHFR) gene has been suggested as one candidate to explain genetic susceptibility to folic acid–sensitive malformations (126). MTHFR is involved in the biotransformation of folate and is highly polymorphic. Some

mutations have been associated with increased risks of malformations such as neural tube defects, cleft palate, and congenital heart disease, which are often seen in relation to exposure to AEDs.

A prevailing hypothesis for many years has been that AEDs are metabolized to toxic reactive intermediates, which are responsible for the teratogenic effects (41, 128, 129, 135–143). The toxic intermediate could be an arene oxide produced during oxidation of phenytoin, carbamazepine, or phenobarbital. In general, epoxides are highly reactive and may bind to fetal macromolecules in the embryo and thus cause teratogenic effects. Such epoxides are metabolized by the enzyme epoxide hydrolase and may accumulate and react if the rate of formation of the epoxide exceeds the elimination by epoxide hydrolase. The balance between enzyme activities catalyzing the formation and the elimination of reactive epoxides may be genetically determined and also affected by interactions with AEDs. Interestingly, some specific combinations of AEDs, notably carbamazepine, phenobarbital, and valproic acid, have been associated with a particularly high rate of malformations (41). Hypothetically, carbamazepine's and phenobarbital's inducing effects on the formation of epoxides and valproic acid's inhibitory effect on epoxide hydrolase could explain this particularly high risk. However, some of the most potent teratogenic AEDs, such as trimethadione, lack the premises to form epoxides. Potentiation of phenytoin teratogenesis by drugs inhibiting the cytochrome (CYP) P450-mediated metabolism (144) also argues against a role for the CYP system in teratogenic bioactivation of phenytoin.

Another postulated bioactivating pathway is co-oxidation of AEDs to free radical intermediates. After interaction with molecular oxygen, these compounds can liberate reactive oxygen species (ROS), which may cause oxidative stress, thereby initiating teratogenicity. Deficiency of free radical–scavenging enzymes, responsible for eliminating ROS, has been associated with malformations in the offspring of epileptic mothers exposed to anticonvulsants (145–147).

A more recent hypothesis suggests that many AEDs, such as phenytoin, trimethadione, carbamazepine, and phenobarbital, exert their developmental adverse effects by induction of episodes of embryonic cardiac arrhythmia during restricted periods of embryonic development (148). According to this hypothesis, the embryonic hypoxia is followed by reoxygenation and generation of ROS, which will cause tissue damage. Typical developmental toxicity effects, such as orofacial clefts, heart defects, distal digital defects, and growth retardation, can be induced in experimental studies by hypoxia, and AEDs have been shown to affect the embryonic heart in animal models (149, 150). These embryonic cardiac effects have been linked to the drugs' ability to block the rapid component of the delayed rectifying  $K^+$  ion current,  $I_{Kr}$  (150). The noninnervated

embryonic heart is dependent on  $I_{Kr}$  for regulation of the cardiac rhythm during a restricted period and is very susceptible to arrhythmogenic action by  $I_{Kr}$  blockers. Drugs, anticonvulsant or otherwise, with such  $I_{Kr}$ -blocking properties have been associated with congenital malformations experimentally and in the clinic (150).

Recently, mechanisms involving homeobox (HOX) genes have also been proposed to explain teratogenicity of antiepileptic drugs (132). Retinoic acid signaling regulates the transcription of such genes, essential for early brain development, and may respond to teratogens (151). Such mechanisms include alteration of the expression of retinoic acid receptor (152) and valproic acid inhibition of histone deacetylases (153–157), considered as key elements in the regulation of many genes playing important roles in cell proliferation and differentiation (159–161).

The mechanisms behind developmental toxicity of AEDs are thus presently far from completely understood and are likely to be multiple and also differ between drugs.

## CONCLUSIONS

More than 40 years of research on risks associated with the treatment of epilepsy during pregnancy have taught us that use of AEDs is associated with a two- to three-fold increase in the risk of major malformations in the offspring. This risk is mainly due to the treatment with AEDs, of which all of the old generation have been shown to be teratogenic. Although the pattern of birth defects apparently varies between drugs, there is limited conclusive evidence on differences in overall teratogenic potential. The available data, however, suggest that the risk of birth defects is higher in association with valproic acid than with carbamazepine. The data in this respect on the new-generation antiepileptic drugs is scarce, with lamotrigine as the only exception. The limited available comparative data indicate that the malformation rates associated with lamotrigine are similar to those seen with carbamazepine. No conclusions can as yet be drawn concerning the teratogenic potential of other new-generation anticonvulsants.

The possibility that exposure to AEDs in utero may adversely affect the intellectual development in the offspring remains a major concern. All available studies have methodological limitations, but there are signals indicating worse outcome, in terms of lower verbal IQ, in children exposed to high doses ( $> 800$  mg/day) of valproic acid. There are no consistent findings indicating similar adverse effects of other old-generation AEDs, whereas we lack data on this issue concerning the new-generation drugs.

Polytherapy with AEDs is associated with higher malformation rates, and probably also increased risks of growth retardation, than is monotherapy. A dose response relationship with respect to birth defects as well as postnatal cognitive development has been demonstrated for valproic acid, and it is reasonable to assume such a relationship also for other drugs. How the teratogenic effects of low dosages of valproic acid ( $< 800$ – $1,000$  mg/day) compare with other antiepileptic drugs remains to be elucidated.

It should be kept in mind that none of these conclusions are based on randomized clinical trials but rather on observational studies. Such studies can demonstrate associations, but because of the existence of confounding factors it is more difficult to provide evidence for a causal relationship. Epilepsy may, in fact, confound the effects of treatment on child well-being because of environmental factors or the effects of its associated genetic background. Even relatively well-established relationships between adverse pregnancy outcomes and drug factors cannot be assumed as if treatment itself were the causal agent, unless they are confirmed by control or matching for confounding variables. Specific clinical indications may confound the assessment of the teratogenicity of individual drugs. Failing to control for appropriate confounders may explain why, apart from the unquestionable teratogenicity of antiepileptic drugs as a group, we lack so much of the needed conclusive data on the developmental toxicity associated with specific AEDs. The ongoing pregnancy registries, which are beginning to accumulate considerable numbers of pregnancies, will allow for more appropriate analyses, including important confounding factors, and thus, in the near future, hopefully provide more conclusive evidence on the differential teratogenic effects of AEDs.

## Pharmacokinetic Principles of Antiepileptic Therapy in Children

*W. Edwin Dodson*

**P**harmacokinetics is the study of changes in drug concentrations in the body of a patient over time for the purpose of understanding the time course of drug actions (1–4). The unique pharmacokinetics of each drug result from both drug-related and patient-related factors (Table 37-1). Patient-related factors are responsible for most of the variability in the relationship between drug doses and drug concentrations. However, differences in drug formulation can substantially influence the time course of drug action.

### FUNDAMENTAL PHARMACOKINETIC CONCEPTS

Pharmacokinetic principles are based on mathematical models. When a model is selected for a specific pharmacokinetic analysis, assumptions must be made to simplify complex physiologic processes. Models are named according to the number of compartments that are considered and according to the type of kinetics that are applied: linear versus nonlinear. A one-compartment model assumes that the body is a single compartment, whereas a two-compartment model assumes that the body has two compartments: a central (vascular) compartment and a peripheral (tissue) compartment.

Although two-compartment models are preferable to one-compartment models, one-compartment models have been used most frequently in pharmacokinetic studies in patients (5).

The physical properties of a drug, such as its size, ionization constant ( $pK_a$ ), lipid and aqueous solubility, and dissolution rate, determine how the drug interacts with physiologic processes in the body. These interactions result in kinetic patterns of absorption, distribution, metabolism (biotransformation), and excretion that are characteristic for each drug, and they determine the concentration of drug that is available to interact at target sites of drug action in the nervous system (6). Most antiepileptic drugs (AEDs) enter the nervous system by passive processes and interact with brain constituents at relatively low-affinity binding sites. However, recent work on multidrug resistance factors suggests that in some cases these factors may actively promote drug efflux out of epileptogenic tissue. At this point, however, the role of these factors in patients' responses to AEDs has not been delineated (7–9).

Drug elimination comprises all of the mechanisms that act to remove a drug from the body. The elimination of AEDs is largely due to hepatic biotransformation and renal excretion. Although hepatic biotransformation can produce active metabolites, which contribute to drug action, most of the time drug metabolites do not have

TABLE 37-1

## Factors That Determine the Pharmacokinetics of a Drug

DRUG-RELATED FACTORS	PATIENT-RELATED FACTORS
Size	Pharmacogenetics
Ionization constant	Age
Lipid solubility	Nutritional state
Aqueous solubility	Disease
Formulation	Comedication
	Route of administration

antiepileptic activity. The total elimination rate is the sum of the elimination rates through all the mechanisms according to the equation

$$k_{el} = k_{renal} + k_{hepatic} + k_{other} \quad (1)$$

### Linear Elimination Kinetic

The mechanisms that eliminate most AEDs are capable of removing much more drug than is usually present. In these circumstances, the elimination mechanisms dispose of a constant fractional amount of the drug per unit of time, independent of the drug concentration. These processes have *linear, first-order* kinetics. When the elimination of a drug has linear kinetics, the relationship between the drug dose and the drug concentration in serum is linear and intuitively predictable.

### Intravenous Dose and Drug Half-Life

It is easiest to evaluate drug elimination after intravenous (IV) dosing, when drug absorption is not an issue (2, 3). Immediately after an intravenous bolus dose, drug concentrations are very high in serum. At first, the drug level declines very rapidly, but later the rate of decline becomes slower (2, 3, 10) (Figure 37-1). The initial rapid decline (alpha phase) is due to the distribution of drug from the central, vascular compartment into peripheral tissue compartments. Later, the slower decline (beta phase) is determined predominantly by drug elimination. For a two-compartment model, the concentration-time curve after an intravenous dose is described by the equation:

$$C_t = A \cdot e^{-\alpha t} + B \cdot e^{-\beta t} \quad (2)$$

The terminal portion of the concentration-time curve is used to determine the *half-life* ( $t_{1/2}$ ) and the *elimination rate constant* ( $k_{el}$ ). The half-life is defined as the time that is required for the amount of drug in the body to decline by a factor of one-half. In a single-compartment model,

FIGURE 37-1

Semilogarithmic plot of intravenous concentration versus time curve based on a two-compartment model. Curve A is obtained by subtracting the extrapolated terminal portions of curve A + B. For more on exponential curve peeling see Riggs (10) and Greenblatt and Koch-Weser (2, 3).

the elimination rate constant is the slope of the declining curve, but in two-compartment models the elimination rate constant is more complex because of the simultaneous effects of drug distribution into the peripheral compartment. In a two-compartment model, the beta half-life is calculated from the terminal portion of the concentration-time curve. The half-life is related to the elimination rate constant according to the following relationship:

$$k_{el} \cdot t_{1/2} = \ln 2$$

The elimination rate constant has the dimensions of a fraction per unit time; the half-life has the dimension of time.

The half-life is important for several reasons. First, it indicates how much time is required for drug levels to stabilize after the dose is changed (Figure 37-2). Whenever the

FIGURE 37-2

Effect of varying half-life on time to reach steady state and on the eventual concentration at steady state. The half-lives of curves A, B, and C are 4, 8, and 12 hours, respectively. Increasing the half-life delays steady state and results in higher concentrations.

dose is changed, five half-lives must elapse before a steady state is reached and drug levels stabilize. Second, under steady-state conditions, the drug concentration is directly proportional to the half-life. If the half-life changes, the steady-state concentration changes. Third, the half-life ordinarily dictates how frequently doses should be administered. In most cases doses should be administered at intervals equal to or less than the half-life to limit the fluctuation in drug levels between doses. For drugs that have a short half-life, retarding absorption by the administration of slow-release formulations also limits the fluctuation in drug levels between doses. This is discussed further with other aspects of drug absorption.

### Volume of Distribution

The apparent volume of distribution ( $V_d$ ) is the volume that the drug seems to occupy in the body. It is an imaginary volume that does not necessarily conform to anatomical compartments. The volume of distribution is the quotient of the amount of drug in the body divided by the drug concentration. Although the volume of distribution can be calculated several ways, the simplest approach is to extrapolate the terminal phase of the intravenous concentration-time curve back to time zero and use that concentration (the theoretical concentration at time zero) to calculate  $V_d$  (2, 3). For example, if there is 100 mg of drug in the body and the drug level at time zero is 10 mg/L, the volume of distribution is 10 L. The relative volume of distribution is the  $V_d$  divided by the patient's weight. If the patient with a  $V_d$  of 10 L weighed 20 kg, the patient's relative volume of distribution ( $V_{d_{rel}}$ ) would be 0.5 L/kg.

The volume of distribution has two important applications. First, it can be used to calculate loading doses. For example, a 100-mg loading dose will result in a level of 20 mg/L in a 10-kg child who has a  $V_{d_{rel}}$  of 0.5 L/kg (dose =  $V_{d_{rel}} \cdot \text{concentration} \cdot \text{weight}$ ). Second, it is an important component of clearance.

### Clearance

Clearance ( $Cl$ ) summarizes all of the factors that act to reduce the drug concentration. Clearance is defined as the volume of distribution that is completely rid of drug per unit time; it has the dimensions of volume per time. Operationally, clearance is the product of the volume of distribution times the elimination rate constant:  $Cl = V_d \cdot k_{el}$ . Clearance is inversely related to half-life; a long half-life causes a low clearance ( $Cl = V_d(\ln 2/t_{1/2})$ ). The relative clearance ( $Cl_{rel}$ ) is the clearance divided by weight.

The relative clearance is the best parameter for comparing drug dose requirements among different groups of patients. It also provides the most reliable basis for determining initial doses, because clearance accommodates for

variations in body water and fat content. However, clearance is rarely used to calculate doses, because the values are harder to remember than doses based on weight.

### Steady State

A steady state exists when the rate of drug input equals the rate of drug output. When drug administration is initiated at a constant dose, the drug progressively accumulates in the body until the clearance equals the dosing rate. Five half-lives are required to nearly reach a steady state.

Although the administration of large loading doses causes drug levels to increase rapidly, loading doses do not necessarily produce the same concentration that will occur at steady state (Figure 37-3). Steady-state concentrations depend on the maintenance doses, which are administered repeatedly. Thus, a steady state should never be assumed until a constant dose has been administered for a sufficient amount of time.

Under steady-state conditions, the average drug level in serum ( $C_m^{ss}$ ) is constant and is equal to the dosing rate divided by the clearance:

$$C_m^{ss} = \frac{D}{\tau} \div Cl \quad (3)$$

After clearance is replaced with its components,  $V_d$  and  $t_{1/2}$ , it can be seen that the average drug level at steady state is directly related to the dosing rate and to the half-life and inversely related to the volume of distribution:

$$C_m^{ss} = \frac{D}{\tau} \cdot \frac{t_{1/2}}{V_d \cdot \ln 2} \quad (4)$$

FIGURE 37-3

Effect of varying half-life after loading doses. Note that, independent of the administration of a loading dose, 5 half-lives are required for levels to stabilize. The half-life for curve D is 8 hrs, and that for curve E is 20 hrs.

## Drug Absorption

Drug absorption is described both in terms of the *absorption rate* and in terms of the extent of absorption, *bioavailability*. The rate of absorption determines when the peak concentration occurs. Slowing the absorption rate postpones and reduces the peak concentration, attenuating the range of the fluctuations in drug concentrations between doses. Bioavailability ( $F$ ) is a measure of the extent of drug absorption that is independent of time. Bioavailability is the quotient of the areas under the concentration-time curves for a nonintravenous dose divided by that for an IV dose. For example, the area under the curve after an oral dose divided by the area after the same dose IV is the bioavailability of the orally administered formulation. Bioavailability is expressed as either a fraction or a percent.

Several factors reduce the bioavailability of orally administered drugs. Failure to absorb the drug due to gastrointestinal (GI) disease, lack of tablet dissolution, and drug insolubility are obvious reasons. Bioavailability is also reduced when drugs are metabolized in the GI tract or in the liver before they reach the systemic circulation (so-called *first-pass metabolism*).

*Bioequivalence* is a measure that compares both the extent of absorption and the rate of absorption, but it does not require an IV dose. The bioequivalence of various oral formulations of a drug is determined before generic formulations are authorized for marketing. Operationally, the absorption rate or time to peak concentration and the areas under the concentration-time curves for different formulations are compared. According to the Food and Drug Administration's definition of bioequivalence, different oral formulations of the same drug are bioequivalent if they differ by no more than 20%. However, these tolerance limits may be too broad for some patients with difficult-to-control epilepsy.

The route of drug administration influences the absorption rate and thereby affects the onset of drug action. IV administration increases drug levels fastest, making the drug available for entry into tissues nearly instantaneously. However, drugs that have limited aqueous solubility, such as carbamazepine, cannot be formulated for IV administration. Intramuscular (IM) administration of some drugs results in slower absorption than oral administration. In the case of lipophilic drugs with relatively poor aqueous solubility, such as phenytoin, absorption after IM administration is slow and erratic, although eventually complete. Among the AEDs, phenobarbital is best documented to be rapidly and reliably absorbed after IM administration. Phenobarbital concentrations usually reach peak values in less than 90 minutes in children (11).

Oral administration of AEDs is the cornerstone of the treatment of epilepsy. By and large, drugs with erratic

or low bioavailability are not suitable for chronic anti-epileptic therapy. Drugs with rapid absorption and short half-lives are manufactured in delayed or slowly absorbed formulations to help sustain drug levels between doses. Examples include valproate (Depakote® Sprinkles) and carbamazepine (Tegretol XR® and Carbatrol). As a general principle, slowly absorbed formulations are preferable for chronic antiepileptic therapy because they attenuate the fluctuations in drug concentrations between doses. The differing absorption rates of different drug formulations have important implications for generic substitution.

Rectal administration of AEDs is important for patients who take drugs that lack parenteral formulations and for emergency situations when drugs cannot be administered either intravenously or orally. Rectal administration is also helpful when epileptic patients undergo surgery and cannot take their medications by mouth (12). Lipophilic antiepileptic drugs such as diazepam are rapidly and well absorbed after rectal administration (13). Typically, drugs in solution are absorbed faster and more reliably than drugs in suppositories. Rectal administration also reduces first-pass hepatic metabolism.

Many AEDs have been given rectally, including diazepam, clonazepam, lorazepam, nitrazepam, ethosuximide, valproic acid, carbamazepine, paraldehyde, and phenytoin (12, 14, 15). Diazepam has an extensive history of rectal administration and has been used to interrupt serial seizures and status epilepticus and to prevent febrile seizures. After rectal administration of diazepam solutions in doses of 0.5 to 1 mg/kg, peak concentrations usually occur in less than 10 minutes (16, 17). The absorption kinetics of carbamazepine in suspension are similar after oral and rectal administration, but rectal administration of carbamazepine suspension produces a strong defecatory urge (18).

## Drug Elimination

The route of drug elimination plays an important role in determining a drug's pharmacokinetics as well as its vulnerability to pharmacokinetic interactions. Drugs that are eliminated mainly by hepatic metabolism to inactive metabolites include carbamazepine, ethosuximide, phenytoin, lamotrigine, tiagabine, zonisamide, and various benzodiazepines. Several antiepileptic drugs are eliminated both by hepatic biotransformation and by renal excretion of unmetabolized drug. These include phenobarbital, felbamate, oxcarbazepine, topiramate, and valproate. All of these are subject to substantial hepatic metabolism, and altered hepatic processing affects serum levels substantially. Gabapentin, pregabalin, and vigabatrin are eliminated exclusively by urinary excretion and are impervious to the effects of other drugs on hepatic drug-metabolizing capacity.

**TABLE 37-2**  
*Effects of Antiepileptic Drugs on Hepatic Drug-Metabolizing Enzyme Systems*

POTENT INDUCERS	FEEBLE OR NO EFFECT	GENERAL INHIBITOR
Carbamazepine, phenobarbital, phenytoin, primidone	Ethosuximide, gabapentin, lamotrigine, levetiracetam, pregabalin, oxcarbazepine, tiagabine, topiramate, vigabatrin, zonisamide	Felbamate, valproate

The vulnerability of an AED to pharmacokinetic interactions depends how it is eliminated, the extent of induction and/or inhibition of the elimination processes, and the resultant capacity of the drug eliminating mechanisms relative to the amount of drug available for elimination (19). AEDs developed prior to 1990 are more vulnerable to interactions than drugs developed subsequently. Factors that influence the propensity for a drug to participate in pharmacokinetic interactions include which enzymes catalyze its metabolism, which enzymes it induces, and which other drugs are shared as substrates by the enzyme. Drugs that are substrates for the same cytochrome P450 isozyme tend to interact, usually inhibiting each other's elimination. The effects of various antiepileptics on hepatic drug-metabolizing capacity are summarized in Table 37-2.

Drugs that depend on hepatic biotransformation for elimination are prone to pharmacokinetic interactions. Among those drugs that are likely to participate in pharmacokinetic interactions, phenytoin is arguably the most sensitive, because the phenytoin-eliminating enzymes are partially saturated at usual doses and concentrations.

In the past two decades, knowledge about the hepatic cytochrome P450 complex expanded considerably. The components of the P450 system that are most relevant to the metabolism of antiepileptic drugs are CYP2C9, CYP2C19, and CYP3A4. Information about these enzymes and their substrates are summarized in Table 37-3 (20–23). Potent inducers of hepatic drug metabolism increase the activity of these three enzymes plus the activities of epoxide hydrolase and uridine diphosphate glucuronosyl transferase. Uridine diphosphate glucuronosyl transferase catalyzes the formation of glucuronide conjugates and plays a major role in the elimination of lamotrigine, oxcarbazepine, and valproate and a minor role for phenobarbital (19).

Valproic acid has a distinctive pattern of elimination. It is metabolized via beta oxidation like a fatty acid, and it is conjugated with glucuronic acid to facilitate urinary excretion. Underdevelopment of the glucuronidation pathway is the major reason that infants and young children eliminate valproate slowly.

Note that valproate and felbamate are inhibitors of hepatic drug metabolism. This has important implications

for pediatric polytherapy of epilepsy. The addition of valproate substantially increases lamotrigine and phenobarbital concentrations. Furthermore, in children valproate approximately doubles the  $t_{1/2}$  of tiagabine, with the average  $t_{1/2}$  increasing from 3.2 to 5.7 hours (24). Likewise, add-on felbamate increases the concentrations of phenobarbital, phenytoin, and valproate. When either valproate or felbamate is added to phenobarbital, phenytoin, or valproate, the doses of the preexistent drug should be reduced (25).

### Nonlinear Kinetics

Although the pharmacokinetics of most AEDs are linear or first order, notable exceptions exist. When the mechanisms that result in drug elimination have linear kinetics, a constant fraction of the drug is absorbed, transported, and eliminated per unit of time. The elimination mechanisms for phenytoin, however, have a low capacity relative to the phenytoin concentrations that are usually present, so these mechanisms are partially *saturated* (26, 27). This partial saturation results in *nonlinear* elimination kinetics and causes the relationship between the phenytoin dose and concentration to be intuitively unpredictable. (Figure 37-4). Other antiepileptic drug pharmacokinetics that are nonlinear include gabapentin absorption and valproate binding. Gabapentin transport into the brain is likely to be saturable as well. Nonlinear kinetic patterns are also designated as saturable, concentration-dependent, or dose-dependent.

When drugs are eliminated by processes with nonlinear kinetics, the fractional rate of drug disposition varies with the dose or drug concentration. As drug concentrations increase, the elimination mechanism becomes progressively saturated. This prolongs the half-life that is measured because a smaller percentage of the drug is eliminated per unit of time as the concentration increases. In this situation, the half-life that is observed should be designated as  $t_{50\%}$  to differentiate it from the usual  $t_{1/2}$ .

When drug elimination has nonlinear kinetics, the apparent half-life ( $t_{50\%}$ ) changes with the dose or concentration. The apparent half-life is directly proportional to the initial concentration that is present when

**TABLE 37-3**  
*The Three Major Components of Cytochrome P450 Drug-Metabolizing Enzymes That Participate in the Elimination of AEDs, with Their Substrates*

CYP2C9	CYP2C19	CYP3A4
<b>MAJOR AED SUBSTRATES</b>

<b>OTHER SUBSTRATES</b>		
Azapropazone Cotrimoxazole Disulfiram Metronidazole Phenylbutazone Propoxyphene Stiripental	Cimetidine Diazepam Felbamate Fluoxetine Imipramine Omeprazole <b>Inhibited by</b>	<b>Inhibited by</b> Cyclosporine A Fluvoxamine Fluoxetine Grapefruit juice Ketoconazole Macrolide antibiotics (erythromycin and triolean domycin)
Sulfaphenazole <b>Inhibited by</b> Amiodarone Fluconazole Fluoxetine Fluvoxamine Miconazole Valproic acid	Felbamate Fluvoxamine Omeprazole Topiramate	Miconazole Nefazadone Sertraline

These relationships provide the basis for numerous pharmacokinetic interactions (20–23). Shared substrates that produce inhibition of drug metabolism consistently are noted. Other shared substrates that have only mild or inconsistent inhibitory effects are listed as other substrates.

the half-life is measured (28). Thus, increasing doses leads to disproportionate increases in drug concentrations. When drug doses are reduced, the opposite occurs; small reductions in dose can cause precipitous declines in drug concentration. Finally, the amount of drug in the body and the concentration of the drug in blood progressively increase if the dosing rate exceeds the capacity for drug elimination.

$$t_{50\%} = \frac{0.5C_i}{V_{\max}} + \frac{K_M(\ln 2)}{V_{\max}} \quad (5)$$

The Michaelis-Menten equations that describe the kinetics of enzyme reactions can be applied to describe nonlinear drug elimination (6). The way this is done is to measure drug levels at two or more steady states and then solve for the nonlinear kinetic parameters: the maximal reaction velocity ( $V_{\max}$ ) and the drug concentration ( $K_M$ )

**FIGURE 37-4**

Dose versus concentration curves for drugs with linear (A) versus nonlinear (B) elimination kinetics.

at which the reaction rate is one-half of the maximal elimination velocity. The critical assumption that underlies these calculations is that at steady state the rate of drug dosing equals the rate of drug elimination. Hence, at steady state the dosing rate equals the reaction velocity. Similarly, the drug concentration is analogous to a substrate concentration. In order to calculate the nonlinear kinetic parameters  $V_{\max}$  and  $K_M$ , it is necessary to know two or more pairs of doses and concentrations. Several methods have been described for calculating  $V_{\max}$  and  $K_M$  (29). These are discussed further in Chapter 49.

$$V = \frac{V_{\max} \times C}{K_M + C} \quad (6)$$

For drugs with nonlinear kinetics, varying the absorption rate changes the apparent bioavailability. Martis and Levy described the effects of bioavailability ( $F$ ), absorption rate ( $k_a$ ),  $K_M$ , and  $V_{\max}$  on the rate of phenytoin concentration change (30).

$$\frac{dC}{dt} = K_a F C_0 \exp(-k_a t) - K_1 C - \frac{V_{\max} C}{K_M + C} \quad (7)$$

In this equation  $k_a$  is the first-order absorption rate;  $C_0$  is the drug concentration at zero time;  $C$  is the concentration at any time  $t$ ;  $F$  is the bioavailability or fraction of the drug that is ultimately absorbed; and  $K_1$  is the overall apparent first-order rate constant.

Equation 7 has been used to evaluate the relationship between absorption rate and apparent bioavailability (31). Based on computer simulations using average values of  $K_M$  and  $V_{\max}$ , the apparent bioavailability declines by 25% as the half time for absorption increases from 0 (intravenous administration) to 1.2 hours.

### Drug Protein Binding

Ordinarily, only total (bound plus unbound) AED levels are measured. However, it is the unbound drug concentration in plasma that is in equilibrium with the unbound drug concentration in the brain. The unbound level correlates better with drug action than does the total level (32, 33). Nevertheless, measuring the total drug concentration in plasma usually works well because total concentrations correlate highly with the unbound concentrations in most patients.

Various AEDs differ in the extent to which they are bound to serum constituents (34–37) (Table 37-4). The binding of ethosuximide, phenobarbital, and primidone is so low as to be clinically irrelevant. However, the binding of carbamazepine, phenytoin, and valproate is sufficiently high that significant changes in unbound drug levels occur when binding is altered (34). Conditions that cause hypoalbuminemia, such as renal disease and

**TABLE 37-4**  
*Binding of Antiepileptic Drugs to Serum Proteins*

DRUG	PERCENT UNBOUND
Carbamazepine	27–40
Clonazepam	15
Diazepam	2

Pregabalin	100
Primidone	70–100
Tiagabine	4
Topiramate	83–91
Valproic acid (high)	10–30
Valproic acid (low)	8–10
Vigabatrin	100
Zonisamide	50–60

From (27, 36, 37).

hepatic disease and certain drug interactions with acidic compounds such as fatty acids, aspirin, and valproate increase the unbound drug concentrations of phenytoin and carbamazepine. Newborns also have reduced drug protein binding because of hypoalbuminemia (35). When drug protein binding is disturbed, therapeutic ranges based on total levels of phenytoin and of carbamazepine no longer apply.

High concentrations of valproate exceed the binding capacity of plasma constituents, resulting in a nonlinear relationship between the total valproate level and the unbound valproate level (38). When total valproate levels are high, the unbound valproate level increases disproportionately.

### MULTIDRUG RESISTANCE

In recent years the possibility has been considered that multidrug resistance factors might play a role in patients' responses to AEDs, especially among patients whose seizures are refractory to AEDs (39, 40). Multidrug resistance factors were first identified in cancer and consist of molecules that transport drugs out of target tissues using energy-dependent processes. By promoting local efflux of drug, they can reduce the drug concentration at target sites of drug action.

Molecules that mediate multidrug resistance include P-glycoprotein (P-gp) and multidrug resistance-associated protein (MDR). Most AEDs are substrates for P-gp (41, 42).

Drug resistance factors have been investigated in several animal models of epilepsy (43–46). Experimentally induced seizures and brain malformations, but not AEDs (47), induce multidrug resistance factors in animals (48, 49). Drug resistance factors have also been identified in human epileptogenic tissue that has been removed surgically, including temporal lobe tissue, cortical dysplasias, and tubers from patients with tuberous sclerosis (9, 50, 51). Multidrug resistance proteins are localized to endothelial cells in brain capillaries and associated astroglia. Whereas in animals multidrug resistance proteins have been shown to reduce the concentrations of AEDs locally, microdialysis of extracellular fluid obtained intraoperatively during epilepsy surgery has shown mixed results (52).

Since multidrug resistance factors are localized to abnormal tissues, they appear to have little or no effect on systemic pharmacokinetics of a drug in the body, such as the volume of distribution, clearance, or half-life. Rather, they may affect the local distribution of the drug within the target epileptogenic areas. If a role in refractory human epilepsy is confirmed for multidrug resistance factors, drugs to inhibit their effects are likely to become topics of great interest.

The expression of multidrug resistance factors is under genetic control. Studies of gene markers linked to polymorphisms of multidrug resistance among patients with refractory epilepsy have generated conflicting results, with some investigators finding genetic markers and others not (8, 53). However, these studies are in the early stages, and they are methodologically complex. Thus, conflicting results at this point do not negate the possibility that genetic influences are important in selected patient populations and might someday help refine treatment (54).

### ADJUSTING DOSES AND THE APPLICATION OF DRUG LEVEL MEASUREMENTS

The practical worth of any drug is specified by its *therapeutic index*. The therapeutic index is defined as the dose that produces toxicity divided by the dose that produces the desired therapeutic effect. Most AEDs have a narrow therapeutic index compared to antibiotic drugs such as penicillin. Furthermore, there is great variability in the therapeutic index of AEDs among individual patients because different types of seizures have variable susceptibility to drugs and because patients vary in their sensitivity to dose-related neurotoxicity.

### GENERIC AED FORMULATIONS

Generic substitution of AEDs has the potential to reduce the cost of antiepileptic therapy. Generic formulations are produced by several manufacturers and are distributed by more numerous intermediate suppliers. These factors facilitate low cost through open market competition, but they make it difficult to track down the origin of a specific generic formulation.

Despite the need for low-cost antiepileptic therapy, the overriding goal of treating epilepsy with AEDs is to administer enough drug to prevent seizures while maintaining drug levels below those that cause dose-related neurotoxicity in the individual patient. In practical terms, fluctuations in AED levels between doses need to be minimized.

As discussed previously, the magnitude of expected fluctuation in levels between doses depends on two factors: first, the drug's elimination rate or half-life, and second, the absorption rate. Because generic AEDs tend to have faster absorption rates than brand-name products, generic substitution sometimes increases the fluctuations in levels between doses, increasing the risk of both subtherapeutic and toxic levels (Figure 37-5). For certain drugs such as phenobarbital, which has a very long half-life, this is a trivial issue and generic substitution is indicated.

The problems that result from switching among formulations with different absorption rates are most severe for phenytoin, because it has nonlinear kinetics. Different phenytoin formulations with different absorption rates have different apparent bioavailabilities. When a formulation is absorbed rapidly, it produces a higher peak concentration, which in turn causes the apparent half-life to be prolonged. As a result, steady-state concentrations can change significantly when phenytoin formulations are switched. For this reason, generic substitution of phenytoin should be prohibited.

FIGURE 37-5

Effect of rapid versus slow absorption rate on fluctuations in drug levels between doses. Reproduced with permission from (34).

For carbamazepine, which has an intermediate to short half-life (18 hours or less, depending on the patient), the issue of generic substitution is complex. Changing the formulation can modify the extent of fluctuation between doses but does not alter the average concentration at steady state unless there is also a problem with tablet dissolution and bioavailability. For some patients who require only low carbamazepine levels to hold seizures in abeyance, generic substitution works well. For others who have a narrow therapeutic index for carbamazepine, generic substitution is highly problematic. These types of patients are at risk to experience both toxicity and recurrent seizures if they are switched to a formulation that is more rapidly absorbed. Thus the patient and the treating physician should be consulted when generic carbamazepine substitution is contemplated.

### EFFECT OF AGE ON AED PHARMACOKINETICS

Age and prior drug exposure affect the child's capacity for drug elimination (55–59). For the purposes of categorizing the effects of age on drug elimination, the following groups have been used: newborns (birth to 6 weeks), infants (6 weeks to 12 months), children (1 year to 11 years), adolescents (11 years to 15 years), adults (> 15 years). These age groupings are somewhat arbitrary, because the pharmacokinetic changes that occur are gradual and because of individual variation in growth and maturation. Adolescence is heralded in individual patients by the transition from Tanner stage 1 to stage 2. For each age group, the children who have prior drug exposure need to be considered separately from those who lack prior drug treatment.

Newborns exposed to drugs in utero usually eliminate antiepileptic drugs at rates that are comparable to those in adults (27). The older AEDs that induce drug-metabolizing pathways in adults also do so prenatally and postnatally. Drugs, such as valproate, that inhibit hepatic drug elimination do so dramatically in newborns and young children. Valproate has extremely long half-lives in newborns and infants who have not been exposed to other inducing agents. Furthermore, most newborns who have seizures do not have prior, intrauterine drug exposure. Consequently, they tend to eliminate AEDs far more slowly than any other age group. Furthermore, the most common cause of neonatal seizures—perinatal asphyxia—may be associated with abnormal hepatic and renal function, which also retard drug elimination. Although the neonatal pharmacokinetic effects of intrauterine exposure to drugs that have become available in the 1990s, such as oxcarbazepine, lamotrigine, gabapentin and topiramate, have not been quantified, they are unlikely to have much impact because they do not induce hepatic drug metabolism.

The postnatal maturation of renal function and hepatic systems for drug conjugation are well recognized. Renal function increases rapidly in the first day after birth and reaches nearly adult capacity by age 3 weeks. Immature hepatic phase II conjugation of nonpolar compounds to water-soluble glucuronides is one reason for slow elimination of antiepileptics, especially valproate, by newborns and infants (60). The maturation of hepatic phase I biotransformation of drugs via the cytochrome P450 system of enzymes varies according to the particular enzymatic pathway.

Different components of the cytochrome P450 system mature at different times during gestation and postnatally (19). The capacity to carry out aromatic oxidations (the principal metabolic pathway for phenytoin and phenobarbital) develops early in gestation. No significant differences have been found between premature and full-term newborns in the development of aromatic oxidations. Postnatally this pathway is induced extensively and has very high capacity by the end of the neonatal period. In fact, infants who have been treated for neonatal seizures have the greatest relative capacity to oxidize these drugs. However, N-dealkylation is more variable (61). Premature newborns have less capacity than full-term newborns to metabolize drugs such as diazepam and methylxanthines via this pathway. Both of these pathways—aromatic oxidations and N-dealkylation—are induced by intra-uterine drug exposure to drugs such as phenobarbital and phenytoin but not by exposure to valproate. In the absence of prior drug treatment, the newborn's relative capacity for N-dealkylation is approximately 20% of adult values at birth and gradually increases to adult capacity by age 2 years (62).

The pharmacokinetics of AEDs change during the neonatal period. After loading doses have been given and maintenance drug therapy is under way, several factors act simultaneously to reduce drug concentrations during the neonatal period. These include accelerating drug elimination, changing routes of drug administration, and recovery from hepatic, renal, or gastrointestinal dysfunction caused by systemic disease. Newborns with seizures experience dramatic increases in the clearance of most of the antiepileptic drugs during the neonatal period (27). Increases by factors of 2 to 4 are common for phenobarbital and phenytoin, causing drug levels to decline by 50% to 75% if constant doses are given. The effects of perinatal disease on drug dose requirements are subtle but can be identified in groups of newborns. For example, newborns with perinatal asphyxia have lower relative clearance for phenobarbital than newborns with seizures due to other causes. The relative clearance of phenobarbital of 4.1 mL/kg/h by asphyxiated newborns is approximately 50% lower than the average phenobarbital clearance of 8.7 mL/kg/h by nonasphyxiated newborns (63). This predicts that, at

equivalent doses, the levels in asphyxiated newborns will be twice as high.

Switching from intravenous to oral drug administration leads to slower drug absorption, reducing and delaying peak concentrations. In the case of phenytoin, slowed absorption causes a reduction in the apparent bioavailability of 20% to 30% (31).

As drug clearance increases during the neonatal period, it is necessary to increase the dose to sustain uniform drug concentrations. However, most neonatal seizures are symptomatic of disorders that are abating during the neonatal period. Therefore, declining drug levels create fewer problems than might be expected because the intensity of the epileptic process tends to abate concurrently.

After the neonatal period, there are two major differences in the pharmacokinetics of AEDs between children and adults: children have higher relative clearance, and children have greater within-group variability in elimination kinetics (27, 55, 64, 65). The effect of age on relative clearance is similar for most of the AEDs. Infants have the highest relative clearances, which are 3- to 4-fold greater than adult values. With advancing age the relative clearance declines until adult values are reached in late childhood or adolescence (66, 67) (Figure 37-6). Among specific age groups the standard deviation of the average clearance is relatively greater in younger patients. For example, the coefficient of variation (the standard deviation divided by the mean times 100%) for relative clearance of phenytoin is more than 50% for children who are less than 5 years old (66). For this reason the relationships between drug doses and levels are more unpredictable in children than in adults. Often, considerable trial and error are required to adjust children's drug levels.

Drug levels are surprisingly stable during the middle and later years of childhood, because increases in body

FIGURE 37-6

FIGURE 37-7

Relationship between age and body surface area (A) and between age and relative hepatic mass (M). Data from Korenchevsky (68) were used to create the figure.

mass are offset by declining relative drug clearance. This means that children do not outgrow their drug doses frequently. Although the adolescent growth spurt does occasionally necessitate dosage adjustments, dramatic changes in relative drug clearance are scarce during adolescence. Noncompliance is far more common and causes drug levels to vary erratically.

The factors that underlie the age-related changes in drug clearance of all of the AEDs correlate with the changes that occur in relative hepatic mass, relative caloric requirements, and surface area relative to body mass during growth to adult size. Children, as compared to adults, have larger surface area relative to body mass, and they are hypermetabolic in order to maintain constant body temperature. With growth and increasing body mass, the surface area relative to body mass decreases, reducing the relative area that is available for radiant heat loss. Concomitantly, the relative hepatic mass and relative production of heat both decline (68) (Figure 37-7). Since most antiepileptic drugs are eliminated by hepatic biotransformation, the declining relative hepatic mass coincides with the decline in drug clearance that occurs with growth. Thus the age-related pattern of declining relative drug clearance seems to be a byproduct of growth in warm-blooded homotherms and results from size-related differences in metabolic rate.

## AEDS IN BREAST MILK

Maternal treatment with antiepileptics is not a contraindication to breastfeeding (69–71). However, the issue of maternal drug administration and breastfeeding is somewhat controversial because of conflicting opinions and recommendations in the literature. Data regarding transplacental partition ratios and breast milk to maternal serum concentration have been reviewed at length (71).

**TABLE 37-5**  
*Pharmacokinetics of Antiepileptic Drugs Acquired from Maternal Sources*

DRUG	HALF-LIFE OF TRANSPLACENTAL AEDS IN NEWBORN		PERCENT OF SERUM LEVEL IN BREAST MILK	
	HOURS	S.D.	AVERAGE	S.D.
Carbamazepine	6–44		41	17
Ethosuximide	41		94	6
Gabapentin			70	10
Lamotrigine			40–80	
Phenobarbital	41–628		41	15
Phenylethylmalonamide	35	6	76	15
Phenytoin	7–69		19	16
Primidone	8–83		72	15
Valproic acid	47	15	27	15

From (27, 75).

Newborns who were exposed chronically to inducing drugs in utero are born with induced drug elimination and may also be tolerant to sedative drug actions. If questions arise about the contribution of the antiepileptic drug to a specific symptom in the infant, measuring drug levels in the infant may provide some insight (72).

The amounts of phenytoin, carbamazepine, lamotrigine, vigabatrin, and valproate that are acquired via nursing are generally insignificant (37, 72–78) (Table 37-5). Although isolated case reports describe both neonatal

sedation and withdrawal symptoms after prenatal intra-uterine and postnatal breast milk-acquired barbiturate exposures, maternal barbiturate therapy is not an absolute contraindication to nursing. Highly lipid-soluble drugs such as diazepam readily penetrate breast milk and theoretically could lead the newborn to accumulate sedating levels, but this rarely occurs. Although the concentration of ethosuximide in breast milk is approximately 90% of the maternal levels, the significance of ingesting this amount is unknown (74, 79).

## Dosage Form Considerations in the Treatment of Pediatric Epilepsy

*William R. Garnett  
James C. Cloyd*

**T**he successful treatment of pediatric epilepsy requires an accurate diagnosis and seizure classification, individualization of antiepileptic drug (AED) dose, and patient adherence. Because pediatric patients may have difficulty swallowing large, solid dosage forms, the successful treatment of pediatric epilepsy is complicated by the necessity of having a dosage form that can be administered to all pediatric patients, including infants and small children. Because Phase III efficacy trials are usually done in adults, dosage forms convenient for pediatric patients are usually not developed until the compound has been proven efficacious. There has been an increase in the number of AEDs that have dosage forms convenient for use in pediatric patients. Also, because of the nonadherence associated with multiple daily dosing, the pharmaceutical industry has developed extended-release formulations that can be given once or twice a day. This technology has also been applied to AEDs. These dosage forms offer the ability to individualize drug administration; however, ignoring the differences among dosage forms can result in a failure of the patient to receive full therapeutic benefit of the medication.

### THEORETICAL ASPECTS IN ANTIEPILEPTIC DOSAGE FORM SELECTION

#### Intravenous Formulations

When an AED is administered intravenously, high blood drug concentrations may be reached very quickly, allowing the drug to distribute rapidly throughout the body (1, 2). Only drugs that are water soluble or that are soluble in a solvent that has little or no pharmacologic activity can be formulated for an intravenous (IV) dosage form. In some cases (e.g., phenytoin), the solvent may contribute to the toxicity that results from excessively rapid infusion (3). Intravenous dosage forms usually are more expensive than oral formulations. The IV administration of AEDs requires the presence of trained medical personnel and specialized equipment, such as infusion pumps and monitoring equipment, which also add to the cost of therapy. Therefore, IV drug administration is indicated only when rapid attainment of blood levels is needed, as in status epilepticus or when the patient is unable or unwilling to take medications by mouth.

FIGURE 38-1

Drug disintegration and absorption. Reproduced from (1) by permission.

### Oral Formulations

Following oral administration, capsules or tablets first must disintegrate, liberating the drug, which then must dissolve in an un-ionized state into intraintestinal fluids before being absorbed (Figure 38-1). While immediate-release drugs are designed to be liberated in the stomach, other drugs, such as Depakote<sup>®</sup>, are formulated to delay drug liberation until the drug reaches the small intestine. Other medications, such as Tegretol-XR<sup>®</sup>, Carbatrol<sup>®</sup>, Depakote-ER, and Phenytek<sup>®</sup> are liberated throughout the gastrointestinal (GI) tract at controlled rates, providing extended release. The dissolution time (the time to dissolve in GI fluids) may be altered by the surface area of the particles. The smaller the particle size, the faster the rate of dissolution. Liquid dosage forms, such as solution (in which the drug is already dissolved) and suspension (in which the drug is suspended as very small particles), generally display more rapid absorption than solid dosage forms. The rate of absorption for oral formulations usually conforms to the following order: solutions > suspensions > capsules > tablets.

Immediate-release oral solids are designed to disperse all of the medication quickly after ingestion. This usually is followed by rapid absorption. If the drug has a short half-life, multiple daily doses are required to prevent peak concentrations, which may result in side effects, and trough concentrations, which may be associated with seizures. Multiple daily doses may result in poor compliance. There is a trend in pharmaceutical development to develop dosage forms that release drug slowly over time rather than all at once.

Dosage forms that are designed to release their drug content slowly have been referred to as controlled-release, prolonged-release, time-release, slow-release, sustained-release, prolonged-action, or extended-action. Although there is some interchange in these terms, there are

technical differences. A controlled-release dosage form is a system in which the rate of release is regulated and is supposed to be constant during GI transit. A sustained-release dosage form releases its contents over an extended period of time. Sustained-release dosage forms provide for the immediate release of an amount of drug that is immediately absorbed and then gradual and continual release of additional drug over the dosing interval. The advantages of controlled-release and sustained-release dosage formulations are (1) reduction in blood drug level fluctuations, (2) enhanced patient convenience and adherence, (3) reduction in adverse side effects, and (4) reduction in health care costs. Potential disadvantages to controlled-release and sustained-release formulations are (1) prolonged effects if the patient develops an adverse drug reaction or is accidentally intoxicated, (2) the possibility of interactions with the contents of the GI tract, and (3) changes in GI motility resulting in “dose dumping,” or all of the drug being absorbed at once (4).

Most drugs are weak acids or weak bases and exist in solution as an equilibrium between the ionized and the un-ionized forms. In these cases, it is the un-ionized form in the gut that passively crosses the GI membrane. A continuous flow of blood to the GI tract ensures movement of drug from an area of high concentration in the gut to an area of relatively low concentration in the blood. Once a drug is dissolved, the rate of absorption is determined by the ratio of ionized to un-ionized forms, because it is the un-ionized form that can diffuse across membranes. Weak acids are absorbed more rapidly at pH 1.0 than at pH 8.0, and the converse is true for weak bases, because there is more of the un-ionized form present. The formulation of poorly soluble drugs as salts may enhance solubility and result in better absorption. Physiologically or pharmacologically induced changes in the GI pH may affect the disintegration of tablets or capsules, the dissolution time, and/or the equilibrium between the ionized and un-ionized forms, which alters the rate and/or amount of drug absorption (4).

Some drugs are absorbed by active transport processes. For example, gabapentin is carried across the GI membrane via a transport enzyme (5). Absorption may become saturated with this type of process. When the amount of drug in the GI tract is low relative to the number of transport enzyme-binding sites, the extent of absorption is high and constant. As the amount of drug approaches the capacity limits of the transport enzymes, the fraction of the dose that is absorbed per unit of time decreases. As a result, increases in dose produce less than proportional increases in serum concentration.

Some of the drug may be metabolized as it passes across the gut wall. Further metabolism may take place in the liver before the drug reaches the systemic circulation. This phenomenon is known as first-pass metabolism. Systemic bioavailability depends on the amount of drug

absorbed across the gut wall and the degree of first-pass metabolism occurring in the GI tract and the liver before the drug reaches the systemic circulation. If a drug has extensive first-pass metabolism, it may not be suitable for oral administration.

The manufacturing process of the dosage form may affect absorption. There are no legal requirements for the excipients used in solid dosage formulations. Excipients may vary from manufacturer to manufacturer and cause different absorption rates that in-vitro dissolution tests do not detect. A change in the excipients of a phenytoin capsule in Australia resulted in greater bioavailability and an epidemic of phenytoin toxicity (6, 7). Other aspects of manufacturing may differ, such as tablet hardness and friability. The particle size of the active ingredient may also be different. Thus, there may be different rates and amounts of drug absorbed from the same dosage form made by different manufacturers. Sometimes there may be differences in absorption between lots of the same manufacturer.

Oral absorption may be altered by a variety of physiologic and pharmacologic phenomena. For example, food decreases the rate but not the extent of absorption of valproic acid, which results in a delayed time to peak (8). Food enhances the bioavailability of carbamazepine (9). Achlorhydria or the coadministration of drugs that reduce or neutralize gastric acid may alter disintegration and dissolution and affect absorption. Antacids in large doses decrease the absorption of phenytoin (10). For drugs with significant first-pass metabolism, food may alter hepatic blood flow and compete with liver enzymes to increase the systemic bioavailability of drugs. Foods and drugs may affect gastric emptying time and drug absorption.

Absorption usually is greater in the small intestine than in the stomach, because the surface area is larger, the permeability is higher, and the blood flow is greater. Therefore, absorption may be altered by changes in gastric emptying and GI transit times. Diarrhea may decrease the absorption of phenytoin and other slowly absorbed drugs because GI transit rate is increased and reduces drug contact time at intestinal absorption sites (3).

Age per se may alter absorption. In the newborn the intragastric pH and the efficiency of gut enzymes change rapidly (11, 12). Because of relative achlorhydria in the newborn and infant, there should be an increased absorption of acid-labile drugs such as penicillin (13). Age effects on pharmacokinetics are discussed in Chapter 37.

### Generic Formulations

When the patent of a drug expires, companies other than the innovator of the drug may manufacture the generic equivalent. The U.S. Food and Drug Administration (FDA) is concerned about generic equivalency,

and generic manufacturers must compare their product with that of the innovator. Bioequivalence tests are determined in vivo to prove that there is no difference in the two products. This usually is done by administering a single equal dose of the brand-name formulation and the generic drug to a population of between 24 and 36 normal healthy adults in a randomized, double-blind, crossover design. Multiple blood samples are collected to determine the amount of drug absorbed, as assessed by the total area under the concentration-time curve (AUC) and the rate of drug absorption as determined by the peak concentration ( $C_{max}$ ), and the time to maximum concentration ( $T_{max}$ ). The means of these parameters are determined, and a ratio of the log-transformed data is determined. Bioequivalence is accepted when the 90% confidence intervals of the ratios of AUC,  $C_{max}$ , and  $T_{max}$  fall between 0.8 and 1.25 of those of the branded drug. A popular misconception is that total absorption may vary between 80% and 125%. In fact, a difference in bioavailability between innovator and generic that is greater than 6% would result in confidence intervals that fall below 0.8 or above 1.25. Unfortunately, generics are only compared to the innovator and never to each other for regulatory approval. The lot-to-lot consistency of brand and generic drugs are regulated by in-vitro dissolution rate testing (14).

The FDA Center for Drug Evaluation and Research publishes annually a listing of approved drug products. The official title of this publication is *Approved Drug Products with Therapeutic Equivalence Evaluations*, but it is commonly known as the Orange Book. The FDA has an A rating and B code for generic drugs. An A coded drug is one that is considered to be therapeutically equivalent to other pharmaceutically equivalent products. For example, a drug with an AB rating would be considered to be products meeting bioequivalence requirements. This applies to all oral generic AEDs. An AA rating applies to conventional dosage forms not presenting bioequivalence problems. This would apply to IV dosage forms such as those for valproic acid. A B code applies to drug products that the FDA does not consider to be therapeutically equivalent to other pharmaceutically equivalent products (15). There are no AEDs with a B code.

Since generic drugs often are less expensive, they may offer an advantage for many patients. The AMA has recognized the equivalency of generic drugs (15). When generic drugs are prescribed, it would be ideal for the patient to remain on the formulation from one supplier. The American Academy of Neurology (AAN) has cautioned against switching suppliers for carbamazepine and phenytoin (16). However, practically this may be difficult to accomplish. Clinicians should know when the source of an AED is being changed. The AAN has recommended that generic switching of AEDs not be done without the consent of the prescriber (17).

### **Intramuscular Formulations**

Absorption of drugs from muscle and subcutaneous tissue is dependent on solubility, ionization, and tissue perfusion. Increases in tissue blood flow increase absorption. Physical activity that changes blood flow rates alters the rate of drug absorption from intramuscular (IM) injections. The location of the injection site also influences the rate of absorption. A standard part of nursing care is to rotate the sites of injection to prevent damage to a particular area. Because different muscle tissues have varying perfusion rates, the rotation of injection sites may result in varying rates of absorption. Injections into muscle tissue have different rates of absorption than injections into fatty tissue. In contrast, the extent of absorption is 100% unless drug is degraded in the tissue. The injection of IM drugs always causes some degree of discomfort, may be irritating to the tissue, and in some cases may result in muscle damage. IM injections require skilled personnel, which limits their use. Therefore, IM injections should be limited to short-term situations.

### **ALTERNATE ROUTES OF ADMINISTRATION: BUCCAL/SUBLINGUAL, NASAL, AND RECTAL**

#### **General Considerations**

Occasionally methods of drug administration other than oral and parenteral routes are needed to treat patients. Circumstances such as out-of-hospital therapy of seizure emergencies, or bridge therapy when taking medications by mouth is not possible, require alternate routes of administration. The choice of therapy depends on the drug's physical, chemical, and pharmacokinetic characteristics, the route of administration, and the indication. These characteristics vary substantially among AEDs. For a given drug, factors such as water and lipid solubility, formulation characteristics, the relative size of the absorptive surface area, and retention time at the absorption site will dictate the onset and intensity of effect. Highly lipid-soluble compounds administered as solutions exhibit the most rapid and consistent absorption. Conversely, poorly water-soluble AEDs administered as suspensions or solid dosage forms may exhibit slow absorption that may permit extended dosing intervals if drug can be retained at the site of administration (18).

#### **Buccal/Sublingual Administration**

Buccal administration is defined as placement of a drug formulation in the buccal pouch of the oral cavity. The buccal mucosa is rich in blood supply, leading to rapid, systemic drug absorption. The pH of the buccal cavity is approximately 6.5 and the cavity has a surface area

of 200 cm<sup>2</sup>, which is similar to the areas of the rectal and nasal cavities. Sublingual administration refers to placement of drug, usually as a solid formulation, under the tongue, with absorption occurring at the mucosal epithelium. The absorptive surface area is smaller than that of the buccal cavity, and the drug product can be easily displaced unless disintegration and dissolution are rapid (i.e., within seconds) (18).

Compared with other routes of administration, the practical advantages of buccal administration are obvious: It is much simpler and safer than intravenous or intramuscular injections; it is less embarrassing and inconvenient for patients and caregivers than intrarectal administration; and it may permit use of larger volumes than would be possible via intranasal administration (18).

Buccal administration, however, has several disadvantages. The maximum rate of absorption is obtained when the solution can be spread uniformly over the buccal pouch and retained in the buccal cavity. This may be difficult to accomplish if the patient's head is moving, as might occur during a seizure, which can result in the pooling or swallowing of the drug solution. Moreover, placement of drug in the buccal pouch during a seizure may be hazardous for both the patient and the caregiver and runs counter to first-aid guidelines for seizures. Regarding sublingual administration, similar problems exist with placement and retention of the formulation under the tongue. When given as solutions, volumes must be small, which often limits the size of the dose. These routes are best suited to treatment of seizure emergencies (18). Research results on this route of administration are discussed in a later section in this chapter.

#### **Intranasal Administration**

The advantages of intranasal drug delivery include easy access; lack of need for patient cooperation; and the possibility of rapid and extensive absorption of selected drugs, resulting in a rapid onset of effect. Overall, the needle-free administration of a drug via the intranasal route is simple and convenient. There are several disadvantages: Only small volumes (<200 µL per nostril) can be administered; the absorptive surface area of the nasal cavity (200 cm<sup>2</sup>) is limited; and the residence time in the cavity is only about 15 minutes as fluids are drained from the nasal cavity to the throat. The choice of therapeutic agent administered intranasally therefore must be limited to highly potent, lipid-soluble drugs administered as solutions. The limitation in volume and the short residence time make this route best suited for treatment of seizure emergencies (18). Results of research on this route of administration are discussed in a later section in this chapter.

### Rectal Formulations

The rectum is a useful route of administration, although there is little intraluminal fluid and the absorptive surface is only 1/10,000 that of the upper GI tract. The disintegration and dissolution problems associated with oral dosage formulations also occur with rectal dosage formulations (19). Solutions and suppositories are the most commonly used rectal dosage forms. Suppositories usually are formulated with a quick-melting base such as cocoa butter. Adequate retention time in the rectum is essential for complete absorption from the rectal dosage forms. Highly lipid-soluble compounds are more rapidly absorbed than less soluble, ionized drugs. The inability to retain the suppository or solution diminishes the usefulness of this route of administration. In contrast to oral administration, first-pass metabolism is significantly reduced with rectal administration—particularly when drug is absorbed from the lower two-thirds of the rectum, where venous drainage bypasses the liver. Rectal administration can be used both for treatment of seizure emergencies and for bridge therapy when a patient is unable to take maintenance AED therapy by mouth. Rectal administration of particular AEDs is discussed in greater detail later in this chapter.

### SELECTION OF PARENTERAL AND ORAL ANTI-EPILEPTIC DOSAGE FORMS IN PEDIATRIC PATIENTS

The factors that influence the selection of a particular dosage form for a child include the need for rapid attainment of therapeutic blood concentrations, the importance of maintaining therapeutic concentrations throughout a dosing interval, the ability to swallow, the ability to retain a rectal dosage form, the palatability of the oral dosage form, and cost.

Ideally, the drug should be available in a parenteral form for IV and IM administration as well as in oral solid and liquid formulations. The availability of a rectal formulation would allow greater flexibility in dosing. Among the AEDs used for maintenance therapy, only phenytoin, phenobarbital, levetiracetam, and valproic acid are available as parenteral formulations. Diazepam is now available in a gel formulation specifically designed for rectal administration.

For maintenance therapy, oral dosage forms are preferable because they are relatively inexpensive and easy to administer. Therefore, when the patient is able to swallow, the AED should be given orally. If the patient is not able to take a tablet or capsule, consideration should be given to chewable tablets or liquids. Patients with a nasogastric tube may be given liquid AEDs, which negates the need for chronic parenteral therapy. Obviously, liquid medicines should be palatable or capable of being mixed

with beverages or enteral feedings without interactions so that the patient is able to ingest the medicine. It is possible to give loading doses of oral medications to attain a therapeutic concentrations more quickly. However, this is often neither rapid enough nor feasible when dealing with an emergency such as status epilepticus.

### Phenytoin/Fosphenytoin

Phenytoin is available in parenteral, capsule, chewable tablet, and suspension formulations. Phenytoin is poorly soluble in water; thus, the parenteral formulation contains propylene glycol and ethanol and is buffered to a pH of 12 to keep the drug in solution. The solvents have inherent pharmacologic activity, including cardiac arrhythmias and hypotension. The combination of cosolvent effects and the alkaline pH commonly cause pain and inflammation at the infusion site. Therefore, phenytoin infusions are limited to a rate no faster than 1 to 3 mg/kg/min in otherwise healthy children (3). Because of the high ionization constant ( $pK_a$ ) of phenytoin, it is not stable in every IV solution. Phenytoin may be mixed with normal saline in concentration ranges of 2 to 20 mg/mL. Use of an in-line 20-micron filter is recommended to reduce the risk of infusing small particle precipitants. Admixtures should be stored for no longer than 24 hours (20).

Although the parenteral formulation of phenytoin may be given by IM injection, this route is not recommended. The high  $pK_a$  of phenytoin results in crystallization in muscle tissue. This results in slow and erratic absorption (21). In addition, IM phenytoin is quite painful and may cause muscle damage (22).

Fosphenytoin is a phenytoin prodrug formed by the addition of a phosphate ester group to the phenytoin molecule. The phosphate ester significantly increases the water solubility of fosphenytoin. The phosphate ester must be cleaved and the compound converted to phenytoin to exert pharmacologic activity. The conversion is done by systemic phosphatases that are found throughout the body. The conversion of fosphenytoin to phenytoin is rapid and complete. The phosphatases are not affected by age, gender, race, hepatic impairment, or renal function (23). An ex-vivo study using blood obtained from premature infants and neonates demonstrated that fosphenytoin is converted to phenytoin in these populations.

Because fosphenytoin is more water soluble than phenytoin, it does not require propylene glycol or ethanol to increase solubility. Fosphenytoin is compatible with all IV fluids, whereas phenytoin should be admixed only with normal saline. Fosphenytoin does not require an in-line filter as phenytoin does (24). Fosphenytoin may be given at a much faster IV infusion rate than phenytoin, and the infusion rate does not need to be altered because of age or underlying cardiac disease. The maximum rate of infusion of fosphenytoin is 150 mg/min compared with

50 mg/min for phenytoin. This means that the patient can be loaded in less time. Fosphenytoin is rapidly converted to phenytoin after administration, with a conversion half-life of approximately 15 minutes. Fosphenytoin is highly protein-bound, as is phenytoin. Therefore, fosphenytoin competes with phenytoin for binding sites, which increases the “free” or unbound portion of phenytoin. When both drugs are given at the maximum rate of administration, fosphenytoin achieves bioequivalency with phenytoin in 7 minutes. If the rate of phenytoin is slowed, higher concentrations of phenytoin may be achieved with the administration of fosphenytoin (25). Another advantage of fosphenytoin is that in comparative studies it causes less thrombophlebitis and less burning, pain, or irritation at the injection site. This results in fewer changes in the site of administration (26). The decreased venous irritation is a particular advantage in premature infants, neonates, and children, in whom venous access is a serious problem. The primary side effects of fosphenytoin are pruritus and paresthesias, which are common to phosphate esters and disappear with a reduction in the infusion rate or when the infusion is completed.

Fosphenytoin can safely be given intramuscularly. Peak phenytoin concentrations occur about 3 hours following IM fosphenytoin. However, free phenytoin concentrations in the accepted target range occur in approximately 30 minutes after an IM injection of fosphenytoin (27). There is no pain or necrosis associated with fosphenytoin after IM administration, and the absorption is rapid and complete. Loading doses of 20 mg/kg have been safely given intramuscularly. In adults, volumes exceeding 20 mL have been safely given as a single injection (28). When given as replacement therapy, fosphenytoin is completely converted to phenytoin, whereas oral phenytoin sodium capsules are 92% phenytoin. Therefore, the trough concentrations may increase. If the patient is at the point of enzyme saturation for phenytoin metabolism, there may be a significant increase in blood concentrations (29).

As noted in Chapter 49, the various formulations of phenytoin differ in content of phenytoin (Table 38-1). The capsule and parenteral formulations of phenytoin contain sodium phenytoin and are only 92% phenytoin. The suspension and chewable tablet formulations of phenytoin

contain phenytoin acid and are 100% phenytoin. Because of the Michaelis-Menten kinetics of phenytoin, these salt differences should be considered when switching dosage forms. Although it would be anticipated that the rate of absorption of the phenytoin suspension would be faster than the rate of absorption from the capsule, a single-dose study in normal volunteers demonstrated that the time to peak concentration,  $C_{max}$ , and AUC time curve for phenytoin extended-release capsules were not different from these parameters for phenytoin suspension when the dose of the suspension was adjusted for the difference in salt concentration (30). It was postulated that the rate of absorption is more dependent on particle size than on formulation. There are also differences in the rate of absorption among the various manufacturers of phenytoin capsules. The innovator's formulation (Dilantin®) provides an extended release. Some of the generic formulations provide faster release. Phenytoin is thus labeled as either prompt-release or extended-release capsules. The FDA recommends that only the extended-release capsules be used for once-a-day dosing (31). The difference in the rate and extent of absorption between the prompt-release and extended-release capsules may affect how rapidly peak concentrations of phenytoin can be obtained. The extended-release capsules display a slower rate and extent of absorption as the dose is increased. This suggests that oral doses need to be larger than IV doses to achieve the same concentration (32). However, if prompt-release capsules are used, phenytoin concentrations are achieved more rapidly, and the prompt-release capsule has been suggested as an alternative in situations where an IV injection is not possible or practical (33). The chewable tablet seems to have a similar absorption profile to phenytoin extended-release capsules when adjusted for salt content.

Although the suspension dosage form has been considered to have rapid settling properties, a recent report measuring settling rates in bottles of phenytoin suspension that were well shaken and then left untouched revealed that no differences in the concentration could be found between the top and bottom of the bottle from time 15 minutes to 4 weeks after resuspension. Only after 5 weeks after resuspension was there a difference between the aliquots taken from the top and the bottom

**TABLE 38-1**  
*Phenytoin Content of Various Products*

PRODUCT LISTED	COMPOUND	PHENYTOIN STRENGTH	CONTENT
Phenytoin capsule	Phenytoin sodium	100 mg	92 mg
Phenytoin capsule	Phenytoin sodium	30 mg	27.5 mg
Fosphenytoin parenteral	Fosphenytoin sodium	50 mg PE/mL	46 mg PE/mL
Phenytoin suspension	Phenytoin	125 mg/5 mL	125 mg/5 mL
Phenytoin chewable tablet	Phenytoin	50 mg	50 mg
Phenytoin parenteral	Phenytoin sodium	50 mg/mL	46 mg

FIGURE 38-2

of the bottle (Figure 38-2) (34). In the same study a dose (5.0 mL) was measured every day simulating patient use by a well-shaken technique (vigorous shaking), a poorly shaken technique (inverted once), and an unshaken technique until the bottle was depleted. Only the unshaken

technique demonstrated differences in the doses taken (Figure 38-3). It was concluded that phenytoin suspension requires minimal agitation to be uniformly mixed and that it has a slow rate of settling. The problems reported with phenytoin suspension in the past possibly reflect

FIGURE 38-3

Effect of shaking techniques on concentration of dose of phenytoin. Reproduced from *Neurology*, February 1989, by permission.

inaccurate measurements by the patient or a failure to understand the Michaelis-Menten kinetics of phenytoin. This dosage form may be very acceptable for young children or for patients with difficulty in swallowing. An accurate measuring device should be used for administration. When changing from oral to nasogastric administration, levels may decrease substantially (see later discussion on nasogastric tubes).

Phenytek™ Capsules contain either 200 mg or 300 mg of the sodium salt of phenytoin. This formulation employs an erodible-matrix delivery system for the extended release of phenytoin. The 200 mg Phenytek™ Capsule has two, and the 300 mg Phenytek™ Capsule has three, erodible-matrix tablets. After ingestion, the capsule shell dissolves to expose the two or three tablets inside. As the outer surfaces of the tablets hydrate, a gel layer containing phenytoin sodium is formed. The initial release of phenytoin sodium from the external layer of the tablets occurs at this stage. Water permeates farther into the erodible matrix, thickening the gel layer and allowing soluble drug to continue diffusing out of the tablets. Once the outer layer of each erodible-matrix tablet is fully hydrated, phenytoin sodium is gradually dissolved in the gastric fluids. Concurrently, water continues to permeate toward the core of the tablet. This multistep process allows solubilized drug to be gradually diffused from the gel layer. In addition, erosion of the tablets over time allows drug to be released by direct exposure to gastric fluids. Phenytoin is released from the tablets in a slow and extended rate with peak concentrations expected in 4 to 12 hours following a single dose. The peak concentrations of prompt-release phenytoin capsules occur within 1.5 to 3 hours. Phenytek™ Capsules are approved for once-a-day dosing. Studies comparing three divided doses of 100 mg of phenytoin to a single daily 300-mg dose of Phenytek™ Capsules indicated that absorption, peak plasma levels, biologic half-life, difference between peak and minimum values, and urinary recovery were equivalent. Two studies comparing the pharmacokinetics of one 300-mg Phenytek™ Capsule to three 100-mg phenytoin (Dilantin®) capsules demonstrated that the two doses were bioequivalent. In the study comparing the effects of food on the bioavailability of phenytoin given as Phenytek™ and Dilantin®, the phenytoin AUC and  $T_{\text{peak}}$  were slightly lower with Phenytek™. However, the  $C_{\text{peak}}$  and half-life with Phenytek™ were slightly greater than with Dilantin® Kapseals®, and the products were considered bioequivalent. Phenytek™ Capsules should not be opened and the contents crushed or taken separately (35).

### Carbamazepine

Carbamazepine is available as a chewable tablet, tablet, and suspension. A single-dose study in normal volunteers demonstrated that the bioavailability of chewable tablets

is comparable to the bioavailability of swallowed tablets (36). The rate of absorption of carbamazepine suspension is faster than that of carbamazepine tablets in single-dose studies in normal volunteers (37). A multidose bioavailability study in epileptic patients comparing equal total daily doses of carbamazepine suspension administered three times a day to tablets administered twice a day also demonstrated that the suspension is absorbed faster than the tablets (Figure 38-4). However, there were no differences in the  $C_{\text{max}}$ , the AUC time curve, or the peak-to-trough fluctuations for either the parent drug or the 10,11-epoxide metabolite (38) (Table 38-2). If the faster absorption rate is not considered in scheduling dosage administration times, the suspension will produce higher peaks (greater chance of side effects) and lower troughs (greater chance of loss of efficacy) than a comparable dose using carbamazepine tablets.

There are controlled-release and sustained-release dosage forms of carbamazepine. The controlled-release formulation is Tegretol-XR®, which utilizes an osmotic release delivery system. The formulation is provided in a wax matrix with a permeable membrane. This allows water from gastric contents to enter the matrix and increase the osmotic pressure. This forces the drug out at a constant rate. For the 100-mg tablet, 10 mg of drug is released per hour for the first 7 or 8 hours and then the rest of the drug is released. The casing of the tablet is excreted in the feces. Patients should be told that although casings will appear in the stool, the drug is being absorbed. Any disruption to the tablet results in a loss of the controlled-release design. Therefore, this controlled-release formulation must not be crushed, chewed, or opened (39). The sustained-release formulation is Carbatrol®, which uses three different types of beads: immediate-release, extended-release, and enteric-release. This formulation is a capsule, and it may be opened and mixed with food. The ability to use this formulation as a “sprinkle” is an advantage in pediatric patients (40).

Both controlled-release and sustained-release dosage forms have been compared with immediate-release carbamazepine in patients with epilepsy. Patients were converted from four-times-a-day dosing with immediate-release carbamazepine to twice-a-day dosing with both formulations in separate studies. In both studies twice-a-day dosing with controlled-release or sustained-release tablets was bioequivalent to the four-times-a-day dosing with immediate-release tablets (39, 40). The controlled-release formulation was compared with the sustained-release formulation in a randomized crossover study in normal volunteers who were dosed for 5 days on each formulation. The two dosage formulations were found to be bioequivalent, although the sustained-release formulation had larger confidence intervals (41).

The advantage of controlled-release and sustained-release carbamazepine is that either may be given twice a day. This optimizes convenience and promotes

FIGURE 38-4

Twelve-hour concentration vs. time profile of carbamazepine tablets vs. suspension.

adherence. In a pediatric patient who cannot or will not swallow oral solids, the sustained-release formulation can be opened and mixed with food.

### Valproic Acid

Valproic acid is available as a soft gelatin capsule containing a liquid, an enteric-coated tablet, a coated particle (sprinkle) capsule, a hydrophilic matrix, controlled release tablet, a syrup, and an IV solution. The bioavail-

ability of the soft gelatin capsule formulation is comparable to that of the solution. The enteric-coated tablet (Depakote) was developed to delay dissolution of the drug until after it leaves the stomach, thereby reducing the incidence of nausea, vomiting, and other types of GI distress. Although the enteric coating does delay and slow absorption, it does not result in true sustained release of valproic acid. For most drugs the minimum (trough) concentration occurs just before the next dose. In contrast, the delayed absorption of enteric-coated valproic

**TABLE 38-2**  
*Pharmacokinetic Comparison of Carbamazepine Tablets and Suspension*

STATISTICAL PARAMETER	TABLET	SUSPENSION	SIGNIFICANCE	POWER	CI (%)
AUC 0-724	192.1	196.9	NS	0.73	12.8
$C_{max}$	8.5	9.4	NS	0.97	18.4
$T_{max}$	3.7	1.5	$P < 0.05$	—	196.0
$C_{min}$	5.3	5.7	NS	<0.99	14.0
$C_{max}$					
$C_{min}$	1.7	1.7	NS	0.92	12.9
Conc <sub>ss</sub>	8.0	8.2	NS	0.73	12.8

FIGURE 38-5

The effect of formulation on the time course of valproate absorption.

acid produces trough concentrations 2 to 4 hours after the dose when given on an empty stomach (Figure 38-5). Coadministration with food extends the time to the trough concentration from 2 to 8 hours after administration, and peak concentrations may occur just before the next dose (42). These changes in normal absorption profiles must be considered in evaluating blood concentrations, particularly if the timing between drug administration and meals varies. Recently, a diurnal effect on valproic acid

absorption from the enteric-coated tablet was also shown (43) (Figure 38-6). Valproic acid is absorbed more slowly, and the amount of drug absorbed is reduced, at night. The enteric-coated dosage form should not be crushed before administering.

A coated particle (sprinkle) formulation of valproic acid is available. The sprinkle formulation is designed to provide slow consistent input, which minimizes peak to trough fluctuations (see Figure 38-5) (44). This dosage form allows the patient or parent to open the capsule and sprinkle the particles over food. It is intended for pediatric use and for patients who have difficulty swallowing solid dosage forms. This dosage form also is particularly useful for patients with large fluctuations between doses who require frequent dosing or who may experience distress with enteric-coated tablets.

Depakote<sup>®</sup> is an enteric coated dosage form of divalproex sodium. The enteric coating delays the absorption of divalproex sodium until after the drug has left the stomach. This enteric coating is designed to reduce the GI side effects associated with valproic acid. Depakote<sup>®</sup> is a *delayed-release* formulation; it is not an *extended-release* formulation (45). Depakote-ER<sup>®</sup> is a hydrophilic-matrix controlled-release tablet system and is an *extended-release* formulation (46). Upon entering the stomach, the film coating dissolves, exposing the hydrophilic polymer matrix tablet. The outer layer of the matrix becomes partially hydrated, forming a gel layer, and drug begins to be released. As fluid enters the tablet, the gel layer increases

FIGURE 38-6

Twenty-four-hour total valproate concentration-time profile following particle and enteric-coated tablets. Reproduced from (43) by permission.

in thickness, extending the release of the drug. The matrix surface continues to become hydrated, allowing for a continued release of drug. Once the outer layer becomes fully hydrated, it erodes and is released from the tablet. Fluid continues to penetrate toward the tablet core. Thus this system of polymer wetting, polymer hydration, drug diffusion, and polymer erosion results in the release of drug in the stomach, small intestine, and large intestine over an 18- to 24-hour period (47, 48). Depakote-ER® is designed for once a day dosing (46).

The absolute bioavailability of Depakote-ER® administered as a single dose after a meal was approximately 80% to 90% relative to an intravenous infusion. In two multiple-dose studies, when administered either fasting or immediately before smaller meals, Depakote-ER® had an average bioavailability of 81%, compared to 89% for Depakote®. Maximum valproate plasma concentrations ( $C_{max}$ ) in these studies were achieved on average 7 to 14 hours after the administration of Depakote-ER®. In one of these studies, the average  $C_{max}$  and minimum plasma concentration ( $C_{min}$ ) at steady state of Depakote-ER® given fasting and with smaller meals were 74% and 82%, respectively, relative to Depakote® given twice a day with smaller meals. In the other study, the average  $C_{max}$  and  $C_{min}$  at steady state of Depakote-ER® were 81% and 85%, respectively, relative to Depakote® given fasting. After multiple dosing, Depakote-ER® given once daily has been shown to produce percent fluctuation (defined as  $100\% \times (C_{max} - C_{min})/\text{average concentration}$ ) that is 10% to 20% lower than that of regular Depakote® given twice a day. Depakote-ER® and Depakote® tablets are not bioequivalent (46). It has been recommended that, in converting a patient from Depakote® to Depakote-ER®, the total daily dose of Depakote® be increased by 14% to 20% given as the Depakote-ER® (49, 50).

### VALPROATE SODIUM INJECTION (DEPACON®)

Valproate sodium is the sodium salt of valproic acid. It is supplied as a 5-mL single-dose vial containing 100 mg of valproic acid per mL. The initial indication of valproate sodium injection was for patients who were not able to take valproic acid orally. The initial infusion guidelines were to dilute the drug with at least 50 mL of a compatible diluent (dextrose 5% in water, normal saline, or lactated Ringer's solution) and administer as a 60-minute infusion. It was recommended that the drug not be given any faster than 20 mg/min. The initial dose was 10 to 15 mg/kg/day (51). In January 2002, the FDA approved an infusion rate of 1.5 to 3.0 mg/kg/min. Clinical studies have shown that higher loading doses and more rapid rates of infusion are well tolerated in pediatric patients. In a study done at the Virginia Commonwealth University/Medical College of Virginia, 10 patients ranging

in age from 2.5 to 16.25 years of age received a total of 38 doses of IV valproate sodium given in doses ranging from 7.5 mg/kg/dose to 42 mg/kg/dose. The mean dose was 23.4 mg/kg/dose. The doses were infused at a rate of 1.5 mg/kg/min to 11 mg/kg/min with a mean rate of infusion of 6 mg/kg/min. No significant side effects were observed. A rapid rate of infusion may be desirable for patients in status epilepticus. Because the protein binding of valproic acid saturates around 50 µg/mL, a rapid rate of infusion would result in higher initial blood concentrations (52, 53). With the saturable binding there would be a higher free fraction. With a higher free fraction, there would be more free drug to diffuse across the blood-brain barrier (53). Rapid intravenous infusions of valproic acid have been used to treat status epilepticus and acute migraine headaches. Parenteral valproic acid should not be given by intramuscular injection.

### Phenobarbital and Primidone

Phenobarbital is available in a parenteral form, a tablet, and a solution. The parenteral form can be given by rapid IV infusion or by IM injection. Absorption from the oral formulations seems to be complete and relatively rapid. Primidone is available as a tablet and an oral suspension. Absorption from both formulations appears complete, with peak concentrations occurring 2 to 6 hours after the dose (54).

### Ethosuximide

Ethosuximide is available as a capsule and a solution. Absorption appears to be complete from both formulations. Ethosuximide has a long half-life even in children. However, some patients may develop GI side effects with once-a-day dosing and require twice-a-day dosing (54).

## NEWER ANTIEPILEPTIC DRUGS

### Felbamate

Felbamate (Felbatol®) is indicated for treatment of children with the Lennox-Gastaut syndrome. It is available as a 400-mg tablet, a 600-mg tablets and a 600 mg/5 mL suspension. Absorption is rapid and nearly complete following oral administration. The tablets and the suspension are bioequivalent to the capsules used in clinical trials. The pharmacokinetics of the tablet and the suspension are similar (55).

### Gabapentin

Gabapentin (Neurontin®) has been studied in patients with epilepsy 3 years of age and older. In addition to having an indication of the treatment of refractory partial

seizures, gabapentin is also indicated for the treatment of postherpetic neuralgia. Gabapentin is supplied as a 100-mg capsule, a 300-mg capsule, a 400-mg capsule, a 600-mg tablet, an 800-mg tablet, and a 250 mg/5 mL oral solution. The bioavailability of gabapentin is not dose proportional; that is, the increase in serum concentration is not proportional to the increase in dose. The administration of two 300-mg capsules and two 400-mg capsules have the same bioavailability as a single 600-mg tablet and a single 800-mg tablet. The manufacturer indicates that gabapentin may be administered by solution, capsule, tablet, or any combination of these formulations (56).

### Lamotrigine

Lamotrigine (Lamictal®) is supplied as 25-mg, 100-mg, 150-mg, and 200-mg tablets and as 2-mg, 5-mg, and 25-mg chewable/dispersible tablets. The lamotrigine chewable/dispersible tablets were shown to be equivalent, whether they were administered dispersed in water, chewed and swallowed, or swallowed whole, to the lamotrigine compressed tablets in terms of rate and extent of absorption. The lamotrigine tablets should be swallowed whole because chewing them may leave a bitter taste. The chewable/dispersible tablet may be swallowed whole, chewed, or mixed in water or diluted fruit juice. If the tablets are chewed, consume a small amount of water or diluted fruit juice to aid in swallowing. To disperse the chewable/dispersible tablet, add the tablets to a small amount of liquid—1 teaspoon (5 mL), or enough to cover the medication—in a glass or spoon. Approximately 1 minute later, when the tablets are completely dispersed, mix the solution and take the entire amount immediately (57).

### Topiramate

Topiramate (Topamax®) is available as 25-mg, 100-mg, and 200-mg tablets for oral administration and as 15-mg and 25-mg sprinkle capsules. The sprinkle capsule contains coated beads of topiramate in a hard gelatin capsule and may be swallowed whole or opened and sprinkled onto soft food. The sprinkle formulation is bioequivalent to the immediate-release tablet and may be substituted as a therapeutic equivalent. If the sprinkle capsule is to be administered as a sprinkle, the patient should be instructed to hold the capsule upright so that the word TOP can be read. The top should be carefully twisted off. This is best done over the food with which the drug is to be mixed. The entire contents of the capsule should be emptied onto a spoonful of soft food. The patient should swallow the entire contents of the spoonful of food and topiramate mixture. The patient should not chew the food or drug and should follow the ingestion

of the food/drug mixture with fluids to ensure that the entire contents are swallowed. The mixture should never be stored for use later (58).

### Tiagabine

Tiagabine (Gabatril®) is supplied as 2-mg, 4-mg, 12-mg, 16-mg, and 20-mg tablets. It is sparingly soluble in water. Tiagabine is well absorbed with food, slowing the rate of absorption but not the extent of absorption (59).

### Levetiracetam

Levetiracetam (Keppra®) is manufactured as 250-mg, 500-mg, and 750-mg scored tablets. It is very soluble in water, and a solution dosage form is now approved. It may be given with or without food. Levetiracetam recently became available in an intravenous form. The IV dosage form is supplied in vials of 500 mg/5 mL. The drug should be diluted in 100 mL (100 mg/mL) of either sodium chloride 0.9%, lactated Ringer's injection, or Dextrose 5% injection USP. The recommended administration time for IV levetiracetam is 15 minutes (60).

### Oxcarbazepine

Oxcarbazepine (Trileptal®) is completely absorbed and rapidly metabolized to its 10-monohydroxy derivative (MHD), which is the pharmacologically active component. Oxcarbazepine is available as 150-mg, 300-mg, and 600-mg tablets and as a 300 mg/5 mL oral suspension. The tablets and the suspension are considered to have the same bioavailability. After a single-dose administration of oxcarbazepine tablets to healthy male volunteers under fasted conditions, the median  $T_{max}$  was 4.5 (range 3 to 13) hours. After single-dose administration of oxcarbazepine suspension, the median  $T_{max}$  was 6 hours. A 10-mL dosing syringe and press-in bottle adapter are provided with oxcarbazepine suspension. The suspension should be used within 7 weeks of first opening the bottle (61).

### Zonisamide

Zonisamide (Zonegran®) is supplied as a 100-mg capsule. Zonisamide may be taken with or without food. Although there is no solution or suspension dosage form of zonisamide commercially available, the capsule may be opened and mixed with apple sauce or juice. The solution is stable for two weeks (62).

### Pregabalin

Pregabalin (Lyrica®) is supplied as 25, 50, 75, 100, 150, 200, 225, and 300-mg capsules (63).

## RECTAL ADMINISTRATION OF AEDS

The rectal route of administration is a practical alternative when oral or parenteral routes are not available (19) (Table 38-3). Rectal administration is often useful in the treatment of emergent conditions, such as prolonged seizures, clusters of seizures, or status epilepticus, when access to a vein is delayed or when therapy is started at home. Additionally, rectal administration can substitute for oral administration of maintenance AEDs when the latter route is temporarily unavailable because of upper GI illnesses, dental procedures, abdominal surgery, or transient GI intolerance to medication (64). Occasionally, rectal administration is indicated when psychiatric or mentally handicapped patients refuse or are unable to take their medications. A commercial diazepam rectal formulation is available in the United States, and the parenteral solution can also be administered rectally.

### Clonazepam

The injectable solution of clonazepam has been administered rectally to volunteers and patients (65, 66). Doses in patients have ranged from 0.05 to 0.1 mg/kg, which produce peak serum concentrations 10 to 120 minutes after administration of the dose. There is no information on the extent of absorption.

### Carbamazepine

Carbamazepine has been given rectally as a suspension, a suppository, and a viscous gel solution (37, 67, 68). The commercially available suspension, when diluted and given rectally, is bioequivalent to the tablet given orally, but the peak concentration occurs later than when taken by mouth (37). The suspension is hypertonic, causing a strong urge to defecate. An extemporaneously prepared

**TABLE 38-3**  
*Antiepileptic Drugs Available for Rectal Administration*

TREATMENT	DOSAGE	DRUG USEFULNESS (MG/KG/DOSE)	PREPARATION	PHARMACOKINETICS	COMMENTS
Carbamazepine	Maintenance	Same as oral	Oral suspension (dilute with equal volume of water) Suppository gel (CBZ powder dissolved in 20% alcohol and methyl hydroxy cellulose)	Peak concentration 4–8 h; 80% absorbed	Definite cathartic effect
Clonazepam	?Acute	0.02–0.1 mg	Parenteral solution	Peak concentration 0.1–2 h	Onset may be too slow for acute use
Diazepam	Acute	0.2–0.5 mg	Parenteral solution	Effect in 2–10 min; peak concentration 2–30 min	Well tolerated; nordiazepam accumulates with repeated doses
Lorazepam	Acute	0.05–0.1 mg	Parenteral solution	Peak concentration 0.5–2 h	Well tolerated
Paraldehyde	Acute	0.3 mL 5 – 25 mg	Oral solution (dilute with equal volume of mineral oil)	Effect in 20 min, peak concentration 2.5 h	Moderate cathartic effect; use glass syringe
Valproic acid	Acute	Same as oral	Oral solution (dilute with equal volume of water)	Peak concentration 1–3 h	Definite cathartic effect
	Maintenance		VPA liquid from capsule mixed into Supocire C lipid base	Peak concentration 2–4 h; 80% absorbed	Well tolerated

suppository has been evaluated in both healthy subjects and patients (67). It was more consistently absorbed than the commercial tablet, with a mean bioavailability of 67 percent and a  $T_{max}$  of 12 hours. A viscous gel containing 200 mg of carbamazepine and 250 mg of methylhydroxycellulose dissolved in 5 mL of 20% alcohol was administered in a single patient and produced therapeutic serum concentrations (44). Rectal carbamazepine is absorbed too slowly to be useful in treating status epilepticus, but it may be tried as temporary replacement therapy when the oral route is not available.

### Diazepam

Diazepam has been given rectally as a solution or gel and a suppository. Rectal administration of diazepam solutions in children results in rapid and complete absorption, with peak concentrations attained within 5 to 15 minutes after administration (69–71) (Figure 38-7). Given the time needed to establish an IV line, the rectal administration of diazepam solution or gel is a practical alternative to IV diazepam in the acute management of severe seizures (72, 73). A double-blind, placebo-controlled trial demonstrated that a rectal diazepam gel (Diastat®) administered by parents or other caregivers was highly effective in interrupting clusters of seizures and reducing subsequent emergent care (74). Another study has shown that home use of a rectally administered diazepam solution was safe and effective in controlling prolonged seizures and preventing febrile convulsions (75). Rectal diazepam has been shown to reduce health care costs, to

FIGURE 38-7

Plasma concentrations of diazepam following administration in different dosage forms. Reproduced from (30) by permission.

reduce caregiver burden, and to reduce parental stress. The most common side effect is somnolence and drowsiness. Suppositories are commercially available in some countries other than the United States, but they are not recommended because absorption is slow and erratic.

### Felbamate

In a single case study, felbamate (FBM) was poorly absorbed rectally. The oral suspension was diluted 1:1 with saline and rectally administered to temporarily replace the oral dosing regimen in a 2-year old child for 4 days (76). FBM concentrations fell throughout rectal administration, indicating little to no absorption. FBM is a lipid-soluble, nonionized medication, making it unclear why it is so poorly absorbed.

### Gabapentin

A report involving two children found that the bioavailability of a gabapentin solution given rectally ranged from 17%–29% (77). Therefore, it should not be administered rectally.

### Lamotrigine

Two studies have assessed the bioavailability of lamotrigine compressed and chewable/dispersible tablets given rectally (78, 79). The tablets were crushed and suspended in. The bioavailability of these suspensions given rectally was compared to the bioavailability of the corresponding tablets given orally. These studies demonstrated that lamotrigine is absorbed rectally but that the bioavailability is less. The bioavailability of the suspension from the compressed tablet was  $0.63 \pm 0.33$  of that of the same tablet given orally, and the bioavailability was  $0.52 \pm 0.23$  of the oral value for the chewable/dispersible tablet.

### Lorazepam

The commercially available parenteral formulation of lorazepam has been given rectally to volunteers and patients (80, 81). Doses of 0.05 mg/kg stopped seizures in eight children. The bioavailability of rectally administered lorazepam was assessed in six volunteers who were given 2 mg of the parenteral solution. The  $T_{max}$  was 67 minutes, and the fraction absorbed averaged 86% with a range of 51% to 118%. The slow absorption of the parenteral solution limits the usefulness of rectal lorazepam for treatment of emergent conditions. Diazepam is absorbed more rapidly and is preferred for rectal administration.

### Midazolam

Midazolam is absorbed rapidly— $T_{max}$  appears to be 10 to 15 minutes—but its bioavailability is erratic and low,

10% to 20%, which makes it difficult to administer an effective dose (82).

### Oxcarbazepine

Clemens et al performed a study in 10 healthy volunteers to characterize the bioavailability of rectally administered oxcarbazepine suspension (300 mg/5 mL) diluted 50% with water. Mean relative bioavailability calculated from plasma AUCs was 8.3% (SD 5.5%) for monohydroxy derivative (MHD) and 10.8% (SD 7.3%) for OXC. The  $C_{max}$  and AUC differed significantly between routes for both MHD and OXC ( $P < 0.01$ ). The total amount of MHD excreted in the urine following rectal administration was  $10 \pm 5\%$  of the amount excreted following oral administration. Oral absorption was consistent with previous studies. The most common side effects were headache and fatigue with no discernable difference between routes. MHD bioavailability following rectal administration of OXC suspension is significantly less than after oral administration, most likely because of OXC's poor water solubility. It is unlikely that adequate MHD concentrations can be reached by rectal administration of diluted OXC suspension (83).

### Paraldehyde

Rectally administered paraldehyde has been widely used to control severe seizures, particularly in children (84, 85). However, information on the efficacy, toxicity, and pharmacokinetics is limited. Rectal bioavailability is 75% to 90% versus 90% to 100% for the oral route. Time to peak concentrations after rectal administration is 2.5 hours versus 0.5 hours for oral administration. Paraldehyde should be diluted with an equal volume of olive oil or vegetable oil to reduce mucosal irritation.

### Phenobarbital

There is no commercially available rectal dosage form for phenobarbital. Graves and coworkers gave seven volunteers phenobarbital sodium parenteral solution rectally and intramuscularly (86). After rectal administration absorption was 90% complete, with a time to peak concentration of 4.4 hours versus 2.1 hours for the IM injection. Suppositories containing phenobarbital sodium are more rapidly absorbed than phenobarbital acid given either orally or intramuscularly (87, 88).

### Phenytoin

Occasionally, there arises a need to administer phenytoin rectally, although no commercial rectal dosage form is available. Several studies of investigational suppository formulations have failed to demonstrate absorption.

Rectal administration of phenytoin sodium parenteral solution in dogs produced low but measurable serum concentrations, but absorption was slow (89). Rectal administration of phenytoin is not recommended.

### Valproic Acid

Valproic acid absorption has been studied after rectal administration of diluted syrup and suppositories. Rectal absorption of the commercially available syrup is complete, with peak concentrations occurring approximately 2 hours after a dose (90–92). High osmolality necessitates 1:1 dilution of the syrup to minimize catharsis. The syrup has been used to treat status epilepticus when other therapy is ineffective. Various suppository formulations are absorbed well, albeit more slowly than the syrup, with time to peak concentration occurring in 2 to 4 hours (93, 94).

### Topiramate

Topiramate is also readily absorbed following rectal administration. In a study of twelve healthy subjects who received either 100 or 200 mg of topiramate orally and a 200 mg dose of topiramate given rectally, the relative bioavailability ( $F_{rel}$ ), which was determined by calculating the dose-normalized areas under the concentration time curves, was  $0.72 \pm 0.18$  h/L for the rectal dose and  $0.76 \pm 0.20$  h/L for the oral dose. The relative bioavailability for topiramate administered rectally was  $0.95 \pm 0.17$  with a range of  $0.68 \pm 1.2$  (95).

### Zonisamide

Nagatomi et al investigated two zonisamide suppositories compared with IV and oral dosing in rats (96). The bioavailability of the hydrophilic base was 96%, and that from the lipophilic base was 108%. The  $C_{max}$  following both rectal suppositories was significantly greater than an equal oral dose, and  $T_{max}$  occurred faster after the hydrophilic-based suppository (2 hrs) than after either the lipophilic-based or the oral dose (4 hrs).

## STUDIES OF OTHER ADMINISTRATION ROUTES

### Buccal/Sublingual

Buccal/sublingual administration of diazepam and lorazepam has been recommended by some clinicians as a part of routine clinical practice. However, there are no studies documenting their efficacy. Limited data exist for pharmacokinetic and efficacy for this route of administration.

Buccal administration of midazolam was studied in 10 healthy adults in a study in which 2 mL of the

intravenous preparation of midazolam 5 mg/mL flavored with peppermint was held in the mouth for 5 minutes, then spat out. The researchers found that changes on electroencephalography were observed within 5 to 10 minutes of administration of the drug, suggesting rapid absorption and onset of effect (97). In a randomized controlled trial conducted in a hospital emergency department, the safety and efficacy of buccal midazolam were compared with those of rectal diazepam (98). The dose used for each drug was determined by the age of the child, with a target dose of about 0.5 mg/kg (from 2.5 mg for children aged 6 to 12 months; 4 mg for those 1 to 4 years; 7.5 mg for those 5 to 9 years; and 10 mg for those 10 years or older). A total of 219 episodes of acute seizures in 177 children were treated. Therapeutic success was defined as cessation of seizure within 10 minutes of drug administration without respiratory depression and without seizure recurrence within 1 hour. A positive outcome was achieved in 56% of patients treated with buccal midazolam, compared with 27% of patients treated with rectal diazepam ( $P < 0.001$ ; odds ratio [OR] 4.1, 95% CI 2.2–7.6). Median time to seizure termination was 8 minutes (range: 5–20 minutes) for buccal midazolam and 15 minutes (range: 5–31 minutes) for rectal diazepam ( $P = 0.01$ ; hazard ratio [HR] 0.7; 95% CI 0.5–0.9).

Greenblatt et al compared the pharmacokinetics of sublingual lorazepam with IV, IM, and oral LZP (99). Ten healthy volunteers randomly received 2 mg of LZP in the following five formulations: IV injection, IM injection, oral tablet, sublingual administration of the oral tablet, and sublingual administration of a specially formulated tablet. Peak plasma concentrations, time to peak concentrations, elimination half life, and relative bioavailability were not significantly different among the formulations. Peak concentrations were highest for the IM route, followed by oral and sublingual; time to peak concentrations was most rapid for the IM route, followed by sublingual and oral. Mean relative bioavailabilities were high for all routes: IM (95.9%), oral (99.8%), sublingual of oral tablet (94.1%) and sublingual of special tablet (98.2%).

It should be noted, however, that the efficacy, safety, duration of effect, and ease of buccal/sublingual administration by nonmedical caregivers have not been evaluated in settings outside of hospitals.

### INTRANASAL

Several benzodiazepines possess the physical, chemical, and pharmacokinetic properties required of effective nasal therapies. Among the benzodiazepines considered for intranasal administration, midazolam has been most extensively studied. In one randomized, open-label trial involving 47 children with prolonged (>10 minutes) febrile seizures, the safety and efficacy of intranasal

midazolam (0.2 mg/kg) were compared with those of intravenous diazepam (0.3 mg/kg) administered over 5 minutes (100). Intranasal midazolam was as safe and effective as intravenous diazepam and resulted in earlier cessation of seizures as a result of rapid administration.

However, the role of intranasal midazolam in treating seizure emergencies remains to be established. There are no adequately controlled trials demonstrating the safety and efficacy of intranasal midazolam for out-of-hospital treatment. Moreover, the short elimination half-life of midazolam—especially in patients taking enzyme-inducing drugs—raises concern as to whether its duration of effect is satisfactory in out-of-hospital settings.

Intranasal lorazepam has also been studied (101). Intranasal LZP was absorbed with a mean percent bioavailability of  $77.7 \pm 11.1\%$ . A double-peak concentration-time curve was observed, indicating possible secondary oral absorption. The time to peak concentration was variable, ranging from 0.25–2 hours. Lorazepam's relatively limited lipid solubility as compared with that of midazolam or diazepam results in a slower rate of absorption and onset of action.

Diazepam has a lipid solubility and potency comparable with those of midazolam and a much longer elimination half-life, properties that make it a good candidate for intranasal administration. The bioavailability of a novel intranasal diazepam formulation has been compared with that of intranasal midazolam in healthy volunteers ( $n = 4$ ) (102). Both midazolam and diazepam were rapidly absorbed, but diazepam's absorption was more extensive and its half-life longer than that of midazolam. Compared with rectally administered diazepam, the nasal diazepam formulation is absorbed to the same extent, but appears to be more rapidly absorbed, resulting in attainment of maximum concentrations as much as 30 minutes earlier (103).

### Nasogastric Tubes

A nasogastric (NG) tube offers an alternative route of drug delivery. However, drug may adhere to the tubing, clog the tubing, or not be absorbed. Occlusion of the tube by the drug is also a concern. Tube occlusions may require replacement of the tube, which is both costly and inconvenient for the patient. Recently, it has been demonstrated that sustained-release carbamazepine (Carbatrol®) can be opened, mixed with 0.9% sodium chloride or apple juice as diluents, and reliably delivered through an NG tube or feeding tube 12 French or greater in size (104, 105). Topiramate has also been reported to be effective in patients with status epilepticus when given through an NG tube (106).

However, absorption from nasogastric tubes is not always comparable to orally administered formulations. When patients who are receiving tube feedings are

switched from IV phenytoin (fosphenytoin) to oral phenytoin administered via a nasogastric tube, there appears to be decreased absorption of the oral formulation. This seems to occur regardless of whether the suspension or the oral capsule dosage form is used. Although the mechanism has not been clearly documented, it has been postulated that phenytoin may bind to proteins in the enteral feeding. Also, the enteral feeding may increase the GI motility, which may decrease the absorption (107). Sometimes very large oral doses may need to be given to maintain the desired serum concentrations in patients receiving phenytoin and enteral feedings via a nasogastric tube. Some practitioners try to stop the enteral feedings for two hours before and two hours after the dose of phenytoin. IM fosphenytoin would be an alternative (3).

### SUMMARY

The selection of AED dosage forms is very important in pediatric epilepsy. Patients may be unwilling or unable to take oral solid dosage forms. Therefore, the availability of alternative oral dosage forms such as suspensions, solutions, and sprinkles is important. Patients who experience concentration-dependent side effects or breakthrough seizures may realize improved control by switching to an alternative dosage form. For example, a controlled-release formulation will provide lower peaks and higher troughs, facilitating better seizure control with less toxicity.

Although it has been the practice to crush oral solids and mix the contents with food, this is not always desirable. Some products, such as Phenytek<sup>®</sup>, Depakote-ER, Depakote<sup>®</sup>, and Tegretol-XR<sup>®</sup>, lose the properties they were designed to provide if the structure of the preparation is disrupted. In some cases, the rate or extent of absorption may be altered when the drug is given with food. It also has been a custom to compound pediatric dosage forms extemporaneously. This is an important way to provide drug in a form that young children can take.

**TABLE 38-4**  
*Medication Administration Guidelines for Infants*

Use a calibrated dropper or oral syringe.  
Support the infant's head while holding the infant in lap.  
Give small amounts of medication to prevent choking.  
If desired, crush non-enteric-coated tablets to a powder and sprinkle on small amounts of food.  
Provide physical comforting to calm the infant while administering medications.

**TABLE 38-5**  
*Medication Administration Guidelines for Toddlers*

Allow child to choose a position in which to take medications.  
Disguise the taste with a small volume of flavored drink or food. Rinse mouth with flavored drink to remove aftertaste.  
Use simple commands in the toddler's jargon to obtain cooperation. Allow the toddler to choose which medications to take first. Allow toddler to become familiar with the oral dosing device.

However, clinicians should be cautious about extemporaneous compounding of pediatric formulations unless they can determine the amount of drug in the formulation, the stability of the product, and the bioavailability. This requires an assay for the compounded product and an assay of the drug in blood. In addition, with compounded drugs, someone should taste the preparation before it is given to the patient. For example, gabapentin has a very bitter taste when it is put into solution. Therefore, when a drug is compounded for pediatric delivery, the new formulation should be tested to ensure that it is being delivered properly. Specialized dosage forms generally are more expensive.

Caregivers should be thoroughly educated in drug administration techniques for children. When carefully instructed, caregivers can properly administer medications (108). Drug administration techniques are summarized in Tables 38-4, 38-5, and 38-6. When doses are given as "teaspoonfuls," caregivers should have a calibrated device for measuring the dose rather than using a common utensil. The volume of "standard" teaspoons varies up to fourfold. Drugs given rectally, such as diazepam, require special caregiver education.

Clinical assessment, selection of a drug, and determination of the dose require special attention in the

**TABLE 38-6**  
*Medication Administration Guidelines for Preschool Children*

Place tablet or capsule near back of tongue and provide water or a flavored liquid to aid in swallowing.  
Do not use chewable tablets if the child's teeth are loose. Use a straw to administer medications that may stain teeth.  
Use a rinse with a flavored drink to minimize aftertaste.  
Allow child to help make decisions about dosage forms, place of administration, which medication to take first, and the type of flavored drink to use.

pediatric patient, as does the selection of the appropriate formulation and dosage form. This last step in the therapeutic plan plays a pivotal role in the ultimate success of therapy. The objective is to ensure the regular and consistent delivery of drug to the brain. When conventional oral tablets and capsules are inappropriate

or impractical, alternate formulations, dosage forms, and routes of administration should be considered. The clinician also must assess the ability of the caregiver to correctly prepare, measure, and administer medications and instruct caregivers about proper drug administration.

## Principles of Drug Interactions: Implications for Treatment with Antiepileptic Drugs

*Barry E. Gidal*

**P**armacokinetic interactions, sometimes leading to adverse clinical situations, have long been recognized as an occasionally unavoidable facet of antiepileptic drug (AED) treatment (1, 2). Since the mid-1990s, a number of newer AEDs have entered the marketplace, both in the United States and globally. One general advantage of these newer medications is an improved pharmacokinetic profile, including a reduced potential for participating in drug-drug interactions, as compared to the older medications.

The aim of this chapter is to summarize in-vitro and in-vivo data regarding drug interactions with both the newer as well as the older, traditional AEDs in terms of absorption, distribution, protein binding, and hepatic induction and inhibition. Clinical implications of these interactions will also be discussed.

### PATIENTS AT RISK

Patients perhaps at the greatest risk for drug interactions are usually those who are the most severely ill. This includes patients in the intensive care unit, geriatric patients, premature neonates, and young children. Drug

interactions may be a significant contributor to both patient morbidity and mortality (3, 4).

Clinicians should recognize that as a group, patients with epilepsy, including both children and adults, tend to receive more medications than does the general population. As the number of concomitant medications increases, so does the likelihood of drug interactions. The patients with the most refractory epilepsy are consequently more likely to encounter problems with drug interactions related to concomitant AED therapy than their controlled counterparts. Although, historically, more attention has been paid to AED-to-AED interactions, there has been increasing attention to the potential for certain AEDs to interact (perhaps adversely) with other concomitant medications that patients may be receiving.

### MECHANISMS FOR COMMON DRUG INTERACTIONS

#### Oral Absorption of Drugs

Most AEDs are well absorbed following oral administration. However, absorption of some compounds can be altered by drug-drug or drug-food interactions. These

interactions can affect maximum plasma concentration, time to reach maximum concentration, and even overall extent of absorption. Among the older, traditional AEDs, oral absorption of phenytoin appears to be the most problematic. Of particular concern is the issue of concomitant administration of an AED with an enteral nutrition supplement. Concomitant administration of phenytoin with these nutritional formulations can result in marked reductions in oral bioavailability (4–6). Because of this interaction, it is commonly suggested that the administration of phenytoin and enteral feedings be separated by at least 2 hours. Unfortunately, this may not be practical, particularly for patients requiring continuous feedings. Alternatively, clinicians can overcome this interaction by simply increasing the phenytoin dosage and using serum drug concentrations as a guide. This approach is also problematic. If for example, enteral feedings are discontinued, or interrupted for a significant period of times, and phenytoin doses are not readjusted downward, there will likely be a marked rise in phenytoin concentrations, potentially leading to drug intoxication. If possible, therefore, this drug-nutrient interaction should be avoided. Concomitant ingestion of food may also delay the rate of absorption of older agents such as valproic acid but is unlikely to impact overall absorption (7).

Generally speaking, oral absorption interactions with the newer-generation AEDs are unlikely to be of clinical significance in most patients. Unlike older, traditional compounds such as phenytoin or carbamazepine, the newer-generation AEDs tend to be quite water soluble and are rapidly and completely absorbed. Indeed, in contrast to the problems described for phenytoin, absorption of newer-generation agents such as gabapentin, lamotrigine, and levetiracetam does not appear to be impaired when coadministered with enteral nutritional supplements (8–9).

When topiramate is administered with food, the rate of absorption is decreased, delaying time to maximum concentration by approximately 2 hours and decreasing mean maximum concentration by approximately 10%, with no significant effect on overall extent of absorption. Conversely, when oxcarbazepine is given with food, the mean maximum serum concentrations of the active monohydroxy metabolite is increased by 23% (10–11). Whether this is clinically meaningful is unclear.

Coadministration of levetiracetam with food delays the time to peak concentration by approximately 1.5 hours and decreases the maximum concentration by 20%; however, the extent of absorption is not affected. Mixing with enteral feeding formulas does not appear to result in significant impairment of absorption, over and beyond that seen with concomitant administration with food (12).

### Role of Drug Transporter Proteins

ATP-dependent drug transporters, including members of the multidrug resistance protein (MRP) family and P-glycoprotein (Pgp), have been implicated as a major limiting factor in drug pharmacokinetics (13). Pgp and MRP are located on the apical side of capillary endothelial cells and are thought to extrude drug molecules back into blood (or intestine) from cells. These efflux pumps appear to act in conjunction with drug-metabolizing enzymes such as CYP 3A4 to limit drug access to both the systemic circulation and various cellular compartments (14). This may be clinically important, in that several of the older AEDs, such as carbamazepine, display the ability to induce the activity of CYP 3A4 and Pgp (15). At the intestinal level, induction of both CYP 3A4 and these efflux pumps would serve to significantly reduce the oral bioavailability of a number of medications. While most attention has been focused on the role of these transporters in modulating oral drug absorption, it has also become clear that these transporter proteins are localized in a variety of tissues including the liver, kidney, blood-brain barrier, and placenta. In addition to potentially limiting oral drug absorption or blood-brain barrier penetration, these drug efflux pumps may be important in protecting the fetus from drug/chemical exposure. Several studies have now demonstrated that Pgp is expressed in the trophoblast layer of the placenta and may provide an important mechanism of protection to the fetus from maternal drug exposure (16).

### IS PROTEIN BINDING RELEVANT?

In most cases, changes in protein binding are not clinically significant, but in some situations these alterations, as a result of either changes in protein concentration (e.g., hypoalbuminemia) or protein binding displacement, may lead to misinterpretation of serum drug concentrations (17).

Protein binding displacement interactions can occur when two highly protein-bound (>90%) agents are administered together and compete for a limited number of binding sites. Typically, the drug with the greater affinity for the binding site displaces the competing agent, increasing the unbound fraction of the displaced drug. It is the unbound drug concentration that is responsible for the drug's pharmacologic activity. Unbound drug concentrations are dependent on the drug dose and drug-metabolizing activity of enzymes (intrinsic clearance). Unbound drug concentrations may rise initially following the concomitant administration of two competing drugs but should return to preinteraction values fairly quickly. In other words, these interactions are transient. Total concentrations of drug, however, will be lower than

expected. If serum concentrations are being monitored, this may lead to misinterpretation.

Among the AEDs, the potential for protein-binding interactions is greatest for phenytoin and valproic acid. Both phenytoin and valproic acid are extensively bound to plasma proteins (>90%). Valproic acid is also an inhibitor of cytochrome P450 2C19, one of the enzymes responsible for phenytoin metabolism. When these two agents are coadministered, unbound phenytoin concentrations are higher than typically expected and total (bound + unbound) concentrations are lower (16). When using this combination, it may be prudent to monitor unbound phenytoin concentrations as well as total.

With the exception of tiagabine (96% protein bound), an advantage of the newer-generation AEDs is that they are not extensively protein bound, and therefore these types of pharmacokinetic interactions are not likely.

### Metabolism: Implications of Enzyme Induction and Inhibition

Most clinically relevant drug interactions result from alterations in drug metabolism, either in the liver or in the gut. Drug-metabolizing enzyme induction can result in an increased rate of metabolism of the affected drug, leading to both decreased oral bioavailability and increased systemic clearance of extensively metabolized concomitant medications. The clinical result therefore would be potentially subtherapeutic serum concentrations of that drug. Conversely, a number of drugs (including several AEDs) have been shown to be inhibitors of various drug-metabolizing enzymes, and concomitant administration of these agents can slow the rate of metabolism of the affected drug and cause increased serum levels of drug, leading to toxicity.

The metabolic pathways of AEDs can vary; however, most metabolism is achieved via oxidative metabolism and/or glucuronidation (18–20). Oxidative metabolism is accomplished via the cytochrome P450 (CYP) isoenzyme system. This system consists of three main families of enzymes: CYP1, CYP2, and CYP3. There are seven primary isoenzymes that are involved in the metabolism of most drugs: CYP1A2, CYP2A6, CYP2C9, CYP2C19, CYP2D6, CYP2E1, and CYP3A4. Of these, the ones commonly involved with metabolism of AEDs include CYP2C9, CYP2C19, and CYP3A4 (21). Another important metabolic pathway for several AEDs, including valproic acid, lorazepam, and lamotrigine, is conjugation via the enzyme uridine diphosphate glucuronosyltransferase (UGT).

Although they do not necessarily contraindicate AED therapy, these pharmacokinetic interactions can clearly complicate therapy in individuals receiving multiple AEDs. In some cases, it may be difficult to distinguish whether a change in a person's clinical state (change in seizure frequency or appearance of toxicity) is due to an additive pharmacologic effect of the added drug or simply due to a change in serum concentration in the original AED. One approach to rational polytherapy would be to combine agents that do not interact with each other. In this way, the confounders of changes in drug disposition can be excluded from the evaluation of therapeutic response to combined AED treatment. Interactions between AEDs and hepatic enzymes are summarized in Table 39-1 and discussed in the following paragraphs.

**Hepatic Enzyme Induction.** Compounds that are hepatic inducers increase the synthesis of enzyme protein and thus increase the capacity for drug metabolism. Induction of hepatic enzymes occurs over a gradual period of days to

**TABLE 39-1**  
*Effect of Antiepileptic Drugs on CYP Isoenzymes or Other Enzyme Systems*

DRUG	EFFECT ON METABOLISM	ENZYMES
Phenobarbital, carbamazepine, phenytoin	Inducers	Broad CYP, UGT inducers
Valproic acid	Inhibitor	CYP 2C19, UGT, Epoxide hydrolase
Gabapentin, pregabalin	No effect	
Lamotrigine	Weak inducer	UGT
Levetiracetam	No effect	
Oxcarbazepine	Inducer (modest)	CYP3A4
Tiagabine	No effect	—
Topiramate	Inhibitor (modest)	CYP2C19
	Inducer (modest)	CYP 3A4
Vigabatrin	None	
Zonisamide	No effect	

weeks and is a reversible process. Addition of an inducer will cause a lowering of serum concentrations of the target drug, conceivably resulting in inadequate therapeutic response. Conversely, removal of an enzyme inducer will cause a rise in the levels of the target drug, potentially causing toxicity.

Among the older-generation AEDs, carbamazepine, phenytoin, and the barbiturates phenobarbital and primidone are inducers of both the cytochrome P450 (CYP) and UGT enzyme systems (18). Combining these agents with other AEDs that are metabolized by either of these enzyme systems can result in markedly enhanced systemic clearance, and reduced serum concentrations of the affected drug, requiring higher doses in order to maintain comparable (as compared to monotherapy) steady-state serum concentrations. An example of this sort of interaction would be the combination of phenytoin and lamotrigine.

Lamotrigine is extensively (>90%) metabolized hepatically by N-glucuronidation via UGT 1A3 and UGT 1A4. Lamotrigine does not appear to significantly alter concentrations of carbamazepine or carbamazepine epoxide (21, 22) nor any of the other AEDs. However, the half-life of lamotrigine is reduced from 24 hours to 15 hours when administered with enzyme-inducing drugs as just described. Following the withdrawal of the enzyme inducers carbamazepine and phenytoin, lamotrigine plasma concentrations have been observed to increase by 50% and 100%, respectively (23).

Levetiracetam shows limited metabolism in humans, with 66% of the dose renally excreted unchanged. Its major metabolic pathway is via hydrolysis of the acetamide group to yield a carboxylic derivative, which is mainly recovered in the urine. Levetiracetam is not significantly metabolized by CYPs or UGTs and appears to be devoid of pharmacokinetic drug interactions (24, 25). Similarly, the drugs gabapentin and pregabalin appear to be devoid of enzyme-inducing (or inhibition) properties.

Oxcarbazepine is converted to 10-hydroxycarbamazepine (OHCZ), the metabolite primarily responsible for pharmacologic activity. This active metabolite is mostly excreted by direct conjugation to glucuronic acid. Oxcarbazepine does not seem to be a broad-spectrum enzyme inducer, although it does possess modest, specific induction potential toward the CYP3A subfamily, as evidenced by the increased metabolism of estrogens and dihydropyridine calcium channel antagonists (1, 2). Clinicians should be aware that this drug does indeed have modest potential for causing enzyme induction interactions, but that this potential may vary among different patients.

Topiramate is approximately 60% excreted unchanged in the urine. It is also metabolized by hydroxylation and hydrolysis. Two of its metabolites are conjugated as glucuronides. While not considered a potent

enzyme inducer, topiramate can increase clearance of valproate by approximately 13% and may lower oral contraceptive serum concentrations (26, 27). Whether these changes in valproic serum concentration are clinically meaningful is unclear. Topiramate metabolic clearance can be increased when it is administered with enzyme-inducing AEDs, thereby reducing half-life and lowering serum concentrations by up to 40%.

Zonisamide is a synthetic 1,2-benzisoxazole derivative that is metabolized in large part by reduction and conjugation reactions. Oxidative reactions involving CYP3A4 and CYP2D6 are also involved. Zonisamide elimination can be altered by other drugs. Specifically, enzyme-inducing drugs such as carbamazepine and phenytoin can significantly increase the clearance of this drug, effectively reducing the half-life of zonisamide by about half.

*Hepatic Inhibition.* Hepatic enzyme inhibition can occur when two drugs compete for the same enzyme site, reducing the metabolism of the target drug. A resultant increase in the object drug can occur if a substantial portion of the target drug is prevented from occupying the enzyme site. Inhibition is usually a rapid process that is dose/concentration dependent. Addition of an enzyme inhibitor may cause a very rapid rise in serum concentrations of the target drug, potentially leading to acute toxicity (18).

In contrast to enzyme induction, inhibition of selected CYP and/or UGT enzymes can be caused by several AEDs of both the older and newer generations. These combinations may result in unexpectedly high serum concentrations of the affected AED. An example is the interaction of valproic acid and lamotrigine. Lamotrigine's half-life is increased to approximately 59–70 hours when it is coadministered with valproate, resulting from valproate's inhibition of glucuronidation. Inhibition of lamotrigine clearance can occur at valproate doses as low as 125–250 mg/day and becomes maximal at dosages approaching 500 mg/day (28). The clinical implication is that lamotrigine dose and dose escalation will need to be substantially reduced in order to reduce the potential for adverse effects (including perhaps severe rash).

Topiramate may decrease the clearance of phenytoin, suggesting inhibition of CYP2C19. Topiramate has been shown to increase phenytoin serum concentration in some patients. While this interaction is not clinically meaningful in most patients, given the non-linear pharmacokinetics of phenytoin, the potential does exist for this interaction to result in phenytoin intoxication.

A significant advancement of oxcarbazepine over carbamazepine is its lack of *susceptibility* to inhibitory interactions. Consistent with its differing metabolism (as compared to carbamazepine), oxcarbazepine's pharmacokinetics are not altered by erythromycin. Oxcarbazepine

**TABLE 39-2**  
**Interactions Between AEDs and Non-AED Medications**

NON-AED MEDICATION				
TYPE	DRUG	AED	INTERACTION	
Adrenergic blockers	Alprenolol	PB	PB increases metabolism; dosage of adrenergic blockers may need to be increased.	
Analgesics	Metoprolol Propranolol Acetaminophen	CBZ, LTG, PB, PHT	Patients on enzyme inducers such as CBZ, PHT, and PB may be at greater risk of hepatotoxicity following acetaminophen overdose. Acetaminophen appears to slightly increase the elimination of LTG.	
	Narcotics	CBZ, PB, PHT	Enzyme inducers (CBZ, PHT, PB) increase the toxicity and decrease the efficacy of meperidine by increasing the conversion to normeperidine.	
	Propoxyphene	CBZ	Propoxyphene inhibits CBZ elimination and may lead to CBZ toxicity. Propoxyphene should be avoided if possible.	
	Salicylates	PHT, VPA	High-dose salicylates displace PHT and VPA from protein-binding sites and may decrease VPA elimination.	
Antiarrhythmics	Disopyramide	PB, PHT	PB and PHT may increase hepatic metabolism of disopyramide and require dosage adjustments.	
	Mexiletine	CBZ, PB, PHT	Enzyme inducers can substantially decrease mexiletine serum concentrations.	
	Quinidine	PB, PHT	Enzyme inducers decrease serum concentrations of quinidine.	
Anticoagulants	Warfarin	CBZ, PB, PHT	Inducers increase warfarin metabolism and decrease hypoprothrombinemic effect.	
Antidepressants	Tricyclics	CBZ, PB	Induction of tricyclic metabolism. Dosage may require adjustment.	
Antidiabetic agents	Tolazamide	CBZ, PB, PHT	Enzyme inducers increase elimination and decrease hypoglycemic effects.	
	Tolbutamide Acetohexamide Glibenclamide			
	Antimicrobial agents	Ciprofloxacin	PHT	Ciprofloxacin increases serum PHT concentrations, probably by decreasing phenytoin elimination.
		Erythromycin	CBZ, BZD, VPA	Erythromycin decreases biotransformation and can markedly increase serum concentrations.
Antifungal	Fluconazole	PHT	Fluconazole decreases biotransformation of PHT and can result in marked increase in serum concentrations.	

**TABLE 39-2**  
(Continued)

NON-AED MEDICATION			
TYPE	DRUG	AED	INTERACTION
Antineoplastics		PHT	Cytotoxic agents appear to decrease oral absorption of PHT with marked reductions in serum PHT concentrations.
Antituberculous agents	Isoniazid	CBZ, PHT, VPA	Isoniazid decreases CBZ, PHT, and VPA elimination and may lead to toxicity.
	Rifampin	BZD, PHT, VPA	Rifampin increases elimination; dosage adjustments may be necessary.
Carbonic anhydrase inhibitors	Acetazolamide	TPM	Concomitant use may lead to increased risk of nephrolithiasis.
	Dichlorphenamide Methazolamide		
Corticosteroids	Dexamethasone	CBZ, PB, PHT	Enzyme inducers increase metabolism of steroids and decrease efficacy. Decreased PHT absorption and subsequent decrease in serum concentrations.
	Hydrocortisone		
	Methylprednisolone Prednisone		
Miscellaneous	Cimetidine	CBZ, PHT, BZD, ESM	Cimetidine decreases biotransformation of CBZ and PHT and may lead to toxicity.
	Clozapine	CBZ	May result in increased risk of bone marrow suppression.
	Enteral feedings	PHT	Decreased PHT absorption and marked decreased in serum concentration.
	Nafimidone	CBZ, PHT	May result in CBZ toxicity.
	Ritonavir	BDZ, ESM	Ritonavir decreases biotransformation of BDZ and ESM and may lead to toxicity.
Selective serotonin reuptake inhibitors	Fluoxetine	CBZ	Fluoxetine has been reported to result in CBZ toxicity by inhibiting CYP3A3/4.

BDZ = benzodiazepines; CBZ = carbamazepine; LTG = lamotrigine; PB = phenobarbital; PHT = phenytoin; PRM = primidone; VPA = valproic acid; ESM = ethosuximide; TPM = topiramate; MSM = methsuximide.  
Source: McInnes and Brodie 1988 (39).

is a weak inhibitor of CYP2C19, however, and, like topiramate, it may increase the plasma concentrations of phenytoin (1).

Because of their primarily renal clearance, and absence of substantial hepatic metabolism, levetiracetam, gabapentin, and pregabalin are not subject to inhibition. In addition, none of these drugs appears to cause inhibition of metabolism of any other medication.

### Interactions Between AEDs and Other Medications

Traditionally, most attention regarding AED pharmacokinetic interactions has been directed toward interactions between various combinations of AEDs. It is important for the clinician to recognize the potential impact that AEDs may have on concomitant medications that a patient receive. For example, many psychotropic

agents, including tricyclic antidepressants, selective serotonin reuptake inhibitors (SSRIs), and antipsychotic drugs are extensively metabolized by one or more of the CYP isozymes (29). This would imply that higher than expected doses of these drugs may be required in patients receiving enzyme-inducing AEDs such as phenytoin or carbamazepine. Conversely, enzyme-inhibiting drugs such as valproate may inhibit the clearance of certain psychotropic drugs such as amitriptyline, nortriptyline, or paroxetine (1, 2).

For example, AEDs such as carbamazepine and phenytoin have been reported to increase the clearance, and consequently markedly lower the serum concentration, of a number of antipsychotic medications including haloperidol, chlorpromazine, clozapine, risperidone, ziprazidone, and olanzapine (2, 30). Valproate appears to have minimal pharmacokinetic interactions impact on these drugs (31, 32).

Antipsychotic drugs are less likely to *cause* pharmacokinetic interactions with AEDs, although both chlorpromazine and thioridazine have been reported to result in increases in phenytoin serum concentrations. Risperidone has been noted to result in modest decreases in carbamazepine concentrations (33).

Many commonly used antidepressant agents such as tricyclics and SSRIs are also metabolized via the CYP system. Consequently, it would be expected that drugs such as amitriptyline, nortriptyline, imipramine, desipramine, clomipramine, protriptyline, doxepin, sertraline, paroxetine, mianserin, citalopram, and nefazodone may display reduced serum concentrations in patients receiving enzyme-inducing AEDs (1, 2, 34, 35). Conversely, comedication with the enzyme inhibitor valproate may cause substantial (50–60%) increases in serum concentrations of drugs such as amitriptyline and nortriptyline.

AED-antidepressant interactions may be bidirectional, and the clinician should recognize that treatment

with certain drugs may result in increased serum concentrations of AEDs, particularly the older, extensively metabolized agents. For example, there are data that suggest that SSRIs such as fluoxetine and sertraline can result in increased phenytoin and carbamazepine serum concentrations.

Examples of other classes of drugs that are extensively metabolized and therefore may be influenced by enzyme-inducing AEDs include stimulants (i.e., methylphenidate), antineoplastics, immunosuppressants, beta receptor antagonists, oral contraceptives, and many antiviral agents such as indinavir, retonavir, and saquinavir (1, 2, 36–38). Table 39-2 provides a representative list of potential AED–non-AED interactions (39).

## SUMMARY

Polypharmacy with multiple concomitant medications is common in patients of all ages who suffer from epilepsy. Clinicians should be aware that many of the older, traditional AEDs such as carbamazepine, phenytoin and the barbiturates have been consistently associated with pharmacokinetic interactions, both with other AEDs, as well as many commonly used medications. In many cases, these interactions may go unrecognized, as routine serum concentration monitoring is not available, or practical in all situations. It would seem prudent therefore for clinicians to monitor clinical response to concomitant medications, and consider potential drug interactions, should sub-optimal patient response (including the appearance of adverse effects) be noted.

Alternatively, clinicians may want to consider using appropriate newer generation AEDs such as that do not seem to interfere, either with drug metabolism, or oral absorption/transport, and thereby avoid these potentially problematic interactions.

## ACTH and Steroids

*Rajesh RamachandranNair*  
*O. Carter Snead, III*

**T**he efficacy of adrenocorticotropin (ACTH) therapy in childhood seizures was first observed by Klein and Livingston in 1950 in a series of children with atypical absence seizures (1). In 1958, Sorel and Dusaucy-Bauloye reported that ACTH was effective in children with infantile spasms (IS). These authors not only reported seizure control in children with IS treated with ACTH but also observed improvements in behavior and electroencephalogram (EEG) (2). Subsequently, a number of studies appeared that reported on the efficacy of corticosteroids in IS and confirmed the utility of ACTH in the treatment of this disorder. Both ACTH and corticosteroids have been used in treating a number of epilepsy syndromes, including Ohtahara syndrome, Lennox-Gastaut syndrome and other myoclonic epilepsies, and Landau-Kleffner syndrome (3). The epilepsy syndromes that respond uniquely to ACTH and corticosteroid therapy have an age-related onset during a critical period of brain development, as well as a characteristic regression or plateau of acquired milestones at seizure onset, and long-term cognitive impairment (4). In addition to beneficial effects on the convulsive state, there are some data to suggest that ACTH, corticosteroids, or both also can improve the short-term developmental trajectory and the long-term prognosis for language and cognitive development in at least some of these patients (5–9).

In this review, we will first discuss the evidence in support of the use of steroids in IS. This will be followed by a review of possible mechanisms of the putative anticonvulsant effects of ACTH and corticosteroids. This will be followed by a discussion of the use of these compounds in epilepsy syndromes other than IS. Finally, we will review the therapeutic potential of neuroactive steroids in epilepsy.

### INFANTILE SPASMS

In 1841, William West, an English physician, provided the first description of IS in his own 4-month old son (10). Later, the association of IS with the sequelae of severe mental deficiency emerged. In 1952, Gibbs and Gibbs first described the interictal EEG pattern associated with infantile spasms and termed it hypsarrhythmia. This pattern was unique and described as showing high-voltage, chaotic slowing with multifocal spikes, and marked asynchrony (11). Over the years, the triad of infantile spasms, hypsarrhythmia, and mental retardation became known as West syndrome (12).

After 1958, studies began to appear in the literature reporting the effectiveness of corticosteroids in the treatment of this disorder (12). There is a marked variability of response rates to these therapeutic agents that probably

is related to the small cohorts reported and the paucity of controlled treatment data. Another confound is that the natural history of IS is poorly understood, particularly the phenomenon of spontaneous remission. Moreover, the literature is replete with marked variations in the dosage of ACTH and/or corticosteroids given, and in treatment duration, of both drugs. In most studies, an objective method of documenting spasm cessation has not been used and response to therapy has been defined in a graded manner, although there is no convincing evidence that spasms respond in a graded fashion to any form of therapy. Usually IS respond in an all-or-none fashion to treatment with ACTH and/or corticosteroids. Finally, most studies have been uncontrolled, unblinded, and retrospective, complicating the establishment of evidence-based recommendations for optimal treatment (12).

The controversies surrounding the treatment of IS outnumber the areas of agreement and encompass the following questions: Which is the most effective therapy: ACTH or corticosteroid? Are other anticonvulsants such as vigabatrin, valproic acid, benzodiazepines, topiramate, zonisamide, or pyridoxine effective against infantile spasms? Is there some other treatment regimen with newer antiepileptic drugs that is effective against infantile spasms? What is the impact of treatment with ACTH compared with corticosteroids on long-term outcome in recurrence of spasms, evolution into other forms of intractable epilepsy, and cognitive or behavioral function? Does treatment change the outcome for a patient with preexisting mental retardation and a structurally abnormal brain? What is the optimal dosage of these drugs, and how long should treatment last? Does the ultimate outcome depend on timing of treatment? Does the efficacy of ACTH depend on the formulation (natural vs. synthetic, sustained vs. short-acting)?

Some of these questions were addressed in a recently published American Academy of Neurology (AAN)/Child Neurology Society (CNS) Practice Parameter on the treatment of infantile spasms (13). In the following few paragraphs we will discuss the key issues addressed by this practice parameter. Important studies published subsequent to the practice parameter also will be discussed in the relevant sections.

### Summary of the AAN/CNS Practice Parameter on the Treatment of Infantile Spasms

Three major questions were addressed in the practice parameter.

1. What are the most effective therapies for infantile spasms, as determined by short-term outcome measures, including complete cessation of spasms, resolution of hypsarrhythmia, and likelihood of relapse following initial response?

2. How safe are currently used treatments?
3. Does successful treatment of infantile spasms lead to long-term improvement of neurodevelopmental outcome or a decreased incidence of epilepsy?

Articles included for critical analysis pursuant to answering these questions and formulating treatment recommendations for infantile spasms had the following inclusion criteria (14–27):

1. A clearly stated diagnosis of infantile spasms
2. An EEG demonstrating hypsarrhythmia or modified hypsarrhythmia
3. Age of 1 month to 3 years.

Infantile spasms were classified as either symptomatic or cryptogenic as defined by the International League Against Epilepsy (ILAE).

Outcome measures included short- and long-term measures. Short-term outcome measures were defined as the following:

1. Complete cessation of spasms
2. Resolution of hypsarrhythmia and, where documented, normalization of EEG
3. Relapse rate

In studies with a mean follow-up of >2 years, the following were considered long-term outcome measures:

1. Nonepileptiform EEG
2. Absence of seizures
3. Normal development

A four tiered classification scheme for diagnostic evidence approved by the Quality Standards Subcommittee was utilized as part of the assessment. This schema is outlined in Table 40-1. Depending on the strength of the evidence under this classification system, specific recommendations were made. The strength of these recommendations is shown in Table 40-2.

Based on this critical analysis it was concluded in the practice parameter that ACTH was probably effective in the short-term treatment of IS and in the resolution of hypsarrhythmia (level B). Time to response was usually within 2 weeks, and an “all-or-none” response had been reported in a number of studies. The data were insufficient to recommend optimal dosage and duration of treatment with ACTH for the treatment of IS (level U). As well, data also were insufficient to recommend treatment of IS with oral corticosteroids (level U). ACTH was more effective than oral corticosteroids in causing the cessation of seizures. Side effects reported for ACTH were common and included hypertension, irritability, infection, reversible cerebral shrinkage, and, rarely, death due to sepsis.

**TABLE 40-1**  
*American Academy of Neurology Evidence Classification Scheme for a Therapeutic Article*

Class I	Evidence provided by a prospective, randomized, controlled clinical trial with masked outcome assessment, in a representative population. The following are required: (a) Primary outcome(s) is/are clearly defined; (b) exclusion/inclusion criteria are clearly defined; (c) dropouts and crossovers are accounted for adequately with numbers sufficiently low to have minimal potential for bias; and (d) relevant baseline characteristics are presented and substantially equivalent among treatment groups, or there is appropriate statistical adjustment for differences.
Class II	Evidence provided by a prospective matched-group cohort study in a representative population with masked outcome assessment that meets (a)–(d) as defined for Class I or a randomized controlled trial in a representative population that lacks one criterion of (a)–(d).
Class III	All other controlled trials (including well-defined natural history controls or patients serving as own controls) in a representative population, where outcome assessment is independent of patients' treatment.
Class IV	Evidence from uncontrolled studies, case series, case reports, or expert opinion.

Although vigabatrin (VGB) is not a steroid, its use in infantile spasms is relevant to this review because steroids and vigabatrin are generally considered to be the only two groups of drugs that work in this disorder—an impression borne out by the Practice Parameter (13). In the analysis that led to the AAN/CNS practice parameter, the evidence for the therapeutic efficacy of vigabatrin in IS was weaker than that for ACTH (level C for vigabatrin vs. level B for ACTH). Hence, vigabatrin was found to be possibly effective for the short-term treatment of IS.

As for the efficacy of ACTH in improving the long-term outcomes in terms of seizure freedom and normal development of children with IS, the data were insufficient (28–31) in that regard (Level U, class III and IV evidence). Similarly, there was insufficient evidence to support the thesis that early initiation of treatment with ACTH improves the long-term outcome of children with IS (Level U, class III and IV evidence).

More recently, the United Kingdom Infantile Spasms Study (32) assessed comparative efficacy of vigabatrin and hormonal treatment of IS in a randomized controlled trial. The primary outcome was cessation of spasms on days 13 and 14. Minimum doses were VGB 100 mg/kg per day, oral prednisolone 40 mg per day, or intramuscular tetracosactide depot 0.5 mg (40 IU) on alternate days. Of 208 infants screened and assessed, 107 were randomly assigned to VGB ( $n = 52$ ) or hormonal treatments (prednisolone  $n = 30$ , tetracosactide  $n = 25$ ). Patients with no spasms on days 13 and 14 consisted of: 40 (73%) of 55 infants assigned hormonal treatments (prednisolone 21/30 [70%], tetracosactide 19/25 [76%]) and 28 (54%) of 52 infants assigned VGB (difference 19%, CI 1–36%,  $P = 0.043$ ). Adverse events were reported in 30 (55%) of 55 infants on hormonal treatments and 28 (54%) of 52 infants on VGB. This study concluded that cessation

**TABLE 40-2**  
*American Academy of Neurology System for Translation of Evidence to Recommendations*

TRANSLATION OF EVIDENCE TO RECOMMENDATIONS	RATING OF RECOMMENDATION
Level A rating requires at least one convincing class I study or at least two consistent, convincing class II studies.	A = established as effective, ineffective, or harmful for the given condition in the specified population.
Level B rating requires at least one convincing class II study or at least three consistent class III studies.	B = probably effective, ineffective, or harmful (or probably useful/predictive or not useful/predictive) for the given condition in the specified population.
Level C rating requires at least two convincing and consistent class III studies.	C = possibly effective, ineffective, or harmful (or possibly useful/predictive or not useful/predictive) for the given condition in the specified population.
	U = data inadequate or conflicting. Given current knowledge, treatment is unproven.

of spasms was more likely in infants given hormonal treatments than in those given VGB.

Infants enrolled in the United Kingdom Infantile Spasms Study were followed up until clinical assessment at 12–14 months of age (33). Neurodevelopment was assessed with the Vineland Adaptive Behavior Scales (VABS) at 14 months of age. Of 107 infants enrolled, five died, and 101 survivors reached both follow-up assessments. Absence of spasms at final clinical assessment (hormone 41/55 [75%] vs. vigabatrin 39/51 [76%]) was similar in each treatment group. Mean VABS score did not differ significantly (hormone 78.6 vs. vigabatrin 77.5). In infants with no identified underlying etiology, the mean VABS score was higher in those allocated hormone treatment than in those allocated vigabatrin (88.2 vs. 78.9; difference 9.3, 95% CI 1.2–17.3). This study reported that better initial control of spasms by hormone treatment in those with no identified underlying etiology might lead to improved developmental outcome.

Kivity and coworkers assessed the long-term cognitive and seizure outcomes of 37 patients with cryptogenic infantile spasms (onset, age 3 to 9 months) receiving a standardized treatment regimen of high-dose tetracosactide depot, 1 mg intramuscularly (IM) every 48 hours for 2 weeks, with a subsequent 8- to 10-week slow taper and followed by oral prednisone, 10 mg/day for a month, with a subsequent slow taper for 5 months or until the infant reached the age of 1 year, whichever came later (8). Cognitive outcomes were determined after 6 to 21 years and analyzed in relation to treatment lag and pretreatment regression. Normal cognitive outcome was found in all 22 (100%) patients of the early-treatment group (within 1 month), and in 40% of the late-treatment group (1–6.5 months). Normal cognitive outcome was found in

all 25 (100%) patients who had no or only mild mental deterioration at presentation, including four in the late-treatment group but in only three of the 12 patients who had had marked or severe deterioration before treatment. This study indicated that early treatment of cryptogenic infantile spasms with a high-dose ACTH protocol was associated with favorable long-term cognitive outcomes. Once major developmental regression lasted for a month or more, the prognosis for normal cognitive outcome was poor.

### Practical Considerations Regarding Dosage

Table 40-3 lists the currently available formulations of ACTH. The biologic activity, expressed in international units (IU), permits a comparison of potency in terms of the relative ability of the peptide to stimulate the adrenals, but may not necessarily reflect the ability of the ACTH preparation to affect brain function. The biologic activity of natural ACTH in the brain may differ from that of synthetic ACTH as a result of ACTH fragments and possibly other pituitary hormones with neurobiologic activity in the brain that are present in the pituitary extracts (5). These compounds could enhance the therapeutic efficacy of natural ACTH (34). Any differences in the biologic effects of sustained ACTH levels provided by the depot formulations, as opposed to those of the short-acting preparations, are unknown. Given in high doses, however, long-acting depot preparations are associated with an increased incidence of severe side effects, including death from overwhelming infection.

The most effective dose of ACTH for remission of spasms is controversial. Notably, in comparison to prednisone, no major advantage was demonstrated by

**TABLE 40-3**  
*Available Preparations of ACTH*

Corticotropin (ACTH 1-39): porcine pituitary extract (short-acting)	
Acthar gel 80 IU/mL	100 IU* = 0.72 mg
Acthar lyophilized powder	100 IU* = 0.72 mg
Cosyntropin/Tetracosactrin (ACTH 1-24): synthetic (short-acting)	
Cortrosyn	100 IU* = 1.0 mg
Cosyntropin/Tetracosactrin (ACTH 1-24): synthetic (long-acting)	
Synacthen depot (CIBA)	100 IU* = 2.5 mg
Cortrosyn-Z (Organon)	100 IU* = 2.5 mg

\*Commercial preparations are described in International Units (IU) based on a potency assay in hypophysectomized rats in which depletion of adrenal ascorbic acid is measured after subcutaneous ACTH injection.

low-dose ACTH, whereas high-dose ACTH was reported to be superior (15, 25). High-dose ACTH (60 IU/day or 150 IU/m<sup>2</sup> per day) has been associated with excellent short-term response rates (87–93%) in prospective studies (14, 25). However; in the only randomized, prospective comparison of ACTH, Hrachovy and coworkers found no difference between high dose and low dose (16). A prospective study of synthetic ACTH by Yanagaki and coworkers compared very low-dose ACTH (0.2 IU/kg per day) to low-dose (1 IU/kg per day) and found equivalent efficacy, with response and relapse rates comparable to other studies (18). Heiskala et al. described a protocol that utilized a stepwise increase in dosage, demonstrating that some patients can be controlled on lower doses of carboxymethylcellulose ACTH (3 IU/kg per day) but others required high doses (12 IU/kg per day). Overall, spasms were controlled initially in 65% of patients, but the rate of relapse was high (35).

Some evidence supports a beneficial effect of high-dose ACTH over low-dose ACTH or oral steroids in cognitive outcome. Glaze and coworkers found no difference between low-dose ACTH (20 to 30 IU/day) and prednisone (2 mg/kg per day) with regard to the cognitive outcome (31). However, in a comparison of high-dose ACTH (110 IU/m<sup>2</sup> per day) and steroids, however, Lombroso showed a higher rate of normal cognitive outcome in cryptogenic patients treated with ACTH than in those treated with prednisone alone (55% vs. 17%) (5). Ito and coworkers also showed a positive correlation between dose and developmental outcome comparing different ACTH dosage regimens retrospectively (36).

The optimal ACTH dose may lie between 85 and 250 IU/m<sup>2</sup> per day. Doses of 400 IU/m<sup>2</sup> per day or higher are contraindicated because of a high incidence of life-threatening side effects. The optimal dose of ACTH required to enhance short-term response and long-term cognitive outcome is unknown; however, relatively high doses given early in the disease, accompanied by a second course in the event of relapse, appear warranted. The following high-dose ACTH protocol (21, 25) has been used successfully by us in treating more than 700 children with infantile spasms.

The child is admitted to a day-care unit to initiate ACTH therapy and to teach parents to give the injection, measure urine glucose three times daily with Chemstix, and recognize spasms to keep an accurate seizure calendar. Any diagnostic workup indicated by clinical circumstances is also performed, including screening for occult congenital infections. Before ACTH is started, an endocrine profile, complete blood count, urinalysis, electrolyte panel, baseline renal function, and calcium, phosphorus, and serum glucose levels are obtained. Blood pressure and electrocardiogram are also assessed. The drug is not given if any of these studies show abnormal results. Diagnostic neuroimaging is indicated before initiation of ACTH or

steroids because of the association of ACTH treatment with ventriculomegaly. The initial dose of ACTH is 150 IU/m<sup>2</sup>/day of ACTH gel, 80 IU/mL, intramuscularly in two divided doses for 1 week. In the second week, 75 IU/m<sup>2</sup> per day is given, followed by 75 IU/m<sup>2</sup> every other day in the third week. Over the next 6 weeks, the dose is gradually tapered. The lot number of the ACTH gel is carefully recorded. Usually, a response is seen within the first 7 days; if no response is noted in 2 weeks, the lot is changed.

Blood pressure must be measured daily at home during the first week and three times weekly thereafter. Control of hypertension is attempted with salt restriction and amlodipine therapy rather than discontinuation of ACTH. The patient is monitored in the outpatient clinic weekly for the first month and then biweekly, with appropriate blood work at each visit. Waking and sleeping EEG patterns are obtained 1, 2, and 4 weeks after the start of ACTH to assess treatment response. As the treatment response is usually all or none, positive results are suggested when properly trained parents report no seizures in a child, whose waking and sleeping EEG patterns are normal. If relapse occurs, the dose may be increased to the previously effective dose for 2 weeks and another tapering begun. If seizures continue, the dose may be increased to 150 IU/m<sup>2</sup> per day and the regimen restarted.

If prednisone is chosen because of its oral formulation and lower incidence of serious side effects, the pretreatment laboratory evaluation described earlier is performed. The initial dose is 3 mg/kg per day in four divided doses for 2 weeks, followed by a 10-week taper (25). A multiple-daily-dose regimen is recommended to produce the sustained elevations of plasma cortisol demonstrated in high-dose ACTH therapy.

### Adverse Effects of ACTH and Steroids

ACTH and steroids, particularly at the high doses recommended for infantile spasms, can produce dangerous side effects. These are more frequent and more pronounced with ACTH (37). Cushingoid features and extreme irritability are seen frequently; hypertension is less common but appears to be associated with higher doses. Vigilance is required for signs of sepsis; pneumonia; glucosuria; metabolic abnormalities involving the electrolytes calcium and phosphorus (38–40); and congestive heart failure (41, 42). Cerebral ventriculomegaly, which is not always reversible, can lead to subdural hematoma (43, 44). The cause of the apparent cerebral atrophy is obscure, but its existence emphasizes the importance of diagnostic neuroimaging before initiation of ACTH.

Because hypothalamic-pituitary or adrenocortical dysfunction can result from ACTH therapy, morning levels of cortisol should be monitored during a taper and any medical stress treated with high-dose steroids (45–47).

Treatment with ACTH or steroids also can be immunosuppressant and associated with infectious complications, such as overwhelming sepsis, perhaps as a result of impaired function of polymorphonuclear leukocytes (48). Both agents are therefore contraindicated in the face of serious bacterial or viral infection such as varicella or cytomegalovirus. Because of the potential for fatal *Pneumocystis* pneumonia as an infectious complication of ACTH therapy, prophylaxis with trimethoprim-sulfamethoxazole, accompanied by folate supplementation and frequent blood counts, may be prudent in infants older than 2 months of age. In rare cases, ACTH can exacerbate seizures (49).

### Potential Mechanisms of Action of ACTH in Infantile Spasms

ACTH is a 39-amino-acid peptide hormone produced, through post-translational modification of the larger peptide pro-opiomelanocortin (POMC), in the anterior pituitary. POMC expression, processing to ACTH, and ACTH secretion are stimulated by corticotropin-releasing factor (CRF) generated in the hypothalamus, and these processes are under negative feedback control by glucocorticoids (50). ACTH secretion is pulsatile and normally has a pronounced diurnal variation, but secretion also increases substantially in response to a range of stressors. The effects of ACTH are mediated via stimulation of the G-coupled cell surface ACTH receptor, which is expressed primarily on adrenocortical cells. This receptor is a member of the melanocortin family and is alternatively known as the melanocortin-2 (MC-2) receptor. ACTH acutely stimulates the synthesis of cortisol in the adrenal gland. ACTH also increases the long-term capacity of the adrenal gland to generate cortisol by inducing a range of steroidogenic enzymes and hypertrophy of the cortex (51). ACTH additionally has the capacity to cross-react with other melanocortin receptors (52).

The pathogenesis of infantile spasms, and therefore the mechanism of action of ACTH and steroids in this condition, are unknown, principally because there is no available animal model for this disorder. Infantile spasms occur within a narrow developmental window in terms of age of onset and can be found concurrently with a variety of congenital abnormalities of brain, which may be causally linked—so-called symptomatic spasms. However, IS also may occur without apparent cause in children with no pre-existing neurologic abnormality at the onset of spasms (i.e., idiopathic spasms). Those children who are not neurologically normal when the spasms appear, yet have no demonstrable imaging or metabolic abnormality, are said to have cryptogenic spasms.

The effect of ACTH and corticosteroids in infantile spasms is frequently all or none, and the steroid-induced seizure-free state is often sustainable even after

drug withdrawal. These observations support the theory that due to various etiologies, a significant stress response is experienced by the developing brain; resulting in this age-dependent epileptic encephalopathy. Within this very narrow developmental window, ACTH and steroids may be able to reset the deranged homeostatic mechanisms of the brain, thereby reducing the convulsive tendency and improving the developmental trajectory.

*The Brain-Adrenal Axis* There is evidence to suggest that the effects of ACTH in infantile spasms may be independent of steroidogenesis. Efficacy studies have demonstrated superiority of ACTH to corticosteroids in treating infantile spasms and also its efficacy in adrenal-suppressed patients. Substantial physiologic and pharmacologic data indicate that ACTH has direct effects on brain function: increasing dendritic sprouting in immature animals; stimulation of myelination; regulation of the synthesis, release, uptake, and metabolism of dopamine, norepinephrine, acetylcholine, serotonin, and gamma-aminobutyric acid (GABA); regulation of the binding to glutamatergic, serotonergic, muscarinic type 1, opiate, and dopaminergic receptors; and alteration of neuronal membrane lipid fluidity, permeability, and signal transduction (53–57). Though activation of glucocorticoid receptors has little direct anticonvulsant effect, it modulates the expression and release of a number of neurotransmitters and neuromodulators, including the proconvulsant neuropeptide corticotropin-releasing hormone (CRH). High brain CRH levels would be predicted to reduce the cerebrospinal fluid ACTH and steroids (58). Many authors have reported reduced levels of ACTH in patients with infantile spasms, compared to their age-matched controls (59, 60). In infant animal models CRH causes seizures and death of neurons (61). These effects of CRH are most marked in developing brain (62). Suppression of the after-hyperpolarization and activation of the glutamatergic neurotransmission are the possible mechanisms by which CRH may mediate these effects. In animals, ACTH appears to down-regulate the CRH expression in amygdala. This effect was found to be independent of glucocorticoid receptor activation but required melanocortin receptors (63). ACTH reduces CRH gene expression in specific brain regions. This effect has been demonstrated in the absence of adrenal steroids and resides within the 4-10 fragment of ACTH, a fragment that does not release adrenal steroids. Melanocortin receptor antagonists blocked this effect, suggesting that the melanocortin receptors are the targets of ACTH action (63).

A hypothesis, therefore, can be generated in which a stress response results in enhanced CRH expression, leading to neuronal hyperexcitability and seizures. By suppressing CRH expression, possibly through the action of peptide fragments of ACTH on melanocortin receptors,

the CRF-induced hyperexcitability may be reduced, hence ameliorating infantile spasms. Clinical trials of ACTH fragments that have no activity on the adrenal axis have been disappointing (64); however, these clinical trials have utilized the 4-9 peptide fragment rather than the 4-10 peptide fragment studied in animal models. The events that precipitate this proposed endocrine abnormality remain unclear.

### THE USE OF ACTH AND CORTICOSTEROIDS IN OTHER SEIZURE DISORDERS

There is limited information concerning treatment of other intractable seizure disorders with ACTH and/or steroids. The Ohtahara and Lennox-Gastaut syndromes are believed to represent earlier and later manifestations, respectively, of a spectrum of infantile epileptic encephalopathies that include infantile spasms. These conditions respond poorly to traditional anticonvulsant drug therapies but are sometimes improved by the antiepileptic drugs used in infantile spasms: ACTH, steroids, benzodiazepines, and valproic acid. ACTH or steroids also may be beneficial in Landau-Kleffner syndrome (65).

#### Ohtahara Syndrome

The Ohtahara syndrome, also known as early infantile epileptic encephalopathy (EIEE), is characterized by spasms beginning within the first three months of life associated with persistent burst suppression on the EEG in all stages of the sleep-wake cycle. Despite reports of improvement in seizures in Ohtahara syndrome following ACTH, vigabatrin, and/or zonisamide therapy, the long-term prognosis is usually unchanged by any treatment (66). Mortality in this epilepsy syndrome is high, and survivors are usually severely handicapped. If used, ACTH should be administered as described for infantile spasms.

#### Lennox-Gastaut Syndrome and Other Myoclonic Seizure Disorders

ACTH and steroids have been found to be useful in younger children with various combinations of severe and intractable seizures, particularly atypical absence, myoclonic, tonic, and atonic seizures. This group includes patients with Lennox-Gastaut syndrome, a disorder characterized by mental retardation, generalized slow spike-and-wave discharges, intractable atypical absence, myoclonus, and frequent ictal falls. Snead and coworkers treated 64 children who had myoclonic seizures without EEG evidence of hypsarrhythmia, or other intractable seizures with either prednisone or ACTH. Seventy-three percent of the children treated with ACTH achieved seizure

control, as opposed to none of the prednisone-treated children; however, there was a relapse rate of >50% observed on discontinuation of the ACTH (25).

In 45 cases of Lennox-Gastaut syndrome treated with ACTH, the immediate and long-term effects and the various factors affecting them were investigated by a follow-up study (67). Twenty-three (51.1%) of the 45 children became "seizure free" for over 10 days. Ten children relapsed into Lennox syndrome within 6 months, and in the remaining 13 children, seizures were suppressed for over 6 months. Of these 13 patients, seizure relapse was observed in eight from 9 months to 7 years later. The other five children followed a favorable course without relapse. Sinclair treated 10 children with Lennox-Gastaut syndrome and intractable seizures with prednisone at a dose of 1 mg/kg/day for six weeks followed by withdrawal over the next 6 weeks, and achieved seizure freedom in 7 and seizure reduction in 3 children. Long-term outcome was not mentioned (68).

In summary, several uncontrolled, retrospective studies suggest that ACTH is superior to oral steroids in Lennox-Gastaut syndrome. If the decision is made to embark upon such treatment for Lennox-Gastaut syndrome, the regimen described in this chapter for ACTH or prednisone is recommended. Nevertheless, ACTH and steroids should be reserved for the most severe and intractable patients. Usually, the best result is temporary relief, because 70% to 90% of patients with multiple seizure types suffer a relapse during the ACTH taper. As well, older patients with Lennox-Gastaut syndrome do not tolerate high dose ACTH as well as those children under the age of 2 years who are receiving the same regimen for infantile spasms.

Uncontrolled trials of steroids or adrenocorticotrophic hormone also have been reported to reduce seizure frequency in severe myoclonic epilepsy of childhood (69), but without a favorable impact on the overall outcome. Myoclonic astatic epilepsy, first described by Doose, is another age-dependent epileptic disorder, characterized by the onset of myoclonic and atonic seizures between 7 months and 6 years of age in a previously normal child, associated with generalized discharges on the EEG. This disorder is resistant to most conventional antiepileptic drugs. Oguni and coworkers retrospectively analyzed 81 patients with myoclonic-astatic epilepsy of early childhood to investigate the most effective treatment. The most effective treatments were ketogenic diet, followed by ACTH and ethosuximide (70).

#### Landau-Kleffner Syndrome and Related Disorders

Described in 1957, Landau-Kleffner syndrome, also known as acquired epileptic aphasia, is characterized by regression in receptive and expressive language,

associated with epileptic seizures (71). The usual presentation occurs between the ages of 2 and 8 years. Behavioral disturbances are frequent, ranging from hyperactivity and aggression to autism and global cognitive deterioration. Some children display sustained agnosia and mutism. Others show a waxing and waning course that parallels the EEG changes. Spontaneous resolution also has been reported. The electroencephalogram typically shows 1- to 3-Hz high-amplitude spikes and slow waves; these may be unilateral, bilateral, unifocal, or multifocal, but often include the temporal region with or without parietal and occipital involvement, and are activated during sleep.

Valproate and benzodiazepines may control the clinical seizures but have only a partial and transient effect on the EEG abnormalities (72). In 1974, McKinney and McGreal described the beneficial effect of ACTH on the characteristic seizures, language regression, and behavioral changes in Landau-Kleffner syndrome (73). Since then, although no controlled prospective trials of ACTH or steroids have been published, case reports and retrospective series have demonstrated improvements in seizure control and language in children treated with varying ACTH or corticosteroid regimens. Marescaux and coworkers reported that corticosteroid treatment resulted in improved speech, suppression of seizures, and normalization of the EEG in three of three children with Landau-Kleffner syndrome (74). Four children with Landau-Kleffner syndrome received early and prolonged ACTH or corticosteroid therapy, with high initial doses (75). In all four cases the EEG promptly became normal, with subsequent long-lasting remission of the aphasia and improvement of seizure control. Three to six years after discontinuation of hormone therapy the children were off medication and free from seizures and language disability. Sinclair and Snyder treated 10 children who had Landau-Kleffner syndrome (8 patients) and continuous spike wave discharge during sleep (2 patients) with steroids. Nine children had significant improvement in language and behavior (76). Use of ACTH or corticosteroids in patients with Landau Kleffner syndrome appears justified; however, further study of dose and duration of therapy is warranted. If ACTH or corticosteroids are chosen to treat LKS, a high-dose regimen, as described in this chapter for infantile spasms, is recommended, with a longer tapering schedule and concomitant use of valproic acid.

### Rasmussen Encephalitis

Rasmussen encephalitis is a focal progressive inflammatory condition of the brain, of unclear etiology. Rasmussen encephalitis is characterized by malignant, progressive, and intractable partial seizures with a high incidence of epilepsy partialis continua. Treatments advocated in

Rasmussen include anticonvulsants, high-dose steroids, ACTH, intravenous immunoglobulin G (IV IgG), plasmapheresis, antiviral agents, and hemispherectomy (77). Dulac, in 1992 (78), reported the results of high-dose IV methylprednisolone (400 mg/m<sup>2</sup>), followed by oral prednisone, in seven patients with epilepsy partialis continua. Six of the seven showed an improvement in seizure control, which was variably sustained over a two-year follow-up period. Hart (79) reported a benefit of steroids, with 10 of 17 patients showing a reduction of 25–75% in seizure frequency. Granata and coworkers reported positive time-limited responses in 11 of 15 patients with Rasmussen encephalitis, using variable combinations of corticosteroids, apheresis, and high-dose IV immunoglobulins (80).

## NEUROSTEROIDS

The term *neurosteroid* was coined by Etienne Baulieu (81) and Paul Robel (82) to refer to pregnenolone, 20- $\alpha$ OH-pregnenolone, and progesterone synthesized in the brain. A more general definition would include all steroids synthesized in the brain. The phrase “neuroactive steroids” refers to steroids that are active on neural tissue. Therefore, they may be synthesized endogenously in the brain or may be synthesized by classic endocrine tissue but act on neural tissues (83).

### Anticonvulsant Properties of Neurosteroids

Grosso and coworkers investigated serum allopregnanolone levels in 52 children with active epilepsy at pubertal Tanner stage I. The interictal serum allopregnanolone levels in the epileptic children were not statistically different from those detected in the control group, whereas postictal levels were significantly higher than the interictal ones. In this subgroup of patients, allopregnanolone levels decreased to the basal values within 12 hours of the seizure. Serum allopregnanolone levels may reflect changes in neuronal excitability, and allopregnanolone appears to be a reliable circulating marker of epileptic seizures. It is possible that increased postictal serum levels of allopregnanolone may play a role in modulating neuronal excitability and represent an endogenous mechanism of seizure control (84).

The brain regulates hormonal secretion and is sensitive to hormonal feedback. This is particularly true of certain highly epileptogenic mesial temporal lobe regions, such as the amygdala and hippocampus (85). The amygdala, in particular, is linked directly to regions of the hypothalamus that are involved in the regulation, production, and secretion of ovarian steroids (86). Neurons containing corticotropin-releasing factor are particularly prominent in the central division of the extended amygy-

dala (87), which shows structural changes in temporal lobe epilepsy (88). Seizures, if occurring in a repetitive manner, are stressful events for the organism, which can cause lack of inhibitory control in the hypothalamus-pituitary axis system (89, 90). Thus, hypothalamus-pituitary axis dysfunction might be induced in epileptic disorders independent of the localization of the focus. Notably, stress and seizures can alter levels of gonadal, adrenal, and neuroactive steroids, which may then influence subsequent seizure activity (91).

Anovulatory cycles are associated with greater seizure frequency (92, 93). This phenomenon may be due to high serum estradiol-to-progesterone ratios that characterize the inadequate luteal phases of anovulatory cycles and to the opposing neuroactive properties of these steroids. Both adult animal models of epilepsy and clinical evidence suggest that estrogen has excitatory and progesterone has inhibitory effects on neuronal excitability and seizures (93). Progesterone protects against seizures in animals and in open-label clinical trials (94, 95). There is also evidence from the work of Lonsdale and Burnham (96) to suggest that an intermediate product of progesterone reduction, 5[alpha]-dihydroprogesterone, exerts potent antiseizure effects in the amygdala kindling model of generalized convulsions in female rats. Androgens also have antiseizure effects. Aromatization of testosterone produces estradiol, which is highly epileptogenic in male rodents (97). Reduction produces androstenediol, which has potent GABAergic properties and inhibits seizures (98).

### Putative Mechanism of Action of Neurosteroids

Electrophysiologic and ligand binding experiments showed that the steroids alphaxolone, allopregnanolone, pregnanolone, allotetrahydrodeoxycorticosterone, and tetrahydrodeoxycorticosterone could all interact with the GABA<sub>A</sub> receptor. It is now clear that these neurosteroids act as allosteric agonists of the GABA<sub>A</sub> receptor and act to enhance GABAergic inhibition in the brain via a single site on the GABA<sub>A</sub> receptor. Other neurosteroids (e.g., pregnenolone sulfate and DHEA sulfate, but not nonsulfated steroids), act as noncompetitive antagonists of the GABA<sub>A</sub> receptor. Modulation of neurosteroid action can result from regionally specific differences in neurosteroid synthesis, as well as from regionally specific differences in GABA<sub>A</sub> receptor subunit composition (99). Further, data suggest that the anticonvulsant effects of progesterone may involve its metabolism to the neuroactive steroid 5-alpha-pregnan-3 alpha-ol-20-one (3 alpha, 5 alpha-THP) and the subsequent actions of this metabolite at GABA<sub>A</sub> receptors (91). Although this activity has been attributed to the reduced progesterone metabolite tetrahydroprogesterone (THP), also known as allopregnanolone,

a GABA<sub>A</sub> receptor-modulating neurosteroid with anticonvulsant properties, a possible role for progesterone receptors also has been raised (100). However, the potent antiseizure properties of progesterone do not require action at the progesterone receptor and can be blocked by preventing reduction of progesterone to its potent GABAergic metabolite tetrahydroprogesterone. Reddy and coworkers used progesterone receptor knockout mice studies to provide strong evidence that the antiseizure effects of progesterone result from its conversion to the neurosteroid THP and not through the actions of progesterone on its receptor (100). The anticonvulsant effects of androgens may be mediated, in part, through actions of the testosterone metabolite and neuroactive steroid 5 alpha-androstane-3 alpha,17 alpha-diol (3 alpha-diol) at GABA<sub>A</sub> receptors (91).

### Potential for Clinical Use

Since progesterone and 3-reduced pregnane steroids have potent anticonvulsant effects, attempts to develop novel antiepileptic drugs with neurosteroidal properties seem reasonable. In preclinical studies, metabolites of progesterone and deoxycorticosterone, as well as the synthetic neuroactive steroid ganaxolone, exhibit a broad anticonvulsant profile in different animal models (101, 102). Ganaxolone is a member of a novel class of neuroactive steroids, called epalons, which allosterically modulate the GABA<sub>A</sub> receptor complex. Ganaxolone is chemically related to progesterone but is devoid of hormonal activity. In animal studies, there appears to be no tolerance to the anticonvulsant activity of ganaxolone when this drug is administered chronically over the course of up to 7 days. In humans, ganaxolone showed a promising pharmacokinetic profile and was well tolerated in a trial with 96 healthy volunteers (103). The steroid proved to be well tolerated, and effective in clinical studies with epilepsy patients (104, 105). Kerrigan and associates (105) found that ganaxolone reduced the frequency of spasms by at least 50% in 33% of 16 children, with medically intractable infantile spasms, who completed the study. Drug-related adverse events (occurring in 10% of the patients) were generally mild and included somnolence, diarrhea, nervousness, and vomiting. The tolerability of ganaxolone at doses up to 36 mg/kg per day was acceptable (106). Ganaxolone monotherapy was evaluated in a randomized, double-blind, presurgical clinical trial. Ganaxolone was administered at a dose of 1,500 mg per day on day 1 and 1,875 mg per day on days 2–8. The tolerability of ganaxolone was similar to that of placebo and the drug showed significant antiepileptic activity, which was measured by the duration of treatment before withdrawal from the study (104). However, like all GABAergic drugs, ganaxolone has the potential to exacerbate absence seizures (107).

## Benzodiazepines

*Kevin Farrell*  
*Aspasia Michoulas*

**B**enzodiazepines bind to a site on the neuronal GABA<sub>A</sub> receptor, a ligand-gated chloride channel, and enhance inhibitory neurotransmission. Their high lipid solubility results in rapid central nervous system (CNS) penetration and they are particularly useful as first-line agents in the management of status epilepticus and seizures occurring repetitively in clusters. Their effectiveness in the chronic treatment of epilepsy is limited by their behavioral effects and their propensity for tolerance in patients with intractable epilepsy.

### CHEMISTRY, PHARMACOLOGY, AND MECHANISM OF ACTION

The base compound is a 5-aryl-1,4-benzodiazepine structure composed of three ring systems. Modifications in the structure of ring system have resulted in several compounds with antiepileptic activity but with different efficacy and side effect profiles. Benzodiazepines augment inhibitory neurotransmission by enhancing the activity of GABA at the GABA<sub>A</sub> receptor (1). When GABA binds to the GABA<sub>A</sub> receptor, it increases the opening of the chloride ion channel, which results in hyperpolarization of the membrane and reduction in neuronal firing (2). Although benzodiazepines bind to

the GABA<sub>A</sub> receptor, they do not activate it directly but rather modulate GABA binding and enhance its effect by increasing the frequency (not duration) of chloride ion channel opening. This increases the inhibitory tone at GABA synapses, which limits neuronal firing and in turn reduces seizure activity (1). At high concentrations, benzodiazepines also influence sodium channel function in a similar fashion to phenytoin and carbamazepine (3). Thus, benzodiazepines raise the seizure threshold, decrease the duration of epileptiform discharges, and limit their spread (3).

The action of benzodiazepines on the GABA receptor may be influenced both by the maturity of the brain and by disease. GABA synapses are present before glutamate synapses in early fetal development, and it has been suggested that GABA acts as the primary excitatory neurotransmitter in the immature brain (4). The potassium-chloride transport that removes chloride ions is not expressed until later in development, enabling chloride ions to accumulate intracellularly, resulting in GABA synapses that are excitatory (4). The exact timing of the switch from GABA excitatory action to inhibitory action is not known but is believed to occur in utero (4). It has been hypothesized that the excitatory action of GABA in early development modulates neuronal migration and differentiation, and it has been suggested that benzodiazepine use in early

pregnancy may have detrimental effects on fetal brain maturation (4).

## ADVERSE EFFECTS

### Toxicity

Respiratory and cardiovascular depression are the most common adverse effects of benzodiazepines used intravenously. Propylene glycol is a solvent used with intravenous diazepam and lorazepam, but not midazolam, and plays a major role in the respiratory depression associated with the first two drugs (5). Comedication with phenobarbital may exacerbate the cardiovascular and respiratory depression. Intravenous benzodiazepines may precipitate tonic status epilepticus in children with epileptic encephalopathies (6).

Chronic treatment with a benzodiazepine may be associated with sedation, fatigue, ataxia, cognitive dysfunction, drooling, and exacerbation of seizures. Abrupt discontinuation may lead to withdrawal symptoms. Headache and gastrointestinal symptoms can occur but are uncommon. Hematologic abnormalities, hepatic dysfunction, and allergic reactions are uncommon.

### Tolerance

Although tolerance probably occurs with all antiepileptic drugs (7), it happens more often with benzodiazepines. The degree of tolerance in animal models is proportional to the agonist efficacy of the benzodiazepine (8). Tolerance to one benzodiazepine does not necessarily result in tolerance to the others (9). The mechanisms underlying tolerance are not clear but may involve down-regulation of GABA<sub>A</sub> receptors, altered postsynaptic sensitivity to GABA, or modification in the expression of genes that encode for the various GABA<sub>A</sub> receptor subunits (10).

The incidence of tolerance to the antiepileptic effect of benzodiazepines is influenced by the type and severity of the epilepsy. Thus, tolerance to clonazepam is observed much less often in patients with typical absence seizures than in patients with West syndrome or Lennox-Gastaut syndrome (11). Similarly, tolerance to clobazam has been reported in 18% to 65% of patients in open studies (12–14), whereas in children who had been previously untreated or who had received only one drug (15), the incidence of tolerance to clobazam (8%) was similar to tolerance to carbamazepine (4%) and phenytoin (7%).

## INDIVIDUAL BENZODIAZEPINES

The use of benzodiazepines in status epilepticus and in the prevention of seizures is outlined in Table 41-1 and Table 41-2 respectively.

## Diazepam

*Biotransformation, Pharmacokinetics, and Interactions.* Rectal diazepam is absorbed via hemorrhoidal veins and then rapidly crosses the blood-brain barrier. Therapeutic blood levels are achieved within 5 minutes and peak levels within 20 minutes (16). Plasma concentrations of 500 ng/mL of diazepam, which are necessary for acute seizure control, were achieved in infants and children within 2–6 minutes following rectal administration of 0.5 to 1 mg/kg (17). Diazepam is absorbed more slowly following oral or intramuscular administration, and these routes are not recommended. Plasma levels decrease by as much as 50% within 20–30 minutes after a single bolus injection (16). This short duration of action following intravenous administration relates to its rapid distribution into fat tissue and to the high protein binding of diazepam.

Diazepam undergoes demethylation to N-desmethyldiazepam, a major metabolite that itself has significant antiepileptic and sedative properties (17). Diazepam and N-desmethyldiazepam are both highly protein bound to albumin (17). The elimination half-life of diazepam is  $10 \pm 2$  hours in infants and  $17 \pm 3$  hours in older children (17). The elimination half-life of N-desmethyldiazepam is longer than that of diazepam, and serum concentrations are two to five times higher in patients receiving long-term treatment (17). The metabolites of diazepam are conjugated with glucuronic acid in the liver and excreted by the kidney.

Diazepam does not significantly influence the pharmacokinetics of other drugs. Valproate comedication decreases protein binding and inhibits the metabolism of diazepam (18), which may result in increased sedation.

*Clinical Efficacy.* Diazepam is effective in the treatment of both convulsive and nonconvulsive status epilepticus and of acute repetitive seizures. Clinical effect is observed usually within 10 minutes of intravenous administration, which is the optimal route for the treatment of status epilepticus (16, 19). The rapid redistribution following a single dose results in an abrupt decline in brain concentration and reduction in the anticonvulsant effect. Consequently, a long-acting anticonvulsant, for example, phenytoin, should be administered concomitantly in children with status epilepticus. Rectal diazepam is absorbed rapidly, which may be useful in small children in whom intravenous access may be difficult. Limited data suggest continuous diazepam infusion may be effective in the treatment of refractory status epilepticus in children (20–22).

Rectal diazepam gel has been shown to be effective and safe in the management of children with prolonged or acute repetitive seizures (23). Sedation was the most common side effect, but no episodes of serious respiratory

**TABLE 41-1**  
*The Use of Benzodiazepines in Status Epilepticus*

DRUG	DOSAGE	COMMENTS
<b>DIAZEPAM</b>		
Intravenous	0.2–0.3 mg/kg; max dose 5 mg in infants and 10 mg in older children; can be repeated after 15 minutes	Administer over 2–5 minutes; rapid administration increases risk of apnea
Rectal solution	0.5–1.0 mg/kg; max dose 20 mg	Prefixed unit doses of 5, 10, 15, and 20 mg; prescribed dose should be rounded to nearest available unit dose
Rectal gel	2–5 years: 0.5 mg/kg 6–11 years: 0.3 mg/kg >12 years: 0.2 mg/kg	
<b>LORAZEPAM</b>		
Intravenous	0.1 mg/kg; max dose 4 mg; can be repeated after 10 minutes	Administer over 2 min
Sublingual	0.05–0.15 mg/kg; max dose 4 mg	Can be used for serial seizures but should not be used for tonic-clonic status epilepticus
<b>MIDAZOLAM</b>		
Intravenous bolus	0.15 mg/kg	Administer over 2–5 minutes; if not effective, continuous infusion should be started
Continuous infusion	1–5 µg/kg/min; max dose 18 µg/kg/min	Initiate treatment at 1 µg/kg/min and increase rate by that amount at 15-minute intervals until seizure control
Intramuscular, intranasal, and buccal	0.2 mg/kg	

**TABLE 41-2**  
*Benzodiazepine Dosages for Prevention of Seizures*

DRUG	INITIAL DOSE	DOSAGE INCREASE	MAXIMUM DOSE
<b>Clobazam</b>	2.5 mg/day < 2 years; 5 mg/day if 2–10 years; 10 mg/day > 10 years	2.5–5 mg/day every 5–7 days; given at night or as b.i.d. dosing	Doses over 30 mg/day rarely improve seizure control
<b>Clonazepam</b>	0.01–0.03 mg/kg/day < 30 kg 0.5 mg/day > 30 kg	0.25–0.5 mg/day every 5–7 days; b.i.d or t.i.d dosing	0.2 mg/kg/day if on enzyme-inducing drugs; 0.1 mg/kg/day in others
<b>Clorazepate</b>	0.3 mg/kg/day	0.3–0.6 mg/kg/day every 5–7 days; b.i.d dosing	3 mg/kg/day (max 60 mg/day)
<b>Nitrazepam</b>	0.1–0.2 mg/kg/day	0.1 mg/kg/day every 5–7 days; b.i.d or t.i.d.	<0.8 mg/kg/day

Abbreviations: b.i.d., twice daily; t.i.d., three times daily.

depression have been reported. Rectal administration can be performed by the parent, which permits treatment at home, decreases emergency room visits, and improves caregivers' global evaluation (24). This is of particular value for children with a history of prolonged seizures (25).

Both oral (26) and rectal diazepam (27) administered intermittently at times of fever have been demonstrated in placebo-controlled studies to be effective in the prevention of recurrent febrile convulsions. Rectal diazepam was as effective as continuous phenobarbital in the prevention of recurrent febrile seizures (28). The potential toxicities associated with antiepileptic drug therapy have generally been considered to outweigh the relatively minor risks associated with simple febrile seizures (29). However, intermittent diazepam may be of value in children who have had a previous prolonged febrile seizure.

Childhood-onset encephalopathies associated with sleep-activated electroencephalographic (EEG) abnormalities may respond to oral diazepam at high doses (30, 31). Oral diazepam (0.5 mg/kg) for 3 to 4 weeks following a rectal diazepam bolus of 1 mg/kg has been reported to be effective in electrical status epilepticus in sleep (ESES) (32). Oral diazepam at a dose of 0.5 mg/kg given 30 minutes before hemodialysis was effective in prevention of hemodialysis-associated seizures in four children who had failed to respond to phenobarbital (33).

**Adverse Effects.** Sedation and ataxia occur commonly when diazepam is used in the treatment of status epilepticus or in the prevention of recurrent febrile convulsions. Respiratory depression and hypotension may occur following intravenous diazepam, particularly if administered rapidly or used in combination with phenobarbital (17), but are extremely rare following rectal diazepam (34). Mild thrombophlebitis may occur following intravenous administration, particularly if diazepam is mixed with a saline solution or is injected rapidly (17). Diazepam may induce tonic status epilepticus in children with epileptic encephalopathies (35). Intermittent oral diazepam prophylaxis has been associated with ataxia, sedation, lethargy, and irritability (36).

**Clinical Use.** In the treatment of children with status epilepticus, an initial intravenous dose of 0.2 to 0.3 mg/kg (maximum dose, 5 mg in infants and 15 mg in older children) of diazepam should be given slowly over 2–5 minutes (17). If needed, the dose may be repeated after 15 minutes. When intravenous access is not available, a rectal dose of 0.5 to 0.9 mg/kg has been used to a maximum of 20 mg (37, 38). In refractory status epilepticus, continuous diazepam infusion has been used successfully (20). Treatment was initiated at 0.01 mg/kg/min and increased by 0.005 mg/kg/min every 15 minutes until seizures were controlled or to a maximum dosage of 0.03 mg/kg/min. A subsequent report has described at an infusion rate up

to 0.08 mg/kg/min (21). Diazepam may precipitate when the intravenous solution is administered in saline solution, and it may adsorb to polyvinyl tubing. Consequently, fresh solution should be prepared every 6 hours when continuous diazepam infusion is being used (39).

Rectal administration of diazepam should be considered when intravenous access cannot be obtained and when administration by a caregiver may be helpful, for example, when a child with a history of prolonged seizures lives far from medical services. The injectable solution can be administered rectally through a soft plastic intravenous catheter, and doses of 0.5 to 1.0 mg/kg have been reported to be effective in a prehospital setting with a maximum dose of 20 mg (16). Rectal diazepam gel (Diasat<sup>®</sup>) is available in unit doses of 5, 10, 15, and 20 mg and is easier to handle, faster to administer, and decreases the chance of dosing errors. Rectal doses of 0.5 mg/kg for children 2–5 years of age; 0.3 mg/kg between 6 and 11 years of age, and 0.2 mg/kg above 12 years to a maximum of 20 mg have been used successfully (40). A second dose may be repeated in 4–12 hours, if needed. If administered at home, caregivers should be given instruction as to when they should seek medical attention. The suggested dosage of oral or rectal diazepam used for febrile seizure prophylaxis is 5 mg every 8 hours when the rectal temperature is  $\geq 38.5^{\circ}\text{C}$ , with a maximum of four consecutive doses to avoid drug accumulation (28).

## Lorazepam

**Biotransformation, Pharmacokinetics, and Interactions.** Lorazepam is a 1,4-benzodiazepine that is metabolized rapidly through hepatic glucuronidation and is excreted by the kidneys (41). It is absorbed more rapidly when administered sublingually than orally or intramuscularly, and peak plasma levels are achieved within 60 minutes (42). The rectal absorption of lorazepam parenteral solution is slow and peak concentrations, which may not be reached for 1–2 hours, are much lower than those achieved following intravenous administration (43). First-pass hepatic transformation decreases the absolute systemic availability of oral lorazepam to 29% of that following intravenous administration (44). Lorazepam is 90% protein bound and rapidly crosses the blood-brain barrier. The maximal EEG effect of intravenous lorazepam is observed approximately 30 minutes after infusion, which is later than with intravenous diazepam, probably as a result of slower entry into the brain (45). Following intravenous administration, there is a rapid fall in blood levels because of the distribution phase. The elimination half-life is  $10.5 \pm 2.9$  hours in children (46) but is longer in neonates (47). Less than 1% is excreted unchanged in the urine.

The clearance of lorazepam is not influenced by acute viral hepatitis (48) or renal disease (49). However, valproate reduces the clearance of lorazepam, possibly as

a consequence of inhibition of glucuronidation (50). There are no other significant interactions with antiepileptic drugs (42), and, in contrast to other benzodiazepines, protein binding of lorazepam is not influenced by heparin (51).

**Clinical Efficacy.** Intravenous lorazepam is more effective than intravenous diazepam in the treatment of status epilepticus; it has fewer side effects and has a longer duration of action (52, 53). Children receiving long-term therapy with another benzodiazepine are less responsive to lorazepam in status epilepticus (54). Sublingual lorazepam has also been shown to be a convenient and effective treatment of serial seizures in children (55). Intravenous or sublingual lorazepam was completely effective in preventing seizures in 29 children receiving high dose busulfan treatment (56). Lorazepam has also been reported to be useful in the treatment of postanoxic myoclonus (57).

**Adverse Effects.** Sedation is the most common side effect of lorazepam, and ataxia, psychomotor slowing, and agitation may also occur. Respiratory depression may occur but less often than with diazepam (52). The treatment of serial seizures with lorazepam has been associated with drowsiness, ataxia, nausea, and hyperactivity (55). Abrupt discontinuation of lorazepam has been associated with withdrawal seizures, which may occur up to 60 hours following its discontinuation (42). Lorazepam has been reported to cause tonic seizures in patients being treated for atypical absence status epilepticus (58–60).

**Clinical Use.** The recommended intravenous dose of lorazepam in children is 0.1 mg/kg (maximum dose, 4 mg) (19). The intravenous rate of administration should not exceed 2 mg/min. The dose can be repeated if necessary after 10 minutes. Sublingual doses of 0.05 to 0.15 mg/kg were effective in 8 of 10 children with serial seizures (55).

## Midazolam

**Biotransformation, Pharmacokinetics, and Interactions.** Midazolam is a 1,4-benzodiazepine with a fused imidazole ring. Prior to administration, the benzodiazepine ring of midazolam is open and is water soluble. However, following administration, the benzodiazepine ring closes at physiologic pH and midazolam becomes lipid soluble. These characteristics permit absorption via the intramuscular route (with less pain at the injection site) and rapid transport across the blood-brain barrier. The absorption of intramuscular midazolam is rapid with 80% to 100% bioavailability (61), and peak blood levels are obtained after approximately 25 minutes (61). Pharmacologic effects are observed within 5–15 minutes but may not be maximal for 20 to 60 minutes (62). Intranasal absorption of midazolam also occurs rapidly,

with mean time to seizure control of 3.5 minutes (range, 2.5–5.0 minutes) (63). Oral midazolam is absorbed relatively rapidly, with peak blood levels being achieved within 1 hour, but first-pass metabolism in the liver limits the availability to 40% to 50% of the oral dose. It is distributed rapidly and possesses a short elimination half-life (1.5–3 hours) in children. The relatively short half-life makes it less likely to accumulate and therefore more suitable for continuous infusion than diazepam or lorazepam. A longer half-life (6.5 hours) has been observed in critically ill neonates (64).

Midazolam is highly protein bound (96–98%) and is metabolized extensively by the cytochrome P450 3A4 enzyme system. Its metabolism is induced by phenytoin and carbamazepine (65). Medications that inhibit the activity of cytochrome P450 3A4, for example, erythromycin and clarithromycin, may prolong the half-life of midazolam (66). Renal failure does not influence the pharmacokinetics of midazolam (67).

**Clinical Efficacy.** Intravenous midazolam was effective in the treatment of refractory status epilepticus in 43 of 44 children in two studies (68, 69). The mean infusion rates in these two studies were 2.0 and 2.3  $\mu\text{g}/\text{kg}/\text{min}$ , with a maximum rate in one study of 18  $\mu\text{g}/\text{kg}/\text{min}$ . Midazolam appears to be as effective in stopping refractory status epilepticus as pentobarbital or thiopental and is associated with fewer adverse effects (70, 71). Continuous intravenous midazolam infusion was as effective as continuous diazepam infusion in stopping refractory status epilepticus but was associated with a higher incidence of seizure recurrence (21). Continuous midazolam infusion was also effective in stopping refractory nonconvulsive status epilepticus in 82% of episodes but breakthrough seizures, which could only be detected by EEG in most patients, occurred in approximately half of the patients (72). Midazolam administered by continuous intravenous infusion (1.6–6.6  $\mu\text{g}/\text{kg}/\text{min}$ ) was effective in controlling seizures refractory to phenobarbital in four of six neonates and was well tolerated (73).

The high water solubility of midazolam permits administration by a variety of routes. Intramuscular midazolam (15 mg) had a comparable effect to intravenous diazepam (20 mg) in the suppression of interictal spikes in adults within 5 minutes (74). Intramuscular midazolam was effective in stopping 64 of 69 prolonged seizures occurring in 48 children (75). A prospective study reported intramuscular midazolam to be more efficacious than intravenous diazepam in the treatment of acute seizures, with a faster cessation of seizures because of more rapid administration (76). Intranasal administration of midazolam was less effective than intravenous diazepam in one study (77) but stopped prolonged febrile seizures more rapidly in another study (78). In addition, the time to seizure cessation was shorter with intranasal midazolam than with rectal diazepam, and

parents felt that the intranasal route was a more favorable means of medication administration (79).

**Adverse Effects.** Drowsiness and ataxia are the most common side effects. Apnea and hypotension may occur following rapid intravenous administration of a bolus of midazolam, but apnea has been reported in only one patient following intramuscular midazolam (80). Thrombophlebitis occurs less often than with diazepam (80). Paradoxical reactions including agitation, restlessness, and hyperactivity have been reported (81).

**Clinical Use.** An initial intravenous bolus dose of 0.15 mg/kg (68, 69) may be followed by continuous infusion at an initial rate of 1  $\mu$ g/kg/min, which may be increased subsequently by 1  $\mu$ g/kg/min every 15 minutes to achieve seizure control. Seizures are controlled at infusion rates less than 3  $\mu$ g/kg/minute in most children, but rates up to 18  $\mu$ g/kg/min have been described (69). Intramuscular administration results in complete and rapid absorption and is particularly usefully if intravenous access is not available or is difficult to obtain quickly. An intramuscular dose of 0.2 mg/kg has been used effectively in children (75). Intranasal and buccal midazolam are safe, effective, and easy to administer, making these routes particularly useful in the home setting. The usual dose is 0.2 mg/kg.

### Clonazepam

**Biotransformation, Pharmacokinetics, and Interactions.** Clonazepam is a 1,4-benzodiazepine, and the bioavailability after oral administration is more than 80% with peak levels occurring between 1 and 4 hours (82). The high lipid solubility results in rapid distribution with easy passage across the blood-brain barrier. The protein binding is 86%. Clonazepam is metabolized initially by reduction to 7-amino-clonazepam and subsequently by acetylation (83). The metabolites, which are pharmacologically inactive, are conjugated to glucuronide and excreted by the kidney. Less than 1% is excreted unchanged in the urine. Clonazepam metabolism involves the hepatic cytochrome P-450 3A4 (84) and comedication with carbamazepine or phenobarbital lowers blood clonazepam levels (82). Acetylation is also a major metabolic pathway and patients who are rapid acetylators are more likely to require higher doses to achieve a response (85). The serum half-life in children is 22–33 hours (86). The plasma half-life following intravenous administration in neonates is 20–43 hours (87).

**Clinical Efficacy.** Intravenous clonazepam was effective in stopping tonic-clonic status epilepticus in all children in a small open study and was considered to have a longer duration of action than diazepam (88). The initial dose was 0.25 mg, which was repeated up to two times. Intravenous clonazepam was also effective in more than 80%

of children and adults with absence status epilepticus (89). Oral clonazepam has been demonstrated in controlled studies to be effective in the treatment of absence (86, 90, 91), myoclonic (90), and atonic seizures (90). Open studies have suggested that clonazepam is also effective in the treatment of photosensitive epilepsy and of primary generalized tonic-clonic seizures, both as monotherapy (92) and in combination with valproic acid (93). In patients with juvenile myoclonic epilepsy, clonazepam is more effective in prevention of myoclonic seizures than of tonic-clonic seizures. This may result in an increased risk of injury to the patient, who is deprived of the warning jerks that pre-empt the onset of the generalized tonic-clonic seizure (94). Clonazepam may also be effective in the treatment of other myoclonic epilepsies, including reflex myoclonic epilepsy, progressive myoclonic epilepsy, posthypoxic intention myoclonus, and *epilepsia partialis continua* (82). Partial epilepsy may also respond to clonazepam in combination with valproic acid (82). Clonazepam monotherapy is associated with reduction in interictal rolandic discharges in children with benign rolandic epilepsy (95) and is more effective than valproic acid and carbamazepine in that regard (96). The addition of clonazepam was also effective in the treatment of children with partial seizures resistant to carbamazepine (97). Studies have demonstrated mixed results with respect to the efficacy of clonazepam in Lennox-Gastaut syndrome, where it has been considered as a third line choice (98).

**Adverse Effects.** The most common adverse effects of clonazepam include drowsiness, ataxia, incoordination, and behavioral changes (34, 99). Comedication with phenobarbital usually exacerbates the drowsiness (100). Diplopia, nystagmus, dysarthria, excessive drooling, and hypotonia may also occur. Initiation of therapy at a low dose followed by a slow increase may reduce the neurotoxicity. Increased appetite and weight gain of more than 20% were reported in 9 of 81 children treated with clonazepam (99). Clonazepam may result in increased seizure frequency (101) and has been reported to induce tonic status epilepticus in Lennox-Gastaut syndrome (6).

The development of tolerance to the antiepileptic effect of clonazepam is dependent on the type of epilepsy. Thus, tolerance did not develop in 23 children with partial epilepsy who were treated with clonazepam monotherapy or clonazepam in combination with carbamazepine (97). Similarly, tolerance to clonazepam is observed less often in patients with typical absence seizures than in patients with West syndrome or Lennox-Gastaut syndrome (11). The use of alternate-day clonazepam has been reported to be associated with significantly less tolerance in an animal model (102), an effect also observed in children (103). Discontinuation of clonazepam may be complicated by transient worsening of seizure control, and status epilepticus may occur with abrupt withdrawal (11). Behavioral changes, including restlessness, dysphoria, sleep disturbance, and

tachycardia, may also occur during clonazepam withdrawal, which should be done gradually (11).

**Clinical Use.** To minimize side effects, clonazepam should be started at a dose of 0.01 to 0.03 mg/kg/day in children under 30 kg and given in two or three daily dosages (104). The dose can be increased by 0.25–0.5 mg/day every 5–7 days to a total dose of 0.1 mg/kg/day, or 0.2 mg/kg/day in patients receiving drugs that induce microsomal metabolism. Clonazepam was effective in seven of eight neonates with seizures when administered by slow intravenous infusion in doses of 0.1 mg/kg (87).

### Nitrazepam

**Biotransformation, Pharmacokinetics, and Interactions.** Nitrazepam, a 1,4-benzodiazepine, is rapidly and totally absorbed in the gastrointestinal tract. It is highly protein bound (85–90%) and has an elimination half-life of 24 to 31 hours (105). Nitrazepam is partially metabolized in the liver and then excreted in the urine. There are no clinically significant interactions with other antiepileptic drugs. Oral contraceptives, steroids, and cimetidine reduce nitrazepam clearance, and rifampin increases nitrazepam clearance (105).

**Clinical Efficacy.** Nitrazepam is generally considered a third line adjunctive medication in the treatment of partial and generalized seizures, including the epileptic encephalopathies of childhood. In a randomized control study in patients with infantile spasms, 75% to 100% reduction in spasm frequency was observed in 52% of patients receiving nitrazepam and 57% of patients receiving adrenocorticotrophin (106), but side effects were less severe in the patients who received nitrazepam. In open studies, nitrazepam has been reported to be effective in the treatment of absence and primary generalized tonic-clonic seizures (107), myoclonic seizures (108), and partial seizures (107). Nitrazepam has also been reported to be effective in the treatment of Lennox-Gastaut syndrome (105, 109, 110).

**Adverse Effects.** Drowsiness, ataxia and incoordination, which are common side effects, may be diminished by initiation of treatment at a low dose followed by slow increase. Increased salivation is a well recognized side effect of nitrazepam in children and is related to both hypersecretion of the tracheobronchial tree and abnormal swallowing, due to delay in cricopharyngeal relaxation (111). This may also result in feeding difficulties and aspiration pneumonia, particularly in children (108, 112). Doses of nitrazepam greater than 0.8 mg/kg/day have been found to be associated with an increased risk of death in children (112), and the risk appears highest in children with intractable epilepsy younger than 3.4 years of age (113). Risk factors included feeding

difficulties, recurrent respiratory tract infections, and aspiration pneumonia.

**Clinical Use.** To reduce the risk of side effects, nitrazepam should be started in children at a low dose (0.1–0.2 mg/kg/day) and the dosage increased every 5–7 days to a maximum of 0.8 mg/kg/day (112). Caution should be taken in patients younger than 4 years of age. Discontinuation of nitrazepam should be gradual to minimize the risk of withdrawal seizures.

### Clorazepate

**Biotransformation, Pharmacokinetics, and Interactions.** Clorazepate is a prodrug that is decarboxylated in the stomach to the active medication, N-desmethyldiazepam. Peak concentrations of N-desmethyldiazepam are normally achieved at 0.5 to 2 hours and, with the slow-release preparation, after 12 hours (114, 115). Serum concentrations of N-desmethyldiazepam increase after meals, which may cause somnolence (114). N-Desmethyldiazepam is 97% protein bound, largely to serum albumin (115). Although N-desmethyldiazepam has an elimination half-life of 55–100 hours, administration of clorazepate once daily is associated with unacceptable side effects because of the relatively high peak concentrations that follow its rapid absorption (115). N-Desmethyldiazepam is metabolized extensively by the liver and its elimination half-life is prolonged in patients with liver disease. Drugs that induce hepatic microsomal metabolism enhance the clearance of N-desmethyldiazepam and patients taking these drugs require higher doses of clorazepate.

**Clinical Efficacy.** Clorazepate was introduced in the 1960s and there have been no controlled studies in children. Improvement in seizure control has been reported in children with partial (116) and generalized seizures (116–118), including children with Lennox-Gastaut syndrome (116).

**Adverse Effects.** Sedation, ataxia, behavioral changes, and drooling, which are the most common side effects of clorazepate in children, often become less pronounced with time. Comedication with phenobarbital increases the probability of behavioral problems (119) and should be avoided. Idiosyncratic reactions are rare (115).

Tolerance limits the usefulness of clorazepate, but animal studies suggest that tolerance occurs less often with clorazepate than with diazepam or clonazepam (115). Withdrawal seizures and behavioral changes may complicate the discontinuation of therapy, which should occur slowly.

**Clinical Use.** The initial dose of clorazepate in children is 0.3 mg/kg/day, and the dose is increased gradually to

achieve seizure control or until side effects appear, up to a maximum dose of 3 mg/kg/day (115, 117).

### Clobazam

*Biotransformation, Pharmacokinetics, and Interactions.* Clobazam, which differs from the 1,4-benzodiazepines by the presence of a nitrogen atom in the 1 and 5 positions of the diazepine ring, is relatively insoluble and cannot be administered intravenously or intramuscularly. Oral clobazam is absorbed rapidly, and peak concentrations are reached in 1 to 4 hours (120). It is highly lipophilic, distributed rapidly, and approximately 85% protein bound. Factors that influence protein binding, for example, liver disease, may affect the free and total levels of the drug (121). Clobazam is metabolized extensively in the liver to several metabolites including N-desmethyloclobazam, which also has antiepileptic activity. The elimination half-life of clobazam is 18 hours, and that of N-desmethyloclobazam is 42 hours (121). Thus, blood levels of N-desmethyloclobazam are approximately 10 times those of clobazam (122), and N-desmethyloclobazam is considered to be responsible for most of the antiepileptic effect in patients receiving clobazam (121).

Comedication with phenytoin, phenobarbital, or carbamazepine increases the N-desmethyloclobazam/clobazam ratio (123). Clobazam increases phenytoin concentrations (124) and may result in phenytoin intoxication (125, 126). Clobazam has also been reported to increase valproate levels, which may remain elevated for several weeks after the clobazam has been withdrawn (127), and may result in valproate toxicity (128). Mild increases in phenobarbital, carbamazepine, and carbamazepine epoxide have also been reported (124).

*Clinical Efficacy.* The use of clobazam in the treatment of epilepsy was pioneered by Gastaut and Low, who reported its effectiveness in patients with partial seizures, idiopathic generalized epilepsy, reflex epilepsy, and Lennox-Gastaut syndrome (129). The antiepileptic effect of clobazam in partial and tonic-clonic seizures has been demonstrated in several placebo-controlled studies (121). In addition, clobazam monotherapy has been demonstrated to be as effective as either carbamazepine or phenytoin in the treatment of children with partial, tonic-clonic seizures, or both, who were previously untreated or who had received only one drug (15). Clobazam appears to have a broad spectrum of antiepileptic activity. In a large retrospective study comprising 1,300 refractory epileptic patients, including 440 children, more than 50% reduction in seizure frequency was observed for each seizure type (except tonic seizures) in 40% to 50% of patients and complete seizure control was obtained in 10% to 30% (128). It has also been reported to be effective in the treatment of reflex epilepsies (130–132),

startle epilepsy (133, 134), epilepsy with continuous spike-waves during slow sleep (135), and eyelid myoclonia with absence (136). Complete seizure control was described in 20% of patients with temporal lobe seizures associated with hippocampal sclerosis, and 75% reduction in seizure frequency in a further 25% (137). Clobazam taken intermittently for 10 days each month around the time of menstruation was effective in the treatment of catamenial epilepsy and was not associated with tolerance (138, 139). Administration of intermittent clobazam has also been used successfully by the author in the treatment of seizures that occur periodically in clusters. Prophylactic clobazam has been used prior to bone marrow transplantation in the prevention of seizures induced by high-dose busulfan chemotherapy (140).

*Adverse Effects.* A major advantage of clobazam over the 1,4-benzodiazepines is the lower incidence of neurotoxicity. In a double-blind comparison of clobazam with phenytoin or carbamazepine in children, the incidence of side effects was similar (15). The side effects of clobazam are generally mild and resolve with dosage reduction. Drowsiness, short attention span, mood change, ataxia, and drooling may occur. These occur less commonly than in patients receiving 1,4-benzodiazepines (13). Marked worsening of behavior has been reported in some patients in open studies but does not appear to occur any more commonly than with carbamazepine or phenytoin (15). Excessive weight gain, which responds to withdrawal of the drug, has been reported (13). Hematologic and hepatic side effects have not been reported, and drug-induced skin rash is extremely rare.

Open studies in children have reported tolerance in 18% to 65% of patients (12–14, 141, 142), but most of these studies comprised patients who had been intractable to several antiepileptic drugs. In a controlled study in children who were previously untreated or who had received only one drug, the incidence of tolerance was similar in patients receiving clobazam (7.5%), carbamazepine (4.2%), and phenytoin (6.7%) (15).

*Clinical Use.* Clobazam should be started at a dosage of 2.5 mg/day in infants and 5 mg/day in older children. The dose can be increased at 5- to 7-day intervals until the seizures are controlled or side effects occur. Although doses of up to 3.8 mg/kg/day can be administered to children without undue side effects, dosages greater than 1 mg/kg/day are rarely associated with improved seizure control (13). In teenagers and adults, the initial dose is 10 mg/day. The dose can be increased at 5- to 7-day intervals, but those who do not respond to 30 mg/day respond rarely to higher doses (121). Clobazam is usually administered at night or twice a day. To minimize the risk of withdrawal seizures, discontinuation should be done gradually over several weeks. Drug level monitoring is not clinically useful.

## Carbamazepine and Oxcarbazepine

*W. Edwin Dodson*

### **CARBAMAZEPINE**

Introduced in 1962 for treatment of trigeminal neuralgia, carbamazepine (CBZ) has emerged as a highly effective treatment of epilepsy with partial and secondarily generalized seizures. It has also been reported to benefit neuropathic pain, certain behavior disorders, and affective disorders. At first, CBZ was used to replace sedating anti-epileptic drugs, but over time it became the initial therapy for treatment of localization-related epilepsy with partial (focal) seizures and epilepsy with generalized tonic-clonic seizures. Although CBZ produces side effects in many patients, the low incidence of cosmetic, cognitive, and behavioral side effects are advantages. The major disadvantages have been its propensity to interact with other drugs, to cause rashes and to aggravate absence and atstatic seizures in patients with generalized epilepsy.

### **Clinical Efficacy**

Carbamazepine is effective in partial (focal seizures), especially complex partial (psychomotor) seizures and generalized tonic-clonic (grand mal) seizures (1, 2). It is ineffective in febrile seizures and absence seizures. Furthermore, children with the Lennox-Gastaut syndrome sometimes have CBZ-induced worsening of several types of seizures, especially atypical absence seizures and atstatic

seizures, also called drop attacks (3, 4). Nonetheless, numerous studies have shown that CBZ is just as effective as other major anticonvulsants when prescribed for the appropriate type of seizure (5–14). For example, in benign rolandic epilepsy, a pediatric epileptic syndrome characterized by partial seizures, CBZ is effective in 94% of patients, producing complete control in 65%. Given its comparable efficacy to other first-line anticonvulsants, the somewhat unique spectrum of adverse effects associated with CBZ differentiates it from other antiepileptics. Although different rates of response to CBZ have been linked to age and gender, these differences appear to be small.

Carbamazepine has been reported to be more effective in girls than boys, and more effective in older patients than in children (15, 16). The causes for these differences are most likely pharmacokinetic, although they may also relate to distribution of seizure types in various age groups. For example, lower CBZ concentrations have been found among nonresponding children (17). Furthermore, young children have accelerated relative clearance of CBZ as compared to older children. Partial or generalized tonic-clonic seizures are the predominant seizure types in 55% and 90% of children and adults, respectively (18, 19).

The major mechanism of action of CBZ is to limit use-dependent increases in sodium conductance, thereby restricting neuronal high-frequency discharges. This mechanism is shared by phenytoin, oxcarbazepine, lamotrigine,

topiramate, and felbamate, but differs from the mechanisms of actions of barbiturates, benzodiazepines, valproate, and succinimides (20). This mechanism at sodium channels correlates with clinical efficacy against partial and generalized tonic-clonic seizures. In experimental animals brain CBZ concentrations of 3.5 to 4.5  $\mu\text{g/g}$  prevent maximal electroshock-induced seizures (21).

Carbamazepine in therapeutic concentrations has few effects on the electroencephalogram (EEG). It does not produce frontal low-voltage fast activity like that caused by barbiturates and benzodiazepines (22). High concentrations of CBZ produce generalized slowing. The effect of CBZ on seizure activity in the EEG varies depending on its efficacy. When CBZ is effective in preventing seizures, focal spikes at first become more brief and sharp and eventually may disappear (23). Discontinuation of CBZ is associated with an increase in the mean dominant rhythm frequency (24). Generalized spike and spike-wave abnormalities either are unaffected by CBZ or worsen (16).

Other uses of CBZ include the treatment of chronic neurogenic pain (25, 26), hemifacial spasm (27), and affective disorders (28–33), although most of the data supporting CBZ use in affective conditions are case reports, retrospective reviews, or open label, uncontrolled trials. Carbamazepine also has been used to treat attention deficit hyperactivity disorder in children and in other psychiatric conditions (34–38). In combination with lithium, CBZ has been used to treat refractory depression, refractory mania, and rapid cycling depression (39–41). Carbamazepine also may be beneficial in the dyscontrol syndrome, a disorder characterized by episodic aggressive outbursts (42, 43). Among impulsive hyperkinetic children with attention deficit disorder, the administration of CBZ is preferred over barbiturates, benzodiazepines and vigabatrin, and other GABA agonists, because the latter cause worsening of behavior in a substantial percentage of patients (18, 44–48).

After patients who have side effects due to other anticonvulsants are switched to CBZ, overall functioning often improves. When this occurs, it has been called a psychotropic action. Subjectively, these changes are described as less dulling of mentation, having a steadier gait, and improved attention and alertness (47). The improvement is most dramatic among patients who are switched from multidrug regimens that include barbiturates to monotherapy with CBZ. On the other hand, CBZ does not enhance cognitive function or behavior in otherwise normal patients unless seizures are occurring frequently enough to impair thinking.

### Chemistry

Carbamazepine is a tricyclic compound related to iminostilbene (49). Although the two-dimensional structure of CBZ resembles tricyclic antidepressants, its three-dimensional

conformation is more akin to phenytoin. Carbamazepine is a hydroscopic, neutral, lipophilic chemical that is soluble in organic solvents but possesses low water solubility. Due to limited aqueous solubility, CBZ has never been formulated for parenteral administration. Its crystalline structure and the structure-dependent dissolution rate of CBZ are sensitive to its extent of hydration. Exposure to high humidity leads to increasing hydration of CBZ causing the progressive development of a crystalline lattice that resists dissolution and is thereby insoluble. Thus patients who take carbamazepine that has been stored in humid and warm environments are at risk to experience drops in carbamazepine levels.

### Biotransformation, Pharmacokinetics, and Interactions in Humans

Carbamazepine is eliminated largely by hepatic metabolism. Unique among unsaturated heterocyclic chemicals, the predominant elimination pathway in humans results in the formation of a stable epoxide that accumulates in serum. This compound, carbamazepine-10-11-epoxide (CBZE), has actions similar to CBZ but it is less potent in experimental models of epilepsy (50). The epoxide is hydrolyzed subsequently to form an inactive 10, 11-dihydroxide, the principal urinary metabolite. Lesser amounts of CBZ are metabolized by aromatic hydroxylation of the lateral rings. Carbamazepine is also a potent broad spectrum inducer of hepatic cytochrome P 450 enzymes, which metabolize other antiepileptic drugs.

#### Pharmacokinetics

Carbamazepine has linear, predictable elimination kinetics (Table 42-1 and Table 42-2). In individual patients,

**TABLE 42-1**  
**Carbamazepine Reference Information**

<b>CARBAMAZEPINE (CBZ)</b>	
Molecular weight	236.26
Conversion factor	CF = 1,000/236.26 = 4.23
Conversion	$\mu\text{g/mL}$ or $\text{mg/L} \times 4.32 = \mu\text{mol/L}$
<b>CARBAMAZEPINE-10,11-EPOXIDE (CBZE)</b>	
Molecular weight	252.3
Conversion factor	CF = 1,000/252.3 = 3.96
Conversion:	$\mu\text{g/mL}$ (or $\text{mg/L}) \times 3.96 = \mu\text{mol/L}$
<b>RATIO OF CBZE TO CBZ</b>	
Monotherapy	0.10–0.20
Polytherapy	0.15–0.66
From (22, 50).	

**TABLE 42-2**  
*Carbamazepine Administration and Pharmacokinetics*

Type of elimination kinetics	Linear
Special pharmacokinetic features	Autoinduction, dissolution-rate-limited absorption
Maintenance dose	10–20 mg/kg/day
Therapeutic concentration range	4–12 mg/L
Half-life (range)	5–36 hours*
Formulations	
Suspension (Tegretol)	50 mg/mL
Chewable tablet (Tegretol)	100 mg
Tablet (Tegretol, generic)	200 mg
Sustained release granules (Carbatrol)	200, 400
Sustained release (Tegretol XR)	100, 200, 400
From (22).	
Half-life varies with duration of therapy (autoinduction), age, pregnancy, and comedication.	

but not in groups of patients, the relationship between CBZ dose and concentration are linear and predictable (51–53). However, when standardized doses of CBZ are given to a large group, there is a wide scatter in the concentrations because of individual differences in CBZ elimination. Therefore, little or no correlation is found between CBZ doses and concentrations in groups (54, 55). Because of this, measurement of CBZ concentrations in blood is an important aspect of individualizing CBZ doses.

**Elimination.** CBZ induces its own metabolism by stimulating the activity of the CYP3A4 isozyme of cytochrome P450, a process called autoinduction (56, 57). Autoinduction causes the elimination rate of CBZ to increase in the days that follow the initiation or modification of doses. Because this process takes several weeks to evolve fully, CBZ pharmacokinetics have also been described as time-dependent kinetics. Among both children and adults who have not previously taken hepatic enzyme-inducing drugs, the half-life of CBZ decreases approximately 50% as autoinduction takes place, with the half-life declining from 36 hours after the first dose to 18 to 20 hours following chronic monotherapy in adults (52, 57). Likewise, studies in children indicate similar magnitudes of change with doubling of CBZ clearance (0.028 L/kg/hr to 0.056 L/kg/hr) after 2 or 3 weeks of therapy (58). Thus in all age groups, autoinduction causes levels to be approximately 50% of what would be predicted from first dose pharmacokinetics. Autoinduction is usually complete 3 to 6 weeks after a change in CBZ dose.

It is important to recognize autoinduction and not to mistake it as noncompliance. If constant doses are given during the first weeks of treatment, the concentration of CBZ increases at first and then declines. When seizures are controlled initially but then recur, autoinduction causing reduced CBZ levels may be the explanation.

The half-life of the epoxide metabolite has been estimated to range from 10 to 20 hours in patients who ceased taking CBZ (57, 59). When CBZE was administered to normal volunteers, a shorter half-life of  $6.1 \pm 0.9$  hours was found (60). Among this same group of subjects the half-life of CBZ was  $26 \pm 4.6$  hours, but autoinduction probably was incomplete.

Carbamazepine elimination is influenced by age, pregnancy, and drug interactions (61). As with other antiepileptic drugs, the relative clearance of CBZ is much higher in young children but declines to adult values in the later years of childhood. Younger patients and pregnant women in their last trimester have higher relative clearance and require higher relative doses than other patients (51). They also have higher ratios of CBZE to CBZ (62).

The ratio of CBZE to CBZ is 10% to 15% in adults. During childhood and pregnancy the ratio is higher, ranging up to 20%. In certain drug interactions involving valproate, the ratio can exceed 50%. Valproate elevates the ratio because it inhibits epoxide hydrolase and increases the epoxide concentration.

**Absorption rate varies with formulation.** The bioavailability of CBZ has been estimated to be 75% to 85% (52, 63). Food variably increases the rate of absorption (52). Larger doses may be absorbed more slowly than smaller ones. Slow absorption facilitates once daily administration in some patients. However, most authorities recommend more frequent administration to minimize the chance of side effects (64) and to minimize the impact of forgotten doses.

Carbamazepine is absorbed slowly after oral administration of tablets, with peak concentrations occurring 4–8 hours after ingestion (22). This tardy absorption results from slow dissolution of CBZ tablets. For this reason, CBZ absorption has been described as dissolution

rate limited (52). Variations in the CBZ formulation significantly affect tablet dissolution rate and thus the absorption rate. Slow-release formulations such as Tegretol XR<sup>®</sup> and Carbatrol<sup>®</sup> slow absorption even more than the Tegretol<sup>®</sup> formulation. Tegretol XR<sup>®</sup> uses the Oros osmotic mechanism of slow release, whereas Carbatrol<sup>®</sup> slows dissolution by coating CBZ-containing particles (65). The Oros formulation consists of an osmotic core surrounded by a semipermeable membrane. When water enters the chamber in the center of the tablet, it forces the drug out of the delivery orifice into the gastrointestinal tract.

Carbatrol is a mixture of beads with three different coatings that dissolve at different rates. The so-called immediate coating dissolves quickly and initiates absorption. A slow-release coating of other beads is removed more slowly and releases the CBZ later. Finally, a pH-sensitive coating triggers dissolution in the alkaline pH of the small intestine (66). Crystalline matrix “retard” formulations, marketed as Timonil Retard<sup>®</sup> or Tegretol Retard<sup>®</sup> in Europe, also significantly attenuate the fluctuation index between doses (67, 68). In some patients this allows twice daily dosing, which is more convenient, encourages compliance, and reduces the chance of side effects (69).

Suspensions and certain generic formulations are absorbed more rapidly than proprietary Tegretol. For some patients, especially children who have short half-lives for CBZ, rapid absorption confounds their treatment, and switching to slow-release formulations can improve seizure control and reduce side effects.

For most patients slow absorption of CBZ is preferred. Generic formulations tend to be absorbed more rapidly than brand name formulations. For patients who require high, nearly toxic concentrations of CBZ for seizure control, switching to a more rapidly absorbed generic formulation can cause both seizure relapse and side effects due to wider fluctuations in CBZ concentrations between doses. Thus, the decision to substitute generic CBZ must be considered on a case-by-case basis. Generic CBZ is suitable mainly for those patients with mild epilepsy who are treated adequately with low levels.

Rapid elevation of the CBZ concentration is desirable for certain patients such as those who have completed video-EEG recording to determine whether they are candidates for epilepsy surgery or those who need their drugs switched rapidly. The administration of 8 mg/kg of CBZ suspension or tablets produces therapeutic levels in 2 and 5 hours, respectively (69).

**Distribution.** The volume of distribution for CBZ ranges from 0.93 to 1.28 L/kg (22). The brain-to-plasma ratio of both CBZ and CBZE is approximately 1, with a range of 0.8 to 1.6 (22, 70). Approximately 75% and 50% of CBZ and CBZE are bound to albumin,

respectively (22). Concentrations of CBZ and CBZE in cerebrospinal fluid (CSF) are consistent with the protein binding values in serum and CSF concentrations equal the unbound fractions in plasma. The CSF-to-plasma concentration ratios average 0.25 and 0.50 for CBZ and CBZE, respectively. Note that the binding of these compounds is low enough that unless CBZ levels are high, the consequences of altered CBZ binding to constituents of plasma are usually trivial and do not justify routine measurement of free CBZ levels (71). Salivary concentrations of CBZ also approximate the unbound concentrations in plasma, although the ratio of CBZ levels in plasma versus saliva varies during the day (72).

Carbamazepine crosses the placenta and penetrates breast milk. Transplacentally acquired CBZ concentrations in newborns at birth correlate highly with those found in maternal plasma (55). Newborns who have been exposed to CBZ in utero experience autoinduction of CBZ metabolism and eliminate CBZ at rates comparable to adults. Among newborns acquiring CBZ transplacentally, the reported half-lives have ranged from 8.2 to 28.1 hours (55). Among mothers taking CBZ, concentrations in their breast milk are so low that nursing infants rarely ingest a substantial dose.

### **Drug Interactions**

Pharmacokinetic drug interactions involve both CBZ metabolism and CBZ binding to serum proteins (73). Numerous drugs including phenytoin, phenobarbital, and primidone induce hepatic enzymes responsible for CBZ biotransformation (74). Phenobarbital has the greatest effect, reducing the average half-life to 10–11 hours in adults. Adult patients taking all three together have an average half-life of 10.6 hours (60). Among patients on polytherapy, CBZ half-lives may be as short as 5 hours, half-lives that are considerably shorter than the average values of 18 to 20 hours reported for adults on CBZ monotherapy (75).

Valproate increases the unbound fraction of both CBZ and CBZE, and it inhibits the hydrolysis of CBZE by epoxide hydrolase, thereby increasing the ratio of CBZE to CBZ (63, 64). Under these circumstances, the valproate concentration correlates with the unbound CBZ fraction (76). Valproate and valpromide reduce the clearance of CBZE by inhibiting hepatic microsomal epoxide hydrolase (77, 78). The highest CBZE concentrations, which sometimes exceed 50% of the CBZ level, occur when CBZ is administered simultaneously with both an inducing agent, such as phenytoin, and with valproate. In these situations CBZE levels may be high enough to contribute to neurotoxicity. Note that routine CBZ levels do not include CBZE.

Patients with “therapeutic” concentrations of both phenytoin and CBZ sometimes develop side effects (57, 65). Evidence has also been found for a pharmacodynamic

interaction between CBZ and phenytoin in experimental animals (79). Pharmacodynamic interactions take place in the target organ and are not secondary to changes in drug concentrations. Morris et al found that in mice, the therapeutic index of combined CBZ and phenytoin was no better than either drug given singly (79). Both efficacy in prevention of seizure and neurotoxicity increased when these drugs are given simultaneously. Although comparable data in humans are lacking, it is highly likely that the toxicities of CBZ and phenytoin are additive in humans.

A toxic pharmacodynamic interaction has also been described between CBZ and lamotrigine (80). Patients who had CBZ concentrations greater than 8 µg/mL developed diplopia and dizziness after lamotrigine was added on, even though the CBZ concentration did not change and lamotrigine levels were in the nontoxic range. After the CBZ dose was decreased, the side effects resolved.

CBZ also accelerates the metabolism of folic acid and biotin (81). Folic acid deficiency can cause psychiatric symptoms and should be considered when patients who have been treated chronically with inducing antiepileptic drugs develop psychiatric symptoms (82). Even more critical, folate deficiency during pregnancy has been linked to neural tube defects and folate supplementation has been recommended for all women of childbearing potential (83, 84). Needless to say folate supplementation is doubly important for women with epilepsy.

Several drugs inhibit CBZ elimination and cause CBZ levels to increase (Table 42-3). Isoniazide and CBZ increase the concentration of each other (85). Among the macrolide antibiotics, erythromycin, triacetyloleandomycin, and clarithromycin inhibit the biotransformation of CBZ, causing predictable increases in CBZ levels and neurotoxicity if the CBZ dose is not reduced (86–89). Other macrolide antibiotics have weaker and inconsistent effects on CBZ levels. Several antidepressants and selective serotonin reuptake inhibitors are competitive substrates with CBZ for CYP3A4 (90). Dextropropoxyphene and the antidepressant viloxazine increase CBZ levels after chronic administration (91). Nicotinamide, which is chemically related to isoniazide, also inhibits CBZ elimination, causing CBZ concentrations to increase (92). Carbamazepine does not interact with disulfiram (93) and cimetidine (94), which are metabolized by CYP2C9 and CYP2C19, but not by CYP3A4 (57, 95, 96).

Add-on therapy with CBZ reduces the concentrations of other anticonvulsants that are eliminated by hepatic metabolism, because it is a potent inducer of cytochrome P 450 (97). Carbamazepine causes ethosuximide levels to decline by an average of 17% and lowers valproate levels twice as much, increasing the clearance of valproate by one-third or more (98). The addition of CBZ to phenytoin usually decreases phenytoin concentrations, but the mechanism of the interaction is complex, with CBZ decreasing both the  $V_{max}$  and the  $K_m$  of phenytoin

\*Interaction is variable. Usually CBZ decreases phenytoin levels, but sometimes the opposite is seen (105)

elimination (99), because it stimulates the activity of cytochromes CYP2C9 and CYP2C19 both of which catalyze phenytoin elimination (98).

The induction of CBZ elimination by other drugs changes the relationship between CBZ dose and concentration. Among children on monotherapy, each 2 mg/kg/day dosage increases the CBZ concentration by 1 µg/mL. When other antiepileptics are given simultaneously, more than 3 mg/kg/day are required to increase the CBZ concentration by 1 µg/mL (55). Typically, patients receiving polytherapy have lower concentrations despite higher doses (100). Furthermore, patients receiving polytherapy need more frequent doses to avoid intermittent side effects, which occur due to wide fluctuations in serum levels (65).

*Changes of drug regimens that involve CBZ.* When adding or deleting CBZ, remember that other inducers of hepatic cytochrome P 450 enhance CBZ metabolism and

vice versa. Thus, when CBZ is added to an antiepileptic drug regimen, it usually lowers the concentration of other antiepileptic drugs that are subject to hepatic biotransformation. For this reason the dose of the first drug should be held constant as CBZ is added until the concentration of the CBZ exceeds 4  $\mu\text{g/L}$ . Then the original drug can be tapered over a period of three or more weeks, depending on the drug. After this is completed, the CBZ level usually increases if the drug that was replaced was a cytochrome P 450 inducer. This process in which discontinuation of an inducing drug leads to an increase in drug level is called dis-induction (70). Note that because discontinuation of benzodiazepines may evoke withdrawal seizures, they should be reduced quite slowly, usually over several months to years. Furthermore, patients with severe epilepsy who are having frequent seizures may need to be hospitalized while their regimens are simplified because of the risk of provoking convulsive status epilepticus by changing the medications.

*Adverse effects.* Carbamazepine is generally well tolerated (101–103). Although some authorities report side effects in as many as 63% of patients (12, 104), most of the side effects do not warrant discontinuation of therapy. In one pediatric study, 43% had side effects. However, these were usually mild and tolerable such that only 3% discontinued the medication and another 3% required a dosage reduction (103). The most frequent neurologic side effect, drowsiness, occurred in 11%. Gastrointestinal complaints were uncommon. In chronic therapy tolerance develops to the neurologic side effects of CBZ and many of them abate completely (102). As with most other antiepileptic drugs, starting at a low dose and slowly escalating to the desired maintenance doses causes fewer side effects than rapidly raising the dose or starting at full maintenance dose (105).

At concentrations greater than 12  $\mu\text{g/mL}$  side effects are increasingly common. Unbound CBZ levels correlate better with neurotoxicity than total CBZ levels in serum (65). Unbound CBZ concentrations of 1.7  $\mu\text{g/mL}$  or more usually produce side effects. High levels of CBZ cause sedation, vertigo, and ophthalmoplegia resulting in the “3-D” triad of drowsiness, dizziness, and diplopia (6, 8, 23, 106). Brief episodes of toxicity can result from transient elevations of CBZ concentrations due to fluctuations between doses (69, 105–107). In these situations it is necessary to administer smaller, more frequent doses—or better yet, switch to a slow release CBZ formulation. When concentrations are less than 8  $\mu\text{g/mL}$ , dose-related side effects are uncommon unless therapy has been initiated rapidly with high doses or unless the patient is taking other medications that have side effects that are additive to the side effects of CBZ (56, 108). Overdoses have been associated with symptoms resembling the central anticholinergic syndrome similar to that caused by tricyclic antidepressants (109, 110).

Whereas high concentrations are likely to cause neurologic side effects, at usual concentrations CBZ appears to have few if any effects on cognitive function (104, 111, 112).

Hyponatremia caused by CBZ occurs in patients of any age (113) but is more common among the elderly (114, 115). It is usually mild and asymptomatic in children (116). Oxcarbazepine is much more likely to cause hyponatremia than CBZ and can be problematic (116). Interestingly, CBZ-induced hyponatremia is said to be reversed by phenytoin (117).

Chronic side effects of CBZ differ from other anticonvulsants. In contrast to phenobarbital and phenytoin, CBZ monotherapy has not been associated with anticonvulsant-induced osteomalacia (118, 119, 120). Similarly, among the antiepileptic drugs CBZ is one of the least likely to cause cosmetic side effects. Gingival hyperplasia is not a problem with CBZ monotherapy (121).

Carbamazepine variably affects other laboratory tests. It lowers the plasma concentrations of thyroid-binding globulin and both bound and unbound T4 and T3 (122), but clinical hypothyroidism is rare among patients taking CBZ. Among the anticonvulsants used to treat major seizures, CBZ is least likely to elevate the gamma glutamyl transpeptidase (123).

Idiosyncratic neurologic adverse reactions include behavioral reactions, tics, asterixis, dystonia, and worsening of seizures, especially atonic or astatic seizures in children with Lennox-Gastaut syndrome (3, 124–127). Dystonia induced by CBZ at usual doses in brain-damaged children is rare and apparently idiosyncratic (128); it is more common with CBZ poisoning and high levels (129). Patients with cerebellar atrophy develop gaze-evoked nystagmus, dizziness, and ataxia at lower CBZ doses and levels than patients who have normal magnetic resonance imaging (130). Acute idiosyncratic, adverse behavioral reactions have occurred among children with psychiatric disorders. Silverstein et al (131) reported episodic bizarre behavior among seven pediatric patients after CBZ was added. However, five of the seven children tolerated CBZ when it was reintroduced later.

*Hematologic side effects.* Severe idiosyncratic hematologic toxicity such as aplastic anemia, agranulocytosis, or thrombocytopenia is rare among patients taking CBZ (132–136). The incidence of these complications has been estimated to be less than 1 per 50,000 (137). Thus in spite of previous concerns, experience has shown CBZ to be safe.

On the other hand, CBZ is associated with a dose-dependent reduction in neutrophil counts in 10% to 20% of patients. In adult psychiatric patients leukopenia occurred in 2.1% of patients who took CBZ and was approximately seven times more likely with CBZ than with valproate or with antidepressants (138). For example,

in one study of 200 children taking CBZ, leukopenia (white blood count  $<4,000$  per  $\text{mm}^3$ ) occurred in 17% of patients less than 12 years old and 8% of children aged 12 to 17 years (138). These changes sometimes persist but usually do not forebode serious problems (7). Rarely does the neutrophil count decline below  $1,200/\text{mm}^3$  (139). For this reason the justification for costly, routine monitoring of blood counts has been questioned (137).

Although there is agreement about obtaining baseline blood counts, there is no consensus about how often blood counts should be determined during CBZ therapy (137, 138). Some authorities almost never obtain blood counts; others do them weekly at the onset of CBZ therapy and then monthly. Emphasizing that many factors influence the white blood count simultaneously, Silverstein et al recommended doing blood counts monthly during the first six months of therapy and every three months thereafter (138).

When starting CBZ, I check blood counts at baseline and after 6 weeks, 3 months, and 6 months if the counts are adequate. If the leukocyte count is consistently at or greater than  $3,500/\text{mm}^3$  and the granulocytes above 1,200, the frequency of the measurements can be reduced. Because of the possibility of a spurious laboratory result, neutrophil counts lower than  $1,200/\text{mm}^3$  and leukocyte counts of less than  $3,500/\text{mm}^3$  should be repeated to confirm the finding before therapy is modified. If the neutrophil count is confirmed to be less than  $1,200/\text{mm}^3$ , the frequency of the observations should be increased. The dose should be reduced or stopped if the neutrophil count is persistently less than  $900/\text{mm}^3$ .

If both anemia and neutropenia occur, obtaining a reticulocyte count, serum iron concentration, and iron-binding capacity provides an indirect indication of hematopoietic activity. The combination of a normal or elevated reticulocyte count with a normal or low iron level is reassuring that the bone marrow is active. On the other hand, a low reticulocyte count plus an increased serum iron concentration indicate that hematopoietic activity is reduced. If this occurs, CBZ should be stopped promptly and a hematologist should be consulted regarding a bone marrow evaluation.

Allergic rash is the most common reason that patients are intolerant of CBZ. The incidence of rash has varied from 4% to 10% in various series (12, 18) and may result from the intradermal production of reactive CBZ metabolites (140). Data from Saskatchewan indicate that the risk of serious rash is about the same with CBZ as with phenytoin, approximately 1 to 4 per 10,000 (141). Most CBZ-induced rashes abate after CBZ is discontinued, but severe rashes have been described (142, 143). Approximately 1 in 3,000 patients who are treated for epilepsy develop hypersensitivity to multiple antiepileptic drugs that have aromatic structures, including phenytoin, primidone, and phenobarbital along with CBZ and in some cases sulfonamides (140,

144–146). When multiple drug sensitivities occur, valproate and clobazam have been recommended (147).

Hypersensitivity reactions characterized by fever, renal, and hepatic toxicity are very rare (136, 148–150). Hepatotoxicity due to CBZ like that caused by phenytoin usually has occurred in the setting of a generalized hypersensitivity response (151). Most of the patients who have developed CBZ-induced hepatic dysfunction have taken it for less than 1 month and usually have associated fever or rash (152, 153). The hepatic histopathology usually indicates an inflammatory granulomatous infiltrate, but a different pathologic picture consistent with chemical hepatic insult also occurs (154). Furthermore, some cases have occurred when CBZ was administered with other potentially hepatotoxic agents such as isoniazide (155). In either case, fatalities are uncommon if the drug is stopped promptly (156, 157).

Carbamazepine therapy has been associated with erectile dysfunction possibly due to CBZ-induced hepatic synthesis of sex hormone-binding globulin and that potentially could lead to reduced unbound concentration of testosterone (158).

Other rare idiosyncratic reactions include systemic lupus erythematosus (SLE) and pseudolymphoma (159–162). Most of the cases of pseudolymphoma seem to be manifestations of the CBZ hypersensitivity syndrome.

### *Monotherapy*

Monotherapy with CBZ is often superior to polytherapy. Approximately 80% of patients with only generalized tonic-clonic seizures (grand mal) can be controlled with CBZ alone as can 69% of patients with partial seizures of certain types (16). The most difficult patients are those who have both partial and secondarily generalized seizures in whom single drug therapy succeeds in less than half. Although most authorities agree that these types of patients deserve a trial of therapy with drug combinations, all patients should have a diligent trial of monotherapy before resorting to polytherapy. Among patients with severe epilepsy, combinations of CBZ, phenytoin, and phenobarbital are more efficacious than monotherapy, but severe side effects are prevalent. Cereghino et al (163) found that 68% of adults who took these drugs concurrently had excessive sleepiness, malaise, and impaired abilities to conduct their daily activities.

In the end the impairment due to neurotoxicity must be weighed against the handicap caused by the seizures. The regimen that allows the patient to function optimally is best. Many patients with persistent seizures and side effects taking polytherapy are better off after having their regimens simplified (164, 165). Schmidt was able to switch 83% of patients with intractable complex partial seizures from two medications to CBZ monotherapy with fewer side effects but no increase in seizure frequency; 36% had fewer seizures (166). In another series, 75% of

FIGURE 42-1

Structures of oxcarbazepine and its 10-monohydroxy derivative.

280 patients had adequate seizure control with monotherapy (155). In yet another series involving mentally retarded institutionalized patients, seizure control was no different on monotherapy versus polytherapy (167). Thus many patients who are having both side effects and seizures benefit from simplified regimens.

### OXCARBAZEPINE

Oxcarbazepine (OXC; Trileptal) is the 10-keto analog of CBZ. It has gained wide acceptance and use for treatment of epilepsy with partial onset seizures (168–170). The main advantages of OXC over CBZ are its relatively reduced capacity for induction of hepatic cytochrome drug metabolizing enzymes resulting in fewer drug interactions and reduced risk of allergic rash (171, 172). Unlike CBZ, oxcarbazepine does not induce its own metabolism and autoinduction is not an issue. Oxcarbazepine and CBZ appear to share the same mechanisms of action and act to limit high frequency firing by acting on voltage-dependent sodium channels (173). Although case reports and uncontrolled studies have suggested that OXC might be beneficial in childhood bipolar disorder (174), prospective controlled trials are generally lacking or negative. In one report OXC was inferior to valproate and was associated with increased aggression (175, 176). In animal models of combination antiepileptic therapy studied by isobolographic analysis, combinations of OXC with topiramate were favorable whereas OXC with either felbamate or lamotrigine were unfavorable due to additive neurotoxicity that was disproportionately greater than efficacy (177).

#### Biotransformation, Pharmacokinetics, and Interactions in Humans

Oxcarbazepine is well absorbed after oral administration and then it is rapidly converted by cytosolic arylketone reductase to the active 10-monohydroxy derivative

(MHD), which is responsible for most of the antiepileptic effect (178) (Figure 42-1). Concentrations of MHD peak 4 to 12 hours following oral doses of OXC (179). Concentrations of both compounds are linearly related to dose and have been reported to be little affected by interactions with hepatic enzyme-inducing agents (179). Neither compound is highly protein bound, with OXC being 60% bound and MHD 40% bound (180). Whereas the half-life of OXC is 1 to 2.5 hours, the half-life of MHD is 8–10 hours in children (181, 182) with longer values reported in normal volunteers, adults, and elderly patients (179). Moreover, as with other antiepilepsy drugs (AEDs), younger children eliminate OXC and MHD faster than older children and adults, with young children (age 2–5 years) having half-lives for MHD that were 30% shorter than those found in older children (age 6–12 years) (183, 184). Although the conversion of OXC to MDH results in a racemic mixture of enantiomers with the dextrorotary isomer being produced in fivefold greater amounts than the levorotary isomer (185, 186), both stereoisomers are active antiepileptic agents. The MHD is eliminated mainly in urine after conjugation to glucuronic acid. Mild to moderate hepatic dysfunction has no effect on OXC and MHD elimination, but renal impairment can necessitate reducing the dose (179). The therapeutic range of MHD has been proposed to be 50 to 140  $\mu\text{mol/L}$  (187) or 15–35 mg/L (179). Oxcarbazepine and MDH can be monitored in saliva (188, 189). Both OXC and MHD cross the placenta and also enter breast milk in concentrations roughly half of those in plasma (190, 191). Clearance of OXC and MHD increases during pregnancy, causing levels to decrease. The extent of this decrease was greater with OXC monotherapy than with other AEDs and the risk of seizures was higher (192).

Both OXC and its metabolite have a spectrum of activity that is similar to CBZ. Oxcarbazepine is effective as add-on therapy in refractory seizures and as initial monotherapy in new onset seizures (193). Although OXC and CBZ seem to share common mechanisms of action,

some patients who are inadequately treated with CBZ improved after they were switched to OXC (194). In a double-blind, randomized study that compared OXC to phenytoin in 193 children aged 5 to 18 years with new onset partial or generalized tonic-clonic seizures, efficacy was equivalent, with approximately 60% of subjects in each group becoming seizure free (195). However, oxcarbazepine was better tolerated as demonstrated by more subjects discontinuing phenytoin due to adverse effects.

#### *Oxcarbazepine Drug Interactions*

Oxcarbazepine inhibits CYP2C19 and, although usually clinically irrelevant, it can increase phenytoin concentrations when phenytoin levels are high to begin with. Both OXC and MHD can induce UDP-glucuronyl

transferase activity. Oxcarbazepine usually has little or no effect on concentrations of valproate, phenobarbital, CBZ, and low concentrations of phenytoin; however, each of these compounds can decrease the concentration of MHD by 20% to 40% (196). Interactions with lamotrigine have been reported to be negligible among psychiatric patients (197). Oxcarbazepine also induces CYP3A4/5, whereby it can lead to reduced concentrations and effectiveness of low estrogen dose oral contraceptives (179, 198, 199).

*Adverse effects.* Studies of cognitive adverse effects of CBZ and OXC have found no differences (200). Like CBZ, OXC has been reported to exacerbate seizures in patients with idiopathic epilepsy, including some patients with benign partial epilepsy of childhood (5, 201–203). Oxcarbazepine has a lower incidence of allergic reactions and is less neurotoxic (204–207). However, it causes symptomatic hyponatremia more frequently than CBZ (205–208), with hyponatremia (<125 mEq/L) occurring in 3% of subjects in initial clinical trials (208). Neurologic side effects are most common and include dizziness, headache, diplopia, ataxia, fatigue somnolence, and rash followed by gastrointestinal side effects of nausea and vomiting (174, 177, 209, 210). Rashes reported with OXC include Stevens-Johnson syndrome and toxic epidermal necrolysis in addition to milder maculopapular eruptions (197). Among patients who have had allergic reactions to CBZ, the risk of allergic cross-reactivity with OXC is 25% (197). As with patients taking CBZ monotherapy, those taking OXC monotherapy also are prone to have reduced concentrations of 25-OH vitamin D, which if untreated heightens the risk of osteopenia (211). In contrast to valproate, OXC treatment of girls aged 8 to 18 years was not associated with increased body mass index (212).

## Ethosuximide, Methsuximide, and Trimethadione

*Blaise F. D. Bourgeois*

### ETHOSUXIMIDE

#### Chemistry, Animal Pharmacology, and Mechanism of Action

Ethosuximide (ESM) is 2-ethyl-2-methyl succinimide, a white crystalline powder with a molecular weight of 141.7. The conversion factor from milligrams (mg) to micromoles ( $\mu\text{mol}$ ) is 7.08 (i.e.,  $1 \text{ mg/L} = 7.08 \mu\text{mol/L}$ ). In animal models, ESM is highly effective against pentylenetetrazol-induced seizures and other models considered to reflect efficacy against absence seizures, including genetically epilepsy-prone rodents, but ESM is ineffective against seizures induced by maximal electroshock, bicuculline, and N-methyl-D-aspartate (1). In view of ESM's narrow clinical spectrum mostly against absence seizures, this selective activity in experimental models has been considered to be a typical example of parallelism between clinical and experimental spectra of activity.

No single unifying mechanism of action of ethosuximide has been identified. The prevailing hypothesis is that thalamic low-threshold T-calcium channels (T for "transient" or "tiny" channels) are involved. It has been demonstrated that ethosuximide, at therapeutic concentrations, can either reduce the number or reduce the conductance of these channels (1–3). However, other studies in thalamocortical neurons of rats revealed an inhibitory effect of ethosuximide on so-called noninactivating sodium

currents and on calcium-dependent potassium channels, but not on low-threshold calcium channels (4).

#### Biotransformation, Pharmacokinetics, and Interactions

*Biotransformation.* Ethosuximide is mostly metabolized by the liver, with only about 20% being excreted unchanged by the kidneys during chronic intake. The main metabolic pathway consists of hydroxylation and then glucuronidation of the metabolites (5–7). The principal cytochrome P450 oxidase involved is CYP3A. No active metabolites have been identified.

*Pharmacokinetics.* The bioavailability of ethosuximide is considered to be complete, and was shown to be equivalent for capsules and syrup (6). Peak levels are reached 3–5 hours after intake, slightly faster with the syrup than with the capsules. The apparent volume of distribution of ethosuximide is about 0.7 L/kg throughout age ranges. Because of lack of binding to plasma proteins, concentrations of ethosuximide in the cerebrospinal fluid (CSF), tears, and saliva are similar to the plasma concentration, and those in breast milk are only 10% to 20% lower (6, 8). Serum ethosuximide concentrations in breast-fed infants amount to about 30% to 50% of the levels of their mothers (8).

The elimination half-life of ethosuximide was found to be 40 to 60 hours in adults and 30 to 40 hours in children, with linear kinetics and no evidence of autoinduction (6) (Table 43-1). Accordingly, steady-state levels are reached after 7 to 10 days of daily intake of a stable dose. As with most antiepileptic drugs, the level-to-dose ratio may decrease during pregnancy (8).

**Interactions.** Enzyme-inducing drugs such as phenytoin, phenobarbital, and carbamazepine can increase the clearance and thus decrease the level-to-dose ratio of ethosuximide (9, 10). Inversely, valproate can inhibit the metabolism of ethosuximide and, at times, significantly raise its plasma level (11). Isoniazid can significantly raise the levels of ethosuximide (12), whereas rifampin may cause a significant decrease in ethosuximide levels (13). Ethosuximide is not known to affect the clearance or levels of any other drug. In particular, there is no known interaction between ethosuximide and oral contraceptives.

### Clinical Efficacy

**Absence Seizures.** Ethosuximide has been used clinically since 1958, mostly as a drug of first choice for typical absence seizures, in particular childhood absence epilepsy (14–16). Other seizure types that may be favorably influenced by ethosuximide include atypical absence and myoclonic seizures, as well as drop attacks.

In the treatment of typical absence seizures, ethosuximide was shown to achieve a seizure reduction of at least 90% in one-half of the patients, and a reduction of the seizure frequency by at least 50% in 95% of patients (14–16). It appears that response rates improved as more patients achieved levels greater than 40 mg/L. The efficacy of ethosuximide and valproate against absence seizures has been compared in at least two studies, which revealed no difference between the two drugs (17, 18). Sixteen patients not previously treated for absence seizures and 29 refractory patients were enrolled in a double-blind cross-over study of ethosuximide and valproate (18). Frequency and duration of generalized spike-wave bursts on electroencephalographic (EEG) telemetry was used as the measure of efficacy. Ethosuximide and valproate were equally effective in previously untreated patients. No difference in efficacy against absence seizures between valproate, lamotrigine, and ethosuximide could be demonstrated in a recent review of the available evidence (19). This lack of difference could be explained by the methodological quality or statistical power of the studies. Reported evidence suggests that, when ethosuximide and valproate alone are ineffective in fully controlling absence seizures, the combination of the two may be effective (20). This observation is in agreement with experimental evidence from studies in mice that revealed a beneficial pharmacodynamic interaction between ethosuximide and valproate (21). The therapeutic effects of this combination was additive, whereas toxic effects were less than additive, and this resulted in a favorable therapeutic ratio.

Absence status and atypical absence seizures may also respond favorably to high concentrations of ethosuximide, although both are generally less responsive to treatment than typical absence seizures (16).

### Other Uses of Ethosuximide in the Treatment of Seizures

Myoclonic seizures associated with various epileptic syndromes, such as Lennox-Gastaut syndrome, severe myoclonic epilepsy of infancy, juvenile myoclonic epilepsy, and myoclonic astatic epilepsy, may also at times respond to ethosuximide (16, 22, 23). A favorable response has been reported with both positive and negative myoclonus (24). Ethosuximide has a role as adjunctive treatment in the management of the Lennox-Gastaut syndrome. In addition to its contribution to a reduction in the atypical absences and the myoclonic seizures, it can be helpful in reducing the frequency of the debilitating drop attacks (25). Two patients with Angelman syndrome and atypical absence seizures that were refractory to valproate had an excellent response to the addition of ethosuximide when levels greater than 100 mg/L were achieved (26).

**TABLE 43-1**  
*Clinical Summary of Ethosuximide*

Elimination half-life (hours)	
Adults	40–60
Children	30–40
Time to steady-state level (days)	7–10
Suggested therapeutic range (mg/L)	40–100
Initial dose	
Adults (mg/day)	250
Children (mg/kg/day)	5–10
Target dose	
Adults (mg/day)	750–1,000
Children (mg/kg/day)	20–30
Common preparations	250 mg capsules 250 mg/mL syrup
Adverse effects	Gastrointestinal upset, vomiting, hiccups, headache, fatigue, ataxia, depression, psychosis, rare bone marrow depression

## Adverse Effects

**Gastrointestinal Adverse Effects.** Benign and fully reversible gastrointestinal side effects are by far the most common adverse reactions to ethosuximide (27). They include mostly abdominal discomfort, vomiting, diarrhea, and hiccups. Some of these effects can improve when the medication is taken at the end of a meal.

**Neurologic Adverse Effects.** The neurologic side effects of ethosuximide can include headaches, sedation, drowsiness, fatigue, insomnia, and ataxia. Rarely behavioral disturbances may occur, including nervousness, irritability, depression, hallucinations, and even psychosis (12, 28). Psychosis has been found to occur in conjunction with eradication of seizure activity, a phenomenon for which the term “forced normalization” has been coined (29). Occasionally, ethosuximide may also cause extrapyramidal reactions, such as dyskinesia (30, 31).

**Idiosyncratic Adverse Effects.** Ethosuximide has been associated with a dose-related reversible granulocytopenia (26), but very rarely also with more severe bone marrow reactions such as granulocytopenia, thrombocytopenia, or pancytopenia (32). Clinical alertness to possible signs and symptoms is likely to be more effective in recognizing such occurrences than routine monitoring of the blood count (33). Other reported rare idiosyncratic reactions have included systemic lupus erythematous (34, 35) and Stevens-Johnson syndrome.

**Effect on Offspring.** Although malformations have been described in infants whose mothers were treated with ethosuximide, this could not be attributed specifically to ethosuximide alone (8). Ethosuximide crosses the placenta readily. Levels in the milk and in the plasma of breast-fed infants have been discussed in the section on pharmacokinetics.

## Clinical Use

The main indication of ethosuximide is in the treatment of childhood absence epilepsy, for which it is a drug of first choice. For this indication, ethosuximide is an effective drug, with mostly benign side effects and only extremely rare severe adverse reactions. However, it should be considered as initial monotherapy only in those children with childhood absence epilepsy who have never experienced a generalized tonic-clonic seizure, against which ethosuximide has no protective effect. Patients with childhood absence epilepsy are at risk for generalized tonic-clonic seizures, especially during the second decade of life. This is also true for patients with juvenile absence epilepsy. Therefore, when treatment of absence seizures is considered or reconsidered in patients

older than the age of 10 years, a drug with the appropriate broader spectrum of activity should be used, such as valproate or lamotrigine, or ethosuximide should be combined with another drug that does provide protection against generalized tonic-clonic seizures.

Other clinical uses of ethosuximide have been discussed in the section on efficacy. In these conditions, such as absence status epilepticus, myoclonic seizures in various epilepsy syndromes, atypical absence seizures, and drop attacks in Lennox-Gastaut syndrome, ethosuximide is almost invariably used as adjunctive therapy, because these seizures are generally more refractory to medications and because they tend to occur in conjunction with other seizure types that do not benefit from ethosuximide.

The initial target dose of ethosuximide is about 20–30 mg/kg/day. It is best to initiate treatment at one-third of this dose, preferably after meals, with two subsequent increases by the same amount at intervals of 5–7 days. Available ethosuximide preparations include 250-mg liquid-filled capsules and 250 mg/5 mL syrup. If capsules are preferred, but the patient’s weight requires increments of 125 mg, the capsules can be frozen and then easily cut in half. The total daily dose can be divided into two daily doses, or also into three daily doses if this makes it easier for the child to take the medication or if it can be shown to improve gastrointestinal side effects. In absence epilepsy, a response is often noted by parents or teachers within a few days, and provocation of seizures by forced hyperventilation also subsides. In addition, childhood absence epilepsy is one of the rare epilepsies in which a dramatic EEG improvement accompanies clinical improvement. Nevertheless, the EEG response may be incomplete, even if the observable clinical response is complete. Therefore, it is recommended to record an EEG after the patient has achieved full clinical control, and the goal of therapy should be normalization of the EEG, if possible (36). If there is doubt as to whether the patient is free of seizures, a 24-hour ambulatory EEG may be quite helpful.

The suggested therapeutic range of ethosuximide plasma levels is 40–100 mg/L (300–700  $\mu\text{mol/L}$ ), but levels below 40 may be fully effective, and levels as high as 150 may be necessary and well tolerated. There are no clear guidelines regarding the need to monitor blood counts for the rare occurrence of bone marrow suppression, and clinical education and observation is likely to provide the best probability of early detection. Once the patient is under good control, there is no need to monitor plasma levels routinely, unless there is a specific question that could be answered by a level. In seizure-free patients with normalized EEG, ethosuximide can be gradually tapered over about 6 weeks after 2 years without seizures, or possibly even after 1 year (37). Because seizure recurrence may be subtle clinically, or significant

subclinical spike and wave discharges may require reintroduction of therapy, it is good practice to repeat an EEG 1–3 months after ethosuximide has been discontinued.

## METHSUXIMIDE

### Chemistry, Animal Pharmacology, and Mechanism of Action

Methsuximide is N,2-dimethyl-2-phenyl-succinimide and has a molecular weight of 203.23. The conversion factor from milligrams (mg) to micromoles ( $\mu\text{mol}$ ) is 4.92 (i.e., 1 mg/L = 4.92  $\mu\text{mol/L}$ ). The efficacy of methsuximide in animal models and mechanisms of action are similar to those of ethosuximide, but the therapeutic index is slightly lower (38).

### Biotransformation, Pharmacokinetics, and Interactions

In the liver, methsuximide is rapidly converted to the active metabolite N-desmethylnmethsuximide (39), which is then further hydroxylated before renal elimination (40). Less than 1% of the methsuximide dose is excreted unchanged by the kidneys. Peak levels of N-desmethylnmethsuximide are reached after 1 to 4 hours (41). The plasma half-life of methsuximide is only 1.0–2.6 hours, with no significant accumulation, whereas the elimination half-life of N-desmethylnmethsuximide has been found to be 34–80 hours in adults and 16–45 hours in children (38, 41) (Table 43-2). In human plasma, N-desmethylnmethsuximide is 45% to 60% protein bound (42). The suggested therapeutic range of N-desmethylnmethsuximide is 10–40 mg/L.

In terms of pharmacokinetic interactions, phenytoin and phenobarbital can raise the levels of N-desmethylnmethsuximide, and methsuximide can inversely also raise the levels of phenytoin and phenobarbital, including Phenobarbital-derived from primidone (43, 44). These interactions may be due to competition for enzyme binding. However, methsuximide may also act as an enzymatic inducer, because it can lower levels of carbamazepine (44, 45) and of lamotrigine (46, 47).

### Clinical Efficacy

Methsuximide has been used clinically since 1956. In the treatment of absence seizures, published evidence suggests that methsuximide is less effective than ethosuximide, achieving seizure control in one-third or fewer of the patients (38, 48). However, in contrast to ethosuximide, methsuximide has been shown repeatedly to have a role as adjunctive therapy in the treatment of complex partial seizures, with responder rates ( $\geq 50\%$  seizure reduction) of at least one-third and up to 80% (44, 48, 49).

**TABLE 43-2**  
*Clinical Summary of Methsuximide*

Elimination half-life of N-desmethylnmethsuximide (hours)	
Adults	34–80
Children	16–45
Time to steady-state level (days)	8–16
Suggested therapeutic range of N-desmethylnmethsuximide (mg/L)	10–40
Initial dose	
Adults (mg/day)	300
Children (mg/kg/day)	5–10
Target dose	
Adults (mg/day)	600–1,200
Children (mg/kg/day)	10–30
Common preparations	150- and 300-mg capsules
Adverse effects	Gastrointestinal upset, vomiting, hiccups, drowsiness, depression

Some success with methsuximide has also been reported in children having atstatic/myoclonic, tonic, and atypical absence seizures (45), as well as in the treatment of juvenile myoclonic epilepsy (50). Methsuximide has been recommended as a fourth line drug in a review on the treatment of Lennox-Gastaut syndrome (23).

### Adverse Effects

Gastrointestinal and neurologic side effects of methsuximide are very similar to those of ethosuximide, but they tend to be more pronounced and less readily reversible without discontinuation of the drug (27). In addition, attacks of hepatic porphyria may be precipitated by methsuximide (51).

### Clinical Use

The target dose of methsuximide is 10–30 mg/kg/day. In children, the drug is often introduced as 150 mg once daily after dinner, with weekly dosage increases by 150 mg/day up to the target dose. Because of the long half-life of N-desmethylnmethsuximide, the medication can be taken twice daily. The recommended range for plasma levels of N-desmethylnmethsuximide is 10–40 mg/L. When methsuximide is taken as adjunctive therapy, attention must be paid to the pharmacokinetic interactions described previously, and the dosages and levels of both methsuximide

and the other antiepileptic medications may have to be followed and adjusted as necessary. This may help with the management of side effects, which could be caused also by changes in concentrations of other medications.

### TRIMETHADIONE

Oxazolidinediones have a historic role as the first generation antiabsence drugs. They were essentially replaced by the mid-to-late 1960s by the succinimides because of the substantially improved safety and tolerability profile of the latter. The oxazolidinediones are covered here mainly for historic reasons and not for the purpose of recommending trimethadione as an alternative to ethosuximide.

#### Chemistry, Animal Pharmacology, and Mechanism of Action

Trimethadione is 3,5,5-trimethyl-1,3-oxazolidine-2,4-dione and has a molecular weight of 143.15. The conversion factor from milligrams (mg) to micromoles ( $\mu\text{mol}$ ) is 6.99 (i.e., 1 mg/L = 6.99  $\mu\text{mol}$ /L). The main active metabolite, dimethadione (5,5-dimethyloxazolidine-2,4-dione), has a molecular weight of 129.12. The conversion factor from milligrams (mg) to micromoles ( $\mu\text{mol}$ ) is 7.75 (i.e., 1 mg/L = 7.75  $\mu\text{mol}$ /L). Like ethosuximide and methsuximide, trimethadione is effective against pentylenetetrazole-induced seizures but not against maximal electroshock-induced seizures (52). In addition, like succinimides, dimethadione was shown to block calcium currents in thalamic neurons (53) and in spinal neurons (54).

#### Biotransformation, Pharmacokinetics, and Interactions

Trimethadione is almost entirely converted to dimethadione in the liver, and less than 5% of an oral dose of trimethadione is excreted unchanged by the kidneys (55). Dimethadione is excreted mostly unchanged by the kidneys. Protein binding of both trimethadione and dimethadione is low. The plasma half-life of trimethadione in healthy adults was found to be 11–16 hours, and the half-life of dimethadione is much longer, 6–13 days (56) (Table 43-3). Pharmacokinetic interactions with other antiepileptic drugs are not known.

#### Clinical Efficacy and Use

Trimethadione has been used clinically since 1945 and was the first drug with a specific effect against absence seizures (57). The spectrum of activity of trimethadione and dimethadione is narrow, with no clear evidence of

**TABLE 43-3**  
*Clinical Summary of Trimethadione and Dimethadione*

Elimination half-life of:	
Trimethadione	11–16 hours
Dimethadione	6–13 days
Time to dimethadione steady-state level (days)	20–30
Suggested therapeutic range of dimethadione (mg/L)	500–1,200
Initial dose (mg/kg/day)	20
Target dose (mg/kg/day)	60 (max 2,400)
Adverse effects	Day blindness (hemeralopia), photophobia, dermatitis, Stevens-Johnson syndrome, bone marrow depression, nephrotic syndrome, myasthenic syndrome, pronounced teratogenicity (fetal trimethadione syndrome)

efficacy other than against absence seizures, although their use has been suggested for the other seizure types in patients with Lennox-Gastaut syndrome (58). Best results in the treatment of absence seizures have been observed at levels of dimethadione between 470 and 1,200 mg/L (59–61). The starting dose of trimethadione is about 20 mg/kg/day, and the dose may be increased gradually at intervals of 2 weeks up to 60 mg/kg/day, if tolerated. It is usually given twice daily, although the half-life of dimethadione should allow once-daily intake.

#### Adverse Effect

Trimethadione has several side effects (56). They include the common side effects of many antiepileptic medications, such as fatigue, sedation, dizziness, ataxia, skin rash, and exfoliative dermatitis. Hemeralopia (day blindness) and photophobia can occur in one-third of patients. Other more specific adverse reactions include a nephrotic syndrome, bone marrow depression, systemic lupus erythematosus, and a myasthenic syndrome. Close monitoring of blood counts and kidney function are necessary. Above all, trimethadione is probably the most teratogenic antiepileptic drug (62, 63). The “fetal trimethadione syndrome” includes, among other features, intrauterine growth retardation, microcephaly, cardiac malformations, malformed ears, and mental retardation.

Less frequent fetal anomalies include genitourinary malformation, epicanthal folds, broad nasal bridge, and cleft palate. Some or all of the features are seen in the offspring of more than two-thirds of pregnant women taking the

drug during pregnancy. It is extremely important to discuss this issue before and during treatment with methadiones with any female patient of childbearing potential or with her parents.

## Felbamate

*Blaise F. D. Bourgeois*

**A**t the time of its release in North America in 1993, felbamate was the first new antiepileptic drug (AED) in 15 years. Several relatively unique features characterize the development and release of felbamate. The clinical trials of felbamate were innovative and unconventional. Felbamate was the first AED to undergo a double-blind trial in hospitalized patients withdrawn from AEDs for presurgical long-term monitoring. It was also the first AED submitted to double-blind monotherapy trials. Finally, the efficacy of felbamate was assessed in the first placebo-controlled trial conducted in children with the Lennox-Gastaut syndrome. After 1 year of very successful marketing as a drug with no serious toxicity, felbamate came very close to being completely withdrawn from the market because of several cases of severe bone marrow and liver toxicity, some of which were fatal. The main indication for felbamate at the present time is as a third or fourth drug in children with the Lennox-Gastaut syndrome and similar forms of epilepsy who failed to respond to other AEDs.

### **CHEMISTRY, ANIMAL PHARMACOLOGY, AND MECHANISM OF ACTION**

Felbamate is 2-phenyl-1,3-propanediol dicarbamate. Like the minor tranquilizer meprobamate, felbamate is

a dicarbamate. However, felbamate appears to have no sedative or tranquilizing properties at therapeutic levels. Felbamate was found to have a relatively wide spectrum of activity in experimental seizure models. It is effective against seizures produced by systemically administered chemical convulsants, such as pentylenetetrazole and bicuculline, but it is even more potent against seizures elicited by maximal electroshock (1). Felbamate was also shown to possess antiepileptic activity in kindling models (2) and in monkeys with epileptic foci created by injection of aluminum hydroxide (3). The neurotoxicity of felbamate has been found to be exceedingly low in animal models, which resulted in a very high protective index (efficacy-to-toxicity ratio) (1). In various animal species, repeated administration of felbamate suggested an excellent safety profile on various body systems, and no tolerance to the antiepileptic effect could be demonstrated after repeated administration in animals.

Several potential mechanisms of action for the antiepileptic effect of felbamate have been identified. Inhibition of glycine-enhanced N-methyl-D-aspartate (NMDA)-induced intracellular calcium currents was shown in mice (4). Findings regarding the effect of felbamate on the gamma-aminobutyric acid (GABA) receptor have been contradictory; both a lack of effect on ligand binding to the GABA<sub>A</sub> receptor (5) and potentiation of GABA responses at high felbamate concentrations (6) have been reported. In addition,

inhibition of excitatory NMDA responses was demonstrated at high felbamate levels (6). Use-dependent inhibition of NMDA currents was also demonstrated at therapeutic concentrations of 50–300  $\mu\text{mol/L}$  in rat hippocampal neurons (7). The blockade of the NMDA receptors by felbamate may selectively affect certain subunits (8). The available information suggests that felbamate has a dual action on excitatory and inhibitory brain mechanisms.

### BIOTRANSFORMATION, PHARMACOKINETICS, AND INTERACTIONS

After a single dose of felbamate in humans, approximately 50% of the drug is excreted in the urine unmetabolized and unconjugated. Approximately 12% is excreted in the urine as *para*-hydroxyfelbamate and 2-hydroxyfelbamate, and most of the remainder of the dose is recovered in urine as unidentified polar metabolites, some of them being glucuronides or sulfate esters (9). Only 2-hydroxyfelbamate and a monocarbamate metabolite could be quantified in plasma during chronic therapy (10). The concentration of these metabolites is too low (approximately 10% of the felbamate concentration) to contribute to the clinical effect, even if they were pharmacologically active. Because of possible pharmacokinetic interactions, these values for the quantitative aspect of felbamate biotransformation may be different in patients taking enzyme-inducing AEDs concurrently with felbamate. In addition, evidence has been found in humans suggesting the formation of several other metabolites, including atropaldehyde (2-phenylpropenal), which is a potentially cytotoxic metabolite of felbamate (11, 12).

The pharmacokinetics of felbamate have been studied in adults (9,13–17) and in children (16). Based on the administration of  $^{14}\text{C}$ -labeled felbamate in adults, an oral bioavailability of at least 90% was estimated (9). Linear absorption at least up to 1,200-mg doses was demonstrated in single-dose pharmacokinetic studies (13, 14). This linearity was also found during chronic administration at doses of 400 to 3,600 mg/day (16). The time to peak concentration is 2 to 6 hours. Felbamate binding to serum proteins is approximately 25% and is independent of the felbamate concentration (18). The elimination half-life of felbamate in adult volunteers not taking other medications ranged from 16 to 22 hours (15). The volume of distribution was calculated to be 0.76 L/kg in adults and 0.91 L/kg in children, and, as for most drugs, the clearance of felbamate was found to be higher in children (19). Brain concentrations of felbamate have been measured in humans and were found to correspond to 60% to 70% of concurrent plasma concentrations (10).

The potential pharmacokinetic interactions between felbamate and other AEDs have been studied quite extensively, and it has been found that felbamate is the cause as

well as the object of several pharmacokinetic interactions. When felbamate is added to phenytoin monotherapy, phenytoin levels are raised in a dose-dependent manner (20). Felbamate at a dose of 1,200 mg/day raised phenytoin levels by an average of 24%, and phenytoin levels were raised by an additional 20% at a felbamate dose of 1,800 mg/day. The dose of phenytoin should be reduced by 20% or more when felbamate is added (21). The addition of felbamate also raises valproate levels, probably through an inhibition of the beta-oxidation pathway of valproate metabolism (22). Valproate levels were found to be increased by 28% at a felbamate dose of 1,200 mg/day and by 54% at a felbamate dose of 2,400 mg/day (18). Inversely, felbamate decreases carbamazepine levels by 20% to 25%; however, the level of the active metabolite of carbamazepine (carbamazepine-10,11-epoxide) was found to be raised by 57% after the addition of felbamate (23). A similar interaction was reported with clobazam, with a decrease in clobazam levels and an increase in N-desmethyl-clobazam in the presence of felbamate (24). In a group of healthy volunteers, felbamate increased the area under the phenobarbital plasma concentration-time curve by 22% (25), and an elevation of methsuximide levels by felbamate was also described (26). No conclusive data are available regarding the effect of felbamate on the levels of other AEDs. The clearance of warfarin was shown to be decreased by approximately 50% by the addition of felbamate (27), and felbamate may accelerate the metabolism of oral contraceptive steroids (28, 29).

Other AEDs also affect the elimination of felbamate. The apparent total body clearance of felbamate is doubled by phenytoin, a known potent enzyme inducer (30). This observation suggests that the felbamate dosage requirements are doubled by the concomitant administration of phenytoin, if the same steady-state serum concentration of felbamate is to be maintained. Carbamazepine also seems to increase the clearance of felbamate but only by about 40% (23). No clinically significant effect of valproate on the clearance or elimination half-life of felbamate was demonstrated (15). A recent observation suggests that gabapentin may decrease the clearance of felbamate by approximately one-third, with a corresponding 50% prolongation of the felbamate half-life (31). If confirmed, this would represent the only known pharmacokinetic interaction involving gabapentin. Significant pharmacokinetic interactions between felbamate and drugs other than AEDs have not been reported.

### CLINICAL EFFICACY

Four pivotal double-blind controlled trials provided most of the available clinical antiepileptic efficacy data for felbamate: a placebo-controlled trial in patients withdrawn from AEDs for presurgical monitoring, two felbamate

monotherapy trials comparing felbamate monotherapy with low dose valproate monotherapy, and a placebo-controlled trial in children with the Lennox-Gastaut syndrome. The so-called presurgical trial was a novel study design. At the end of a period of seizure monitoring with partial or complete withdrawal from their conventional AEDs, 64 adult patients with documented partial onset seizures were randomized to felbamate or placebo (32). In addition to their anticonvulsant regimen at the conclusion of the presurgical evaluation, the patients were either rapidly titrated to felbamate 3,600 mg/day over 3 days or they received placebo. The predetermined efficacy variable of the study was the time to the fourth seizure or completion of a total of 28 days with less than four seizures, with an initial 8-day inpatient period. At the end of the inpatient period, the dose of one AED was adjusted to the premonitoring dose. Thus, patients were discharged neither taking placebo alone nor taking placebo with only a low dose of anticonvulsant. Patients experiencing four seizures within 28 days were restarted on the full dose of the medications they were taking before monitoring. For patients receiving felbamate, the time to the fourth seizure was significantly longer than for those receiving placebo. Four seizures within 28 days occurred in 46% of the patients taking felbamate as opposed to 88% of the patients randomized to placebo. These results clearly established that felbamate has antiepileptic activity in humans with epilepsy, but they did not demonstrate the ability of felbamate to reduce seizure frequency over a longer period in outpatients not withdrawn from AEDs.

The monotherapy studies were designed to compare felbamate with low dose valproate (15 mg/kg/day) against partial seizures (33, 34). The design of these studies was also novel and unique. After felbamate, 3,600 mg/day, or low dose valproate were added in a double-blind parallel manner to the previously administered drug, this drug was withdrawn over 28 days. Because 50% of the patients were to be converted to 15 mg/kg/day of valproate alone, the predetermined endpoint and primary efficacy variable consisted of escape criteria (a predefined degree of seizure exacerbation). The number of patients meeting the escape criteria during the observation period of 112 days was significantly higher in the low dose valproate group than in the felbamate monotherapy group in both studies, showing that felbamate alone has unequivocal efficacy over a period of 112 days against focal onset seizures in adults. However, it is difficult to derive a quantitative assessment of the efficacy. These two studies do not represent a comparison between felbamate and valproate, which was used as a relatively safe placebo. One advantage of such monotherapy studies is that they provide an exclusive assessment of the side effects of the new drug being tested. Adverse experiences were mild to moderate, and their incidence was lower during the monotherapy portion of the trial. However, the monotherapy phase

was after day 28. Most drugs cause more side effects during the first month of treatment; therefore, the lower incidence of side effects observed after day 28 may also be attributed to tolerance and not to the fact that the drug regimen had been reduced to monotherapy.

A double-blind, placebo-controlled, add-on study of felbamate was carried out in 73 patients with the Lennox-Gastaut syndrome (mean age, 13 years; range, 4–36 years) (35). An observation period of 56 days was preceded by a 14-day titration period. The previous AED doses remained unchanged, and felbamate was titrated to 45 mg/kg/day or a maximum of 3,600 mg/day. The total number of seizures during a 4-hour period of video-EEG recording, the total number of atonic seizures (drop attacks) as reported by the parents or guardians, and the global evaluations of the patients' quality of life were chosen as the primary efficacy variables. In terms of the total frequency of seizures, felbamate was significantly superior to placebo and was particularly effective in reducing drop attacks, the most debilitating seizure type in these patients. There was an inverse correlation between felbamate plasma levels and the daily number of drop attacks. Additionally, in patients receiving felbamate, the global evaluation scores were significantly higher than in those receiving placebo. When the total number of seizures during a 4-hour period of video-EEG recording was compared, no significant difference between felbamate and placebo was found. The most likely cause of this lack of difference is probably the high spontaneous day-to-day variability in seizure frequency in patients with the Lennox-Gastaut syndrome. This study is of particular interest for two reasons: The Lennox-Gastaut syndrome is notoriously refractory to treatment, and there had been no previous double-blind controlled study of any therapeutic modality in this syndrome. Significant positive behavioral effects in children with Lennox-Gastaut syndrome treated with felbamate have also been reported (36).

A double-blind monotherapy study of felbamate in children with partial seizures was initiated, but it was interrupted when the emergence of serious side effects led to marked restrictions on the use and the promotion of felbamate. The effectiveness of felbamate as an AED that was demonstrated by controlled trials was clearly confirmed by clinical experience during widespread use after its release. Physicians who have used felbamate in many patients with epilepsy comment that felbamate achieved remarkable seizure control, even in some patients who had been previously refractory to AEDs. In addition, uncontrolled reports have suggested that felbamate may be effective in the treatment of absence seizures (37), juvenile myoclonic epilepsy (38), infantile spasms (39–41), and acquired epileptic aphasia (Landau-Kleffner syndrome) (42). In 36 pediatric patients with various forms of epilepsy, the responder rate ( $\geq 50\%$  seizure reduction) was 69% at 3 months, 47% at 1 year, and 41% at 3 years

(43). The authors estimated that the best results had been obtained against simple partial seizures with or without secondary generalization, as well as against tonic and atonic seizures.

### ADVERSE EFFECTS

Almost exactly a year after felbamate's release, it became evident that the fate of felbamate would be determined much more by its side effects than by its antiepileptic efficacy. Felbamate was initially intensely and broadly marketed as a safe AED that did not display the toxic features of established AEDs and did not require laboratory monitoring. The more common side effects of felbamate in adults and in children, in monotherapy and with concomitant AEDs, are summarized in Table 44-1 (44). The higher incidence of side effects during adjunctive therapy is likely to be due to pharmacokinetic and pharmacodynamic interactions with other AEDs. The gastrointestinal side effects, including anorexia with weight loss, have been by far the most prominent of these side effects. The quoted numbers of 2% to 3%

probably underestimate the true incidence of weight loss. The weight loss occurs mostly during the first 3 months of treatment, with subsequent stabilization, and represents approximately 2% to 5% of the body weight. In one series of patients, 34% lost more than 4 kg and 11% lost more than 8 kg (45). Another significant and rather persistent problem in children has been insomnia and irritability. Two children developed involuntary movements, consisting of choreoathetosis in one child and an acute dystonic reaction in the other child (46). A 15-year-old boy taking felbamate was reported to have presented with symptomatic ureteral kidney and bladder stones, which were identified as consisting of felbamate (47). Crystaluria and even renal failure have been observed in cases of felbamate overdoses (48, 49).

The first year of postmarketing use revealed that felbamate was associated with a relatively high incidence of life-threatening side effects. In August of 1994, almost a year after the release of felbamate, the number of cases of aplastic anemia that had accumulated was such that the drug came close to being withdrawn from the market (50, 51). The aplastic anemias were diagnosed between 2.5 and 6 months after the onset of felbamate therapy. A warning was mailed to all physicians in the United States. In addition, several cases of severe and occasionally fatal hepatotoxicity were reported (52). Promotion of felbamate came to a virtual standstill, all ongoing clinical trials were suspended, and a warning was included in the package insert, requiring frequent laboratory monitoring of patients treated with felbamate. Although exact numbers are difficult to determine in such cases, and some degree of underreporting must be assumed, the reported numbers of cases are as follows (51, 53): 34 patients with aplastic anemia were reported and 14 have died; 23 cases were confirmed, of whom 7 have died; among 18 reported patients with hepatotoxicity, felbamate was considered to be the likely cause in 7 (Table 44-2). The estimated denominator is a total of 110,000 patients treated with felbamate in the United States after its release. Using this denominator, the calculated worst-case risk of developing either one of these two complications is approximately 1 in 2,700, with a worst-case risk of death of approximately 1 in 4,800 (Table 44-3). The risk of aplastic anemia could be as much as 10 to 100 times higher than in the general population and 20 times higher than with carbamazepine (53). Although many children have been treated with felbamate, aplastic anemia was not reported in any child younger than the age of 13 years. The only other patient younger than 20 years old was 18 years of age, and this patient was also the youngest patient to die from aplastic anemia. If the risk of aplastic anemia is discounted, the calculated risk of death from a severe felbamate complication in the pediatric age range would be approximately 1 per 20,000. This number is somewhat lower than the rate of valproate

hepatic fatalities for monotherapy patients over the age of 2 years and definitely lower than the rate of hepatic fatalities from valproate polytherapy for patients under the age of 10 years (54). This comparison provides a perspective that should help us define the current and future place of felbamate in the treatment of epilepsy. Valproate and carbamazepine have also at some point raised significant concerns of serious idiosyncratic toxicity.

Just as risk factors were identified for valproate, there may also be identifiable risk factors for felbamate toxicity. They may include a history of allergy or cytopenia with previous AEDs, polytherapy, and clinical or serological evidence of a concomitant immune disorder (51). Individuals in whom abnormally high amounts of possibly cytotoxic felbamate metabolites such as atropaldehyde or 2-phenylpropenal accumulate are at higher risk of toxicity (55–59). This and other hypotheses are being explored to identify patients

at risk of a severe reaction (60, 61). Fluorofelbamate is a felbamate analog synthesized by substitution of fluorine for hydrogen at position 2 of the propane chain. Fluorofelbamate cannot be metabolized to 2-phenylpropenal and has been investigated as a possibly safer alternative to felbamate (62, 63).

## CLINICAL USE

The current clinical experience with felbamate has been reviewed in a recent consensus paper (64). At the present time, the main indication for felbamate is in patients with the Lennox-Gastaut syndrome whose seizures remain uncontrolled despite trials with other AEDs such as valproate, clonazepam, lamotrigine, and topiramate. Felbamate can also be considered as a third-line drug in patients with refractory focal onset seizures (65). If felbamate fails to demonstrate marked seizure reduction after a 2- to 3-month trial, it should be discontinued without delay to reduce or avoid unnecessary exposure of the patient to the risk of a severe reaction. Inversely, in a patient who has been receiving felbamate for 18 months or more, it is probably safe to continue the treatment (65).

To minimize the occurrence of initial adverse reactions, felbamate must be introduced cautiously. Titration of the felbamate dose usually must occur simultaneously with a reduction in the dose of concomitant AEDs because of both pharmacokinetic and probable pharmacodynamic drug interactions. Although precise guidelines have been provided, a slower titration than the one recommended may be at times advisable. A felbamate dose of 1,200 mg/day is recommended during the first week in adults, with a reduction of concomitant AED dose(s) by one-fifth to one-third. During the second week of treatment, the dose is to be increased to 2,400 mg/day. If monotherapy is the goal, the concomitant AED dose should be reduced by another one-third during the second week. During the third week of treatment, if necessary and if tolerated, the

**TABLE 44-3**  
*Risk of Aplastic Anemia and Hepatotoxicity Associated with Felbamate Therapy (Denominator is 110,000 Patients)*

	OVERALL RISK	RISK OF DEATH
Aplastic anemia		
Lower limit ( $n = 3$ )	1:37,000	
Upper limit ( $n = 23$ )	1:4,800	~1:15,800
Most probable ( $n = 14$ )	1:7,900	
General population	1:500,000	
Hepatotoxicity	1:15,700–1:6,100	1:31,400–1:12,200
Combined risk (worst case)	1:2,700	1:4,800

felbamate dose is to be increased to 3,600 mg/day. In adult patients, doses of 5,000 to 6,000 mg/day have been commonly used. If felbamate is introduced in a patient who is not taking an enzyme-inducing AED, a slower titration is recommended. After an initial dose of 1,200 mg/day, the dose is increased by increments of 600 mg/day at intervals of 2 weeks. Titration is similar in children, the doses corresponding to 1,200, 2,400, and 3,600 mg/day in adults being 15, 30, and 45 mg/kg/day, respectively. Although it is generally better to keep the titration doses below rather than above these recommended doses, maintenance doses may often safely exceed 45 mg/kg/day in children. Because of felbamate's potential for bone marrow and liver toxicity, complete blood count and transaminases should be ordered before initiation and then at regular intervals. Although no rigid schedule can be established for this monitoring, testing after 1 month and then every 2–3 months would

be reasonable, with somewhat longer intervals after the first year.

No definite therapeutic range for plasma felbamate levels has been established. In adults taking 3,600 mg/day of felbamate in monotherapy, plasma levels were 65 to 80 mg/L (33, 32). A tentative target range of 30–60 mg/L (125–250  $\mu$ mol/L) has been suggested (66). In children, the values for felbamate levels in milligrams per liter (mg/L) were found to be approximately the same as the dose in mg/kg/day (35). Felbamate levels in 41 adult patients were analyzed by Harden and coworkers (67) and divided into low range (9–36 mg/L), mid range (37–54 mg/L), and high range (44–134 mg/L). Anorexia and complaints of severe side effects occurred significantly more often in the high level group, but significantly more patients in this group also reported decreased seizure frequency.

## Gabapentin and Pregabalin

**Gregory L. Holmes**  
**Phillip L. Pearl**

**G**abapentin (GBP), or 2-[1-amino-methylcyclohexyl]acetic acid, and pregabalin (PGB), or (S)-3-(aminomethyl)-5-methylhexanoic acid, are structural, but not functional analogs of gamma-aminobutyric acid (GABA). GBP (Neurontin®) has U.S. Food and Drug Administration (FDA) approval for adjunctive therapy of partial seizures in children 3 years of age or older, while PGB (Lyrica®) is approved for adjunctive therapy of partial seizures in adults. GBP received FDA approval in 1993 and PGB in 2005.

While the drugs have a number of similarities, there are also some differences in the molecules that are pertinent to children. GBP and PGB will be discussed separately here.

### GABAPENTIN

#### Chemistry, Animal Pharmacology, and Mechanisms of Action

Gabapentin (Figure 45-1) has structural similarities to GABA (Figure 45-2), the major inhibitory neurotransmitter in the human brain. As GABA does not cross the blood-brain barrier, conformational restriction of the GABA molecule, with binding into a cyclohexane system, confers lipid solubility to the molecule and facilitates the penetration of the blood-brain barrier.

Testing in animals has demonstrated that GBP had considerable antiepileptic properties (1, 2). It is effective in the maximal electroshock test in rodents, protects against aspartate- and strychnine-induced and audiogenic tonic-clonic seizures, and prevents seizures in the Mongolian gerbil, a model of reflex epilepsy (1, 2). GBP prolongs time to clonic activity, tonic extension of the extremities, and death in mice after intraperitoneal (ip) injections of N-methyl-D-aspartate (NMDA) but not of kainic acid or quinolinic acid (3). When kainic acid, quinolinic acid, or glutamate was injected into the lateral ventricles of rats, there were no clear effects of GBP on the seizures (4). GBP reduces after-discharge duration in the kindling model (2, 5). GBP has been shown to be effective in preventing seizures following kindling in immature rats (6). These animal studies suggest that GBP should be clinically useful for partial seizures.

While GBP protects mice from clonic convulsions in both the subcutaneous pentylentetrazol test and the intravenous threshold test (7), in a rat genetic model of absence epilepsy GBP actually increased spike-and-wave bursts (8). In the lethargic (*lh/lh*) mouse model of absence seizures, Hosford and coworkers (9) found that GBP had no effect on absence seizure frequency. Although efficacy against pentylentetrazol seizures suggests that the drug should be useful in absence seizures, the finding that it is not effective in these animal models of absence seizures raises concerns about the efficacy of the drug in this seizure type. As will be

FIGURE 45-1

Molecular structure of gabapentin (GBP).

discussed, GBP has not been demonstrated to be effective in the treatment of childhood absence seizures.

In a developmental study, Mareš and Haugvicová (10) administered GBP before pentylenetetrazol to rats starting at 7 days. GBP suppressed or at least restricted the tonic phase of generalized tonic-clonic seizures at all the developmental stages studied. Cilio et al (11) found that GBP increases latency and decreases intensity of flurothyl induced seizures in immature rats.

GBP exhibits low acute toxicity in mice, rats, and monkeys and no significant systemic toxicity in four species after multidose administration for up to 52 weeks. GBP is not teratogenic and does not affect fertility or general reproductive parameters (5, 12). Pancreatic acinar cell tumors have been found in male Wistar rats receiving very large doses of GBP (2,000 mg/kg). These tumors were not observed in female rats or male or female mice. The tumors were low-grade malignancies, did not metastasize, and did not alter survival. The rat pancreatic tumor is not a generally accepted model of human pancreatic cancer, and human pancreatic tumors have not been reported in patients taking GBP (13).

Despite the similarity of GBP to GABA, binding experiments in rat brain and spinal cord have shown that GBP has no significant affinity for the GABA<sub>A</sub> or GABA<sub>B</sub> binding sites as measured by [<sup>3</sup>H]muscimol and

FIGURE 45-2

Molecular structure of gamma-aminobutyric acid (GABA).

[<sup>3</sup>H]baclofen displacement, respectively (5, 14). GBP does not inhibit binding of [<sup>3</sup>H]diazepam at the GABA receptor, has only modest inhibitory effects on the GABA-degrading enzyme GABA-aminotransferase, does not elevate GABA content in nerve terminals, and does not affect the GABA uptake inhibitor. However, GBP significantly increases GABA concentrations in human neocortical slices made from tissue resected during epilepsy surgery (15). Petroff and coworkers (16) used magnetic resonance spectroscopy to estimate GABA brain concentrations. GABA was elevated in patients with partial seizures taking GBP compared with patients matched for antiepileptic drug (AED) treatment. There appeared to be a dose-related response; patients taking high-dose GBP had higher levels of GABA than those taking standard doses.

GBP does not have an effect at the NMDA receptors, non-NMDA glutamate receptors, or strychnine-insensitive glycine receptors. Based on the lack of a GBP effect on sustained repetitive firing of action potentials in mouse spinal cord neurons, it does not appear that the drug has an effect on voltage-dependent Na<sup>+</sup> channels (17, 18). While GBP was not found to have any significant effect on any Ca<sup>2+</sup> channel current subtype (T, N, or L) (18), studies have demonstrated that the drug may act by binding to the alpha<sub>2</sub>delta1 subunit of the calcium channel (19). Inhibition of Ca<sup>2+</sup> currents via high-voltage-activated channels containing the alpha<sub>2</sub>delta1 subunit, leading in turn to reduced neurotransmitter release and attenuation of postsynaptic excitability, is a biologically plausible mechanism and one that is consistently observed at therapeutically relevant concentrations in pre-clinical studies of GBP (Figure 45-3) (20–26).

Because the maximal anticonvulsant effect in the maximal electroshock threshold model is not seen until 2 hours after intravenous (IV) administration, the anticonvulsant effect is probably a result of delayed or indirect pharmacologic action (5, 27). GBP appears to bind to a high-affinity site in membrane fractions of rat brain tissue (28, 29) and is predominantly located on neurons in the brain (28). Binding of GBP is highest in the superficial layers of neocortex and dendritic layers of the hippocampus, with low levels of binding in the white matter and brainstem (28). GBP binding is not affected by valproate, phenytoin, carbamazepine, phenobarbital, diazepam, ethosuximide, or any other neuroactive substance (30). Binding of radiolabeled GBP to this protein is inhibited by leucine, isoleucine, valine, and phenylalanine, which indicates that GBP may bind to a site in the brain that resembles the large neutral amino acid transporter described in other tissues (31). It is possible that this may result in a decrease in the uptake of branched-chain amino acids into neurons; consequently, decreased neuronal glutamate synthesis may occur (32).

FIGURE 45-3

Mechanism of action for GBP and PGB. (A) The action potential propagates down the axon through activation of voltage-gated Na<sup>+</sup> channels. As the action potential reaches the synapse, voltage-gated Ca<sup>2+</sup> channels open and allow the influx of Ca<sup>2+</sup>. (B) Ca<sup>2+</sup> influx triggers movement of synaptic vesicles to the synapse with release of neurotransmitters into the synaptic cleft. GBP and PGB bind to the alpha<sub>2</sub>delta subunit of the Ca<sup>2+</sup> channel and prevents the influx of Ca<sup>2+</sup>, thus preventing release of the neurotransmitters noradrenaline, glutamate, and substance P.

### Biotransformation, Pharmacokinetics, and Interactions in Humans

The absorption of GBP is dose-dependent (33). Sixty percent of a 300-mg dose of GBP is absorbed, compared with 35 percent of a 1,600-mg dose (34, 35). The drug is transported into the blood from the gut by a saturable transport mechanism, the L-system transporter of amino acids (36, 37). Because of this dose-dependent bioavailability, plasma concentrations of the drug are not directly proportional to dose throughout the range of doses studied (37). In adults, mean steady-state maximal and minimal concentrations ( $C_{\max}$  and  $C_{\min}$ , respectively) of GBP were proportional with doses up to approximately 1.8 g daily. At higher

doses, however,  $C_{\max}$  and  $C_{\min}$  continued to increase, but the rate of increase was less than expected (36).

Maximum GBP concentrations occur 2–3 hours after administration of the drug. GBP absorption pharmacokinetics are not altered following multiple-dose administration, and accumulation of the drug following multiple-dose administration is predictable from single-dose data. While food has no effect on absorption (34), aluminum hydroxide–magnesium hydroxide antacid decreases the extent of GBP bioavailability by 20% when administered simultaneously or 2 hours after GBP ingestion (38).

Once absorbed, the drug is widely distributed throughout the body. GBP does not bind to plasma

proteins to any clinically relevant extent, and protein displacement of drugs is not a concern with GBP. GBP readily crosses the blood-brain barrier in rodents and humans (39). GBP concentrations in cerebrospinal fluid (CSF) and brain tissue are approximately 20% and 80% of corresponding serum concentrations (35). After 3 months of treatment with 900 or 1,200 mg/day of GBP, brain concentrations of GBP in spinal fluid varied from 6% to 34% of those in plasma (40). There does not appear to be a linear relationship between plasma and CSF concentrations (41).

GBP oral clearance is directly related to creatinine clearance in children (42). When oral clearance is normalized for body weight, young children (<5 years) have higher and more variable values than older children. In 12 children treated with GBP as add-on therapy, Khurana and coworkers (43) found apparent clearance rates to range from 115 mL/kg/hr to 1446 mL/kg/hr with a mean of  $372 \pm 105$  and a median of 292 mL/kg/hr. On a weight basis, 33% larger doses are required for young children (<5 years) to achieve the same exposure as older children (42). GBP pharmacokinetics can vary substantially among pediatric patients (44).

Once a steady state is reached, blood levels should not fluctuate. Because GBP is not metabolized but is excreted unchanged through the kidneys, clearance of the drug is related to creatinine clearance (32, 45). Renal clearance of the drug approximates glomerular filtration rate with an elimination half-life ( $t_{1/2}$ ) in normal healthy adults of 5–9 hours (36). In patients with normal renal function, steady-state can be achieved within 2 days. Autoinduction does not occur with this drug.

Doses of GBP should be decreased in patients with renal impairment in whom the peak plasma concentrations of GBP are increased and occur later than in patients with normal renal function (46, 47). GBP is removed by hemodialysis, and patients undergoing this therapy need to be placed on maintenance doses of the drug. Guidelines are provided in the package insert by the manufacturers.

The usefulness of GBP serum levels has not yet been established (3, 32, 48, 49). The United Kingdom Gabapentin Study Group found that the mean and median plasma GBP concentrations were higher in responders than in nonresponders, but the group did not provide any specific data (50). Sevenius and coworkers (49) found seizure frequency to be decreased in patients with serum GBP concentrations above 2 mg/L. Crawford and coworkers (51) reported a significant therapeutic benefit from 900 mg GBP per day, which resulted in plasma GBP levels of 2–6 µg/mL. Of interest is a patient described by Brodie (48) with renal impairment who reported a 67% reduction in seizure number without side effects while taking 6,000 mg of GBP daily. The patient had a plasma GBP level of 61.2 mg/L. In an open-label study of efficacy of GBP in a pediatric

population, Khurana and colleagues (43) found that patients with a greater than 50% reduction in seizures had a mean serum concentration of 3.7 µg/mL.

Because GBP is not protein-bound or metabolized in the liver, there are no significant drug interactions with the other commonly used antiepileptic drugs: carbamazepine, phenytoin, or valproate (7, 52). In addition, GBP pharmacokinetics have not been significantly changed by concomitant administration of other AEDs (45). Studies of the effects of GBP on oral contraceptives report no changes in concentration of the contraceptive components (34, 46). Cimetidine use modestly reduces oral and renal clearance of GBP; however, this is of minimal clinical significance and requires no adjustment in GBP dosages (34).

### Clinical Efficacy

Although GBP has been primarily studied in partial seizures in adults, the drug is widely used in children, and there have been a number of studies in children (53, 54).

A total of 792 patients with refractory partial seizures with or without secondary generalization were studied in five double-blind, placebo-controlled, parallel-group studies in adults (55). A minimum of four partial seizures were required per month. Patients received GBP or placebo as add-on therapy for 12 weeks after a 12-week baseline phase, during which concurrent AED therapy was maintained at prestudy levels and baseline seizure frequency was obtained. A total of 307 patients received placebo and 485 received GBP doses of 600, 900, 1,200, or 1,800 mg/day.

The primary efficacy variable was responder rate, which is defined as the percentage of patients experiencing at least a 50% reduction in seizure frequency from baseline to treatment. In this series of placebo-controlled trials, the responder rate in the placebo group was approximately 10%, compared with 20–25% in the patients receiving placebo. The greatest seizure reduction was seen among patients receiving 1,800 mg/day of GBP.

In a study of 129 patients with refractory generalized seizures, Chadwick and colleagues (56) randomized patients to either placebo or 1,200 mg/day of GBP as add-on therapy. While GBP provided greater reduction in the frequency of generalized tonic-clonic seizures than placebo, the results were not statistically significant. GBP was tolerated well in this study.

Appleton et al (57) evaluated GBP as add-on therapy for refractory partial seizures in 247 patients, aged 3–12 years, enrolled from 54 centers in a 12-week double blind, placebo-controlled study and randomized to receive either GBP or placebo. Each patient was receiving one to three AEDs. The response ratio (i.e., reduction of seizure frequency), for all partial seizures was significantly better for GBP-treated patients ( $P = 0.04$ ), and the responder rate, defined as the percentage of patients exhibiting more than

50% reduction in seizure frequency, favored GBP versus placebo, although this did not reach statistical significance. The double-blind trial was subsequently continued into a six month open-label extension study (58). Eighty (34%) of 237 children, aged 3–12 years, who received GBP, showed a >50% reduction in partial seizures.

A large number of patients on GBP have been followed for many years in open-label trials (59–62). Sivenius (60) treated patients with GBP for more than 4 years and found a significant reduction in seizure frequency (>50%) during the follow-up period in five of the seven patients. Likewise, Handforth and Treiman (61) entered 23 patients with intractable epilepsy into an open-label treatment study after a blinded, placebo-controlled, add-on efficacy study. Nine patients had no improvement in seizure control and discontinued the GBP, whereas, the remaining 14 patients continued on the GBP. Seven patients on GBP were followed up for 4 years. Maintenance of the efficacy of GBP was investigated in five long-term, open-label studies in a total of 774 patients (59). A majority of these patients had previously participated in a placebo-controlled study and subsequent short-term, open-label extension, reflecting a retention rate of 66%. The responder rate remained relatively stable over time, and patients who were responders in early phases continued to respond in later phases (12–18 months). The authors also noted that GBP discontinuation did not cause a rebound increase in seizures.

Leiderman and colleagues (63) presented data on 240 patients who entered an open-label trial after completion of a double-blind, placebo-controlled trial of GBP for partial seizures. GBP was continued in 78 (33%) patients for 3 years, 65 (27%) for 4 years, and 40 (17%) for 5 years. The maximum treatment period was 7 years with a mean treatment duration of 843 days. This study demonstrated that GBP can be tolerated for long periods of time.

Patients who have a response to GBP with add-on therapy may be converted to monotherapy. In an ongoing study of an open-label extension of a double-blind, multicenter trial of GBP in partial seizures, 54 of 250 (22%) patients were able to have concurrent antiepileptic drugs discontinued (64). The patients were allowed to take up to 4,800 mg/day.

In a study of the efficacy of GBP in children with refractory partial seizures, Khurana and colleagues (43) reviewed their results in 32 children with refractory partial seizures in which GBP was added to the drug regimen. GBP was given in a dose ranging from 10 to 50 mg/kg/day with a mean dose of 26.7 mg/kg/day for children with partial seizures with or without secondary generalization. Compared to baseline, eleven patients (34.4%) had a greater than 50% reduction in seizure frequency, and four patients (12.5%) had a 25% to 50% decrease.

GBP has been found to be an effective antiepileptic drug in children undergoing cancer therapy (65, 66). In a retrospective analysis, Khan et al (65) reported that seizures were controlled in 74% of 50 children on chemotherapy who developed epilepsy (91% of the leukemia group, 57% of the brain tumor group, and 75% of the other tumor group).

*Comparison of GBP with Other AEDs in Partial Seizures.* There are few studies comparing GBP with other AEDs in adults, and none that directly compare the antiepileptic efficacy of GBP with those of other AEDs in children. Anhut and coworkers (67) randomized newly diagnosed patients with a minimum of two partial seizures to one of four parallel fixed-dose treatment groups: 136 patients received one of three GBP doses—300, 900, or 1,800 mg/day, and 46 patients received 600 mg/day of carbamazepine (CBZ). The authors found similar efficacy for the two drugs: 42% of the GBP-treated group and 48% of the CBZ-treated group were responders.

*Other Seizure Types.* GBP has been used in one double-blind study of absence seizures in children (68). Unfortunately, a small dose of GBP (15–20 mg/kg/day) was used in the study. In this study of 33 children, GBP was not effective in reducing seizure frequency. No children had an exacerbation of seizure frequency. There is no information available regarding the usefulness of GBP in neonatal seizures, atonic, or tonic seizures. In rare cases, GBP may exacerbate myoclonic seizures (69, 70).

## Adverse Events

In general, GBP is very well tolerated in children. Adverse effects with GBP are uncommon and typically consist of somnolence, dizziness, ataxia, fatigue, nystagmus, headache, tremor, diplopia, and nausea and vomiting (13, 71). In the five placebo-controlled trials in adults, 76% experienced at least one adverse event, compared with 57% of patients treated with placebo. Most of the side effects were mild and transient, and few patients have withdrawn from studies because of adverse side effects (13, 71). In a review of adverse events with GBP, Ramsay (13) noted that in controlled clinical trials, approximately 7% of patients receiving GBP withdrew, compared with 3% of those receiving placebo, with the most common complaints in the GBP-treated patients being somnolence and ataxia. Urinary and fecal incontinence have been reported with GBP (72). Like several other AEDs, GBP can rarely exacerbate seizures (73).

Side effects do not appear to have a strong relationship to dose. In a study of 245 patients randomized to placebo or GBP, Anhut and colleagues (72) found that 69% of patients receiving 900 mg/kg/day and 64% of those

receiving 1,200 mg/kg/day had adverse events, compared with 52% in the group that received placebo. Weight gain has been reported in some women but has not been a major issue in children. Severe, life-threatening adverse events have not been reported (13). The most significant serious side effects include rash (0.54%), decreased white blood count (0.19%), increased blood urea nitrogen (0.09%), decreased platelets (0.09%), and angina or electrocardiographic changes (0.04%) (13). Changes in clinical laboratory values during GBP therapy are usually transient, isolated occurrences, most of which have not been considered to be of clinical concern or related to GBP therapy (13, 55). The incidence of rash compares quite favorably with other AEDs.

GBP has been associated with behavioral disturbances in some children (74–78). For the most part, these disturbances appear to be most prominent in children with preexisting behavioral disturbances. Wolf and coworkers (74) described three children with learning disabilities who developed behavioral problems with hyperactive behavior and explosive outbursts consisting of aggressive and oppositional behavior. The behavior improved once GBP was stopped. Lee and colleagues (76) from Children's Hospital in Boston described seven children who received GBP as adjunctive medication and subsequently developed an intensification of baseline behaviors as well as some new behavioral disturbances. These behaviors included tantrums, directed aggression, defiance, and hyperactivity. All of the children had attention deficit hyperactivity disorder and developmental delays before institution of GBP. The exacerbation of GBP-associated behaviors may be dose-related in some patients. Since reduction of the dose results in improvement in some children. It is not always necessary to discontinue GBP in children with adverse behavioral changes if it has been useful in reducing seizure frequency (75, 76). The behavioral problems do not appear to be totally confined to children, since hypomania with GBP in an adult patient has been reported (79).

In a 12 week, multi-center, double-blind, placebo-controlled trial of 247 children aged 3–12 years, Appleton et al (58) found that only six (5%) in the GBP group and three (2%) of the placebo group were withdrawn from the study because of adverse events. Compared to the placebo group, children on GBP experienced more somnolence (8.4%) and hostility (7.6%). Behavioral changes (hostility and emotional lability) occurred more in the GBP-treated children than in those receiving placebo. In all patients, the intensity of these behavioral changes was mild to moderate. Findings in the open label extension study were similar (58).

No disturbances of memory or learning have been reported with GBP. In a study of normal subjects, a psychotropic effect characterized by improvement in

concentration, numerical memory, complex reactions, and reaction time test was reported with GBP (61). Because of the excellent safety profile and lack of interactions, the drug is increasingly being used in the treatment of epilepsy in children with other medical conditions who are receiving medications.

### Clinical Use

The drug comes in 100-, 300-, 400-, 600-, and 800-mg capsules and a solution 250 mg/5 mL. There is no IV form of the drug. Because clearance of GBP is greater in children than in adults, higher doses, on a milligram-per-kilogram basis, are needed in children (43). GBP can be started at 10–15 mg/kg/day and increased every three days, if necessary, until the child is receiving a dose of 30–40 mg/kg/day. The effective dose of GBP in patients 5 years of age and older is 25–35 mg/kg/day. The effective dose in children aged 3–4 years is 40 mg/kg/day. The maximum daily dose has not been established. However, we have had children who tolerated and required over 80 mg/kg/day. Because of the dose-dependent bioavailability and short half-life, most children should take the medication three times a day. While GBP has a saturable, dose-dependent absorption, this becomes a problem with dosing only when high doses of GBP are required. Gidal and coworkers (80) found that there were minimal differences in bioavailability between 3,600 mg/day given three or four times daily. When the dose was increased to 4,800 mg/day, a 22% increase in absorption was found with four-times-a-day dosing compared with dosing given three times a day.

Because there are no drug interactions, doses of other antiepileptic drugs do not need to be adjusted. However, if the patient does well on GBP, it is recommended that other antiepileptic drugs be reduced and eliminated. As mentioned previously, withdrawal of GBP has not been associated with a rebound increase of seizures (61). Nevertheless, it is recommended that GBP be tapered over several months once the decision is made to withdraw the drug.

GBP can be rapidly initiated. In a study of patients 12 years of age or older, GBP was started either gradually (300 mg/day for one day, 600 mg/day for one day, then 900 mg/day), or as an initial dose of 900 mg/day (81). Patients tolerated 900 mg/day as well as the escalation dose. Of the four most common adverse events (somnolence, dizziness, ataxia, fatigue), only one, dizziness, occurred more often in the rapid initiation group.

### SUMMARY

GBP was initially released as adjunctive therapy for the treatment of partial seizures in adults. Since the drug

has been released, there have been a number of studies demonstrating its efficacy and safety in children. In addition to its antiepileptic properties, the drug has been found to be useful in pain management. GBP has a number of highly desirable properties. There is no protein binding; the drug is not metabolized; and it is excreted unchanged through the urine. There are no significant drug interactions with other antiepileptic drugs, and other antiepileptic drugs do not alter the pharmacokinetics of GBP. The drug appears to have a narrow therapeutic profile. It is effective against partial seizures, although the majority of studies have used the drug as add-on therapy, and it has some efficacy in primarily generalized convulsive seizures. The drug is not effective in the treatment of absence or myoclonic seizures. The side effect profile of the drug is quite attractive. No significant idiosyncratic reactions have been reported. The most common side effects have included dizziness, fatigue, and headache. Rarely, children have adverse behavioral effects such as hyperactivity and agitated behavior. These children usually have preexisting behavioral disturbances.

### PREGABALIN

Pregabalin (PGB), like GBP, is a structural, but not functional analog of the inhibitory neurotransmitter GABA (Figure 45-4). Pregabalin has been in development for over a decade (82) and is the most recently released antiepileptic drug in the United States at the time of this writing. In addition to its efficacy in partial seizures, the drug is also effective in the treatment of neuropathic pain (83) and anxiety (84).

#### Chemistry, Animal Pharmacology, and Mechanism of Action

PGB has been tested in a variety of rodent models of seizures (85, 86). PGB inhibits tonic extensor seizures in rats with high-intensity electroshock, low-intensity

FIGURE 45-4

Molecular structure of pregabalin (PGB)

electroshock seizures in mice, and tonic extensor seizures in the DBA/2 audiogenic mouse model. At high doses, PGB ( $ED_{50} = 31$  mg/kg) prevented clonic seizures from pentylentetrazole in mice and prevented stage 4–5 behavioral seizures (lowest effective dose = 10 mg/kg) in the kindling model. PGB was not effective in the spontaneous absence-like seizures in the Genetic Absence Epilepsy Rats from Strasbourg (GAERS). In rodents, PGB caused ataxia and decreased spontaneous locomotor activity at dosages 10- to 30-fold higher than those required to stop seizures. PGB has shown efficacy in animal models of anxiety (87).

#### Biotransformation, Pharmacokinetics, and Interactions in Humans

Absorption is extensive, rapid, and proportional to dose (88). PGB absorption from the gastrointestinal tract is proportional to doses up to 150 mg/kg, which contrasts to the partially saturable absorption of GBP in rats (33, 89). The transport of PGB across membranes is largely explained by its substrate action at the L-amino acid transport system (89). However, the lower affinity ( $K_M$ ) and higher capacity to accumulate PGB appears to facilitate transmembrane absorption *in vivo*.

Time to maximal plasma concentration is approximately one hour, and steady state is reached within 24–48 hours (88, 90). Absorption with food has no clinically relevant effect on the amount of PGB absorbed.

PGB does not bind to plasma proteins and is excreted virtually unchanged (<2% metabolism) by the kidneys (91). It is not subject to hepatic metabolism and does not induce or inhibit liver enzymes such as the cytochrome P450 system. PGB has a clearance (mL/min) of 45–75 and has a half-life of 5–7 hours (88, 92, 93). PGB demonstrates highly predictable and linear pharmacokinetics in adults.

PGB has no substantial pharmacokinetic drug-drug interactions (82, 90, 94). Brodie et al (94) examined the effect of PGB on steady state concentration of carbamazepine, phenytoin, lamotrigine, and valproate in adult patients with partial seizures. The blood levels were unaffected by PGB. Likewise, PGB steady-state pharmacokinetic parameters were similar among patients on the four drugs. The authors also noted that PGB in combination with carbamazepine, phenytoin, lamotrigine, and valproate was well tolerated.

The drug crosses the blood-brain barrier and binds potently to the  $\alpha_2\delta$  subunit of the P/Q voltage-gated calcium channel (Figure 45-3) (95–97). As a result, PGB reduces calcium current at the terminal (95), reducing the release of glutamate (21, 22), noradrenaline (96), and substance P (98). PGB has no effect on GABA<sub>A</sub> and GABA<sub>B</sub> receptors (82). Likewise, PGB has no discernible effect on GABA uptake or degradation (14, 15, 82).

### Clinical Efficacy

Approval for PGB in the United States was based on three multicenter, randomized, double-blind, placebo-controlled trials in which efficacy and tolerability were assessed in patients with refractory epilepsy (99–102). In addition, a large international study evaluated GBP in adult patients with refractory partial seizures (103).

A total of 1,052 patients 12 years or older were entered into the U.S. studies, with 758 receiving PGB and 294 placebo. The patient population had refractory epilepsy and experienced at least six seizures and no 4-week seizure-free period during the 8-week baseline phase. Approximately 75% were on two other AEDs, and about a quarter were on three AEDs. In the first study, patients received PGB 50, 150, 300, or 600 mg/day (99); in the second study, patients received 50 or 600 mg/day (102); in the third study, patients received 600 mg/day (100). Patients receiving doses of 150, 300, or 600 mg/day had statistically fewer seizures than the placebo group, with a clear dose-response relationship. The responder rate, defined in the studies as the percentage of patients with  $\geq 50\%$  reduction in seizure frequency, approached 50% at 600 mg/day. While direct comparison between PGB and other antiepileptic drugs is difficult, the responder rate with PGB appears to be similar to the response with the other new AEDs (82).

In an international study, 341 patients were randomized to placebo, PGB fixed dose (600 mg/day), or PGB flexible dose 150 mg and 300 mg/day for 2 weeks each and then 450 mg and 600 mg/day for 4 weeks each (103). All patients were refractory patients who were taking one to three AEDs. Both PGB regimens significantly reduced seizure frequency, compared to control, by 35.4% for the flexible dose and 49.3% for the fixed dose, versus 10.6% for placebo. Most adverse events were mild or moderate.

Efficacy of PGB was seen early in the study, with reductions in seizure frequency noted during the first week of therapy. There were no differences in responder rate between twice-daily and three-times-daily dosing.

### Adverse Effects

The drug was well tolerated, with most adverse side effects central nervous system based. In adult patients, the adverse effects are dose dependent and occur within the first two weeks of treatment. Up to 33% of patients receiving PGB and 10% of those receiving placebo withdrew from the clinical trials because of adverse events (88). Common side effects associated with PGB, occurring in  $>10\%$  of patients in epilepsy studies, include dizziness, somnolence, ataxia, asthenia, and weight gain (82, 88). Over 20% of patients report dizziness and somnolence.

### Clinical Use

PGB comes in 25-, 50-, 75-, 100-, 150-, 200-, 225-, and 300-mg capsules. In adults, PGB in doses of 150 to 600 mg/day has been shown to be effective as adjunctive therapy in the treatment of partial-onset seizures. There are no guidelines for dosing in children. The authors typically start with a dose of 1–2 mg/kg and slowly titrate upward by 1–2 mg/kg per week until seizure control is achieved or adverse events occur.

PGB is a Schedule V controlled substance. In a study of recreational users ( $n = 15$ ) of sedative/hypnotic drugs, including alcohol, PGB reported subjective ratings of “good drug effect,” “high,” and “liking,” to a degree that was similar to a single dose of diazepam. In clinical studies with over 5,500 patients, 4% of PGB and 1% of the placebo group reported euphoria as an adverse effect (package insert, Lyrica®). Whether such an adverse side effect occurs in children is not yet known.

# 46

## Lamotrigine

*John M. Pellock*

**L**amotrigine was first approved for marketing in Ireland in 1993 and soon thereafter in most other countries, including the United Kingdom and the United States. It was initially recommended for use as adjunctive therapy in the treatment of partial seizures, but it was soon identified as possessing a much broader scope of antiepileptic action. It is one of the new broad-spectrum antiepileptic drugs (AEDs), resembling valproate in its multiple uses. Lamotrigine is nonsedating and offers several advantages, but it must be used correctly, especially in children (1–3).

### **CHEMISTRY, ANIMAL PHARMACOLOGY, AND MECHANISM OF ACTION**

Lamotrigine (LTG) is the name given to 3,5-diamino-6-(2,3-dichlorophenyl)-1,2,4-triazine. It is a stable white powder with solubility of less than 1 mg/mL in water and 1 mg/mL in ethanol. Lamotrigine was initially developed on the basis of a probably mistaken hypothesis that some AEDs were efficacious because of an antifolate effect. A series of phenyltriazines were investigated by the Wellcome Foundation and led to the development of lamotrigine. Although it has significant antiepileptic action, its action as an antifolate is minimal (4). The

identified mechanisms of action of this drug do not explain its broad range of therapeutic efficacy (5). The sole documented cellular mechanism of action is sodium channel block, a mechanism shared by phenytoin and carbamazepine. These drugs are, however, ineffective against absence seizures, and unless the sodium channel block from lamotrigine is quite unique, other mechanisms should explain its broad clinical efficacy (5). This block is both voltage and use dependent. Lamotrigine abolishes hind limb extension in the maximal electroshock model in both mouse and rat, and no tolerance is found after 28 days of dosing. Similar median effective dose ( $ED_{50}$ ) values are obtained in maximal seizure tests with picrotoxin and bicuculline, but LTG has no effect on pentyl-enetetrazol (PTZ) threshold or clonus latency after PTZ administration, as is shown with ethosuximide and valproate and would be expected because of LTG's efficacy in absence seizures. Lamotrigine delays the development of electrical kindling in the rat and modifies seizures. A feature that clearly distinguishes it from phenytoin and carbamazepine is its inhibition of visually evoked afterdischarges in the rat, a model in which valproate and ethosuximide are also efficacious. Studies suggest that lamotrigine reduces the effects of glutamate on the rat's spinal cord. The use- and voltage-dependent aspects of lamotrigine interactions at the sodium channel may be hypothesized to be responsible both for LTG's effects in

blocking veratridine-induced, but not potassium-induced, glutamate release and in reducing epileptic activity in hippocampal neurons. Coulter suggests that there are as yet undefined mechanisms through which lamotrigine works in addition to the sodium channel effects, which would be primarily responsible for the efficacy observed clinically in partial and generalized tonic-clonic seizures (5).

### BIOTRANSFORMATION, PHARMACOKINETICS, AND INTERACTIONS

Lamotrigine is well absorbed, and there is a negligible first-pass metabolic effect, so that its bioavailability is virtually 100 percent. It is uniformly distributed throughout the body with a volume of distribution of 1.1 L/kg in volunteers. It is biotransformed hepatically and excreted in urine primarily as the resultant glucuronide conjugates, with only 8 percent of the compound unchanged in humans. Hepatic dysfunction, and particularly Gilbert's syndrome with its functional impairment of UGT (uridine diphosphate glucuronosyltransferase), result in lower lamotrigine metabolism and subsequent clearance (4). Metabolites are not thought to be active. Lamotrigine is approximately 55% bound to plasma proteins, which is of little clinical significance (4, 6).

The pharmacokinetics of lamotrigine in children are similar to those in adults (6). Lamotrigine exhibits first-order linear pharmacokinetics. Lamotrigine absorption is unaffected by food. In patients, the volume of distribution is between 1.25 and 1.47 L/kg. The serum half-life of lamotrigine is between 24.1 and 35 hours in drug-naïve adults, but it is significantly altered by enzyme-inducing and enzyme-inhibiting drugs, including AEDs in particular. Clinical trials have demonstrated no evidence of auto-induction or saturable metabolism. Young children, less than 5 years, eliminate lamotrigine somewhat faster than older children and adults. A half-life of  $7.7 \pm 1.8$  hours was noted in young children receiving enzyme-inducing AEDs as cotherapy (7).

The most clinically significant pharmacokinetic finding regarding lamotrigine is that metabolism of the agent can be affected by concurrent drugs. The dosing schedule therefore must be altered whenever enzyme-inducing or enzyme-inhibiting agents are being administered before the addition of lamotrigine. Similarly, alterations in dose may be required whenever one of these AEDs is added or removed as lamotrigine is continued. The half-life of 24.1 to 35 hours in healthy adult volunteers is decreased to approximately 14 hours (6.4–32.2 hours) in those receiving enzyme-inducing drugs, such as phenytoin, carbamazepine, phenobarbital, and primidone, and increased to 30.5–88.8 hours in volunteers receiving valproate (6, 8). Whereas valproic acid decreases the clearance of lamotrigine, lamotrigine has been reported to increase the clearance of valproic acid by up to 25 percent in healthy volunteers.

Lamotrigine has no significant interaction on carbamazepine or carbamazepine epoxide levels. Lamotrigine has little effect on the plasma levels of oral contraceptives (9), but hormonal therapy (including oral contraceptives) and pregnancy have been noted to interact significantly with lamotrigine, causing a decrease in plasma levels and anti-convulsant effect (10).

### CLINICAL EFFICACY

Since the introduction of lamotrigine as a broad-spectrum AED, its use in both partial and generalized seizures has increased in adults and children. Although licensure and specific labeling vary, clinical practice includes use as both adjunctive and monotherapy for the treatment of various types of epilepsy.

The initial trials of lamotrigine were performed in adults with refractory partial onset epilepsy. Using double-blind, add-on, placebo-controlled trials of either crossover or parallel design, data from 457 adult patients with refractory partial epilepsy were used as the basis of the initial efficacy reports (11–19). Five of these six studies with crossover design showed significant reduction in seizure frequency with an overall 50% reduction in 25% of the patients. In these patients, who were formerly primarily on enzyme-inducing concomitant AED therapy, doses of lamotrigine ranged from 200 to 500 mg/day, with a suggestion that doses of 400 to 500 mg were more efficacious than lower doses. In addition to the seizure efficacy, nearly half of the patients reported positive global opinions regarding therapy with lamotrigine versus 22% receiving placebo. Efficacy as monotherapy in adults with partial seizures has also been established in follow-up studies and in two trials comparing monotherapy lamotrigine to that with carbamazepine or phenytoin (20, 21). Forty-three percent of patients treated with lamotrigine and 36% of patients treated with phenytoin were seizure free at the end of 24 weeks, and similar efficacy was noted with carbamazepine, as 39% of patients on lamotrigine and 38% on carbamazepine became seizure free. The rates of withdrawal were greater for those treated with phenytoin and carbamazepine than for patients treated with lamotrigine (19–22). In children, lamotrigine has shown utility in a broad range of pediatric epilepsy syndromes in addition to similar efficacy for partial seizures (23). It has been successfully used to treat primary generalized tonic clonic seizures (24), juvenile myoclonic epilepsy (25, 26), infantile spasms (27), Rett syndrome (28), absence seizures (29, 30), and seizures associated with the Lennox-Gastaut syndrome (31, 32). Myoclonic seizures, however, may not respond as well to lamotrigine therapy (33). In five open-label trials involving 285 pediatric patients, aged 1–13 years, with treatment-resistant epilepsy, 34% of all evaluable patients experienced at least a 50% decrease in seizure

frequency at 12 weeks, and 41% experienced the same improvement at 48 weeks (23). Children with absence seizures, both typical and atypical, appeared to have the best response. In addition, the global evaluations reported improvement in 69% of children at 12 weeks and 74% at 48 weeks of follow-up. Rash accounted for a 7.4% discontinuation rate, whereas the overall safety data revealed a 30% discontinuation rate. In a long-term continuation study (34), similar results were noted, with 73% maintaining improvement during the follow-up period of up to 4 years. The improved global functioning, which includes increased attention and alertness, has been reported in both pediatric and adult trials, and this is especially pronounced in children with concomitant developmental and/or attentional problems (23, 31, 35). More recently, positive and negative psychotropic effects have been noted during the treatment of mentally retarded persons with epilepsy (36).

The double-blind, placebo-controlled trial of lamotrigine in the treatment of 169 patients with Lennox-Gastaut syndrome, aged 3–25 years, clearly establishes the drug as being efficacious in this difficult to treat encephalopathic epilepsy of childhood (31). Patients received either lamotrigine 50–400 mg/day (1–15 mg/kg/day), based on weight and the absence or presence of valproate coadministration or placebo as add-on therapy for 16 weeks. At the time of final evaluation, 33 percent of patients taking lamotrigine and 16 percent of patients taking placebo achieved a seizure reduction of at least 50% ( $P < 0.01$ ). Figure 46-1 reveals the median change from baseline and the frequency of all major seizures, drop attacks, and tonic-clonic seizures during this trial. This controlled study clearly demonstrates that lamotrigine may be one of the most effective AEDs in the treatment of patients with Lennox-Gastaut syndrome.

A double-blind, randomized, placebo-controlled trial of lamotrigine add-on therapy for partial seizures in children and adolescents was performed with 201 treatment-resistant patients (37). Lamotrigine significantly reduced the frequency of all partial and secondarily generalized seizures versus placebo (44% vs. 12.8%). Neurotoxicity was only slightly more common in the lamotrigine-treated group. Although the overall rash rate was equal in the placebo group and the actively treated group, two patients receiving lamotrigine developed serious rash that resulted in hospitalization. A similar number of patients from each treatment group withdrew from the study. Thus, lamotrigine was effective for the treatment of partial seizures in children, and the safety profile was similar to that seen in adults. An interim report of an open-label phase of a similar trial performed in infants aged 1–24 months with refractory partial seizures suggests similar success (38).

The efficacy of lamotrigine monotherapy for typical absence seizures in children was studied through a “responder-enriched” study design in children and adolescents with newly diagnosed absence epilepsy. During

**FIGURE 46-1**

Median change from base line in the frequency of all types of major seizures, drop attacks, and tonic-clonic seizures during the 16-week treatment period. The values above the bars are the percentages of patients. Because of rounding, not all percentages total 100. From (31).

the initial open-label dose escalation phase of the study, 71.4% of patients in the intent to treat, or 82% as evaluated in the protocol analysis, became seizure free. Individual patients responded at doses ranging from 2 to 15 mg/kg/day. In the placebo-controlled, double-blind phase, more

patients remained seizure-free when treated with lamotrigine (62%) than with placebo (21%;  $P = 0.02$ ). In the 42 children enrolled, adverse effects included abdominal pain, headache, nausea, anorexia, dizziness, and hyperkinesia. Ten patients reported or experienced rashes, but in only one case was the rash considered attributable to lamotrigine. No patients were withdrawn because of adverse events (30). In addition to childhood absence and generalized tonic clonic seizures, the syndrome of juvenile myoclonic epilepsy (JME) has been studied to assess the broad-spectrum activity of lamotrigine. Timmings (25) initially studied 17 patients with JME who had experienced intolerable side effects or were uncontrolled with valproate. No difference in seizure control was observed between the two groups, with patients titrated to maximum daily dose of 500 mg lamotrigine and 2,500 for valproate. In an open-label study, Morris and colleagues (26) reported in patients previously treated with valproate ( $n = 63$ ), 85% became seizure free, and 70% had no myoclonus during 8 weeks of maintenance. In new-onset patients ( $n = 29$ ), 75% became seizure-free and had no myoclonus.

Retrospective reviews (39–42) showed generally positive results for the control of patients with JME and in primary generalized epilepsy. Adverse effects are in the ranges reported in other studies. The control of myoclonic seizures is variable and ranges from excellent to seemingly being exacerbated in individual patients, but some people have the entire spectrum of seizures controlled with lamotrigine (43).

## ADVERSE EFFECTS

The toxicity profile of lamotrigine includes common adverse events seen with other AEDs, including dizziness, diplopia, headache, ataxia, blurred vision, nausea, somnolence, and vomiting (1, 2, 4, 19, 35, 37). These classic neurotoxic adverse effects were more commonly seen in trials using adjunctive therapy and less frequently noted when lamotrigine was administered as monotherapy (Table 46-1). During the clinical trials, rash was the most common reason for discontinuation of lamotrigine and subsequently has become the most feared adverse effect, as the potential for developing a life-threatening rash associated with lamotrigine administration has been recognized.

The overall rash rate during the administration of lamotrigine is approximately 10 percent to 12 percent (44, 45). The rash associated with lamotrigine was initially described as maculopapular or erythematous in appearance, displaying characteristics of a delayed hypersensitivity reaction. It was thought to be self-limited, and no alterations in dosing were suggested. Recent work indicates that the immunologic changes associated with lamotrigine-induced rash may be considered an immune-mediated hypersensitivity reaction (44). This rash typically appears within the first 4 weeks of therapy and is rarely seen after 8 weeks. Subsequently, mostly children and fewer adults have developed a more severe erythema multiforme-type eruption, sometimes progressing to desquamation with involvement of mucous membranes resembling Stevens-Johnson or Lyell syndrome. Some patients clearly had

a generalized hypersensitivity reaction, but in others the reaction was limited to the skin. Reviews concerning the incidence of lamotrigine-associated rash confirm that it is slightly higher in children and when lamotrigine is initiated during concomitant therapy with valproate (45). It also has been suggested that rapid increases in rate of titration of lamotrigine will increase the risk of rash (17, 35, 45). Although a potential metabolite has been suggested as responsible for this reaction, none has been proven (46), but the hypersensitivity syndrome has been confirmed by lymphocyte stimulation *in vitro* (47). At present, it is estimated that approximately one adult in 1,000 and one child in 100–200 treated with lamotrigine may be at risk for this potentially life-threatening dermatologic reaction (45). Prior AED hypersensitivity reactions may be a predisposing condition (48). The incidence of rash in placebo-controlled trials evaluating adjunctive therapy with lamotrigine in pediatric patients (<16 years) was 14% ( $n = 168$ ) for patients receiving lamotrigine and 12% ( $n = 171$ ) for patients receiving placebo (49). The overall rate of discontinuation due to any rash in all premarketing clinical trials with lamotrigine as adjunctive therapy was 4.4% ( $n = 1,081$ ) in children. The prescribing information in the United States for lamotrigine (Lamictal®) contains a boxed warning concerning serious rashes requiring hospitalization and discontinuation of treatment in associated with its use. As stated in the package insert: “Other than age, there are as yet no factors identified that are known to predict the risk of occurrence or the severity of rash associated with lamotrigine. There are suggestions, yet to be proven, that the risk of rash may also be increased by (1) coadministration of lamotrigine with valproate (includes valproic acid and divalproex sodium), (2) exceeding the recommended initial dose of lamotrigine, or (3) exceeding the recommended dose escalation for lamotrigine. However, cases have been reported in the absence of these factors.” Postmarketing evaluations continue to show that nearly all cases of life-threatening rashes associated with lamotrigine have occurred within 2 to 8 weeks of treatment, but isolated cases have been reported after prolonged treatment greater than 6 months. The incidence of these serious rashes, including Stevens-Johnson syndrome, is approximately 0.8% (8/1000) in children < 16 years of age and 0.3% (3/1000) in adults. In a prospectively followed cohort of 1,983 pediatric patients taking adjunctive lamotrigine, there was one rash-related death (50). Of particular interest are the data from a registry for all serious cutaneous reactions in western Germany, which has existed since 1990. Since 1996, all of Germany has been included in this registry (51–54). In this academically based registry of an intensive reporting system, it is felt that almost all cases of Stevens-Johnson and toxic epidermal necrolysis are detected prospectively and confirmed by expert review. During the last six months of 1993, when lamotrigine was first marketed in Germany, there

were five cases of Stevens-Johnson syndrome or toxic epidermal necrolysis associated with lamotrigine reported in an estimated 4,050 adults patients exposed to lamotrigine. Four patients were also receiving valproate. In the third quarter of 1993, the dosing regimen was amended (starting dose when used with VPA was reduced from 15 mg daily to 25 mg alternative days), and physicians were educated accordingly. Despite the continued increase in use of lamotrigine from 1994 to the present, the incidence of these serious reactions has declined significantly. The German registry data through 2001 estimate Stevens-Johnson occurrence in 0.04% of children and 0.02% of adults (55). These data suggest that careful selection of patients and dose titration may improve the risk/benefit ratio in patients, and especially children, when treated with lamotrigine.

The warning in the prescribing information distributed with lamotrigine that the medication “should ordinarily be discontinued at the first sign of rash” may not be followed outside the United States because of the benign nature of most episodes of rash, even those associated with lamotrigine. When rash is associated with flu-like symptoms and malaise, myalgia, lymphadenopathy, or eosinophilia, this suggests a hypersensitivity reaction. The development of these reactions is more common in those who have experienced prior allergic symptoms to medications, particularly those who have experienced allergic or hypersensitivity reactions to AEDs. It is unclear that the present recommendations suggesting slower dosage titration truly reduce the rate of rash, but recognizing the risk patterns and paying careful attention to titration and dose schedule are mandatory. The clinician’s challenge is to work with the family and patient to determine which possible skin changes indicate a serious dermatologic complication. The time course of appearance (within 4–8 weeks), associated symptoms, distribution over the body, and rash characteristics may significantly help in making a decision to discontinue therapy.

Lamotrigine is felt by many to be a nearly ideal AED because of its favorable long-term adverse effect profile, once rash does not occur during the first few months of use. Its relative lack of interactions with other drugs made it a preferred agent in many. In 2006, emerging data from the north American Antiepileptic Drug Pregnancy Registry detected an elevated prevalence of isolated, nonsyndromic cleft palate deformity in infants exposed to lamotrigine monotherapy during the first trimester of pregnancy compared to the reference population (3 in 564; 8.9 per 1000 vs. 0.37 per 1000) (56). This information suggests that lamotrigine should be used in pregnancy when the potential benefits outweigh any possible risk to the developing fetus.

The adverse-effect profile of lamotrigine must be balanced against its broad spectrum efficacy and

seemingly positive effects on cognition and behavior (57, 58).

### CLINICAL USE

National and international guidelines and expert consensus statements select lamotrigine as a major AED for the treatment of both partial and generalized epilepsy (59–63). Its indication for bipolar mood disorders further enhances lamotrigine's utility in the treatment of children with comorbid behavioral disorders, especially depression (49). Despite the neurobehavioral toxicity noted, it is well tolerated in most adults and children. Direct comparisons reveal positive behavioral and quality of life ratings of patient perceptions. In healthy young adult volunteers, lamotrigine and gabapentin had no performance or other changes, whereas topiramate demonstrated neurocognitive interference after acute and chronic dosing (58). The term *brightening* has been used as patients seem to become less sedated and more alert and attentive.

Because of concomitant AED interactions and the potential to increase life-threatening rash (see the section on adverse effects), the dosing of lamotrigine must be carefully approached. Table 46-2 lists the recommended doses for children and adults (6, 10). Initial dosing, using the 2-mg, 5-mg, or 25-mg tablets, is frequently appropriate in children, especially those receiving valproate. The 2-mg or 5-mg dispersible tablets allows for correct dosing to be accomplished even in most infants. It is recommended that titration of dosage be done every 2 weeks until the desired clinical effect, usual maintenance dose, or clinical toxicity occurs. It is imperative that one prescribe the initial dose in children on enzyme-inducing AEDs at 0.6 mg/kg/day, but this initial

dose must be decreased to 0.15 mg/kg/day if valproic acid is being administered (10). Note that the usual maintenance dose while on valproate is approximately one-third that otherwise required if enzyme-inducing AEDs continue to be administered without valproate. Although there is no noted pharmacokinetic interaction with carbamazepine or other AEDs, we have found that as lamotrigine doses are increased in some patients to over 600 mg/day, increased neurotoxicity is observed. This pharmacodynamic interaction can be alleviated by reducing existing higher doses and levels, particularly of carbamazepine, slightly (typically by only 100–200 mg/day) to allow further escalation of lamotrigine.

Initial blood level determination in those experiencing improved seizure control were below 5 µg/mL. Subsequent experience would suggest that levels at least 12–15 µg/mL are well tolerated by some people, especially when lamotrigine is used as monotherapy, with continued seizure improvement as doses are titrated upward. Nevertheless, more neurotoxicity is to be expected at levels in this upper range or above.

### FORMULATIONS

The preparations of Lamictal (lamotrigine) available in the United States have increased in number and quality. Tablets are available in doses of 25, 100, 150, and 200 mg and chewable dispersible tablets are available in doses of 2 mg, 5 mg, and 25 mg. It is extremely important for the clinician to be sure to indicate tablet or chewable/dispersible tablet when prescribing medications, depending upon the ability of the child to swallow the dosage form. Generic formulations are now available.

**TABLE 46-2**  
*Lamotrigine Dose Recommendations in Children and Adults*

CONCURRENT AED	WEEKS 1 AND 2	WEEKS 3 AND 4	USUAL MAINTENANCE DOSE
Children			
EIAED	0.6 mg/kg/day	1.2 mg/kg/day	5–15 mg/kg/day
Monotherapy	0.3 mg/kg/day	0.6 mg/kg/day	2–8 mg/kg/day
Valproic Acid	0.15 mg/kg/day	0.3 mg/kg/day	1–5 mg/kg/day
Adults			
With EIAEDs but no VPA	50 mg/day (once a day)	100 mg/day (2 divided doses)	300–500 mg/day (2 divided doses). Escalate dose by 100 mg/day every week
With EIAEDs and VPA	25 mg every other day	25 mg/day	100–400 mg/day (2 divided doses). Escalate dose by 25–50 mg/day every 1 or 2 weeks

EIAED: enzyme-inducing antiepileptic drug. Modified from (6, 11).

## CONCLUSION

Lamotrigine is a broad-spectrum AED that is effective against both partial and generalized convulsive and nonconvulsive seizures. Its efficacy has been demonstrated in numerous studies in both adult and childhood epilepsy. It joins valproate, felbamate, topiramate, zonisamide, and levetiracetam as broad-spectrum

agents. Each agent differs slightly in efficacy profiles and reported adverse effects. Improved behavior and brightening has been commonly reported in those taking lamotrigine, whether adjunctive AEDs have been removed or continued. Careful dose titration should be followed during the initiation of this agent, and removal of concomitant agents will allow optimization of monotherapy and total dosing.

## Levetiracetam

**Raman Sankar**  
**W. Donald Shields**

**L**evetiracetam (LEV), (–)-(S)-alpha-ethyl-2-oxo-1-pyrrolidine acetamide (Figure 47-1), is an antiepileptic drug (AED) chemically related to the nootropic (cognition-enhancing) agent piracetam (1). Since piracetam was known to suppress myoclonic jerks (2), similar drugs were evaluated for anticonvulsant efficacy, leading to the discovery and development of levetiracetam as an AED.

Levetiracetam (LEV) has been available in the United States since 2000 and is marketed under the trade name Keppra®. It is currently indicated as adjunctive therapy in the treatment of partial-onset seizures in adults and children  $\geq 4$  years of age. It was recently approved for treatment of myoclonus as well. However, it is used in patients younger than 4 years, as monotherapy and in other epilepsy types.

### **CHEMISTRY, ANIMAL PHARMACOLOGY, AND MECHANISM OF ACTION**

#### **Preclinical Studies**

The pharmacologic activity of levetiracetam has been evaluated in rats and mice. Levetiracetam is not active in the classical acute models of maximal electroshock

(MES) and pentylenetetrazole (PTZ) seizures in mice (3). However, LEV does display potent and selective protection against kindling in a broad range of animal models of chronic epilepsy (3–5). This profile distinguishes LEV from most other AEDs, which demonstrate similar activity in both acute and chronic seizure models (3).

The fact that levetiracetam protects animals that have been made epileptic via kindling establishes its anticonvulsant activity (4). However, in addition to its anticonvulsant activity, LEV may also be antiepileptogenic, as suggested by the fact that LEV exposure retards the acquisition of kindling (5). It is important to note that this type of antiepileptogenic activity has been demonstrated by some newer AEDs (6–8), but not by others (9).

Levetiracetam also has a high safety margin, as evidenced by a remarkable separation between the dose that protects against convulsions and the dose that impairs rotarod performance. This observation was borne out of data in corneal electroshock-kindled mice and Genetic Absence Epilepsy Rats from Strasbourg (GAERS), which showed a high therapeutic index for LEV (3). Additionally, LEV demonstrates activity in animal models believed to represent generalized epilepsy. Levetiracetam has been shown to protect against seizures induced by acoustic stimulation in sound-sensitive mice (10) and rats (11) and against spike-and-wave discharges in GAERS rats (11). Levetiracetam was able to terminate self-sustaining status

FIGURE 47-1

Levetiracetam [(–)-(S)-alpha-ethyl-2-oxo-1-pyrrolidine acetamide].

epilepticus in rats and displayed synergy with diazepam in this model (12). Some limited animal data also indicate neuroprotective effects of LEV in models of status epilepticus (13, 14).

### Mechanism of Action

Fortuitously, LEV was discovered to have antiepileptic properties prior to undergoing NIH-standardized animal-model testing, which showed that LEV was not active in the standard models (15). This observation was an indication that LEV has a novel mechanism of action. It also indicates that the NIH-standardized screening may be missing important therapeutic agents and opportunities. Further evidence supporting novel activity lies in the fact that LEV does not produce changes in neuronal excitability by modulation of any of the three main mechanisms underlying classical AED activity (i.e., use-dependent blockade of voltage-gated sodium channels, inhibition of low-threshold [T-type] calcium currents, and augmentation of GABAergic inhibitory responses) (16–18).

In-vitro testing has shown that LEV does not displace ligands specific for 55 different binding sites, including receptor systems, reuptake sites, second messenger systems, and channel proteins (3). The exact mechanism of antiepileptic action of LEV remains to be elucidated; however, the following preclinical studies indicate that certain atypical cellular effects may be involved in reducing neuronal excitability:

- In isolated CA1 hippocampal neurons, LEV inhibits high-voltage-activated calcium currents (19, 20), with selective blockade of N-type calcium channels (20).
- From studies in isolated hippocampal, spinal, and cerebellar neurons, and in sound-susceptible mice, LEV has been shown to suppress negative allosteric modulators (zinc and beta-carbolines) of GABA- and glycine-gated currents (21). Although hyperexcitability may underlie some of the genetic epilepsies that are presently regarded as channelopathies, the acquired epilepsies seem to reveal anatomic and physiologic evidence of seizure-associated circuit rearrangement, which may be, in part, responsible for their intractability. Space in this chapter does not permit extensive discussion of the role of mossy fiber sprouting in the epileptogenic process, but it should be mentioned that mossy fiber sprouting is seen both in experimental models of temporal lobe epilepsy as well as in human hippocampi resected during surgical treatment of mesial temporal lobe epilepsy. Mossy fiber synapses release zinc, and zinc antagonizes GABA-mediated inhibition. The ability of LEV to reverse this interference by zinc of GABAergic inhibition (21) may thus be relevant to its effect on chronic or established epilepsy in animal models.
- One study, in isolated CA1 hippocampal neurons, suggests that LEV may produce a modest reduction in the delayed-rectifier potassium current, thereby lengthening repolarization time (22). A more recent study, however, detected no effect of LEV on the delayed-rectifier potassium current (23).
- Levetiracetam has shown activity in blocking *synchronization* in a slice experiment in which conventional AEDs such as valproic acid, benzodiazepines, and carbamazepine (CBZ) were inactive (24, 25). This is quite interesting because conventional AEDs have been shown to have impact mainly on *hyperexcitability*, even though the two underpinnings of the epileptic state are hypersynchrony and hyperexcitability. How does LEV accomplish this? Could it be antagonizing currents mediated by gap junctions that are responsible for “local” synchrony? We do not know for certain, but the possibility is intriguing.
- Levetiracetam has been shown to bind to a synaptic vesicle-associated protein known as SV2A (26). Mice homozygous for SV2A gene disruption exhibit deficiency in action potential-dependent GABAergic neurotransmission and develop spontaneous seizures (27). It has been proposed that SV2 may enhance neurotransmitter release probability at quiescent synapses by priming vesicles (28). The full details pertaining to the interaction of LEV with vesicle docking and neurotransmitter release remains to be elucidated.

## BIOTRANSFORMATION, PHARMACOKINETICS, AND INTERACTIONS IN HUMANS

Over 30 clinical studies have evaluated both the single- and multiple-dose pharmacokinetics of LEV following oral administration. Data from these studies have delineated the pharmacokinetic profile of LEV (29, 30) (Table 47-1).

### Absorption and Distribution

Pharmacokinetic data in adults show that LEV is rapidly and almost completely absorbed after oral administration. Absolute oral bioavailability is nearly 100%, and food does not affect the extent of absorption, but does slow the rate of absorption. Peak plasma levels are generally achieved within 1 hour following oral administration in fasted subjects, and steady-state plasma levels are reached after 2 days of twice-daily dosing. Levetiracetam exhibits linear pharmacokinetics at recommended doses (29). Levetiracetam is not extensively bound (10%) to plasma proteins, and its volume of distribution is close to that of intracellular and extracellular body water (29).

### Metabolism and Elimination

Levetiracetam is not extensively metabolized in humans (24% of a dose). The main metabolic pathway involves enzymatic hydrolysis of the acetamide group, is independent of the cytochrome P450 system, and results in the formation of the major metabolite of LEV, which is pharmacologically inactive (29,30). Levetiracetam plasma half-life is 7.0 hours and is unaffected by dose or repeated administration. Elimination of both LEV and its major metabolite is via renal excretion, whereby 66% of a dose is excreted as unchanged drug. Total body clearance of LEV is 0.96 mL/min/kg. Renal clearance is 0.6 mL/min/kg and is directly proportional to creatinine clearance (29,30).

In patients with renal impairment, the elimination half-life of LEV is prolonged and total body clearance is decreased 35% to 60%, compared with that in healthy subjects. Thus, daily maintenance doses should be reduced in these patients. Levetiracetam is dialyzable; therefore, supplemental doses should be given to patients following dialysis (29, 30).

Elderly patients experiencing age-related renal function decline may also require dose reduction of LEV based on their estimated creatinine clearance. Patients with hepatic impairment have no changes in LEV pharmacokinetics, and therefore require no dose reduction (29).

**TABLE 47-1**  
*Levetiracetam Pharmacokinetic Profile*

PARAMETER	EFFECT
Absorption	Rapidly and almost-completely (>95%) absorbed No saturable absorption No food interaction
Distribution	
$t_{\max}$	1.3 hr
$C_{\max}$	2.3 $\mu\text{g/mL}$
AUC	222 $\mu\text{g} \cdot \text{hr/mL}$
Enzyme kinetics	Linear kinetics; $C_{\max}$ and AUC are proportional in single doses up to 5000 mg
$t_{\text{ss}}$	After 48 hr
Plasma-protein binding	<10%
$V_d$	0.5–0.7 L/kg
Metabolism	Minimal; in blood to the inactive deaminated metabolite L057 Not dependent on the hepatic CYP system No auto-induction
Elimination	In urine; 66% as parent drug, 24% as L057
$t_{1/2}$	Adults 6–8 hr, elderly 10–11 hr, children 6 hr

$t_{\text{ss}}$ , time to plasma steady-state concentration;  $t_{1/2}$ , elimination half-life.

### Pediatric Pharmacokinetics

Pharmacokinetic data in children derive from a multicenter, open-label, single-dose titration study (31). Twenty-four patients (aged 6 to 12 years) received oral LEV as adjunctive therapy at a dose of 20 mg/kg/day. In this pediatric study, LEV clearance was 30 to 40% higher than in adults, resulting in a lower C and area under the curve (AUC) equated for a 1 mg/kg dose. A correspondingly shorter half-life, of 6.01 hours, was observed. Additionally, no significant gender or age differences in pharmacokinetic parameters of LEV were noted. Based on these data, a dose equal to 130% to 140% of the usual daily adult dose in two divided doses, on a weight-normalized level, may be the most appropriate daily maintenance dose in children.

## Drug Interactions

Early study of metabolic interactions indicated a low potential for LEV drug interactions (32), and support of this observation has been borne out in additional studies. Pooled data from pivotal Phase III trials confirm that LEV has no known interactions with other AEDs (33). Additionally, LEV does not influence the pharmacokinetics of an oral contraceptive containing ethinyl estradiol and levonorgestrel; on the basis of serum progesterone and luteinizing hormone levels, it does not affect contraceptive efficacy (34). Levetiracetam also does not affect the pharmacokinetics of digoxin (35) and warfarin (36).

## CLINICAL EFFICACY

### Partial Seizures

The efficacy of LEV in adults has been evaluated extensively. Three randomized, double-blind, placebo-controlled clinical trials conducted in the United States and Europe that enrolled 904 patients were pivotal in supporting LEV efficacy as adjunctive therapy in adults with refractory partial-onset seizures with or without secondary generalization (37–39). All three of these studies evaluated LEV using similar methodology. After an 8-week to 12-week baseline period, patients entered a titration phase where, upon randomization, they had doses titrated upward every 2 weeks over a period of 4 to 6 weeks to a final dose of 1,000, 2,000, or 3,000 mg/day in divided doses, or placebo. Subsequent to titration, a

12-week to 14-week evaluation phase, followed by an optional open-label phase, was completed. A pooled efficacy analysis of these placebo-controlled studies (40) indicates the following. In all three of these studies and in all dose groups, compared with placebo, treatment with LEV resulted in reduced seizure frequency that was statistically significant. Patients receiving LEV achieved a 31% median decrease in seizures from baseline, compared with only a 5.4% median decline in placebo-treated patients ( $P < 0.001$ ). Additionally, 35% of LEV-treated patients achieved 50% seizure reduction, compared with 9.4% of placebo-treated patients ( $P < 0.001$ ). In these studies, increasing response was associated with increasing dose. Whereas the 50% responder rate in placebo-treated patients was 9.4%, 50% responder rates at doses of 1,000, 2,000, and 3,000 mg/day were 28.6%, 35.2%, and 39.5%, respectively. This same trend was seen in patients who were 100% responders (Figure 47-2).

Other blinded, placebo-controlled (41) and open-label trials (42, 43) support efficacy in partial seizures established by the three pivotal trials. In these trials, conducted using doses from 1,000 to 4,000 mg/day, responder rates in patients with partial-onset seizures ranged from around 40% to 60%.

Outside of the traditional clinical trial setting, LEV performance has also been studied in a large, phase IV community-based (KEEPER) trial of 1,030 subjects (44). In this 16-week study involving five office visits, adult outpatients with partial-onset epilepsy received add-on LEV therapy. Overall, 57.9% of patients achieved 50% seizure reduction, and global evaluation scores were improved

FIGURE 47-2

Pooled response rates by dose from pivotal phase III trials (40).

compared to baseline in nearly 75% of patients. Results of a subset analysis revealed that these findings confirm efficacy results seen in phase III trials. In the SKATE trial, 178 adult patients were treated for 16 weeks with 1,000, 2,000, or 3,000 mg LEV in an open-label, add on study of medically refractory patients. The retention rate at 16 weeks was 84.8%. The 50% responder rate was 46.6% with 16.7% of patients achieving seizure freedom (45).

### Monotherapy Studies in Partial Seizures

The data are limited for the use of LEV for monotherapy but there is no reason to assume that it cannot be used as monotherapy in many patients. A responder-selected study of monotherapy was performed in 286 patients. The study began as an add-on study with patients receiving either placebo or 1,500 mg twice daily. Patients who had at least a 50% reduction in seizures entered into a monotherapy phase with a 12-week down-titration of previous medications followed by 12 weeks of monotherapy at 1,500 mg twice daily. In the initial placebo controlled component of the study, 42.1% of the LEV group achieved a 50% reduction compared with 16.7% of controls. In the LEV monotherapy group, the median percent reduction was 73.8%. Nine of the original 181 patients randomized to LEV were seizure free on monotherapy (46). Data from retrospective chart reviews also provide a basis for efficacious monotherapeutic performance. In a review of 45 patients with newly diagnosed partial-onset epilepsy, 5 of 11 patients on LEV therapy for at least 6 months achieved 50% seizure reduction, and 6 became seizure free (47).

A randomized, placebo-controlled trial (48) comparing LEV ( $n = 288$ ) and controlled-release carbamazepine (CBZ,  $n = 291$ ) in new-onset epilepsy produced equivalent seizure-freedom rates using conservative doses (LEV, 500 mg twice daily vs. CBZ 200 mg twice daily). One-year remission was achieved by 86% of the patients treated with LEV, while CBZ resulted in remission in 89.3% patients (48).

### Generalized Seizures

A number of uncontrolled or retrospective reports suggest that LEV may be of value in patient with generalized seizures. In a small case series of three patients who had failed at least three other AEDs, monotherapy for primary generalized epilepsy (PGE) was assessed (49). All three patients became seizure free for at least 6 months on LEV therapy. Wever reported on ten patients with generalized seizures, including 6 with PGE and 4 with Lennox-Gastaut syndrome. One became seizure free, and 4 more had a > 50% reduction in seizures (50). The add-on monotherapy trials in children by Lagae et al (51) confirmed the efficacy of LEV in both partial and gener-

alized epilepsies. A retrospective study of 59 intractable epilepsy children reported a >50% reduction in 40% of intractable partial seizures, 55% of generalized seizures, and 61% of those with mixed seizures (52).

Two studies that assessed the response of spike-wave density in patients with idiopathic generalized epilepsy with baseline and post-treatment 24-hour EEG have reported impressive results (53, 54). Gallagher et al (53) reported complete cessation of spike-waves in 9 of 10 patients studied in the awake state and significant reduction during sleep. Rocamora et al (54) reported a 72% reduction in median spike-wave duration in their 8 patients. Efficacy of LEV on a variety of epilepsy syndromes involving myoclonus is discussed under a separate heading below. It should be noted, under the present heading, that data submitted to the U.S. Food and Drug Administration (FDA) on the efficacy of LEV on myoclonus associated with juvenile myoclonic epilepsy (JME) has resulted in approval in the United States for that indication. This is consistent with the open-label experience with LEV on JME reported by Specchio et al (55). As of April 1, 2007, LEV has received approval from the FDA for use in primary generalized tonic-clonic seizures in patients 6 years of age or older.

### Pediatric Studies

Following the establishment of its efficacy and safety in adults, levetiracetam adjunctive therapy was evaluated in an open-label trial in children. The 24 pediatric patients enrolled in the open-label, single-dose pharmacokinetic study (31) were also evaluated subsequently for levetiracetam efficacy and safety (56). After a 4-week baseline period, these children (mean age 9.4 years) participated in a 6-week titration phase, followed by an 8-week evaluation phase in which doses ranged from 20 to 40 mg/kg/day. Compared with their baseline seizure frequency, 12 of 23 (52%) patients who entered the evaluation phase achieved 50% seizure reduction, and 5 of 23 (21.7%) achieved 75% seizure reduction. Two patients remained seizure free throughout the evaluation period. In another open-label study of 39 pediatric patients (mean age 8.6 years) with refractory epilepsy, adjunctive levetiracetam therapy was evaluated during a 9-month treatment period (57). Results of this study support reduced seizure frequency, improved cognition and behavior, and good tolerability.

A double-blind placebo-controlled trial of LEV as adjunctive therapy was performed in 198 children with medically intractable partial seizures. The reduction of LEV treated patients over placebo treated was significant at 26.8% ( $P = 0.0002$ ) with a >50% reduction in 44.6% of the LEV group. Significantly, 6.9% of LEV-treated patients became seizure free (58). This study led to FDA approval of LEV as adjunctive therapy for children.

Verrotti et al (59) used LEV in 21 patients with benign rolandic epilepsy (BECTS) and found that all of the patients had at least a 50% reduction in seizures. A longer follow-up study comparing the efficacy of oxcarbazepine (OXC) to LEV in rolandic epilepsy by the same group found 19 of 21 (90.5%) children treated with LEV to be seizure free, compared to 13 of 18 (72.2%) treated with OXC (60).

Case reports suggest that LEV may be helpful in children with seizures due to tuberous sclerosis (61). While one specific case of LEV-responsive Landau Kleffner syndrome has been reported (62), other reports (63, 64) describe the utility of LEV in syndromes of continuous spikes and waves during slow sleep (CSWS). There are no convincing data to advocate the use of LEV in catastrophic childhood epilepsies such as infantile spasms or Lennox-Gastaut syndrome.

### Myoclonus

Several open-label studies of LEV in myoclonus due to a variety of underlying disorders have been reported. In a study of juvenile myoclonic epilepsy, 38 patients were enrolled and titrated to a dose of 3,000 mg/day over 2 weeks. Half of the 10 newly diagnosed patients were seizure free, as were 11 of 38 previously refractory patients (55), indicating that LEV may be a reasonable alternative to the more traditional medications such as valproic acid. LEV appears to be effective in many patients with Unverricht-Lundborg disease, with 8 of 13 patients demonstrating a measurable improvement. Most responders were the younger patients in the study (65). The report by Labate et al (66) involved both patients with idiopathic and symptomatic generalized epilepsies and myoclonus. They reported 50% or greater seizure reduction in 82% of the 35 patients studied.

## CLINICAL USE IN PEDIATRIC PATIENTS

Levetiracetam is an appropriate medication to use in the pediatric age group. It is approved for add-on therapy for partial seizures in children >4 years and for myoclonus associated with JME. It has also received approval for use in patients 5 years of age or older for primary generalized tonic-clonic seizures. However, it should be noted that special consideration must be given to use of levetiracetam in children. Based on pharmacokinetic data, levetiracetam clearance is enhanced in children as compared to adults. Thus, in patients under the age of 12, 130–140% of the adult daily dose, normalized to body weight, may be appropriate.

The fact that many adult patients will respond to 1,000 mg/day should be taken into account when prescribing for children. It is prudent to start at a low dose, then titrate upward slowly, as this may diminish the propensity for adverse effects. Levetiracetam is cur-

rently available as tablets and as a liquid preparation, so it can be readily administered to children of all ages and children with special needs, such as those fed by gastrostomy tube.

### Long-Term Studies

Long-term clinical usefulness of LEV has been evaluated. In one study, data from all 1,422 epilepsy patients exposed to LEV during any phase of development were analyzed (67, 68). The median duration of treatment was 399 days (range 1–8 years), and the median reduction from baseline in seizure frequency over the entire treatment period was 39.6%. Furthermore, no decrease in efficacy was observed over time in each cohort exposed to LEV ranging from 6 to 54 months.

Other studies looking at refractory epilepsy patients followed for 1 year support findings of sustained efficacy. In one open-label study of 98 patients, 57 achieved 50% seizure reduction and 14 were seizure free for the first year. This study particularly attempted to investigate types of patients who would not be eligible for clinical trials because of factors such as mental retardation and comorbid neuropsychiatric disorders (69). Another study reported a 26% seizure-free rate at one year, and this benefit correlated with the fact that 77% of patients continued on LEV therapy at 1 year (70).

### Quality of Life Studies

The effect of LEV on quality of life has been investigated. Using the 31-item Quality of Life in Epilepsy (QOLIE-31) questionnaire, patients randomized to LEV at 1,000 or 3,000 mg/day or to placebo were studied over an 18-week period. Significant improvements in several areas, including seizure worry, overall quality of life, cognitive functioning, and total score, were seen in patients taking LEV compared with those taking placebo (71). A subsequent evaluation of a subset of these patients who were followed for 4 years indicates that improvements in QOLIE-31 scores remained stable during the 4-year follow-up period (72).

## ADVERSE EFFECTS IN ADULTS

The majority of clinical safety data on LEV derive from four large, well-controlled trials (three pivotal phase III and one supportive phase III), which included 769 patients who received levetiracetam and 439 who received placebo (37–39, 41, 73).

A pooled analysis of these four trials found that the most frequently reported treatment-emergent adverse events associated with LEV adjunctive therapy were somnolence, asthenia, infection, and dizzi-

**TABLE 47-2**  
*Incidence of Adverse Experiences Reported More by LEV-Treated Patients Than by Placebo-Treated Patients, by Body System*

<b>BODY SYSTEM/ PREFERRED TERMS</b>	<b>LEVETIRACETAM (n = 769)</b>		<b>PLACEBO (n = 439)</b>	
Body as a whole				
Asthenia	113	14.7%	40	9.1%
Headache	105	13.7%	59	13.4%
Infection	103	13.4%	33	7.5%
Pain	52	6.8%	26	5.9%
Nervous system				
Depression	31	4.0%	10	2.3%
Dizziness	68	8.8%	18	4.1%
Somnolence	114	14.8%	37	8.4%
Nausea	34	4.4%	19	4.3%
Insomnia	24	3.1%	11	2.5%
Nervousness	30	3.9%	8	1.8%
Respiratory system				
Pharyngitis	47	6.1%	17	3.9%
Rhinitis	34	4.4%	11	2.5%

Data are for events reported by  $\geq 3\%$  of levetiracetam-treated patients.  
Source: (73). Data on file, UCB Pharma

ness (Table 47-2). Overall, a total of 15.0% of patients receiving LEV and 11.6% receiving placebo either discontinued or had a dose reduction as a result of an adverse event (73).

CNS adverse events, often seen in AED-treated patients, occurred in LEV-treated patients. The most common, somnolence and asthenia, were reported by 14.8% and 14.7% of LEV-treated patients, compared with 8.4% and 9.1% of placebo-treated patients, respectively. A total of 3.4% of LEV-treated patients experienced coordination difficulties (reported as ataxia, abnormal gait, or incoordination), compared with 1.6% of placebo-treated patients. Somnolence, asthenia, and coordination difficulties occurred most frequently within the first 4 weeks of treatment. Additionally, 13.3% of LEV-treated patients experienced behavioral symptoms (reported as agitation, hostility, anxiety, apathy, emotional lability, depersonalization, and depression) compared with 6.2% of placebo patients. The majority of these behavioral adverse events were reported early in therapy and occasionally led to withdrawal (73).

Regarding hematologic adverse events, minor but statistically significant decreases compared with placebo in total mean red blood cell (RBC) count, mean hemoglobin, and mean hematocrit were seen in LEV-treated patients. However, all mean values for these parameters remained within normal laboratory ranges. There were small mean decreases in white blood cell (WBC) count from baseline to the final visit in LEV-treated patients. However,

no patient required discontinuation due to underlying neutropenia, and the infection adverse events were not related to WBC changes (73).

No significant changes were noted in liver function tests, renal function, or body weight (73).

There are no adequate and well-controlled studies of LEV in pregnant women; thus, it is assigned Pregnancy Category C. Some of the major known mechanisms that mediate AED teratogenicity (74), such as activation of cytochrome P450 systems and inhibition of histone deacetylation, do not apply to LEV. Extensive transfer of LEV from plasma to breast milk (ratio  $\approx 1:1$ ) has been described (75, 76), but infants had very low serum concentrations of LEV. Clinical judgment regarding the benefit of LEV therapy should be exercised, and the finding is not generally considered a contraindication to the use of LEV in breastfeeding mothers.

#### ADVERSE EFFECTS IN PEDIATRIC PATIENTS

Regarding safety, the most common adverse events reported were headache, infection, anorexia, and somnolence. No significant alterations in mean clinical laboratory values or in concomitant AED plasma concentrations were observed. Safety data from various studies (56–58) suggest that, as in adults, LEV is generally well tolerated in children. One area of note, however, is the occurrence of emergent behavioral side

effects. Specifically, aggression, emotional lability, oppositional behavior, and psychosis have been described in some children taking levetiracetam (56–58, 77). In the aforementioned study of 24 patients by Glauser et al, the incidence of emotional lability was 12.5% (56). Wheless and Ng studied 39 children and reported that 15 of these patients experienced behavioral side effects. Furthermore, 11 of these 15 patients were developmentally delayed or mentally retarded (57). A small review of four pediatric epilepsy cases by Kossoff et al reports that each of these patients experienced treatment-emergent psychosis that was reversible (77). These studies also indicate that the treatment-emergent behavioral side effects are reversible, have a higher incidence in children with a history of behavioral emotional problems, and may be associated with rapid titration (56–58, 77). A meta-analysis of AED-associated behavioral and psychiatric adverse events suggested that the incidence of such effects with LEV is not substantially different from that associated with most new-generation AEDs (78).

## CONCLUSION

Levetiracetam has emerged as an important new anti-convulsant medication for patients with many different types of epilepsy. Initial data led to approval as adjunctive therapy in adults. More recent data have extended this to the pediatric population and to use in myoclonic seizures associated with JME. It has also received approval for use in primary generalized tonic-clonic seizures in patients 6 years of age or older. The recent availability of an intravenous solution with comparable bioavailability to the oral preparations (79, 80) provides flexibility in administration to patients unable to take the oral medications, including patients immediately after surgical procedures. It can be useful in patients with myoclonus or with generalized seizures and is an attractive option in view of the excellent safety and lack of drug interactions associated with its use. These advantages have resulted in extensive use of LEV for the treatment of seizures in patients on complex medical regimens such as cancer chemotherapy or medications to prevent rejection of transplanted organs.

## Barbiturates and Primidone

*Robert S. Rust*

**B**arbiturates constitute the oldest category of anticonvulsant medications that continue to be widely used in the management of epilepsy and other disorders. Their usefulness derives from a combination of efficacy, safety, and low cost. These virtues account for the fact that barbiturates likely remain among the most widely employed anticonvulsants in the world. Although phenobarbital (PB) is the major focus of this chapter, other drugs are reviewed, particularly mephobarbital, pentobarbital, and primidone. Mephobarbital (MPB) is a useful alternative to PB, more widely employed in some other countries, such as Australia, than in the United States. Like primidone, it undergoes biotransformation to PB. Among the more sedative barbiturates, pentobarbital has been useful in the management of severe and persistent seizures that do not respond to more routine anticonvulsant therapy. Primidone (PRM) is not actually a barbiturate, although it is subject to biotransformation into PB and probably exerts most of its anticonvulsant effects in that form. Because the major antiepileptic effects and side effects can be ascribed to the PB metabolite and because of pharmacokinetic and pharmacodynamic similarities, it is quite appropriate to consider PRM in this chapter.

### PHENOBARBITAL

Phenobarbital is 5-ethyl-5-phenyl substituted barbituric acid, with a molecular weight of 232.23. It is a weakly acidic substance with a  $pK_a$  that is usually reported as 7.3 (1–4). The free acid has low aqueous and relatively low lipid solubility; however, the sodium salt, which is used for intravenous (IV) and intramuscular (IM) preparations, is freely soluble in slightly alkaline aqueous solutions.

### Mechanisms of Action

Phenobarbital exhibits a wide spectrum of anticonvulsant activity, conferring protection to animals subjected either to electroshock or to chemically induced (pentylene-tetrazol or bicuculline) experimental seizures (5, 6). This spectrum is shared by most barbiturates and is consistent with their wide spectrum of activity in clinical seizure disorders.

Understanding of the antiepileptic activity of PB has been limited by the incomplete state of our understanding of the mechanisms of epilepsy. Current views suggest that PB modulates the postsynaptic effects of certain neurotransmitters. The modulation is thought to affect both the inhibitory substance gamma-aminobutyric acid (GABA) and such excitatory amino acids as glutamate.

Whether by these or other mechanisms, antiepileptic barbiturates appear to elevate the threshold to chemical or electrical induction of seizures in ways that differ from and are in some respects superior to those of phenytoin (7).

A large body of information has accumulated concerning the ability of barbiturates to depress physiologic excitation in the nervous system and enhance inhibition of synaptic transmission. PB shares with pentobarbital (PnB) the capacity for selective postsynaptic augmentation of GABA-mediated inhibition and depression of glutamate- and quisqualate-mediated excitation in at least some central nervous system (CNS) regions (8–14). Barbiturate augmentation of GABA-stimulated postsynaptic inhibition appears to be due to activation of a subset (alpha-beta) of the GABA<sub>A</sub>-receptor gated chloride channels (13, 15). These receptors differ from those that are activated by benzodiazepines and are differentially expressed in brain (16). These postsynaptic effects are produced at clinically relevant concentrations (12, 13). Evidence that phenobarbital may elevate concentration of kynurenic acid in relevant brain tissues suggests yet another mechanism whereby this anticonvulsant may control epilepsy. This novel mechanism may be shared by phenytoin, felbamate, and lamotrigine (17).

The reduction of voltage-activated calcium currents may in part account for the sedative and anesthetic effects of barbiturates and may possibly play a role in the efficacy of PnB and very high concentrations of PB in suppressing seizures (13). This is another potential mechanism whereby these agents may work in the setting of intractable status epilepticus with barbiturate coma and may represent one of the mechanisms for production of anesthesia (13).

### Pharmacokinetics

**Absorption.** Phenobarbital is rapidly and nearly completely absorbed after oral or IM administration to infants or children. For most children older than 6 months of age or adults, it is likely that peak serum concentrations of PB are achieved by 2 hours after oral and 2–4 hours after IM bolus administration of the usual age-appropriate maintenance doses. The bioavailability of most oral and parenteral formulations is essentially quantitative (85–100%) through a wide range of doses in otherwise healthy children (>6 months of age) or adults. Rectally administered parenteral solutions of sodium PB are well absorbed at all ages, although the latency to peak concentration may be slightly longer and the bioavailability slightly lower than after IM administration (18).

**Distribution.** Phenobarbital disseminates into all body tissues. At lower serum pH the ionized fraction of serum PB is smaller, and therefore diffusion into tissues is enhanced, leading to lower serum but higher tissue

concentrations. More alkaline serum produces opposite effects (4). Only approximately 50% or less of circulating PB is bound to serum proteins in most patients whose ages are greater than 3 to 6 months. Equilibration of PB across the blood-brain barrier is relatively slow. Twelve to 60 minutes are required for maximal brain-to-plasma PB ratios in adult mammalian brain after IV administration. These data suggest that (1) dosage of PB should be based on lean body mass to avoid overdosing obese individuals (19, 20), and (2) sufficient time for maximal brain penetration should be allowed to occur after bolus administration of PB before administration of additional doses.

Phenobarbital readily crosses the placenta and is secreted in breast milk (21, 22). Breast milk concentrations were  $36 \pm 20\%$  and  $41 \pm 16\%$  of maternal serum concentrations in two studies (23, 24). The newborn infants of mothers treated with PB have levels equivalent to those of their mothers immediately after birth (23, 25–28). Estimates of the apparent volume of distribution (*Vd*) of PB vary over nearly a fourfold range but are generally larger in infants and small children than in older individuals (29–31). The *Vds* for newborns and infants less than 4 months of age treated with IV PB average approximately 0.9 to 1.0 L/kg, independent of body weight, dose, gestational age, or occurrence of asphyxia (29, 32–35). Older children and adults exhibit *Vds* that range from approximately 0.45 to 0.7 L/kg more or less irrespective of route of administration (36–38).

**Metabolism and Elimination.** Phenobarbital may be excreted unchanged or may undergo biotransformation before excretion. The most quantitatively important fates for PB metabolism include (1) aromatic hydroxylation to *p*-hydroxyphenobarbital (PBOH) and (2) *N*-glucosidation to 9-*D*-glucopyranosyl phenobarbital (PNG) (39, 40). On average (with wide interindividual variation), approximately 20% to 30% of a daily dose of PB is converted to the pharmacologically unimportant PBOH, apparently by at least one cytochrome P450 isozyme. In most children and adults, about half of the PBOH is excreted unchanged and about half is excreted as a PBOH-glucuronide conjugate that is formed in liver (41). Although PB is the classic inducer of hepatic microsomal metabolism, it does not appear to induce significant changes in its own metabolic rate or plasma clearance in humans, although slight effects may occasionally be detected (42, 43).

Phenobarbital has the longest half-time of elimination of any of the frequently used anticonvulsants. The two-standard-deviation range for half-time of elimination in children and adults is 24 to 140 hours, resulting in the capacity to eliminate between 11% and 50% of total body PB in 24 hours (42, 44–48). Elimination half-time is longest in premature and full-term newborns, with various

studies showing mean values of 100 to 200 hours with standard deviations of 30% to 80% (full range across these studies of 59 to greater than 400 hours) (31, 33, 49–52). Clearance may vary from day to day in individual babies (52); however, the rate of elimination may double by the second week of life and tends to continue to increase for the ensuing few weeks. Infants 6 weeks to 12 months old have the shortest mean half-times of elimination (30–75 hours) of any age group (31, 35, 53, 54). At age 2 months half-time of elimination is usually in the range of 39 to 55 hours. Children 1 to 15 years of age typically have half-time of elimination of 37 to 73 (68 ± 30) hours, while subjects 15 to 40 years of age have 53 to 141 (100 ± 20) hours half-time of elimination (30, 55). Perinatal asphyxia may considerably decrease the clearance by newborns, probably due to the combination of renal and hepatic dysfunction (22, 35, 38, 53, 56–65). Clearance of unmetabolized PB may be higher at higher rates of urine formation (66–68) or in more alkaline urine, as both of these conditions reduce the rate of PB resorption in the distal nephron. Eightfold increase in the rate of urine formation may increase PB clearance by three- to fourfold (69, 70). This effect may be considerably enhanced by the alkalization of urine with sodium bicarbonate (4).

### Interactions with Other Drugs

Although some drugs affect PB kinetics, most of the pharmacokinetically important interactions encountered with the use of PB are those caused by the effects of PB on the kinetics of other drugs. The most common key encountered effect that PB has on the metabolism of other drugs is to increase their biotransformation, thereby increasing their clearance rate. PB is the prototypical inducer of the hepatic mixed-function oxidase system that comprises, among other elements, the numerous isoenzymes of cytochrome P450 and of NADPH-cytochrome c reductase.

A list of drugs for which this effect may be clinically important is provided in Table 48-1 (43, 71–94). In several instances, as indicated in Table 48-1, PB may result in increased concentrations of potentially toxic metabolites. The enhancement of potential valproate toxicity to kidney and liver must be considered in cases in which these drugs are used in combination. Renal tubular injury may be exacerbated by the increased dose of valproate required in some patients taking PB (92, 93), while the chance of hepatic injury may be increased because of PB-induced production of the “4-en” metabolite of valproate, which appears to be toxic to hepatocytes (95–98). Phenobarbital co-administration may increase the risk for valproate-induced hyperammonemic encephalopathy, perhaps by means of unfavorable effects on ammonia clearance (99).

**TABLE 48-1**  
*Drugs Subject to Kinetic Alteration When Administered to Patients Receiving Phenobarbital*

#### SHORTENED HALF-TIME OF ELIMINATION AND/OR PEAK LEVELS

Acetaminophen (71)*
Amidopyrine (43)
Aniline
Antipyrine (72)*
Bishydroxycoumarin (73)
Carbamazepine, 10,11-carbamazepine epoxide (74–76)
Chloramphenicol (77)
Chlorpromazine (78, 79)
Cimetidine (80)
Cyclosporine (81)
Doxycycline (82)
Ethylmorphine
Flunarizine (83, 84)
Griseofulvin (85)
Haloperidol (86)
Hexobarbital
Meperidine (87)*
Mesoridazine (86)
Methadone (88)*
Methsuximide (89)
Nortriptyline (90)
Theophylline (91)
Valproic acid (92, 93)*
Warfarin (94)

\*May result in increased levels of toxic metabolites.

Although PB induces the metabolism of phenytoin, the degree of that effect is seldom great enough to cause an adjustment of phenytoin dosage (100, 101). Other important potential effects of comedication with PB include inadequate anticoagulation with warfarin (43, 73, 94), reduction of serum levels of exogenously administered prednisone or dexamethasone (102, 103), or failure of oral contraception (104, 105). Co-administration of PB with warfarin or other medications can be managed when the combination is essential. In such cases, care must be taken to adjust anticoagulants with any changes in PB discontinuation (106). The effect of PB on these various drugs may become manifest within days to weeks of initiation of comedication.

Less commonly, other drugs affect PB kinetics. The most important of these in everyday practice is the interaction of PB and valproic acid. Accumulation of PB occurs in most patients who are comedicated with PB and valproate, accompanied by a lower than expected serum level to dosage ratio of valproate. The rate and magnitude of these effects are variable but generally require lowering

of PB and increasing of valproate dosages as compared with what might be expected with monotherapy (107). Valproate-related weight gain and thrombocytopenia may also be dose-related. Elevation of PB levels may occur within days of initiation of valproate, but more typically the increase occurs slowly over a number of weeks.

### Pharmacodynamic Interactions

Little is known about the pharmacodynamic interactions of PB and other drugs. It was long argued that PB potentiated the antiepileptic effects of phenytoin; therefore, the two drugs were coadministered in many patients for several decades. There is no scientific data upon which such a contention, or the view that PB may potentiate the antiepileptic potency of carbamazepine, can be based (108, 109). Currently, it is more widely held that the combination of these and other antiepileptic drugs more often exacerbates side effects than enhances desirable effects, although there are few objective data to support this clinical impression. The combination of PB with other sedative medications, such as benzodiazepines, may provoke status epilepticus, including tonic motor status in patients with Lennox-Gastaut syndrome (110).

### Adverse Effects

Experience has demonstrated that PB generally is a very safe and predictable medication. Nonetheless, it does produce various undesirable effects. The majority of these are reversible effects that can be tolerated but reduce the attractiveness of PB therapy. Serious side effects also occur, but they are rare. The most frequently encountered adverse characteristics of PB are (1) sedation, (2) disturbances of mood and behavior and possibly cognition, and (3) induction of hepatic metabolism, producing various effects on the disposition of a wide variety of other drugs (as discussed in preceding paragraphs). Exacerbation of seizures may possibly occur with weaning and discontinuation of phenobarbital maintenance. Serious allergic reactions may occur.

*Sedation and Behavior.* Although phenobarbital has the most favorable ratio of antiepileptic potency to sedative properties among the antiepileptic barbiturates, it is certainly more sedating than most other anticonvulsants (111). Drowsiness is most common at the initiation of therapy, afflicting as many as one-third of newly treated patients. Sedation may occur even at very low doses and may persist for several days, occasionally as long as several weeks (45). Sedation may return with dose increases, and there may be a dose-related increment in difficulty awakening in the morning or increase in the frequency with which a nap is required. However, many patients do not experience significant sedation after

initially becoming accustomed to the medication, despite many-fold increases in dose (112, 113). Patients receiving chronic PB therapy are least likely to feel drowsy if their serum level falls between 15 and 30  $\mu\text{g/mL}$ , but there is considerable individual variation in tolerance. Some patients complain of little sedation with levels as high as 50  $\mu\text{g/mL}$ , while others find levels of 10 to 15  $\mu\text{g/mL}$  intolerable because of lethargy (114).

*Mood Disturbance.* Studies have shown that 30% to 42% of children with febrile seizures treated with PB prophylaxis experience deterioration in behavior, the majority having relatively low PB levels (i.e., less than 15  $\mu\text{g/mL}$ ). Hyperactivity, irritability, belligerence, intermittent agitation, disruptive and defiant behavior, insomnia, and uncharacteristic episodic sedation are among the most frequent troublesome manifestations—effects that are not related to dose or serum level (115–117). Hyperkinetic characteristics have occurred in as many as 79% of children treated with any drug for epilepsy (118), and disturbances of behavior similar to those noted occur in at least 18% of children who have had at least one febrile seizure without any prophylactic anticonvulsant (119).

Several well-designed studies have failed to find a significant incidence of behavioral deterioration of children treated with PB (120, 121). In a particularly well-designed, double-blind, placebo-controlled study of toddlers, the rate of hyperactivity was no different whether treated with PB or placebo. There were few significant PB-related side effects, and those that did occur (irritability and sleep disturbance) responded to dose reduction (120). The prospective, double-blind, randomized, crossover study of Young and coworkers (122) showed no significant worsening of behavior with either PB or mephobarbital. Drugs that are converted into PB, such as methylphenobarbital and primidone, are regarded by some as less likely to produce behavioral side effects than PB; however, these hypotheses have not been subjected to careful trials in children. One study of the *treatment* of childhood behavioral disturbances with PB or PRM has shown these drugs to be *beneficial* in 33% and 11% of children, respectively (123).

*Higher Cortical Function.* Very early in what has been nearly nine decades of clinical use of PB, the intellectual function of many epileptic patients improved as their seizures came under better control with PB. With a wider choice of antiepileptic medications and other treatments now available, disturbances of cognition, especially attention and memory, and of skilled motor functions may occur in patients as a consequence of the medication rather than of the epilepsy. In an era of quite limited antiepileptic medication choices, Lennox (124) noted the additional toll that medications might take on epileptic

patients with brain injuries, changes readily observed by patients, families, and teachers that were “often subtle and difficult to measure.” Nearly 60% of the epileptic patients treated with PB whom Lennox studied did not appear to have such difficulties.

Hillesmaa and coworkers (125) found decreased rate of fetal head growth for human infants of mothers taking PB. Although some early studies documented changes in various measures of intelligence and learning in patients of various ages with some onset of epilepsy, no patterns of deterioration attributable to PB treatment were found. In individual cases IQ measurements increased, while others decreased with PB treatment (126, 127). Dosage in many of these early cases was lower than is now typical, and these studies did not address issues of compliance or attempt to relate intellectual dysfunction to drug levels. A subsequent study suggested, but did not prove, that the everyday intellectual performance of children on PB was deficient as compared with what might be expected given their performance on standardized tests of intellectual function (128). Schain and coworkers (129) found improvement in intelligence subtest scores, attentiveness, and impulse control in children who had their PB replaced with carbamazepine, although these children exhibited the simultaneous and potentially confounding variable of improved seizure control. Subtle but statistically significant lowering of performance- and full-scale IQ, verbal and nonverbal task subtest scores, and deterioration of behavior were found to be a consequence of PB as compared with valproate therapy of epilepsy in a more recent double-blind crossover study (130). Similar results were obtained in another study (131), which also provided evidence on repeat testing for impairment of learning and cognitive development while on PB compared with valproate-treated or untreated control groups.

Several additional studies have aroused concern, especially in the setting of febrile seizure prophylaxis with PB. Hirtz and coworkers (132) and Farwell and colleagues (133) demonstrated that mean IQ scores of large cadres of such children were 5.2 to 8.4 points lower than anticipated, compared with untreated or placebo-treated control groups. A disparity of at least 5 points was shown to persist for as long as 6 months after PB prophylaxis had been discontinued in both studies. Various concerns have been raised about certain aspects of the design of these studies, including low enrollment rates of eligible children, incomplete testing of significant fractions of enrolled children, and particularly the intention-to-treat design. Thus, in the case of one study (133), some children in the placebo group actually received PB, while less than two-thirds of those in the PB-treated group received PB throughout the entire study period (2 years), and one-third of the treatment group had little if any PB exposure or low drug levels during follow-up. An earlier, smaller, but particularly well designed and executed study did

not show any such significant effect of PB prophylaxis on infant developmental scales over an 8- to 12-month follow-up interval. However, Stanford-Binet Intelligence scale assessment suggested that in some of these children there were negative effects of PB on performance of certain memory tasks that were drug concentration related, but the effect was not statistically significant (120).

*Dependence and Withdrawal.* Prolonged administration of PB produces both habituation and dependence; therefore, significant withdrawal signs and symptoms may be provoked by abrupt discontinuation of the drug. Patients may experience anxiety, irritability, insomnia, mood disturbance, emotional lability, hyperexcitability, and tremulousness, various gastrointestinal disturbances, confusion, or delirium. Therefore, chronically administered PB should be withdrawn slowly to prevent these various reactions as well as withdrawal seizures. Seizures that occur during withdrawal of PB (whether the withdrawal is suggested by the physician or undertaken by the noncompliant patient) do not necessarily indicate that the drug remains therapeutically indispensable. In many cases slower rates of withdrawal permit the drug to be withdrawn without seizure recurrence (112, 134, 135). A similar abstinence syndrome may occur in newborn infants of mothers treated with PB, given the ease with which PB crosses the placenta, rendering a level in the neonate that is close to that found in the mother (50). The abstinence syndrome of the newborn may persist for days to weeks and is likely to be better tolerated and of shorter duration in infants whose mothers received the usual antiepileptic doses of PB than in infants of PB-abusing mothers.

*Overdosage.* Intoxication with PB can occur because of dosing errors, coadministration of valproic acid, accidental ingestion, and suicide attempts. We have observed several instances in which IV PB boluses have been administered in the emergency department to patients on chronic primidone therapy who have presented to the emergency room in status epilepticus, with failure to recognize that primidone is metabolized into PB. Rapid administration of a full loading dose of PB (20 mg/kg) to patients with PB levels of 30 to 40  $\mu\text{g}/\text{mL}$  is particularly likely to prompt the development of pulmonary edema and respiratory failure. More frequently encountered are cases in which valproate is added to chronic PB therapy and patients developed progressive lethargy 3 to 5 weeks later with elevated PB levels. Inattention, drowsiness, and dysarthric slurring of speech that may resemble drunkenness are often exhibited by patients acutely intoxicated with PB. Curiously, plasma levels similar to those that produce such effects acutely may be tolerated without evident ill effects after the dose is slowly increased with chronic therapy. Other findings observed in patients that

have toxic plasma concentrations (usually  $>40 \mu\text{g/mL}$ ) include dizziness, constricted pupils, nystagmus, ataxia, or coma (generally with levels above  $60 \mu\text{g/mL}$ ).

Phenobarbital levels in excess of  $80 \mu\text{g/mL}$ , although well tolerated in carefully monitored patients with appropriate cardiorespiratory intervention, are potentially lethal if such support is not provided. Such high levels, particularly if acutely achieved, may occasionally produce both cardiac and respiratory dysfunction (136). However, cardiac dysfunction is significantly less likely to occur with PB than with PnB. Indeed, levels in excess of  $130 \mu\text{g/mL}$  appear to be tolerated reasonably well by patients receiving appropriate intensive care support and requiring burst suppression for the management of intractable seizures.

**Other Adverse Effects.** Phenobarbital therapy has been associated with hypocalcemia more commonly than with vitamin D-deficient osteomalacia (137). This may be the result of mixed-function oxidase induction resulting in enhanced clearance of 25-hydroxy-cholecalciferol (138). The patients who are particularly vulnerable to “phenobarbital rickets” are those who have received many years of PB therapy, are poorly mobile, and have limited exposure to sunlight; diet also may play a role. Symptomatic patients may respond to the administration of 4,000 units of vitamin D each day or  $125 \mu\text{g}$  of vitamin  $\text{D}_3$  each week. Prophylactic administration of vitamin D is not recommended (139–142).

Such serious consequences as Stephens-Johnson syndrome, erythema multiforme, or toxic epidermal necrolysis are rare, but they do occur. Malaise, fatigue, fever, and eosinophilia typically accompany allergic rash, which may start centrally and spread to the face and extremities. Variable degrees of hepatic inflammation may accompany the hypersensitivity reaction in children, including fulminant fatal liver necrosis (143–145). Connective tissue disorders including Dupuytren contracture, Ledderhose syndrome (plantar fibromatosis), Peyronie disease, frozen shoulder, and aching joints have been associated with PB.

### Clinical Use

Phenobarbital is indicated in the treatment of partial, simple, or complex seizures, as well as primary or secondarily generalized motor seizures (tonic, clonic, tonic-clonic) in all age groups. It is the drug of choice in the treatment of most forms of neonatal seizures and for prophylaxis of febrile seizures, and it is among the most valuable agents for the management of status epilepticus. Well-designed studies of adults have shown that PB, PRM, phenytoin, and carbamazepine are equally effective in the management of generalized motor seizures (146), and although there may be differences in efficacy in treatment of partial seizures, they are slight. The cooperative VA study showed

complete control of primary generalized tonic-clonic seizures in 43% of men receiving PB or phenytoin, 45% of those receiving primidone, and 48% of those receiving carbamazepine. Only 16% achieved complete control of partial or secondarily generalized seizures with PB, compared with 43% with carbamazepine (147). Other studies of adults have demonstrated similar results (148, 149). One large noncrossover study of 3- to 14-year-old children with generalized tonic-clonic seizures showed a 22% rate of remission with PB monotherapy, compared with 34% for phenytoin, 40% for carbamazepine, and 16% for valproate. One study showed that localization-related seizures with secondary generalization were completely controlled in only 3% of patients on PB, as compared with 21% with phenytoin, 25% with carbamazepine, and 4% with valproate (150).

Plasma concentrations of PB required for control of generalized tonic-clonic seizures may be bimodally distributed. Schmidt (151) found that the majority of responding patients achieved control at PB levels of  $18 \pm 10 \mu\text{g/mL}$  but that a significant minority achieved control at levels of  $38 \pm 6 \mu\text{g/mL}$ . One-third of patients considered to have intractable partial complex seizures (e.g., with PB levels less than  $20 \mu\text{g/mL}$ ) were found to improve significantly if “adequate” PB or PRM levels were achieved (i.e., levels high enough to achieve control without intolerable side effects). An additional 16% responded if either of these drugs at higher concentrations was combined with phenytoin or carbamazepine (151, 152).

For the management of children under 1 year of age who present with focal or generalized motor seizures excepting infantile spasms, PB represents an attractive “first choice” agent because of its relative ease of administration, reliable kinetics, wide therapeutic window, and safety as compared with phenytoin or valproate. It is less frequently chosen in older children because of sedative qualities and potential effects on behavior. Nonetheless, it remains a valuable reserve agent for older children who cannot be managed effectively with other drugs. There is no clear indication that PB is any less effective than any other major anticonvulsant as alternative therapy for the management of anticonvulsant drug-resistant, localization-related seizures, and it should be among the drugs that are tried in succession in those difficult cases (149, 153). The use of PB as part of polytherapy for such resistant seizures may introduce difficulties because of sedative effects and induction of hepatic enzymes. One study showed that one-third of patients receiving combinations containing PB had improved seizure control when PB was eliminated from the regimen (154).

**Initiation of PB Therapy.** Phenobarbital loading can be achieved by IV or oral administration. IV loading typically requires administration of 15 to 20 mg/kg for

newborns or very young infants and 10 to 20 mg/kg for older infants and children. The drug may be administered as a single dose or in two doses divided by a few hours (34, 155, 156). A number of different approaches to oral loading have been described. Administration of 6 to 8 mg/kg/day for 2 days followed by an age-appropriate daily maintenance dose will quickly render plasma levels of at least 10  $\mu\text{g/mL}$  (148, 157). Bourgeois (158) demonstrated that the PB dose could be increased over 4 days as total daily doses of 3, 3.5, 4, and 5 mg/kg/day on successive days to achieve, in a linear fashion and without significant interim sedation, a serum level of approximately 20  $\mu\text{g/mL}$  at 96 hours. The maintenance dose must be adjusted thereafter to prevent toxic accumulation of PB. Without some form of initial loading, as many as 30 days may be necessary to achieve maximal steady-state PB concentrations (159). Obese adolescent patients may have a volume of distribution of 0.5 L/kg or less, and suitable adjustment in their loading dose must be considered in some cases.

Daily maintenance dose requirements for children are higher, on a weight basis, than those for adults, averaging 2 to 4 mg/kg/day (155, 160). To maintain plasma levels of 10 to 25  $\mu\text{g/mL}$ , Rossi (161) recommended oral maintenance doses of  $4.79 \pm 1.3$  mg/kg in infants aged 2 to 12 months,  $3.5 \pm 0.99$  mg/kg in children aged 1 to 3 years, and  $2.31 \pm 0.74$  mg/kg in those 3 to 6.5 years. The data of others would suggest that for children older than 3 years who weigh less than 40 kg, doses of 1.5 to 3 mg/kg/day are appropriate, whereas doses no greater than 1 to 1.5 mg/kg/day may maintain satisfactory levels for adolescents and adults who weigh more than 40 kg (148, 157). The PB dose may be administered entirely at bedtime or divided throughout the day, depending on degree of sleep disturbance and susceptibility to behavioral abnormalities or sedative effects. Once-daily administration is beneficial to some but not all patients. Multiple daily administration may in some cases improve compliance for forgetful parents.

*Neonatal Seizures.* Phenobarbital is the most widely employed drug for the management of neonatal seizures. This practice reflects familiarity with the agent and widely shared confidence in the efficacy and safety of PB in neonates rather than any well-established evidence for the superiority of this agent over other anticonvulsants. The choice of PB may be based more on the dosing inconvenience or potential risks associated with other drugs than on any demonstrated superiority of PB (162, 163). Thus, the second most commonly employed agent, phenytoin, carries risks for tissue injury if tissues are infiltrated at the site of IV line placement or for adverse cardiac effects if the rate of administration is excessive, problems that are less frequently encountered with fosphenytoin. However,

nonlinear kinetics make oral administration of phenytoin a problem in very small infants.

The initiation of PB therapy for seizures in newborns should start with IV administration of a loading dose of 16 to 20 mg/kg delivered as a single bolus or as two divided boluses. Volume of distribution of an administered bolus of PB to a neonate has been variously estimated at 0.81 to 0.97 L/kg, with 15% to 20% deviation of such mean values, and does not vary as a result of gestational age of the newborn infant (164, 165). From a practical vantage point, a volume of distribution of approximately 1.0 L/kg can safely be presumed in most cases, a loading dose of 20 mg/kg resulting in a peak serum level of 20  $\mu\text{g/mL}$ . Plasma protein binding of phenobarbital averages 22% to 25% in neonates, approximately half the value that is anticipated in older children and adults (166).

Successful control of neonatal seizures is seldom achieved with serum levels less than 16  $\mu\text{g/mL}$ ; initial loading should attempt to achieve serum levels ranging from 15 to 25  $\mu\text{g/mL}$ . Electrographic monitoring has shown that many clinically responding newborns show persistence of electrographic seizures after routine loading doses (167). Although the significance of electrographic activity in the newborn without clinical seizures remains uncertain, infants with recalcitrant *clinical* seizures require additional loading boluses delivered as 10 mg/kg at intervals of one to several hours. At plasma concentrations of at least 40  $\mu\text{g/mL}$  as many as 77 percent to 85 percent of neonates respond (168, 169). Serum levels as high as 60 to 80  $\mu\text{g/mL}$  appear to be tolerated by most newborns, although such high levels may necessitate greater degrees of cardiorespiratory support, compromise clinical examination, and interfere with feeding. Svenningsson and coworkers (170) found that plasma PB concentrations in excess of 50  $\mu\text{g/mL}$  in newborns were associated with slowing of heart rate to less than 100 beats per minute. This is a potentially serious matter, because the neonate lacks the reflexive capacity to alter stroke volume in compensation for bradycardia.

Newborns respond to an initial loading dosage of 20 mg/kg, a serum level of 20  $\mu\text{g/mL}$ , and oral or IV total daily maintenance dose 2.25 to 4 mg/kg. Although doses of 5 mg/kg/day are widely recommended, the continuation of such a dose through the first few weeks of life generally results in accumulation to serum levels significantly in excess of 20 mg/dL (34, 52, 171). Plasma clearance of PB usually increases after 1 to 2 weeks of life and may require modification of maintenance dosage in some but not all cases.

*Status Epilepticus.* The ease and relative safety of administration, wide therapeutic window, and long duration of action combine to make PB a particularly attractive choice in the treatment of status epilepticus. Negative aspects of the use of this drug include the relatively low

lipid solubility, sedative effects, and the possible provocation of respiratory depression, hypotension, or pulmonary edema. Thus, benzodiazepines and phenytoin are the usual first-line treatments for status epilepticus in children of most ages. On the other hand, PB can be administered more rapidly and in higher concentration than phenytoin, and it can be administered intramuscularly if necessary. IM administration of a full loading dose to a well-perfused location may achieve brain levels adequate for the control of some seizures in less than an hour and is indicated if no better access can be achieved.

The rate of administration of sequential boluses of PB determines the risk for cardiopulmonary complications, which is lower for PB than for PnB or too rapidly administered phenytoin. In general, the rate of IV administration of PB for treatment of status epilepticus should be 2 mg/kg/min for children who weigh less than 40 kg. The rate should be 100 mg/min for children and adults who weigh more than 40 kg. Slower rates may be required in special cases, such as in patients with acute cardiac disease (e.g., tricyclic overdose). In general, respiratory depression is not seen below plasma levels of 60  $\mu\text{g/mL}$ , and hypotension may not arise as a complication of PB until after even higher levels are achieved. Pulmonary edema is an uncommon complication and usually requires very massive PB bolusing over short time intervals to high levels. The most widely accepted practice for PB administration in treatment of status epilepticus in the PB-naïve patient is to administer at total loading dose of 20 mg/kg. This quite reliably produces a plasma level close to 20  $\mu\text{g/mL}$ . It is clear that the administration of only a partial loading dose (e.g., 10 mg/kg) to the anticonvulsant-naïve patient usually is inadequate. Seizures may well diminish or stop, but they often recur as the PB becomes distributed throughout the body. Respiratory support is usually required as the plasma level rises above 50 to 70  $\mu\text{g/mL}$ , and pressor support may be required above levels of 70 to 90  $\mu\text{g/mL}$ , whether as the result of PB, of the causative illness, or both.

**Febrile Seizures.** Phenobarbital has been the most commonly employed prophylactic agent for prevention of febrile seizures. As febrile seizures are generally without significant immediate or long-term serious medical consequences, there has been significant momentum away from providing prophylactic treatment. Enthusiasm for prophylactic treatment has diminished because (1) approximately two-thirds of children have just one febrile seizure, (2) recurrent febrile seizures have exceedingly low risk for untoward consequences, (3) PB and other agents introduce a risk for various drug-related side effects (115), and (4) it has been difficult to provide convincing proof that prophylaxis is effective. Although there is some evidence supporting the effectiveness of treatment with PB, sodium valproate, or benzodiazepines, it is not conclusive proof.

PB is usually judged a safer choice than valproate for administration to very young children, and long-term prophylaxis with benzodiazepines poses unacceptable problems with sedation and tachyphylaxis. However, PB is not without risk, as the death of one child has been ascribed to the use of PB for prophylaxis against febrile seizures (144). The efficacy of PB as prophylactic therapy has recently come into question (172).

There is evidence to suggest that if PB prophylaxis is to be effective, steady-state serum concentrations of 16 to 30  $\mu\text{g/mL}$  are required (173). This study demonstrated a 4% risk for recurrence in children with such levels compared with approximately 20% rates of recurrence for untreated children and for those with PB levels of 8 to 15  $\mu\text{g/mL}$ . Several more recent studies have failed to demonstrate a difference in outcome between groups of children at risk for febrile seizures who received either PB or valproate for prophylaxis compared with children who received no prophylactic anticonvulsant medication (133, 174, 175). However, these studies did not control for the important element of compliance by assessing serum PB levels at time of recurrence. Compliance with PB prophylactic regimens for febrile seizures is notoriously low (176). Herranz (177) found that 20% of children treated with PB prophylaxis for febrile seizures had recurrences at mean levels of  $16.4 \pm 2.8 \mu\text{g/mL}$ , compared with 88% of those treated with PRM (mean PB levels  $14.1 \pm 3.7 \mu\text{g/mL}$ ) and 92% of those treated with valproate (mean levels  $35.2 \pm 5.9 \mu\text{g/mL}$ ). Side effects were experienced by 7% of those on PB, 53% of those on PRM, and 45% of those on valproate, although most side effects were tolerable.

PB is discontinued gradually in most cases. This is based on evidence that dependence on PB results in provocation of seizures if the rate of decline of PB levels is too rapid. This presumption has been placed in question in one study of patients with partial complex seizures that appeared to demonstrate that the risk for seizures was not dependent on rate of withdrawal but on the achievement of a concentration below 15 to 20  $\mu\text{g/mL}$  (178).

## OTHER BARBITURATES

The N-methylbarbiturates (methylphenobarbital and metharbital) and the anesthetic pentobarbital have all been used as anticonvulsants.

### Methylphenobarbital

Methylphenobarbital (Mebaral<sup>®</sup>, MBL), although infrequently used in the United States, is widely employed in some countries, such as Australia. A considerable portion of the administered dose is rapidly cleared as the R-enantiomer; therefore, the dose of racemic MBL should

be approximately twice the PB dose required to achieve satisfactory clinical effects (179–181). The single oral dose half-time of elimination for the R-enantiomer has been estimated at  $7.5 \pm 1.7$  hours, compared with  $69.8 \pm 19.7$  hours for the S-enantiomer and  $98.0 \pm 19.7$  hours for the PB metabolite (182).

MBL clearance is almost entirely by biotransformation with urinary excretion of the major metabolites, which are PB and *para*-hydroxymethyl PB (as a phenolic glucuronide conjugate) (180, 183, 184). PB is the only pharmacologically important biotransformation product. The capacity to generate this product may increase with chronic therapy because of increased rate of MBL clearance with faster rates of appearance and higher peak levels of PB. Naïve subjects may excrete less than 11% of their MBL dose as PB, while subjects exposed to MBL or PB may increase that amount to more than 50% (183). Because PB has a smaller volume of distribution and is cleared more slowly than MBL, plasma PB levels may accumulate over time to much higher values than simultaneous serum MBL values. Many or most of the drug interactions experienced with chronic MBL therapy are thought to be due to PB, and any interaction or side effect that has been described for PB can occur with MBL therapy.

The experimental and clinical spectrum of MBL is similar to that of PB (185). It may be administered once or twice daily. Because of the tendency for PB levels to accumulate to higher serum levels than MBL levels over the long term and the greater availability of PB level determinations, most clinicians follow up only the PB level in patients taking MBL. Doses that are calculated to produce therapeutic steady-state PB levels may result in unacceptable drowsiness during the initial phases of therapy, and therefore compliance may be poor. Starting with half the expected dose and accelerating the dose over 1 to 2 weeks avoids this problem but delays the achievement of the desired steady-state peak PB concentrations to as long as 4 to 5 weeks after initiation of therapy. Full initial doses may be started in patients who have recently been treated with PB or other “inducing” anticonvulsants. At steady state, PB concentration is generally 7 to 10 times greater than the total (R + S) MBL concentration in serum.

### Pentobarbital

Pentobarbital (PnB) is a 5-ethyl-5 (1-methylbutyl) barbiturate that is clinically employed as a sodium salt (Nembutal®). It is a short-acting barbiturate. The half-time of elimination in adults ranges from 18 to 50 hours and is dose dependent. The partition coefficient for PnB is approximately 11 times greater than that for PB. This reflects much faster lipid solubility, accounting for shorter latency in onset of activity, shorter duration of action, and faster metabolic degradation. The superior lipid solubility

may be in part responsible for the fact that PnB is much more potently sedative and hypnotic than PB. Acutely achieved blood concentrations of 0.5 to 3  $\mu\text{g/mL}$  produce approximately the same degree of sedation as PB levels of 5 to 40  $\mu\text{g/mL}$ . PnB levels  $\geq 10$  to 18  $\mu\text{g/mL}$  usually induce coma. When PnB is employed as a constant infusion of 0.3 to 4.0 mg/kg/hr after bolus administration of 15 mg/kg over 1 hour, the serum half-time of elimination ranges from approximately 11 to 23 hours in adults (186).

Pentobarbital is indicated for the treatment of status epilepticus that is unresponsive to such first-line therapies as benzodiazepines, phenytoin, or PB. The aim of PnB therapy is to produce coma with suppression-burst pattern on EEG; therefore, the sedative properties of this drug are not deleterious. On the other hand, PnB is more likely than PB to have negative effects on cardiac contractility and to require the addition of cardiotoxic medications to support blood pressure and perfusion when employed in the usual doses. Particular caution should be used in the management of patients who have cardiac disease and those whose seizures are the result of hypoxic-ischemic injury or tricyclic overdose, because the negative effects on cardiac function may be particularly deleterious in such settings. Barbiturate anesthesia (with PnB more commonly than thiopental or methohexital) is considered by many neurologists to be the ultimate form of therapy for status epilepticus that has proved intractable to the usual combinations and dosages of short- and long-acting anticonvulsants, including PB (187, 188). Treatment with PnB has not been proven to be superior to the use of very high doses of PB to achieve burst suppression or control of seizures.

Lowenstein and associates (186) reviewed their results with eight retrospectively studied and six prospectively enrolled patients treated with PnB, thiopental, or methohexital anesthesia; only one of these patients was a child. PnB loading with 15 mg/kg over 1 hour to the prospective group resulted in prompt cessation of seizures in patients treated with this protocol. PnB was infused at rates that varied from 0.3 to 4.0 mg/kg/hr, and additional boluses were administered as needed of 5 mg/kg (maximum of 30 mg/kg of bolus drug in the first 12 hours) to achieve and maintain burst suppression. The median peak serum PnB level for patients treated in this fashion was 10.8  $\mu\text{g/mL}$  (range 6.5–21.2  $\mu\text{g/mL}$ ). Treatment resulted in a favorable outcome for three of these six adults, whereas one had a poor outcome and two had indeterminate outcomes. Only two of these six required pressors. Significant drop in blood pressure occurred within a few hours of initiation of therapy in 9 of the 14 patients of the entire group reported by these investigators.

Lowenstein and colleagues stopped PnB after approximately 12 hours of treatment, restarting therapy

if seizures recurred. Duration of infusion ranged (in the prospective group) from 11 to 77 hours. For those patients who recovered function after cessation of anesthesia, brainstem functions returned in 6 to 24 hours, and various forms of motor activity returned in 1 to 72 hours. Some possible withdrawal phenomena occurred, including repetitive twitching of the extremities, resembling activity observed in some cases of barbiturate overdose and difficult to distinguish on a clinical basis from seizure activity (186, 189, 190). Patients receiving particularly high doses of PnB were found in some instances to have profound weakness and areflexia that persisted for as long as 2 weeks (including as many as 5 days of complete paralysis after cessation of infusion), despite much more rapid recovery of alertness and intellectual interactiveness. This effect may have been the result of PnB-induced dysfunction of peripheral nerve function or release of neurotransmitter in the peripheral synaptic cleft, as has been observed experimentally (191, 192). These transient forms of dysfunction may introduce confusion into attempts to assess patients for "brain death" or to estimate prognosis.

### PRIMIDONE

Primidone (PRM), 5-ethylidihydro-5-phenyl-4,6 (1H, 5H) pyrimidine-dione or 2-desoxy-phenobarbital, was synthesized in 1949 and was shown to be effective in the treatment of major motor epilepsy shortly thereafter (193). It is therefore the third oldest anticonvulsant that continues in regular use (194). It has just two carbonyl substituents of the pyrimidine ring rather than the three that are characteristic of barbiturates. Hepatic biotransformation renders two main metabolites of PRM: phenylethylmalonamide (PEMA) and PB. The identification of PB as a metabolite raised questions as to the importance of the other substances in control of seizures, a subject that remains controversial. Although it has remained difficult to clearly demonstrate the contribution that PRM and PEMA make to clinical management of epilepsy independent of the effects of PB, there are both experimental and clinical data that support the view that they are pharmacodynamically important.

#### Anticonvulsant Activity

The fact that PRM has anticonvulsant properties is suggested by several lines of evidence, including the facts that (1) administration of PRM lowers the plasma level of PB required to protect animals against experimental forms of seizure, and (2) protection against seizures is afforded in the few hours after a single PRM dose is administered before the achievement of significant levels of PEMA or PB (5, 6, 195–197). The potency of PRM is equal

to or possibly superior to that of PB in the prevention of electroshock-induced seizures, but it has much less activity against chemically induced (pentylenetetrazol or bicuculline) seizures (6, 194, 195, 197). This is similar to the spectrum of activity exhibited by phenytoin and carbamazepine.

Baumel and coworkers (196) roughly estimated the potency ( $ED_{50}$  for prevention of maximal electroshock seizures) of PRM to be 25% more and that of PEMA to be 90% less than that of PB. They also found that PRM had no detectable antichemoconvulsant activity, while PEMA is approximately 0.025 as potent as PB for prevention of that form of experimental seizure. Other researchers in a variety of animal lines have found somewhat different potency ratios of these compounds (5, 197, 198), but PRM and PB generally have had similar antielectroshock potency, while PEMA has been 12- to 18-fold less potent. Experimental evidence (5) suggests that PRM is approximately 2.5 times less neurotoxic than PB and that the two substances are synergistic in seizure control, possibly exerting different mechanisms of action. Bourgeois and coworkers established that a ratio of 1:1 brain concentration of PRM to PB achieved the best therapeutic index (ratio of therapeutic efficacy to toxicity) in control of seizures (5). A therapeutic range for PRM trough concentration of 3 to 12  $\mu\text{g/mL}$  has been suggested (199), but somewhat higher levels may be tolerated. Although PEMA also has anticonvulsant properties, the potency appears to be too low to contribute much to the antiepileptic effects or toxicity of PRM at the usually encountered plasma concentrations of clinical practice (158). Monitoring of serum PEMA levels in patients treated with PRM has no practical value.

#### Pharmacokinetics

Peak serum PRM levels are achieved in approximately 3 hours in adults and 4 to 6 hours in children after single-dose ingestion of tablets in doses of 12.5 to 20 mg/kg (200). Brand-name tablets probably have nearly complete bioavailability, with 72% to 100% of a single oral dose excreted in urine as PRM or its metabolites (200–202). Absorption of generic preparations may be less reliable (203). Absorption of PRM tablets is reduced by concurrent acetazolamide administration (204). Volume of distribution of PRM and of PEMA after single oral dose has been estimated at 0.86 L/kg and 0.69 L/kg, respectively. There is less than 10% plasma protein binding of either PRM or of PEMA (205, 206).

Biotransformation of PRM is very complicated. PEMA and PB are the two major metabolites with antiepileptic potency. It has been difficult to estimate the relative contribution of PEMA and PB to the pharmacodynamic properties of PRM, including both antiepileptic potency and toxicity, although these properties have been studied

carefully in animals (5, 6). Zadavil and Gallagher (207) showed that, on average, approximately 65% of a single IV PRM dose is excreted unchanged in the urine within 5 days of administration to adults, while 7% is excreted as PEMA and 2% is excreted as PB. The rate of conversion of PRM to PB is much slower than that to PEMA. Under steady-state conditions of chronic administration, approximately 25% of monotherapeutically administered PRM can be relied on to be converted to PB (208). The bioconversion of PRM to PB shows age-related variation. In general, the more complete transformation of PRM to PB by children aged 0.5 to 6.5 years often results in disappointingly low PRM to PB serum ratios, although there is considerable individual variability (209, 210).

PRM and its various metabolites are primarily (at least 75–77%) renally excreted (207). The half-time for elimination of orally administered PRM ranges from 10 to 15 hours in adults on monotherapy, but comedication with antiepileptic inducers of hepatic biotransformation enzymes lowers this time to 6.5 to 8.3 hours (201, 204, 207, 211). On average, half-time of elimination for PRM in children ranges from 4.5 to 11 hours, lower with phenytoin comedication than with PRM monotherapy (200). The hepatic immaturity of newborns accounts for half-times of PRM elimination that vary from 8 to 80 hours.

In one study of steady-state PRM monotherapy, the average trough serum concentration to total daily dose of PRM for PRM, PEMA, and PB were  $0.78 \pm 0.25$ ,  $0.64 \pm 0.39$ , and  $1.47 \pm 0.53$ , respectively (212). At steady state, PB levels are almost always higher than PRM levels. Because PB is probably responsible for many of the toxic effects of PRM, especially sedation, attempts have been made to diminish the biotransformation of PRM to PB. As noted previously, a brain ratio of 1:1 for PRM and PB concentrations has been established experimentally as ideal for the achievement of maximal therapeutic efficacy with minimal toxicity (5). Both nicotinamide and isoniazid have been tried for this purpose, but gastrointestinal, hepatic, and other possible toxicities have limited the usefulness of such approaches (213–215). In most clinical situations, PRM levels are of relatively little value as management tools. They may be useful in two situations, however: (1) assigning a cause for possible drug side effects or (2) establishing that the conversion rate of PRM to PB is unfavorably rapid and therefore that the use of the more expensive and inconvenient-to-administer PRM is poorly justified.

### Drug Interactions

Coadministration of PRM and some other major antiepileptic drugs to adults decreases excretion of unchanged PRM after a single dose by more than one-third. This is the result of fourfold increase in the conversion rate to

PEMA and 50% increase in conversion to PB. Interactions with various anticonvulsants may result in considerable changes in the ratios of PRM, PEMA, and PB. Phenytoin is the most potent accelerator of PRM biotransformation, while carbamazepine has a lesser effect (204, 209, 216, 217). Bourgeois (158) showed that, on average, coadministration of PRM with either phenytoin or carbamazepine, or both, resulted in 50% reduction in the trough PRM level at steady state compared with that expected with monotherapy. PEMA levels increased by 17% and PB levels by 60% under those polytherapeutic conditions, and the trough ratio of PB to PRM increased by as much as threefold. Application of the data obtained in Bourgeois's study predicts that with PRM monotherapy a steady-state PB level of 16.5  $\mu\text{g/mL}$  can be expected to be associated with an average PRM level of 10  $\mu\text{g/mL}$ , but that the coadministration of phenytoin or carbamazepine, or both, increases the average PB level to a level of 26.5  $\mu\text{g/mL}$ , while the average PRM level falls to 5  $\mu\text{g/mL}$ . If the total daily dose were increased by approximately 100% to maintain the serum PRM level at 10  $\mu\text{g/mL}$ , the PB level at steady state could be expected to rise to as much as 58.3  $\mu\text{g/mL}$ . Thus, polytherapy with these agents can be expected to lower the therapeutic index of PRM significantly because of the unfavorable ratio of PRM to PB in brain compared with the experimentally ideal 1:1 ratio.

When polytherapy is considered necessary, problems of enzymatic induction are avoided by combining PRM with noninducing agents such as valproate, gabapentin, lamotrigine, topiramate, tiagabine, or benzodiazepines (218). However, combination with valproate produces the unfavorable kinetic problems encountered when PB and valproate are combined (218). Combination with benzodiazepines may produce intolerable sedation. Coadministration of PRM and valproate tends to produce lesser degrees of PB accumulation than are observed with PB and valproate coadministration (as stated previously). This may be because valproate inhibits not only PB clearance but also the conversion of PRM to PB (219). Thus, if it is judged necessary to coadminister valproate with PB, it might be better to administer the latter as PRM. Acetazolamide may diminish the gastrointestinal absorption of PRM, and carbamazepine may in some cases inhibit biotransformation of PRM to PB (215).

### Toxicity

Animal studies demonstrate that PRM has less toxicity to the nervous system and other organs than PB (5, 194). Nonetheless, toxic effects, particularly those of the CNS, are common. They are reported at some point in their therapy by one-half to two-thirds of patients who are treated with this drug (147, 220–222). PRM therapy is unsuccessful and is discontinued in 10% to 30% of

patients. Discontinuation is much more commonly the result of intolerable side effects than to lack of therapeutic efficacy (147, 221). Side effects of PRM therapy closely resemble those seen with PB. It has been difficult to distinguish the contributions of PRM compared with PB in the elicitation of these problems. Time of onset of side effects and the development of tolerance assist in making this determination.

Sensations variously characterized as sleepiness, light-headedness, dizziness, weakness, or intoxication are very common, if not universal, at the initiation of PRM therapy (211, 223). They develop within a few hours of ingestion of PRM, but there is considerable individual variability in susceptibility to these dose-related effects, which range from mild to severe and incapacitating affectation (224, 225). Cross-tolerance occurs in patients who are in the process of changing from PB to PRM therapy, but those changing from phenytoin or carbamazepine do not experience such cross-tolerance (223). These very early effects are due to PRM, because they occur before any significant accumulation of PB and usually wane within a few days, despite the fact that that is the time at which PB levels begin to rise (226, 227). The severe effects can be avoided by administration of a small "test dose" at the onset of therapy to determine whether the individual patient is highly susceptible. These effects can be minimized in all patients by careful attention to the speed and amplitude of the acceleration of the dosing schedule to achieve full doses (211, 225).

There is a second family of more persistent sedative side effects that develop during the chronic phase of PRM therapy. These chronic side effects are quite similar, if not identical, to those reported by some patients treated with PB. Patients and families report abnormalities of energy level, attentiveness, behavior, and learning. The frequency with which they are reported, and their amelioration in at least some cases when PRM is discontinued, suggest that the medication may be in part or entirely responsible. Rodin and coworkers (228) compared the effects of PRM and carbamazepine as adjuncts to phenytoin therapy and found that PRM produced more significant impairment of performance in a cognitive-perceptual test battery than carbamazepine, especially with regard to concentration and fine motor performance (229). The fact that these types of difficulties are quite similar, if not identical, to the problems reported during PB therapy, and the observation that they are most troublesome during the chronic phase of therapy, when the PB-to-PRM ratio is highest, suggest that PB is the likely culprit. It is unlikely that PEMA, which contributes little to the anticonvulsant potency of PRM, plays any significant role in CNS or other forms of PRM-related toxicity (205).

Virtually all of the other PB-related side effects can occur with PRM therapy, including the various connective tissue problems such as contracture formation,

joint problems, and Peyronie's disease. One study has suggested that in children, PRM is less likely to produce any more significant side effects than phenytoin or PB (117). Transient nausea, vomiting, dizziness, and drowsiness may occur with initiation of PRM therapy, a peculiar combination of side effects that are seldom seen in patients who start on PB (147).

### Overdosage

Little is known about the relationship between peak PRM concentrations and short-term toxic effects. Acute PRM overdosage (PRM levels exceeding 80–100  $\mu\text{g}/\text{mL}$  in tolerant patients) may produce varying degrees of CNS depression ranging from somnolence or lethargy to deep coma, flaccidity, and loss of deep tendon reflexes (227, 230, 231). The degree of these abnormalities tends to correlate with PRM levels rather than PB or PEMA levels in the acute interval, although the ensuing rise in PB levels produces additional CNS depression (227, 232).

Massive overdosage may result in hypotension and acute renal failure in association with crystalluria, especially when serum PRM levels exceed 200  $\mu\text{g}/\text{mL}$  (233). Fatal cases of PRM ingestion have been reported. However, with appropriate management (gastric lavage, administration of activated charcoal, forced diuresis, and supportive measures) patients have recovered without permanent sequelae from ingestion of as much as 22 grams of PRM (225). Crystalluria (largely crystallized PEMA) after administration of large amounts of PRM was first observed in rats (194) and is an almost constant feature of serious PRM overdosage in humans (234). It has not been shown to result in chronic renal failure even after massive overdosage with acute renal dysfunction (231). Massive overdosage can be effectively treated with hemoperfusion (233).

### Clinical Use

Early uncontrolled, retrospective studies demonstrated that PRM could be used with considerable success as an adjuvant drug in the management of generalized tonic-clonic seizures, localization-related seizures, and myoclonus epilepsies (220, 235–239); however, some more recent controlled studies have shown less favorable results. These data, combined with the availability of a wider range of major anticonvulsants and decreased enthusiasm for polytherapy, have reduced the popularity of this agent. Early comparison studies failed to demonstrate that PRM had some unique value, in the treatment of any particular type of epilepsy or population of patients, compared with PB or phenytoin, drugs that were less expensive and in some ways easier to use (208, 240, 241). Therefore, it appears that the benefits of PRM therapy and the potential toxicity do not support the use

of this agent as first-line therapy for any seizure type or syndrome (114).

One possible exception is the treatment of epilepsy occurring in patients with long QT syndrome, because PRM may have some value in the treatment of the cardiac dysrhythmia (242). However, most patients who have seizures in association with the long QT syndrome have them only in association with cardiac decompensation, which may be effectively treated with other medications. On the other hand, PRM continues to be useful as a third-line agent for treatment of occasional patients affected with almost any form of epilepsy for which PB is indicated, including age groups ranging from the neonate (243) to the adult. The exception to this principle is the fact that PRM has little value in the management of status epilepticus, because there is no commercially available parenteral formulation. PRM may be effective in the prophylaxis of febrile seizures (174).

Various direct comparisons of PRM to PB, phenytoin, or carbamazepine treatment in patients of various ages have shown these drugs to have similar efficacy for oral treatment of partial, secondarily generalized, and generalized tonic-clonic seizures (147, 208, 228, 241, 244). However, most of these studies do not control for PB levels. Reinterpretation of one of the best of these studies (208) has suggested that a subgroup of patients may enjoy better control at any given PB level if that level is achieved as the result of PRM rather than PB oral therapy (245). One crossover comparison showed that PRM was superior to orally administered PB in the management of generalized tonic-clonic seizures (246). The VA Epilepsy Cooperative study comparison of PRM to PB, phenytoin, and carbamazepine showed the highest rate of failures in treatment of partial or secondarily generalized seizures occurred with PRM therapy, failure that usually was due to drug discontinuation or poor compliance early in the course of treatment because of intolerable side effects (147). Sapin and coworkers (247) found that PRM exerted antiepileptic effects in neonates that were independent of the effects of PB.

Two potential benefits of the choice of PRM rather than PB are (1) the possibility of achieving seizure control in a given subject at lower serum PB levels than are required with the administration of PB itself, and (2) the possibility that in certain settings PRM is a "better" drug than PB. Others have argued that most or all of the clinically significant antiepileptic effect of PRM is simply due to its conversion into PB (248, 249). This is particularly likely to be true when PRM is administered too infrequently during the day to achieve the most favorable serum ratio of PRM to PB. In most patients this requires administration every 6 hours, which may be inconvenient. Because of unfavorable effects in the PRM-to-PB ratio, there are reasons to believe that there is no advantage to employing PRM in combination with

phenytoin, acetazolamide, or carbamazepine. Unfortunately, most patients who now receive PRM are patients with intractable epilepsy on polytherapy with complicated dosing schedules.

When administered to adults as monotherapy, PRM can be administered twice daily because the half-time of elimination for PRM typically is 10 to 15 hours. However, the shorter elimination half-time that is typical of most children and most patients on polytherapy mandates administration of this drug at 6-hour intervals if advantage is to be taken of the presumed antiepileptic potency of PRM. Administration to newborns is little studied, but in the event that administration of PRM were judged important, once-daily dosing is theoretically possible. So great is the variation of elimination half-times observed in the newborn (23) that individualization of dosage for newborns would be prudent, as would careful follow-up to ensure that toxic accumulation of metabolites does not occur.

### Treatment Guidelines

If there are no coadministered drugs that interfere with metabolism or distribution, an initial daily PRM dose of approximately 20 mg/kg/day will result, after 2 to 3 weeks, in a steady-state PB level ranging from 10 to 30 µg/mL. Neonates typically require maintenance doses of 15 to 25 mg/kg/day, infants 10–25 mg/kg/day, and children 10–20 mg/kg/day (23). The total daily dose should be divided into three or four times of administration, as noted previously, given the short half-time of elimination of PRM; the peak serum concentration typically is achieved 3 to 5 hours after each dose. Initiation of PRM monotherapy in patients who are not already receiving barbiturates should in many cases start with a low single daily dose at bedtime (e.g., one-fourth of a 250-mg tablet for patients who weigh more than 20 kg) with subsequent upward titration at 3-day intervals (158). Not every patient will require or tolerate steady-state dosage at 20 mg/kg/day. In some cases, relatively large initial doses may be tried to more rapidly achieve serum levels that are effective in controlling seizures. For example, it has been shown that the administration to neonates of 25 mg/kg/day, divided into three doses, produces a serum PRM level of approximately 10 mg/dL by day 3, a level that is sufficient to control the seizures of many neonates independent of the associated PB level (246). Monitoring PRM or PEMA levels confers little therapeutic advantage in most clinical situations.

Changing patients from chronic oral PB therapy to PRM is usually easily accomplished by administering four to five times as much PRM each day as the discontinued total daily PB dose. In patients who are not on PB, rapid initiation of PRM therapy can be achieved by first loading with PB (250). Rapid escalation of oral PB loading

can be achieved using PB doses of 3 mg/kg/day on the first day of treatment, 3.5 mg/kg/day on the second day, 4 mg/kg/day on the third day, and 5 mg/kg/day on the fourth day. This approach results in a linear accumulation of PB in the serum to approximately 20 µg/mL on day 4 without significant sedation. The PB can be discontinued on the following day and replaced with a full maintenance PRM dose of between 12.5 and 20 mg/kg/day (158).

Immediate initiation of PRM at an amount expected to produce serum concentration of 20 to 30 µg/mL can be undertaken by IV loading of 20 mg/kg of PB (producing a serum concentration of 20 µg/mL) and initiation of 20 mg/kg/day of PRM divided into three or four doses. Any patient loaded with enough PB to achieve serum PB

concentrations of at least 20 µg/mL within 3 days after initiation will experience significant degrees of sedation (250).

## Discontinuation

In general, the considerations that arise with regard to drug discontinuation are similar to those previously noted for PB. One small study suggested that withdrawal-related seizures may be more likely with PRM than with PB (251). Theodore and coworkers (178) found no relationship between the peak dose or rate of withdrawal of PRM or PB and the occurrence of seizures. In their study, seizures were most likely to occur as the PB level fell between 15 and 20 µg/mL.

## Phenytoin and Related Drugs

*W. Edwin Dodson*

**S**ince phenytoin was introduced for the treatment of epilepsy by Merritt and Putnam in 1938, it has become one of the most widely used and extensively investigated antiepileptic drugs. It has been administered to patients of all ages and thus provides a good model for evaluating the effects of age on pharmacokinetics. In addition, phenytoin is unique among the commonly prescribed antiepileptic drugs because of its nonlinear elimination kinetics (Figure 49-1) (1, 2).

### CHEMISTRY

Phenytoin is a weak acid, having a  $pK_a$  of 8.06 (3) (Table 49-1). Phenytoin sodium is approximately 92% phenytoin, a difference that is sometimes important because of phenytoin's nonlinear elimination kinetics. Phenytoin has limited aqueous solubility, approximately 20 mg/L, unless solubilizing agents are added to the solution. Parenteral formulations of phenytoin are strongly basic and contain the alcohols propylene glycol and ethanol. These formulations are potentially cardiotoxic and thus should be administered slowly intravenously to avoid bradyarrhythmia and hypotension. The phenytoin prodrug fosphenytoin has enhanced solubility and circumvents this hazard; although it is considerably safer

for intravenous (IV) administration, it is also considerably more expensive.

### CLINICAL EFFICACY

The spectrum of activity of phenytoin includes status epilepticus, partial seizures, partial seizures secondarily generalized, tonic seizures, and generalized tonic-clonic seizures (4, 5). Increasing doses and levels of phenytoin are associated with progressive reduction of seizures in adults (6) and in children (7). When administered following head trauma, phenytoin reduces the risk of seizures within the initial seven days, but it has no effect on the long-term development of epilepsy (8). Long a mainstay in the treatment of status epilepticus, phenytoin has been displaced as the drug to use first by lorazepam (9).

Although the therapeutic range is widely quoted at 10 to 20 mg/L, individual patients may require lower or higher levels for successful treatment. Phenytoin is not effective against generalized absence seizures and may increase their frequency; it is also ineffective in preventing recurrent febrile seizures. Phenytoin has been widely used to treat neonatal seizures, including neonatal status epilepticus (10, 11, 12). After phenobarbital fails to control neonatal seizures, the chance that phenytoin will succeed is approximately 50% (13, 14). However, the

FIGURE 49-1

Dose versus concentration curve for drugs with nonlinear elimination kinetics. Reproduced with permission from (2).

response of neonatal seizures caused by hypoxia, ischemia, or hemorrhage is poor (15). Phenytoin is also used to treat kinesigenic choreoathetosis (16).

### PHENYTOIN ADMINISTRATION

Phenytoin is available for parenteral and oral administration (Table 49-1). Although IV phenytoin is effective in stopping status epilepticus and in preventing recurrent seizures, it is slower acting than a benzodiazepine in stopping acute convulsions (17). However, when status has been interrupted by a short-acting drug such as diazepam, phenytoin can be administered next to prevent seizure recurrence. When phenytoin is administered intravenously, it must be given slowly to reduce the risk

of cardiovascular toxicity (Table 49-2). For this reason, the safer formulation fosphenytoin is preferred because of the desirability of stopping status epilepticus as rapidly as possible.

Phenytoin has several advantages in the acute treatment of seizures. It is not sedating and thus does not potentiate sedation and respiratory depression as do benzodiazepines and barbiturates. When seizures persist after administration of phenytoin in status, cumulative doses of up to 30 mg/kg can be given initially but should not be exceeded unless it is documented that phenytoin levels are not excessive, because high phenytoin levels can cause seizures. Intramuscular phenytoin is not effective in the acute treatment of seizures.

In chronic oral therapy, phenytoin usually can be administered twice daily. Because of the nonlinear kinetics of phenytoin, it is best to begin with a low average dose and increase the dose stepwise until the desired clinical result is obtained. In young children, initial doses of 8–10 mg/kg/day are reasonable, whereas older children, adolescents, and young adults should begin with 6–8 mg/kg/day (18). As the dose is raised, progressively smaller increases should be made to avoid disproportionate increases in phenytoin level and resultant toxicity. If precise adjustment of phenytoin levels is necessary, the distinction between phenytoin and phenytoin sodium becomes an important consideration when mixing or switching to different products that contain phenytoin. The concentration of phenytoin in contemporary suspensions remains fairly uniform, but, in the past, suspensions were ill advised because of the tendency for phenytoin to settle out. Doses from the top of the bottle were lower than expected, whereas those from the bottom were higher than expected, because the suspended medication settled to the bottom after standing. In all instances when phenytoin dose has been changed, patients should be reexamined to evaluate whether the dose is correct because of the unpredictable relationship between phenytoin dose and concentration.

TABLE 49-1  
*Phenytoin Reference Information*

Molecular weight of sodium phenytoin	274.25
Molecular weight of phenytoin	252.26
pK <sub>a</sub> of phenytoin	8.06
Conversion factor	CF = 1000/252.3 = 3.96
Conversion	μg/ml (or mg/L) × 3.96 = μmoles/L
Formulations	
Phenytoin suspension (Dilantin)	50 mg/mL
Phenytoin (Dilantin Infatabs)	50 mg
Phenytoin sodium (Dilantin Capsels)	30, 60, or 100 mg
Type of elimination kinetics	Nonlinear

**TABLE 49-2**  
**Aspects of Phenytoin Administration**

Intravenous dose	15–20 mg/kg*
Intravenous administration rates	
Rate in adults	< 50 mg/min
Rate in infants and children	< 3 mg/kg/min
Maintenance dose	6–20 mg/kg/day
Therapeutic concentration range	10–20 mg/L
*Administer slowly to avoid cardiovascular toxicity.	

### BIOTRANSFORMATION, PHARMACOKINETICS AND INTERACTIONS IN HUMANS

Phenytoin is largely eliminated by enzymatic biotransformation in the liver to 5-parahydroxyphenyl, 5-phenylhydantoin (HPPH), which is the major metabolite, and to a dihydrodiol that accounts for approximately 10% of phenytoin metabolites in urine. Both of these metabolites are thought to be derived from a highly reactive arene oxide (epoxide) intermediate (19, 15). Negligible amounts of unmetabolized phenytoin are excreted in urine.

Phenytoin is metabolized by the cytochrome P450 enzymes CYP2C9 and CYP2C19 (20, 21). In some families that metabolize phenytoin slowly, mutations have been identified that account for these pharmacokinetic differences (22). Odani et al. identified a mutation of CYP2C9 caused by a substitution of leucine for isoleucine at position 359 that results in a reduction of 33% in maximal capacity to metabolize ( $V_{max}$ ) phenytoin among Japanese people. Mutations in CYP2C19 reduced  $V_{max}$  by as much as 14%.

Phenytoin has nonlinear kinetics in all age groups (1, 23–30). As the dose and concentration of phenytoin increase, the eliminating mechanism becomes progressively saturated, reducing the fraction of phenytoin that is eliminated per unit of time. This leads to a nonlinear relationship between phenytoin dose and concentration (Figure 49-1). Because increasing doses cause disproportional rises in the phenytoin level, smaller increments in dose should be made as the phenytoin level approaches the therapeutic range. Phenytoin kinetics are best characterized by Michaelis-Menten equations. However, the concept of half-life is widely used in clinical pharmacokinetics and therefore merits discussion (Table 49-3).

### PHENYTOIN HALF-LIFE

The kinetics of phenytoin elimination are concentration-dependent. Although the half-life of phenytoin is widely quoted and discussed, applying the concept of a half-life

**TABLE 49-3**  
**Phenytoin Pharmacokinetics**

Protein binding	90%
Volume of distribution	
Newborns	0.8–1.2 L/kg
Older children and adults	0.7–0.9 L/kg
Half-life	Concentration-dependent
Nonlinear kinetic parameters	
$K_M$	5 mg/L
$V_{max}$	10–20 mg/kg/day

\*\*See text for details.

to phenytoin kinetics is technically improper, because phenytoin does not have first-order elimination kinetics. The apparent half-life ( $t_{50\%}$ ) of phenytoin changes depending on the concentration range over which it is measured. As a consequence of phenytoin's nonlinear elimination kinetics, increasing concentrations lead to prolongation of the apparent half-life. When phenytoin levels are high, the apparent half-lives can be quite prolonged (25, 30). As the level declines, the rate of phenytoin elimination accelerates and the apparent half-life becomes shorter (Figure 49-2). Thus, at different concentrations, different half-lives can be measured in a single patient. The apparent half-life is sometimes designated by  $t_{50\%}$ . As was shown in equation 5 in

**FIGURE 49-2**

Log phenytoin concentration versus time curve that was obtained in a 14-month-old who ingested a large dose of phenytoin. Note that the observed half-life becomes progressively shorter as the concentration declines. Reproduced with permission from (18).

FIGURE 49-3

Relationship of the initial concentration ( $C_i$ ) to the apparent half-life that was observed in an infant taking phenytoin. As the concentration increased, the apparent half-life ( $t_{50\%}$ ) was prolonged.

Chapter 23, the  $t_{50\%}$  is directly related to the concentration at which the  $t_{50\%}$  is determined (Figure 49-3).

Because the  $t_{50\%}$  of phenytoin varies, it takes longer than expected for patients to reach a steady state. This is particularly a problem when patients take relatively high doses that are close to their maximal phenytoin eliminating capacity ( $V_{max}$ ). As a rule of thumb, at least two weeks should be allowed before phenytoin levels are considered to be at steady state after the dose is changed. In some patients who have very high levels, even more time may be required.

The changing  $t_{50\%}$  of phenytoin is occasionally useful in clinical situations. For example, small increases in the average phenytoin level can be achieved by giving the total daily dose as a single dose (31). This increases the average level slightly because the large single dose produces a higher initial phenytoin concentration, thereby prolonging the  $t_{50\%}$ . Dividing the daily dose into more frequent daily doses has the opposite effect and slightly lowers the average concentration.

### NONLINEAR KINETICS, $K_M$ AND $V_{MAX}$

Phenytoin kinetics are best characterized by Michaelis-Menten kinetic parameters  $K_M$  and  $V_{max}$ . Children and adults have similar  $K_M$  values of approximately 5 mg/L. However, children have higher capacity to eliminate phenytoin than adults, resulting in higher  $V_{max}$  (2, 23, 24, 32). Much of the variation in  $K_M$  is caused by drug interactions.

There are several methods for calculating the  $K_M$  and  $V_{max}$ . The easiest and most reliable method is the direct linear plot (33). This is a graphic solution that

can be performed at the bedside. The method depends on knowing the patient's phenytoin level at two or more pairs of doses and steady-state concentrations. The concentrations should be obtained at consistent times after doses. When phenytoin is given twice daily, the best times to measure the level are just prior to a dose and 8 hours after a dose (34). Once  $K_M$  and  $V_{max}$  are known, it is possible to estimate the relationship between future doses and concentrations.

The direct linear plot technique for calculating  $K_M$  and  $V_{max}$  is fairly simple and is illustrated in Figure 49-4 (35). The negative value of the phenytoin level is plotted on the horizontal axis and the dose is plotted on the vertical axis. The dose and level pairs are connected by lines that are extended up and to the right, where they intersect. This point of intersection is used as a fulcrum for determining  $K_M$ ,  $V_{max}$ , and other dose-level relationships. A horizontal line drawn from the point of intersection to the vertical axis is  $V_{max}$ . A vertical line drawn from the intersection indicates  $K_M$  on the horizontal axis. The relationships between other doses and levels are solved by drawing additional lines from the point of intersection as shown in Figure 49-4.

There are many nomograms and related methods for predicting the relationship between phenytoin dose and concentration in various groups of patients (29). Although these provide heuristic exercises in clinical pharmacology, they are untrustworthy guides to phenytoin dosing. In one study, significant errors in predicted levels occurred in 21% to 38% of subjects (36). Large errors are most likely among patients who need high phenytoin levels. For this reason, every patient whose phenytoin dose is changed should be reevaluated after an appropriate interval (29). Although nomograms can reduce trial and error

FIGURE 49-4

Direct linear plot (35). In this example  $K_M = 4$  mg/L and  $V_{max} = 12$  mg/kg/day. Predicted values are indicated by the dotted line. Insert indicates the shape of the dose versus concentration curve. See text for details.

in estimating phenytoin doses, they are no substitute for patient follow-up.

### PHENYTOIN ABSORPTION

The nonlinear kinetics of phenytoin can affect the apparent extent of phenytoin absorption (bioavailability). Slowing the absorption rate has the practical result of reducing the apparent bioavailability (37). Computer simulations indicate that, at average values of  $K_M$  and  $V_{max}$ , increasing the absorption half-life from 0 to 1.2 hours causes the apparent bioavailability to decrease by approximately 25% (38). If the actual fraction that is absorbed also decreases slightly, the reduction in apparent bioavailability is greater. For example, with 90% absorption and an absorption half-life of 0.9 hours, the apparent bioavailability declines to 69%.

Although phenytoin is well absorbed after oral administration, the rate of absorption depends on the formulation. Changing excipients has been associated with changes in steady-state levels (39). But, even without changes in excipients, other aspects of tablet formulation can affect the absorption rate. Thus switching formulations can change the phenytoin levels significantly. For this reason, generic substitution of phenytoin should be discouraged.

In infants, peak phenytoin concentrations occur 2 to 6 hours after oral dosing (40). In older children, peak concentrations occur 3 to 10 hours following oral doses. The administration of phenytoin with food further delays the time to peak concentrations in patients of all ages (41). However, phenytoin taken postprandially produces 40% higher concentrations than when it is taken before meals (42). Thus the relationship between phenytoin doses and meals should be consistent.

Intramuscular administration of phenytoin is associated with slow and erratic absorption (43). Because of the low solubility of phenytoin, it can crystallize and precipitate at the injection site. Although phenytoin absorption is eventually complete, intramuscular administration of phenytoin is unreliable and should be avoided (44). If intramuscular administration is needed, fosphenytoin should be given.

### PHENYTOIN DRUG-PROTEIN BINDING

The unbound drug concentration, not the total drug concentration, determines the drug's action. Phenytoin is normally 90% bound to constituents of serum, mainly to albumin. In diseases with hypoalbuminemia, such as renal disease, hepatic disease, severe malnutrition, burns, and pregnancy (45, 46), unbound phenytoin levels increase such that the total phenytoin levels no longer provide

reliable indicators of the unbound levels. In these situations, measuring the unbound phenytoin level is sometimes indicated.

Phenytoin binding is also reduced by bilirubin and acidic compounds such as fatty acids, including valproic acid, and salicylate, which displace phenytoin from protein binding (47). Among developmentally disabled patients, hypoalbuminemia and comedication with valproate have been associated with unbound phenytoin fractions as high as 17% (48). When the unbound phenytoin fraction increases chronically, hepatic metabolism compensates such that the unbound concentration is readjusted to the previous steady-state level. This leads to a decline in the total phenytoin level, but the effect on unbound levels is insignificant. Thus, chronic changes in binding have a negligible effect on unbound phenytoin concentrations unless the dose is changed (49). On the other hand, acute changes in phenytoin binding such as those associated with dialysis may cause transient and symptomatic changes in unbound phenytoin levels. Rapidly fluctuating valproate levels can increase unbound phenytoin levels transiently, resulting in transient phenytoin toxicity (50).

### EFFECT OF AGE ON PHENYTOIN PHARMACOKINETICS

The maximal capacity to eliminate phenytoin is affected by genetic factors, age, sex, and drug interactions (51, 52). However, it is important to note that the nonlinear kinetics of phenytoin have confounded most clinical investigations of the effect of age on phenytoin kinetics. When linear kinetic parameters such as half-life or relative clearance are used, the nonlinear kinetics often obscure age-related pharmacokinetic differences (25, 53). In a practical sense, the nonlinear kinetics of phenytoin influence relative dosage requirements more than does age.

#### Newborns

Newborns who are exposed to phenytoin in utero usually eliminate transplacentally acquired phenytoin at rates that are comparable to those in adults. Studies of urinary metabolites indicate that these newborns rapidly metabolize phenytoin (54). On the other hand, newborns with seizures eliminate phenytoin slowly at first, but later, during the neonatal period, they eliminate it rapidly after their drug-eliminating mechanisms have matured (26).

Among all age groups, premature and full-term newborns who were not exposed in utero to inducing agents have the lowest relative capacity to eliminate phenytoin; thus, they require the lowest doses on average. Phenytoin concentrations and apparent half-lives vary

extensively in newborns with seizures, more so than in any other age group. Newborns with seizures have several factors that act simultaneously to produce unstable phenytoin levels. These include nonlinear phenytoin kinetics, postnatal maturation of hepatic function, induction of phenytoin elimination by phenobarbital and other drugs, and slowed phenytoin absorption, which occurs after the newborns have been switched from intravenous to oral dosing. Most newborns who receive phenytoin have been treated previously with phenobarbital. Phenobarbital affects the hepatic biotransformation of phenytoin, increasing both  $V_{\max}$  and  $K_M$  (2, 55). For this reason the changing phenytoin kinetics during the neonatal period preclude the use of steady-state methods for analyzing the nonlinear kinetics of phenytoin. These changes make it necessary to increase the phenytoin dose during the neonatal period if consistently high phenytoin levels are needed.

High phenytoin concentrations occur after intravenous loading doses, often leading to very long apparent half-lives in the first and second week of life. The phenytoin half-lives that have been reported in newborns vary widely, with extremes of 6 hours to more than 200 hours after intravenous therapy (11, 26, 56). Bourgeois and Dodson (2) found that the phenytoin  $t_{50\%}$  ranged from 6.9 to 140 hours, with an average value of  $57.3 \pm 48.2$  hours. In newborns aged 3–5 weeks, the  $t_{50\%}$  decreased by two-thirds.

After the first week of life, shorter phenytoin half-lives have been reported, but some newborns continue to have prolonged half-lives if phenytoin levels are high (11, 51). Painter et al. (9, 11) reported an average value of  $104 \pm 17$  hours during the second week of life. In a different group of 16 newborns with seizures, half-lives diminished considerably after the first week of life (26). Among children more than 1-week-old, there was good correlation ( $r = 0.88$  to  $0.93$ ) between the apparent half-life and the initial phenytoin concentration (26). Correcting for initial concentration revealed that newborns ages 3–5 weeks had the shortest half-life, averaging 19.7 and 12 hours at initial phenytoin concentrations of 18 and 10 mg/L, respectively.

After the first or second week of life, the capacity for phenytoin elimination increases and phenytoin concentrations often decline. Older newborns and young infants require doses as high as 18 to 20 mg/kg/day to achieve therapeutic levels (4). If declining concentrations occur when phenytoin administration is switched from the intravenous to the oral route, the changing dose requirements give the appearance of malabsorption of phenytoin (11, 12).

Newborns absorb phenytoin slowly but completely after oral administration, with less than 3% of administered phenytoin found in feces (57). Studies using stable isotope-labeled phenytoin also indicate complete absorption (58).

Similarly, comparisons of levels obtained after intravenous and oral doses indicate complete absorption of orally administered suspensions (59). Thus the decline in phenytoin levels that takes place in the second or third week of life is caused by an increasing capacity for phenytoin biotransformation plus the unique consequences of nonlinear elimination kinetics. Despite numerous statements to the contrary, newborns do not malabsorb phenytoin. Reliable concentrations can be produced by oral administration even in premature newborns (59).

It is technically difficult to actually measure phenytoin bioavailability in newborns because of the changing elimination kinetics during the newborn period. For this reason, computer simulations have been used to provide insight into the problem. These simulations indicate that the changing phenytoin elimination kinetics ( $V_{\max}$  and  $K_M$ )—and the slower absorption rates that occur after phenytoin administration is switched from intravenous to oral routes—both affect the phenytoin level (38). For example, slowing the absorption rate of phenytoin decreases the apparent bioavailability by as much as 26%.

The effects of varying the absorption rate and  $K_M$  on the apparent extent of phenytoin absorption are modest compared to the large changes that occur when  $V_{\max}$  increases. Based on computer simulations, increasing  $V_{\max}$  is expected to produce sizeable reductions in apparent bioavailability even when absorption is complete (38). For example, increasing  $V_{\max}$  threefold from 5 mg/kg/day to 15 mg/kg/day causes the apparent bioavailability to decrease by 77%. Variations in  $K_M$  cause smaller changes in apparent bioavailability; changing  $K_M$  from 5 mg/L to 1 mg/L decreases the apparent bioavailability to 67%. Increasing  $K_M$  from 5 to 10 mg/L, such as might occur because of an interaction with phenobarbital, has the opposite effect.

### Infants and Children

Among all age groups, infants have the highest relative capacity to eliminate phenytoin, causing them to have average dosage requirements that are fourfold greater than adults.  $V_{\max}$ , but not  $K_M$ , changes with increasing age (2, 24) (Figure 49-5). After phenytoin-eliminating capacity peaks during infancy, it declines during childhood to adult values (23). In one study the  $V_{\max}$  in infants ranged from 11 to 30 mg/kg/day and averaged 17.9 mg/kg/day (2). The average values in older children and adults are approximately 8 to 10 mg/kg/day in various studies. Although most of the variation in  $K_M$  is caused by drug interactions,  $K_M$  does vary independently as well. In one study 28% of children had a  $K_M$  of 2.5 mg/L or less (2). This low value of  $K_M$  makes it technically difficult to adjust phenytoin levels when levels are greater than 10 mg/L because the dose versus concentration curve becomes progressively steep and nonlinear (Figure 49-6).

FIGURE 49-5

Relationship between age and  $V_{\max}$  for phenytoin elimination. Reproduced with permission from (2).

The higher relative clearance for phenytoin in children gradually declines until adult values are reached around ages 10–15. (See Figure 37-6.) During this period, changes in body weight are offset by declining relative drug clearance, such that dosage changes are less frequent than expected. However, within any age group, individual patients deviate significantly from the group average. There are several causes for this variation: foremost among these are drug interactions and intercurrent illness.

### Adolescents

No major changes in phenytoin kinetics have been described in adolescence. However, phenytoin concentrations fluctuate during the menstrual cycle. Although

FIGURE 49-6

Dose versus concentration curves for varying values of  $K_M$  when  $V_{\max}$  is held constant at 15 mg/kg/day. Note that, as the values for  $K_M$  decline from 10 to 2 mg/L, the curve becomes more nearly vertical through the concentration range of 10 to 20 mg/L. (A)  $K_M = 10$  mg/L; (B)  $K_M = 5$  mg/L; (C)  $K_M = 2$  mg/L.

these fluctuations are usually modest, concentrations are higher at midcycle, when ovulation occurs, than at the time of menstruation. This suggests that increased concentrations of estrogen and progesterone interfere with phenytoin biotransformation (60). The fluctuations in phenytoin levels are most extensive in patients who have the highest concentrations.

### DRUG INTERACTIONS AND NONLINEAR KINETICS OF PHENYTOIN

Phenytoin is both a cause and a casualty of pharmacokinetic drug interactions. First, it is a potent inducer of many enzymes in the cytochrome P450 drug-metabolizing system (61). By this mechanism, the addition of phenytoin increases the clearance and decreases the concentrations of most other antiepileptics that are eliminated by hepatic metabolism. Examples include carbamazepine, methsuximide, primidone, valproate, and most of the antiepileptic drugs that have been introduced in the 1990s, including felbamate, topiramate, and lamotrigine. Besides enhancing the clearance of these compounds, phenytoin also stimulates the clearance of steroids, including oral contraceptives, and the clearance of vitamins, including vitamin D, folic acid, and vitamin K (61, 62).

Phenytoin elimination is extremely vulnerable to drug interactions by virtue of its dependence on hepatic metabolism for elimination and its nonlinear kinetics (63). Even though general trends can be described, the direction and extent of these interactions are highly unpredictable. For this reason diligent clinical follow-up is required whenever a comedication is added to or deleted from treatment regimens that include phenytoin.

Phenobarbital consistently increases both the  $V_{\max}$  and  $K_M$  of phenytoin elimination (2). Thus phenobarbital has conflicting effects, acting simultaneously as an inducer and as a competitive inhibitor of phenytoin elimination. In groups of patients, the addition of phenobarbital to phenytoin regimens produces no change in the average phenytoin level, but, in individual patients, phenytoin levels can change significantly.

Drug interactions can make the adjustment of phenytoin easier or more difficult, depending on the drug that is involved. The phenobarbital-phenytoin interaction facilitates the titration of phenytoin levels in the upper part of therapeutic range (see Figure 49-5). This pharmacokinetic benefit is due to the increased value of  $K_M$  for phenytoin elimination, which leads to a mild degree of flattening of the phenytoin dose versus concentration curve. As a result, the dose to concentration relationship becomes more linear and more predictable. Carbamazepine interacts with phenytoin elimination by inducing cytochrome P450 enzymes CYP2C9 and CYP219 (20, 64, 65). The net effect of this interaction is to reduce

both the  $K_M$  and  $V_{max}$  for phenytoin elimination (2, 66), which is a complex interaction that usually leads to a reduction in phenytoin level. This interaction makes readjustment of phenytoin levels technically difficult because of the reduced  $K_M$  value and increased nonlinearity of the dose-to-concentration relationship. Herbal treatment with *Ginkgo biloba* also induces CYP2C9 and has been reported to lower phenytoin levels (67). Valproate interacts with phenytoin by displacing it from binding sites on albumin and increasing the unbound phenytoin fraction. Valproate reduces the  $K_M$  of phenytoin elimination but has no effect on  $V_{max}$  (2). However, switching from the standard formulation of sodium valproate to a slow-release formulation can cause the phenytoin level to increase. Suzuki et al (68) found that the average phenytoin level went from 14.4 to 18.7 mg/L when the valproate formulation was switched to the slow-release formulation.

Certain drug interactions usually increase the phenytoin level. Chloramphenicol consistently inhibits phenytoin elimination, thus increasing phenytoin levels (69). Conversely, discontinuing chloramphenicol causes phenytoin levels to decline dramatically. Isoniazide also usually increases phenytoin levels. According to the Boston Collaborative Drug Surveillance Program, 27% of the patients who take isoniazide plus phenytoin develop phenytoin toxicity if the phenytoin dose is not adjusted (70).

### EFFECT OF ILLNESS ON PHENYTOIN PHARMACOKINETICS

Intercurrent illness can cause changes both in seizure threshold and in drug levels. Among all antiepileptic drugs, phenytoin levels are most liable to change during intercurrent illness. Infectious mononucleosis, influenza immunization, streptococcal pharyngitis, and any illness that causes fever can cause reduced phenytoin levels (71–73). One study indicated that, during febrile illness, phenytoin levels decrease by approximately 50%, declining from 16 to 8 mg/L on the average (73). Changes of this magnitude are expected to contribute to seizure recurrence in some patients.

Chronic renal disease is usually associated with alterations of phenytoin binding. In nephrotic syndrome, phenytoin binding is reduced to 80%, doubling the unbound phenytoin fraction (74). In addition, the half-life of phenytoin is decreased in uremia (75). After successful renal transplantation, phenytoin binding returns to normal (76). Although dialysis removes relatively little phenytoin, dialysis can remove significant amounts of water, thereby altering the patient's serum albumin concentration (77). This can, in turn, reduce the unbound fraction of phenytoin following dialysis even though the

total phenytoin level does not change (78). In these situations measuring the unbound phenytoin concentration may be necessary.

Significant hepatic disease is associated with hypoalbuminemia and with increased concentrations of bilirubin and bile acids in serum, which can alter phenytoin binding. In addition, the hepatic biotransformation of phenytoin is variably impaired if hepatic parenchymal function is reduced, such as occurs in hepatitis or passive hepatic congestion due to heart failure. Again, in this case measuring the unbound phenytoin level is sometimes indicated.

### ADVERSE EFFECTS

Phenytoin causes some degree of side effects in the majority of patients, but only an estimated 10% to 40% of patients require a change of medication (79). In a study conducted among children in India, the risk of more than one side effect was 32%, 40%, and 19% for children treated with either phenobarbital, phenytoin, or sodium valproate, respectively. However, most of the side effects associated with phenytoin disappeared after phenytoin dosage adjustment (80).

In a British randomized comparison of phenytoin with carbamazepine, phenobarbital, and sodium valproate, all four drugs had equivalent efficacy, but there were substantial differences in side effects. After a high percentage of the children assigned to phenobarbital developed side effects, it was withdrawn from the study. Among the remaining agents, phenytoin was withdrawn in 9% of children compared to 4% withdrawal rates because of unacceptable side effects for carbamazepine and valproate (81).

Overall, the incidence of side effects with phenytoin is similar to that with carbamazepine, but the nature of the side effects differs. In children, the cosmetic side effects of gingival hyperplasia and hirsutism are notably common and aggravating after chronic phenytoin therapy.

Idiosyncratic side effects of phenytoin include blood dyscrasia, allergic reactions, and certain forms of neurotoxicity. Idiosyncratic neurotoxicity is a problem primarily in patients who are abnormal neurologically and who do not manifest the usual signs of phenytoin toxicity. Immune-mediated reactions to phenytoin usually occur within the first two months of therapy. These include rashes, fever, lymphadenopathy, eosinophilia, serum sickness with hepatic and renal dysfunction, and polymyositis (82). Pseudolymphoma consisting of rash, fever, and lymphadenopathy is rare.

Phenytoin is one of many drugs that can cause the antiepileptic drug hypersensitivity syndrome. This syndrome consists of rash, fever, lymphadenopathy, and

visceral organ involvement—especially involvement of the liver or the kidneys. The estimated incidence is 1 in 3,000 exposures to phenytoin. Approximately 70% to 80% of patients demonstrate cross-reactivity with phenobarbital, primidone, and carbamazepine (83). The risk of serious skin rashes, defined as rashes extensive enough to require hospitalization, has been estimated at 2.3–4.5 per 10,000 for phenytoin compared to 1–4.1 for carbamazepine (84). Other forms of rash, such as fixed drug eruptions, have been linked to phenytoin as well (85).

Rarely, movement disorders are caused by phenytoin. These usually occur in patients who are neurologically abnormal (86). Both bradykinesia and choreoathetosis have been described. Both can occur on either an idiosyncratic or a dose-related basis, although the latter is more common, with most affected patients having levels greater than 20 mg/L (87, 88, 89). Choreoathetosis has occurred after intravenous therapy and may be long lasting (90, 91). Note that choreoathetosis can also be caused by carbamazepine and by ethosuximide (89, 92, 93).

Dose-related adverse effects of phenytoin may be either acute or delayed, appearing only after chronic treatment. The acute dose-related neurotoxicity of phenytoin was well described by Kutt et al. more than two decades ago (55). Nystagmus occurs at levels of 15–25 mg/L; ataxia occurs at levels greater than 30 mg/L; and mental changes, with lethargy and mental clouding, occur at levels above 40 mg/L. Most patients with levels 20 mg/L have nystagmus. Blood levels above 60 mg/L cause difficulty sitting up. Although rare, ophthalmoplegia is also dose related (94). Paradoxically, seizure frequency increases at phenytoin levels above 30 mg/L in some patients (95, 96). Among patients with severe epilepsy, this becomes a thorny management issue because certain patients require equally high levels for seizure control. The adverse effect of seizure exacerbation has been linked to several other drugs in addition to phenytoin, especially carbamazepine, gabapentin, phenobarbital, vigabatrin, and lamotrigine (97, 98). However, carbamazepine-exacerbated seizures may be controlled by replacing carbamazepine with phenytoin (99).

Phenytoin-induced encephalopathy with dementia is also rare. Usually subacute and insidious, this is more likely to occur in neurologically abnormal patients who do not manifest the usual progression of concentration-related toxic signs. It is usually reversible after phenytoin is discontinued (100–102).

Delayed adverse effects of phenytoin include peripheral neuropathy, reduced vitamin D levels, bone demineralization, and cosmetic changes (103). The cosmetic side effects of hirsutism and gingival hyperplasia are more common with phenytoin than with other antiepileptics. The incidence of gingival hyperplasia is approximately 40%, but percentages as high as 69% have been reported in patients in India with tuberculous meningitis who were

treated chronically with phenytoin (104). Although not all studies agree, the risk of gingival hyperplasia appears to be directly related to the phenytoin dose and level and inversely related to age (105, 106). Factors that are unrelated to increased risk of this side effect include sex, age at onset of treatment, and duration of treatment (106). Other factors include genetic predisposition, plaque-induced gingival inflammation, immunological status, and the induction of growth factors. Overall, gingival hyperplasia is more common in children than in adults. Poor oral hygiene further increases the risk; preventive dental hygiene programs reduce the incidence and severity of this problem (107, 108).

The pathogenesis of gingival hyperplasia has not been completely elucidated. Reactive intermediates are thought to play a role. Microsomes from gingival tissue do have the capacity to metabolize phenytoin (109). Phenytoin also increases serum concentrations of basic fibroblast growth factor threefold. Furthermore, basic levels of fibroblast growth factor have correlated better with the extent of gingival overgrowth than age, phenytoin dose, duration of phenytoin administration, and serum phenytoin level (110).

The question of whether chronic phenytoin therapy at ordinary levels causes cerebellar and brain stem atrophy remains unanswered despite years of concern (111–113). The problem is complicated because cerebellar atrophy also occurs in patients with severe epilepsy who have not received phenytoin. In one study of mentally retarded patients, the incidence of cerebellar atrophy (28%) was similar in phenytoin-treated and untreated patients (114). Most cases of persistent ataxia and cerebellar and brain stem atrophy have occurred after chronically high levels of phenytoin and clinical signs of intoxication. However, brief periods of intoxication, and even single episodes of severe phenytoin intoxication, have been followed by cerebellar atrophy with permanent disability (115, 116). The issue is especially complex in mentally handicapped patients, who may not show the usual signs of phenytoin intoxication despite levels that would ordinarily be considered toxic (117). Nonetheless, high phenytoin levels have been temporally linked to the permanent loss of locomotion in mentally handicapped patients who had high levels chronically.

## ADVANTAGES AND DISADVANTAGES OF PHENYTOIN

Historically, phenytoin has been one of the most widely used antiepileptic drugs in childhood epilepsy, but, over the past two decades, its use in children has diminished. Phenytoin has several special features that are advantageous compared to other antiepileptic drugs (Table 49-4). These include its availability for parenteral administration

TABLE 49-4

*Summary of Special Features Regarding Phenytoin Administration in Childhood Epilepsy*

Nonlinear elimination kinetics
Frequent drug interactions
Fosphenytoin preferred for intravenous and intramuscular administration
Need for slow intravenous administration of phenytoin
Unreliable intramuscular absorption of phenytoin
Paradoxical ability to cause seizures at high concentrations
Cosmetic and cognitive side effects
Generic substitution problematic

and its efficacy in status epilepticus. Pediatric physicians have extensive experience with phenytoin, and most are familiar with administering it to children. It is nonsedating. Disadvantages include the cosmetic and cognitive side effects and its complex nonlinear pharmacokinetics. The major adverse cognitive effects include slowing of motor and mental processes and variable impairment of memory.

### Fosphenytoin

The intravenous administration of phenytoin has long been hazardous because of the need for alkaline pH and high concentrations of solvents (propylene glycol) in order to keep phenytoin in solution. The invention of fosphenytoin, the disodium phosphate ester of phenytoin, has circumvented both of these problems, resulting in safer phenytoin formulation for parenteral administration (118–120). Despite substantially increased cost compared to phenytoin, fosphenytoin has gained wide acceptance because of safety considerations (121,122).

Fosphenytoin can be administered intravenously and intramuscularly and can be used to administer phenytoin parenterally for extended periods if necessary (123–125). The phosphate ester is hydrolyzed rapidly by nonspecific hepatic phosphatases, releasing phenytoin. Although the half-life of the hydrolysis is approximately 8–15 minutes (126), the concentration of unbound phenytoin increases more rapidly because fosphenytoin displaces phenytoin from binding sites in blood (127, 128). As a result, the newly liberated phenytoin is largely unbound until the fosphenytoin concentration declines.

The fosphenytoin dose is prescribed and administered as equimolar amounts of phenytoin, called “phenytoin equivalents.” Thus the loading and maintenance doses of fosphenytoin in phenytoin equivalents are identical to phenytoin doses (129). Fosphenytoin infusion

causes fewer adverse effects than intravenous phenytoin (125). Unique side effects compared to phenytoin are pruritus and perineal paresthesias (130). Hypotension occurs less often following fosphenytoin intravenous infusion than with phenytoin but may occur later, after the infusion (131, 132). Compared to intravenous phenytoin, fosphenytoin infusion is less likely to be painful or to cause erythema, irritation at the infusion site, or venous cording (132, 133). It has not been reported to cause purple glove syndrome as intravenous phenytoin can. Occurring mainly in elderly patients, purple glove syndrome consists of progressive edema, pain, and discoloration of the limb following intravenous phenytoin infusion. (134).

### Other Antiepileptic Compounds Related to Phenytoin

The other hydantoins with antiepileptic potential use include mephenytoin (Mesantoin), a N-methylated compound, and ethotoin (Peganone), which is N-ethylated (135). Information about the use of these drugs in children is scant. Whereas phenytoin has two phenyl groups in the 5 position of the hydantoin ring, mephenytoin has both a phenyl and an ethyl group, like phenobarbital; ethotoin has a single phenyl group in the same position. Like other N-alkylated compounds, both ethotoin and mephenytoin are dealkylated in the body. The spectrum of activity of these compounds is similar to that of phenytoin, but their side effects differ; both compounds have a lower incidence of gingival hyperplasia and hirsutism. The genetic basis for variability in mephenytoin metabolism has been described (135).

Mephenytoin use was discouraged by potentially fatal blood dyscrasias that occurred in an estimated 1% of patients; it is no longer marketed in the United States. The N-demethylated metabolite nirvanol is a racemic mixture of dextro- and levorotary isomers and accumulates in serum. Nirvanol, possibly the dextrorotary isomer, is responsible for most of the anti-convulsant activity of mephenytoin. Nirvanol has a long half-life in adults, ranging from 77 to 176 hours (135–137). Among adults nirvanol levels of 25–40 mg/L have been associated with improved seizure control (138). Both of these compounds have largely become pharmacogenetic probes for characterizing cytochrome P450 isozymes (139).

Since 1949 only 33 references regarding ethotoin have been listed in *Index Medicus* and there are no references on its use since 1993. Nonetheless, ethotoin remains useful for patients with intractable epilepsy, where its role is bottom tier (140). It has nonlinear kinetics; one study reported  $V_{max}$  to range from 50 to 95 mg/kg/day and  $K_M$  to range from 9 to 43 mg/L in children (141). Among patients switched from phenytoin to ethotoin, gingival hyperplasia recedes. The incidence of hirsutism

and ataxia is also said to be lower with ethotoin. Doses have ranged from approximately 20 to 50 mg/kg/day. The best contemporary source of information about how to use ethotoin is online at Wikipedia (<http://en.wikipedia.org/wiki/Ethotoin>) and at the pharmaceutical website where prescribing information is posted ([http://www.ovationpharma.com/images/products/pdf/peganone\\_pi.pdf](http://www.ovationpharma.com/images/products/pdf/peganone_pi.pdf)).

## Sulthiame

*Dietz Rating*  
*Nicole Wolf*  
*Thomas Bast*

### CHEMISTRY, ANIMAL PHARMACOLOGY, AND MECHANISM OF ACTION

Sulthiame (STM) is a sulfonamide derivate, N-(4-sulfamoylphenyl)-1,4-butansultam (Figure 50-1), a crystalline powder, with a molecular weight of 290 g/mol (1).

STM has no antibacterial properties, and although it is a weak carbonic anhydrase inhibitor it has no diuretic activity at therapeutic doses.

<sup>35</sup>S-STM is well absorbed from the gastrointestinal tract in rats; 80% of the dose of STM is excreted unchanged in the urine during the next 48 hours and only a small amount is found as an inactive hydroxylated derivative in urine (2). STM readily penetrates into tissues and brain and reaches concentrations similar to those found in plasma. STM half-lives in animal studies are variable and range from ~4 hours in rabbits to 4.5–7.3 hours in dogs and ~15–30 hours in rats (2).

Long-term observations in rats and dogs did not show toxic effects on organs such as liver, kidney, or bone marrow. The acute toxicity after oral intake calculated as LD<sub>50</sub> is >5,000 mg/kg in rats and mice and in rabbits ~1,000 mg/kg (3).

Tests investigating adverse effects on reproduction were performed by feeding rats with STM at doses ranging from 30 to 300 mg/kg. With higher doses, animals became lethargic, appetite decreased, and pregnant

animals gained less weight. A significant and dose-dependent decrease in fetal weight with doses higher than 100 mg/kg was observed, and even fetuses exposed to a dose of 30 mg/kg STM were, albeit not significantly, smaller than controls (D. Lorke, personal communication 1985).

In a model designed to investigate the influence of antiepileptic drugs (AEDs) on the developing brain, neuronal apoptosis increased in the brain of newborn rats exposed to standard anticonvulsants such as phenytoin (PHT), phenobarbital (PB), carbamazepine (CBZ), vigabatrin, or valproate (VPA). With STM, neuronal death was comparable with exposure to VPA or vigabatrin, however not as prominent as with PHT or PB (4, 5).

STM was proven to be effective against maximal electroshock (MES) (ED<sub>50</sub> = 35 mg/kg) and pentylenetetrazol-induced seizures (ED<sub>50</sub> = 260 mg/kg) in mice, however it was ineffective against strychnine-induced seizures (3). The therapeutic index (LD<sub>50</sub>/ED<sub>50</sub>) of STM in MES was 10 times higher than that of PB and 4 to 5 times higher than that of PHT. In a primate model—photosensitive baboons (20–125 mg/kg i.v.)—STM did not show anticonvulsant properties (6). In amygdaloid-kindled seizures in rats, Albertson and coworkers reported no efficacy (7); whereas another group found some effects, which were, however, much weaker and not comparable to those of CBZ, PHT, PB, or zonisamide demonstrated by the same group (8).

FIGURE 50-1

Structural formula of sulthiame.

Like acetazolamide—although 10–20 times weaker (3)—STM has carbonic anhydrase-inhibiting properties (9, 10). A familiar and still accepted explanation for the anticonvulsant effect of STM is the inhibition of carbonic anhydrase activity, mainly in glial cells. Subsequently, carbon dioxide concentrations increase, leading to acidification of both intracellular and extracellular space. By acting via N-methyl-D-aspartate (NMDA) receptors and calcium currents, this acidification reduces the excitability of neurons. In addition, there seems to be an independent effect of STM on the function of neuronal ion channels. In isolated neurons from guinea pig hippocampus, STM reduced inactivating sodium currents without changing potassium currents. Therapeutic concentrations of 1 to 10  $\mu\text{g}/\text{mL}$  decreased sodium currents to about 20% and led to impairment of repetitive generation of action potentials and a reduction of the maximum discharge frequency by 20% to 40% (11).

### BIOTRANSFORMATION, PHARMACOKINETICS, AND INTERACTIONS IN HUMANS

A total of 80% to 90% of oral STM is excreted mostly unchanged in urine, and 10% to 20% is lost with feces after biliary secretion (2). In humans, 32% of a single dose of STM is excreted by the urine within the first 24 hours. The protein binding of STM amounts to 29%.

STM serum peak levels were reached after 4 hours (range, 2–8 hours) after a first single oral dose of 5 mg/kg in children with epilepsy taking other AEDs (12). May et al calculated the STM interquartile range (25th to 75th percentile) of serum concentrations as being between 2.3 and 5.8 (mean, 4.7)  $\mu\text{g}/\text{mL}$  in 86 patients (2–89 years) on chronic  $9.1 \pm 4.67$  mg/kg STM therapy in combination with other AEDs, mainly CBZ, VPA, or PB (13). In various studies, a linear correlation between STM serum concentrations and the dose/body weight in children and adults could be demonstrated with an STM dose of 4 to 16.7 mg/kg (9, 13, 14). Children need higher doses per kilogram of body weight than adults to reach comparable serum levels (13). After a single first STM load, serum

half-life was calculated to be 3.7 hours (range, 2–7 hours) (12). May et al found somewhat longer STM half-lives ( $8.65 \pm 3.0$  hours) at steady-state in children and adults on stable comedication with CBZ, VPA, or PB. Half-lives are shorter in children than in adults ( $7 \pm 2$  hours vs.  $12 \pm 2$  hours) (13).

The decline of plasma concentrations followed in most cases a first-order kinetic; only a few patients' data were in favor of saturated kinetics. Steady state is reached 3 to 4 days after beginning treatment with STM. This short half-life explains the considerable daily fluctuations in STM concentrations, which explains the failure to establish a correlation between STM drug concentrations and anticonvulsive effect (13, 15).

Sulthiame is known for its interaction with phenytoin (16–18). In one study, adult patients with epilepsy on a stable dose of 300 mg PHT daily were started on a concomitant administration of 200 to 800 mg of STM. This caused a rise in serum PHT after one week and prolonged PHT half-life substantially (17). In some patients with already critical PHT serum concentrations, adding STM can provoke PHT intoxication (19). Olesen and Jensen already speculated that this increase of PHT levels is due to a direct inhibition by STM of the *para*-hydroxylation of PHT (18), which was later proven (20). CBZ decreases STM concentrations, probably secondary to enzyme induction (13). STM increased CBZ-epoxide by >30% in 6 of 39 patients, whereas CBZ levels remained unchanged, and PHT levels increased by >30% in 3 of 5 patients (21). No interactions with VPA were observed (13).

### CLINICAL EFFICACY AND SPECTRUM OF ACTIVITY

Sulthiame is one of the older AEDs, developed in the 1950s and introduced into the market in the 1960s. Therefore, much of our knowledge today comes from case studies and open trials of that period. Only two prospective studies evaluating the efficacy of STM in benign epilepsy of childhood with centrotemporal spikes (BECTS) (22) and West syndrome (23, 24) were performed according to recent recommendations of the International League Against Epilepsy (ILAE).

#### History

Results of the first open trials, mainly in adult patients with temporal lobe seizures according to the classification then in force, were published in 1960 (24–26); 23 of 81 patients treated with STM (200–1,200 mg/day) became seizure free (28%), 9 of the 23 taking STM monotherapy; the mean length of follow-up was 6 months (25). Of these 9 patients, 3 stopped STM medication. Seizures relapsed

but could be controlled again after reintroduction of STM. Such a high success rate of 28% could not be reproduced in other trials (26, 27).

In 1960, Doose et al were the first to demonstrate the efficacy of STM in children with epilepsy (28, 29); 129 children with focal, mainly “psychomotor” seizures, secondarily generalized tonic-clonic seizures, as well as generalized grand mal seizures and petit mal with or without grand mal, were treated and observed for over 6 months. Doose et al made the surprising observation that the best effects of STM were seen in children with psychomotor seizures, being regarded as especially difficult to treat at that time. With STM monotherapy, 13 of 24 children with psychomotor seizures and a further 24 of 41 children with focal seizures (simple and complex partial seizures with or without grand mal) became seizure free; in 7 children a reduction in seizure frequency of >50% was seen. In reading this old study with our present knowledge, we understand how close Doose et al were to discover independently the concept of benign epilepsy with centrotemporal spikes (BECTS), which was proposed first in 1958 by Nayrac et al and 2 years later by Nayrac and Beaussart (30) and Gibbs and Gibbs (31). It is of historical interest that the focal discharges in the first electroencephalogram (EEG) of a 10-year-old patient later shown to normalize under treatment with 400 mg/day STM would be classified today as rolandic spikes (Figure 50-2) (26).

In 1974, Green et al published a double-blind, cross-over study comparing the efficacy of STM with that of PHT, which was defined as the “standard of comparison for anticonvulsant testing” (16). The design of this study is quite unusual, and lack of detailed data makes it impossible to draw one’s own conclusions.

In this study, 67 patients with partial seizures with or without secondary generalization were included. In an open phase, all patients were first placed on a monotherapy with PHT for 2 months before the blinded phase started, during which patients were randomized to either PHT or STM. Whereas PHT was titrated to an individual dose during the open phase, in the blinded phase a ratio of 4:1 STM to PHT was calculated, meaning either that patients remained taking the same dose of PHT, or that a fourfold dose of STM was added, resulting in STM doses of 3.7 to 64.0 mg/kg. In most cases, this dose was 17 to 50 mg/kg (mean, 31.2 mg/kg), being well above recommended doses even at that time. A total of 10 of 67 patients were already lost during the first open phase on PHT monotherapy, and 36 more during the blinded part of the study—11 taking PHT and 25 taking STM. Only 21 of 67 patients completed the study, 11 taking PHT, 10 taking STM. Of these 21 patients, 10 had fewer seizures with PHT, 9 with STM. Nevertheless, the authors stated that “sulthiame has very little value as a primary anticonvulsant agent” and concluded that “it seems logical . . . to ascribe the benefit of sulthiame in the control of seizures to the fact that it raises serum PHT levels. . . . it is easier, more precise and less expensive to increase PHT serum level by administering more PHT than by giving sulthiame.”

Callaghan et al (14) came to similar conclusions when analyzing 10 adult patients (14–75 years of age; mean, 32.7 years) allocated to 3 to 10 mg/kg/day STM. They concluded that “STM did not appear to be of benefit to patients with severe and frequent seizures. The improvement (seen) was related to an increase in serum phenytoin levels” (14).

FIGURE 50-2

Electroencephalogram in a 10-year-old boy (a) before and (b) after a 30-day treatment with 400 mg of sulthiame.

These interpretations stopped further clinical trials with STM for a long time in most parts of Europe and North America.

### Spectrum of Efficacy

STM is proven to have specific action in BECTS. After BECTS was recognized as a distinct epileptic syndrome in children (30–32), the efficacy of STM was reevaluated by Dose et al (33). In a retrospective open study with a follow up from 7 months to 7 years they reported that 48 of 56 children (85%) with typical benign partial epilepsy became permanently seizure-free with 4 to 6 mg/kg/day STM.

A 6-month prospective, randomized, double-blind, placebo-controlled multicenter study of STM in BECTS, following the recommendation of the ILAE, was published in 2000 (22); 194 patients were screened, and 66 children (40 males, 26 females; age 8.3; range, 3.1–10.7 years) with the diagnosis of BECTS and two or more seizures during the past 6 months were randomized to either STM or placebo for 6 months of treatment. The primary effectiveness was the rate of treatment failure events per group, which were defined as the first seizures after a 7-day run-in period, intolerable adverse effects, development of another epileptic syndrome, or termination of the study by the parents or the investigator. The trial was stopped when the first interim analysis showed a significant superiority of STM treatment; 25 of 31 patients in the STM group (80.6%) but only 10 of the 35 placebo-treated group (28.6%) completed the trial ( $P < 0.0001$ ). In only 4 children taking STM but in 21 taking placebo, the failure event was a seizure. Two parents of the placebo group withdrew. All other failure events were due to termination of the trial by the investigators after the interim analysis.

The efficacy of STM in typical and atypical benign idiopathic partial epilepsies was shown by case reports from single centers and in some prospective as well as retrospective open studies (34–36).

In an open prospective trial between 1988 and 2001 and a follow-up of more than 12 months, 21 children with BECTS, atypical rolandic epilepsy, Landau-Kleffner syndrome, or continuous spike waves during slow sleep (CSWS) were treated with STM. In 15 children STM was the first and only treatment, whereas 10 children had had another treatment before STM. Of 21 children with seizures, 13 became seizure free, including 10 of 16 patients with BECTS. In 6 of 10 STM was the first drug (36).

A total of 125 children with various epileptic syndromes treated with STM as monotherapy or add-on between 1989 to 1998 were analyzed retrospectively in a multicenter study; 24 of 26 patients with benign rolandic epilepsy of childhood (including 3 atypical cases) and all 13 children with benign occipital epilepsy of childhood

were treated with STM only. A total of 29 of these 39 children became seizure free, and a further 6 of 39 showed a reduction of seizures of  $>50\%$  (37).

In a retrospective analysis, 111 consecutive patients with BECTS seen at five pediatric neurology outpatient clinics and one private clinic were collected. All patients were treated with either STM or CBZ according to the institutional policy. Efficacy was defined by seizure freedom for more than 2 years. In 67% of patients treated with STM “seizures disappeared,” whereas in 74% treated with CBZ “seizures abated.” Authors stated no significant difference regarding efficacy between the two drugs. It is noteworthy that 5 of 8 patients who were switched to STM after failing CBZ became seizure free, whereas none of the 3 patients having failed STM became seizure free after treatment had been changed to CBZ (38).

In another single center study, 35 patients with typical rolandic epilepsy treated either by STM ( $n = 17$ ) or CBZ ( $n = 16$ ) or other AED ( $n = 2$ ; primidone, PHT) were analyzed. A total of 15 of 17 patients in the STM group, but only 9 of 16 in the CBZ group became seizure free. The author speculated that in 3 of the 15 STM children, and in 6 of the 9 CBZ children, this outcome could have been due to the natural outcome of BECTS (34).

Of 8 children with atypical benign partial epilepsy, 5 became seizure free with STM, 1 with CBZ and 1 with ACTH. In 2 children, it was believed that the epilepsy was worsened by CBZ. Both became seizure free when switched to STM (34).

Gross-Selbeck reported further data on Landau-Kleffner syndrome (LKS) and CSWS treated with various AEDs, including STM. Two of four children with LKS showed a normalization of EEG under STM alone or in combination with clobazam; in the two others the EEG markedly improved. One of three children with CSWS on STM  $\pm$  clobazam became seizure free and showed a substantial amelioration of the EEG abnormalities (34). Wakai et al report on a 5-year-old, previously normal boy who developed a loss of acquired language, auditory agnosia, and atypical absences and complex partial seizures as well as CSWS. When he received 80 mg/day of STM, there was an excellent outcome regarding all clinical symptoms, accompanied by an improvement of EEG changes and disappearance of CSWS (39).

The second prospective, randomized, double-blind, placebo-controlled, multicenter study on STM, following the guidelines of the ILAE, was done in patients with West syndrome (23); 33 infants with newly diagnosed typical West syndrome (clinically infantile spasms and hypsarrhythmia in the EEG) were included in the study. To exclude pyridoxine-dependent seizures, all received for the first 3 days of the baseline phase 150 to 300 mg/kg pyridoxine. On day 4 they were randomized to either STM or placebo. STM was started with 5 mg/kg/day and

increased to 10 mg/kg/day when after 3 days no response was recorded. At the end of day 9, an EEG was recorded and study medication revealed. In the 16 patients in the placebo group, neither spasms nor hypsarrhythmia disappeared. In the STM group 6 of 17 infants showed a complete clinical and EEG response. In the follow-up period none of these six children on STM monotherapy relapsed ( $P < 0.022$ ). Three patients of the STM group who failed during the trial period became free of seizures after the STM dose was increased to 15–16.4 mg/kg/day. All but one patient of the placebo group received STM in the open follow-up. Four of these 15 patients also became seizure free.

Lerman and Nussbaum (35) reported on the use of STM in patients with epilepsies with myoclonic seizures comprising cases of Lennox-Gastaut syndrome, myoclonic petit mal, myoclonic seizures in Unverricht-Lundborg disease, and juvenile myoclonic epilepsy (JME). In the retrospective analysis of 12 adolescents and young adults with juvenile myoclonic epilepsy, 8 were controlled completely on STM alone (doses, 400–800 mg/day). In 4 of these 8 patients STM was the first drug; in the remaining 4 STM replaced previous drugs, even combinations of several AEDs (35). Ten patients with JME were treated by STM only; 7 of 10 became seizure-free, and another 3 of 10 had a reduction of seizures by  $>50\%$  (37). Kurlemann et al, investigating STM efficacy in newly diagnosed epilepsies, reported on one child with a childhood absence epilepsy who became seizure free by STM monotherapy as the first drug (40).

STM was shown in old (15, 24–26, 41–45) and new open, prospective and retrospective studies to have effects as add-on treatment in cryptogenic or symptomatic localization-related epilepsy in adults as well as in children (21, 37, 40, 46). A total of 17 of 42 children aged 3 to 18 years with a symptomatic localization-related epilepsy treated by STM became seizure free, and another 12 of 42 had a reduction in seizures of  $>50\%$  (37). Kurlemann et al reported on 48 consecutive children seen at one institution and suffering from simple or complex partial seizures; 28 of 48 (65.1%) treated by STM, which was the first AED in most patients, became seizure free (40). In an institutional analysis of 49 children with a pharmaco-resistant focal epilepsy, 8 became seizure free after add-on STM and 6 more patients had a reduction of seizures by  $>50\%$  (follow-up in most cases  $>21$  months) (46).

Recently, in a prospective open-label study with 48 adult patients with refractory epilepsy classified either as cryptogenic or symptomatic localization-related epileptic syndromes, STM was given as add-on at a dose of 200 to 600 mg/day. STM and concomitant AEDs were adjusted at the discretion of the investigator as indicated by patient tolerability. A total of 36 of 48 patients completed the titration and continuation phase and could be analyzed. Overall seizure frequency against baseline

level was significantly reduced by 36%, with a significant reduction in complex partial and generalized seizures, in the number of clusters and number of days affected by seizures ( $P < 0.01$  to 0.001). Twenty-two patients experienced at least a  $>50\%$  reduction in seizure frequency; three became completely seizure free. After more than 2 years, 17 patients having a  $>50\%$  reduction of seizure frequency still received STM (21).

### Effect of STM on Epileptiform EEG Activity

At least in Europe, the impact of focal discharges in BECTS on cognitive function, language performance, and overall intellectual development is a highly discussed issue. Transition of rolandic spikes to CSWS is possible (34, 47, 48). Normal neuropsychological and motor functions before and declining with the onset of CSWS have been described (49). There are reports that CBZ—although effective to treat seizures in BECTS—does not substantially alter the EEG pattern and may even lead to deterioration, including transition to CSWS. Therefore, the influence of STM on the EEG abnormalities in BECTS as well as in CSWS is of special interest.

In a prospective double-blind trial on STM versus placebo in BECTS, 179 sleep EEGs were recorded at screening and after 4 weeks, 3 months, and 6 months of therapy. All EEGs were analyzed by a blinded reviewer using a standard protocol and building a score by collecting data on epileptiform activity (number of foci, proportion, propagation). At screening, no difference was found between the two groups. A total of 80 foci were identified in 59 patients with sufficient EEG data. Most of them had only one focus, 15 had two, and 3 had three independent foci. The number of patients with EEG normalization was significantly higher in the STM group than in the placebo group. EEG normalization was transient in 12 of 31 in the STM and 4 of 35 in the placebo group and persistent in 9 in the STM and 1 in the placebo group. Using a complex score for intraindividual comparisons during follow-up, the STM group displayed a significant improvement of this EEG score at 4 weeks and at 3 and at 6 months (50).

In another study, the EEG in 21 of 25 children with BECTS and related disorders was controlled 3 to 6 months after the introduction of STM. In 4 of 21 a total disappearance; in a further 9 of 21 a marked decrease of discharges in the EEG was seen. Of these 13 children with EEG improvement, a second control EEG remained normal, respectively further improved, in 9 cases. In the EEG of the 4 remaining children epileptiform discharges increased again compared to the first control (36). In another group of patients with benign partial epilepsies of childhood, EEG data before and during STM treatment were available in 20 of 39 patients. Complete EEG normalization was obtained in 13 patients 1 to 3 months

after initiation of treatment. This EEG normalization was transient in all patients, although seizure control was maintained (37). Similar data were reported in an open trial in 27 children with BECTS; in 70.4% the EEG was normalized.(40) In his retrospective study, Gross-Selbeck emphasized the EEG features and treatment-induced EEG changes in BECTS. Of 33 patients suffering from typical and atypical rolandic epilepsy, 16 were treated with CBZ. In this group, the EEG showed no clear improvement, the patients suffered even temporary EEG deterioration, whereas in 14 of 17 patients treated with STM the EEG showed clear improvement and normalized in 7 children (34). In a study comparing CBZ and STM, EEG normalization was defined only for patients who became seizure free and in whom an EEG was done during the first year after the last seizure. EEG data were available in 19 patients who became seizure free with CBZ; in 8 of those 19 the EEG was normalized. In the STM group EEG data were available for 7, who responded to STM; 5 of 7 had a normalized EEG (38).

Since the first description of subclinical electrical status epilepticus during sleep (ESES) in children by Patry et al (51), later called CSWS, there is an ongoing debate on the relationship between BECTS and related syndromes such as atypical rolandic epilepsy, CSWS, or Landau-Kleffner syndrome. CSWS has been observed to develop in children with prior idiopathic partial epilepsies—either BECTS (34, 47) or idiopathic childhood occipital epilepsy (48). It was suggested to try STM in these conditions. In a study on STM in typical and atypical rolandic epilepsy and related epilepsy syndromes ( $n = 21$ ), 4 children with cognitive disturbances associated with “focal sharp waves” but without recognized clinical seizures were included and treated with STM. A total of 19 of 21 of all children were investigated by formal neuropsychological testing before and under STM therapy. Neither stagnation nor decline of individual performance was observed. In the four cases without seizures, an improvement of test performance could be documented; but the authors stated that it was not possible to conclude with certainty whether this was the natural evolution or the result of decreased epileptiform discharges (36). Gross-Selbeck reported improvement of language and overall intellectual development in children with atypical benign partial epilepsy and Landau-Kleffner syndrome after STM, which was accompanied by an EEG improvement not obtained with various other AEDs tried previously (34).

Besides its effect on idiopathic rolandic spikes, STM also seems to be effective against focal discharges in symptomatic epilepsy. In adult patients with temporal lobe epilepsy (TLE) (age, 16–43 years) the EEG showed “considerable improvement” in 20 of 35 “marked responders” (>75% reduction of seizure frequency), follow-up being at least 6 months (52). But there is also

contradicting evidence. In a prospective blinded study the number of epileptiform discharges during the first 20 minutes of each waking tracing or the first 20 minutes of sustained sleep EEG was counted. More patients treated with STM showed an increase in epileptiform patterns than those taking PHT (53). Whereas 8 of 13 patients completing the trial had fewer epileptiform patterns compared to baseline at the end of the PHT phase, in 11 of 16 patients the number of epileptiform patterns increased when taking STM. Recently, Kurlemann et al reported on 48 children suffering from symptomatic epilepsies with simple or complex partial seizures and found—besides the clinical improvement—an EEG normalization in 65% of the patients receiving STM (40).

### ADVERSE EFFECTS

Data coming from prospective studies are insufficient to draw final conclusions on adverse effects in STM, because the number of patients is limited and the observation time short. There are no severe, life-threatening adverse effects described. In prospective and retrospective studies, most often hyperventilation or dyspnea are reported. Somnolence or drowsiness or apathy and paresthesias in the fingers and periorally are other frequently encountered side effects. Hyperventilation and apathy are certainly dose related. This does not seem to be true for paresthesias. Still, all three symptoms may disappear even if the STM dose remains unchanged. Fenton et al reported on one adult with a pronounced hyperventilation and an increased ventilation at rest. The ventilatory capacity was normal and  $p\text{CO}_2$  was substantially reduced but returned to normal after cessation of STM (43). Tröger et al found a decrease in serum bicarbonate and pH and elevated base excess, that is, signs of a mild compensated metabolic acidosis (54). This adverse effect can easily be explained by the inhibition of carbonic anhydrase activity by STM.

Already in the older literature of the 1960s and 1970s psychiatric problems were reported with the higher doses of STM used at that time. In a retrospective multicenter study on 125 patients with different epilepsies and epileptic syndromes, adverse effects associated with STM were regarded “as minimal” (37); main adverse effects were hyperventilation (19), paresthesias (8), and drowsiness (5). However, psychiatric syndromes (3), anorexia (2), sensation of fear (2), and forced normalization (1) were reported. STM discontinuation was necessary in 4 because of psychiatric problems (3), hyperventilation (1), and paresthesias (1). Tröger et al reported a 4.5-year-old boy receiving 15 mg/kg/day of STM developing hallucinatory symptoms after 3 weeks. The authors claimed that drug-associated metabolic acidosis caused this symptom; it disappeared within 1 day after discontinuation of STM (54). Poor concentration,

depressed mood, fatigue, and lack of drive were observed in a 9-year-old boy with BECTS treated with STM in a dose of 5 mg/kg/day. The Developmental Test of Visual Perception (Frostig) revealed a significant drop in performance (55). In rare cases children taking STM became unable to conduct even simple mathematical tasks that they had been able to perform without any difficulty before (own observation, unpublished). Already in 1964, Fenton et al reported the "inability to think clearly" in three adults under STM (43). All these disturbances resolved within a few days, or even within hours after discontinuation of STM (23). Comparing CBZ and STM in an open, multicenter trial on 111 patients, 11 of 73 taking CBZ discontinued the treatment because of adverse reactions and 4 of 27 taking STM discontinued treatment because of paresthesias ( $n = 3$ ) or severe behavioral problems ( $n = 1$ ) (38).

It had been speculated that STM, as a weak carbonic anhydrase inhibitor, like acetazolamide or zonisamide, may change the urinary pH, thus increasing the risk of urolithiasis. Nevertheless it was shown that urinary pH remains in the normal range with STM treatment (56). In concordance with these findings crystalluria is less often observed in children taking STM than in those taking acetazolamide or zonisamide, indicating an elevated risk of developing urolithiasis (57).

There is one report on a reversible adverse effect on liver function. A 10-year-old child receiving 4.3 mg/kg/day STM developed a progressive elevation of liver enzymes alanine aminotransferase (ALT), aspartate aminotransferase (AST), and gamma-glutamyl transpeptidase (GGT) to a maximum of 946 U/L, 416 U/L, and 68 U/L, respectively, without any other clinical signs of hepatic disturbance except for a mild increase in bilirubin to 1.2 mg/dL. All laboratory findings normalized within 6 weeks after discontinuation of STM (58). There are no other reports on adverse effects influencing hepatic function, blood count, or renal function.

## CLINICAL USE (INCLUDING PREPARATIONS, DOSAGE, TITRATION, AND PRECAUTIONS) AND LABORATORY MONITORING

For the treatment of BECTS and related epileptic syndromes a dose of 4 to 8 mg/kg/day of STM is recommended. In West syndrome, the STM dose should be increased from 5 to 10 mg/kg/day up to 20 (to 25) mg/kg/day. Whether in older children the intake of more than 10 mg/kg/day is of any benefit is still under discussion. Though half-lives are short and require, in theory, three daily doses, we believe from our clinical experience that two doses per day are sufficient in most cases.

Although no specific adverse effects are described, blood count and renal and hepatic functions should be checked every 6 to 12 months, as in any long-term treatment. In the special case of severe hyperventilation it is worthwhile to check base excess, bicarbonate level, and  $p\text{CO}_2$ ; in some children the addition of bicarbonate may be useful to help continuing treatment with STM.

Serum levels need not be controlled in patients treated with STM. The dose should be titrated according to efficacy and side effects.

STM is available at least in Argentina, Australia, Austria, Czech Republic, Germany, Hungary, Israel, Slovakia, and Switzerland.

No allergic reactions were reported in cases with known sulfonamide intolerance. STM should be used with caution in acute porphyria, hyperthyroidism, hypertension, and decreased renal function (46). There are no data regarding teratogenicity of STM in humans. In rats STM significantly reduced placental and fetal weight secondary to reduced food intake by pregnant animals treated with 100 to 300 mg/kg/day. A slight, however significant, reduction in the birth weight of rat pups is found even after 30 mg/kg/day STM during pregnancy. No malformations have been reported so far.

## Tiagabine

**Shlomo Shinnar**

**Richard Civil**

**Kenneth W. Sommerville**

**I**n the last few years, a new generation of antiepileptic drugs (AEDs) has been developed (1, 2), with much interest in drugs that work on the gamma-aminobutyric acid (GABA) system. GABA is the primary inhibitory neurotransmitter in the mammalian nervous system (3, 4). Increasing the effects of the GABA system is theorized to prevent seizures. This type of prevention has already been noted with the barbiturates and benzodiazepines, which act on the GABA receptor. Valproate, a GABA analog, is an effective AED against a variety of seizure disorders, although its precise mechanism of action remains unclear (5, 6). Recent attempts to utilize the GABA system have focused on GABA metabolism and have resulted in the development of two new drugs. One drug, vigabatrin (Chapter 54), available in much of the world but still experimental in the United States because of concerns about retinal toxicity, is an irreversible inhibitor of GABA transaminase (1, 5, 7). By blocking degradation vigabatrin raises the levels of GABA. The second drug, tiagabine (Gabitril), was approved by the FDA for the adjunctive treatment of partial seizures in adults and adolescents in 1997.

Tiagabine was developed as a designer drug to block GABA uptake by presynaptic neurons and glial cells (1, 3, 8–13). This blocking should increase GABA concentration in the synapse, resulting in longer duration of action

in the synaptic cleft without substantially altering total brain GABA levels. Tiagabine has undergone extensive clinical trials in adults with intractable partial seizure disorders (14–19). Less information is available on the use of tiagabine in children, although some clinical trials were done (20–23). In this manuscript, we review the available data on tiagabine with an emphasis on its use in the pediatric age group. Because tiagabine is a relatively new drug and its use in epilepsy has decreased over time, the pediatric data are relatively sparse. This chapter reviews the available data, including the recent safety data, with an emphasis on the pediatric aspects.

### PHYSICOCHEMICAL CHARACTERISTICS

Tiagabine hydrochloride is a whitish, odorless crystalline powder with the chemical name (-)-(R)-1-[4,4-Bis(3-methyl-2-thienyl)-3-butenyl] nipecotic acid hydrochloride. The chemical formula is  $C_{20}H_{25}NO_2S_2 \cdot HCl$ , and the structure is shown in Figure 51-1. It is 3% soluble in water and is insoluble in hexane. The nipecotic acid moiety of the molecule has an asymmetric carbon, and the R (-) enantiomer is four times more potent than the S (+) enantiomer. The name *tiagabine* refers to the R (-) enantiomer, which consists of nipecotic acid joined to a lipophilic anchor.

FIGURE 51-1

Chemical structure of tiagabine HCl.

Animal experiments demonstrated that nipecotic acid was anticonvulsant and could preferentially block glial and neural GABA uptake in mice (24). However, nipecotic acid had to be injected intracerebrally in animals because it did not cross the blood-brain barrier. The addition of a lipophilic anchor to nipecotic acid allowed passage across the brain barrier and maintained the desired property of blocking GABA uptake. The resulting compound is tiagabine hydrochloride and is referred to as tiagabine.

### MECHANISM OF ACTION

Tiagabine increases the amount of GABA available in the extracellular space by preventing GABA uptake into presynaptic neurons, as schematically shown in Figure 51-2. The increased GABA enhances inhibitory

FIGURE 51-2

Tiagabine inhibits the uptake of gamma-aminobutyric acid (GABA) in the synaptic cleft.

effects on receptors of postsynaptic cells. This effect was confirmed in hippocampal rat slices, in which tiagabine prolonged GABA-mediated inhibitory postsynaptic potentials (25).

In-vitro work in adult rats has shown that tiagabine blocks GABA uptake by binding in a stereospecific and saturable fashion to the GABA recognition sites in neurons and glial cells (26). Tiagabine binds to a class of high-affinity binding sites that most likely represent the GABA transporter GAT-1 (27).

The action of tiagabine is confined to blocking GABA uptake. Tiagabine is not itself taken into neurons or glia. Tiagabine is highly selective for the GABA system and does not affect other neurotransmitters. Tiagabine binds weakly to the benzodiazepine and  $H_1$  receptors, but only at concentrations 20 to 400 times those required to inhibit GABA uptake (26). This binding is unlikely to be clinically relevant.

Tiagabine is an anticonvulsant in a variety of animal models of epilepsy, including pentylenetetrazol (PTZ)-induced seizures (11), DMCM-induced seizures (8), and, at high doses, seizures induced by maximal electroshock (11) (DMCM, methyl 6,7-dimethoxy-4-ethyl-beta-carboline-3-carboxylate, is a proconvulsant that is an inverse agonist of the benzodiazepine receptor).

Tiagabine has shown other anticonvulsant activity in animal models. Tiagabine suppresses amygdala-kindled seizures in rats (8) and is effective in treating convulsive status epilepticus in cobalt-lesioned rats (28). Tiagabine also has moderate efficacy in the genetically determined generalized epilepsy in photosensitive baboons. Tiagabine may have a proconvulsant effect that has been noted with other AEDs. Spike-and-wave discharges were noted after control of motor status at doses of more than 5 mg/kg in both lesioned and normal rats (28). In a strain of rats (WAG/Rij) that are genetically prone to epilepsy—a strain that is considered an animal model of generalized nonconvulsive absence epilepsy—type II spike wave discharges were increased at dose of 3 mg/kg and 10 mg/kg, but not at doses of 1 mg/kg, which is closer to the therapeutic range (29). In these epilepsy-prone rats, the increase in spike-wave discharges was not correlated with behavioral abnormalities in the animals. These data suggest that tiagabine may exacerbate absence seizures. However, tiagabine is effective in blocking PTZ-induced seizures, which often predicts efficacy against generalized seizures.

The adult animal data suggest that tiagabine may have efficacy in treating some types of both partial and generalized seizure disorders. Data are lacking on the effects of tiagabine on experimental seizure models in the developing brain of animals. This lack is unfortunate, because some AEDs have age-dependent effects on seizures (30–32), but it is a common problem with all AEDs in early clinical usage.

## METABOLISM AND PHARMACOKINETICS

Animal studies have shown that tiagabine is rapidly absorbed and has a short half-life, 1 to 3 hours in rats and 1 to 2 hours in dogs. Bioavailability is 25% in dogs and 50–75% in rats (9). Tiagabine, like many other AEDs, is metabolized by the hepatic cytochrome P450 system (33). Metabolites include 5-oxotigabine, which is excreted in the urine. Tiagabine is also conjugated with glucuronic acid, and metabolites are excreted via urine and via feces through the biliary system (9).

Studies in adult volunteers have shown that tiagabine is rapidly absorbed from the gastrointestinal tract and peak plasma concentrations ( $C_{max}$ ) are achieved within 2 hours. Absorption is linear and independent of the dose (34). The rate—but not the extent of absorption—is reduced by food. The time to peak plasma concentration ( $T_{max}$ ) after a meal is more than twice that in the fasting state. However, although the  $C_{max}$  is lower, the area under the curve (AUC) is similar (35). Clinical trials were therefore performed with patients taking tiagabine after a meal in order to reduce the possible peak-related toxicities without altering the total amount of drug absorbed.

In normal volunteers, the mean half-life of tiagabine is 4 to 9 hours and is independent of the dose. Because tiagabine is metabolized by the hepatic cytochrome P450 system, it has a shorter half-life in patients taking drugs that induce that system, such as barbiturates, carbamazepine, and phenytoin (36). When given in single or multiple doses, tiagabine does not appear to induce or inhibit hepatic microsomal enzyme systems (34, 37).

Tiagabine is extensively metabolized by the hepatic microsomal system because less than 2% is excreted unchanged in the urine (34, 38, 39). Radiolabeled [ $^{14}C$ ]tiagabine studies in human volunteers showed that 25% was excreted in the urine and 63% in the feces (40). Tiagabine has no identified active metabolites (40). Tiagabine does not appear to accumulate appreciably in plasma with multiple dosing. In Phase I studies of healthy volunteers given daily doses over a 5-day period, both the peak levels and the AUC increased proportionally with the dose, as would be expected in a drug with linear pharmacokinetics (34). The therapeutic half-life, as distinct from the serum half-life, is unclear. Microdialysis studies in patients given oral tiagabine demonstrated extracellular GABA levels in the brain that rise within about 1 hour after oral dosing (41) but are not sustained more than a few hours and do not completely correlate with the serum concentrations (40). The duration of the antiepileptic activity, which is presumably mediated by these changes in GABA, remains unclear and has not been precisely studied.

Tiagabine is heavily protein bound, although it does not appear either to displace or to be displaced by most of the commonly used drugs (42, 43). In-vitro studies

showed that tiagabine is over 95% protein bound, primarily to albumin and a glycoprotein.

Tiagabine pharmacokinetics were studied in patients with epilepsy who were taking tiagabine as add-on therapy. Steady state tiagabine doses ranged from 24 to 80 mg/day in four divided doses (44). All patients were taking enzyme-inducing concomitant AEDs. Results showed that tiagabine had linear kinetics in this population also, with a linear dose-response curve for peak concentrations ( $C_{max}$ ) as well as for the AUC. Although the kinetics remained linear, the half-life of tiagabine was shorter in patients taking AEDs that induce the cytochrome P450 system than for those on monotherapy or taking noninducing AEDs (36). This difference is expected and explains why the dosages used in this study were considerably higher than those tolerated by healthy volunteers who were not taking enzyme-inducing AEDs. The dosage ranges in this study exceeded the upper doses of 56 mg/day used in the randomized clinical trials in the descriptions that follow.

The most important drug interaction of tiagabine to date is the effect of enzyme-inducing AEDs. The half-life of tiagabine was shorter and the AUC smaller for the same dose in patients receiving enzyme-inducing AEDs (carbamazepine, phenytoin, phenobarbital, primidone) than in those on tiagabine monotherapy (9, 36, 45). The pharmacokinetics of tiagabine in patients taking an AED that was not enzyme inducing, such as valproate, were similar to those in healthy volunteers. Dosages of tiagabine need to be substantially higher in patients taking concurrent enzyme-inducing AEDs than with monotherapy or noninducing AEDs. Similar guidelines have been suggested for the recently approved AED lamotrigine (46, 47). Although the half-life of tiagabine is shortened by the concurrent use of enzyme-inducing AEDs, it is not prolonged by the concurrent use of valproate, as is the case with lamotrigine and phenobarbital (46–49).

Tiagabine has little effect on other AEDs. Tiagabine does not appear to affect the kinetics of carbamazepine or phenytoin (42). However, tiagabine did reduce the peak concentration and the AUC of valproate by approximately 10% (49). The reason for this reduction is expected to be of little or no clinical importance. Because tiagabine is metabolized by the 3A isoform subfamily of the hepatic cytochrome P450 system (33), there is potential for interaction with other drugs with similar metabolism, including other AEDs, cimetidine, theophylline, warfarin, and digoxin. However, no clinically significant interactions have been found between tiagabine and these drugs (43). Surprisingly, a recent study showed no interaction with erythromycin (50).

Oral contraceptives are also metabolized by the cytochrome P450 system. In one study, tiagabine, given at a dose of 8 mg/day as monotherapy to healthy young women, did not affect the metabolism of oral contraceptives (37, 43). Higher doses of tiagabine would not be

expected to have an interaction because tiagabine is neither an inducer nor an inhibitor of the cytochrome P450 system, but data are lacking to confirm this impression.

Tiagabine pharmacokinetics behave predictably in hepatic and renal disease (51, 52). There is no effect from renal impairment, and there is reduced clearance and a longer half-life with hepatic impairment. Patients with hepatic disease require lower doses to attain similar concentrations than healthy subjects.

Single-dose tiagabine pharmacokinetics have been studied in children (20). In this study, 25 children ages 3–10 with complex partial seizures who were taking one AED were given a single dose of 0.1 mg/kg of tiagabine, and plasma concentrations were checked over the next 24 hours. The mean half-life of tiagabine was 3.2 hours in the 17 children on enzyme-inducing concomitant AEDs (carbamazepine or phenytoin) and 5.7 hours for the 8 children on valproate (noninducing AED). This result is comparable to the adult data. Clearance rates, peak plasma concentrations, and AUC of tiagabine were affected by the concurrent AEDs in a manner similar to adults. The clearance of tiagabine was two times higher in children than in noninduced adults with epilepsy when the rate was adjusted for body weight. However, when adjusted according to body surface area, clearance rates of tiagabine in children were 1.5 times higher than in noninduced adults with epilepsy. The results indicate that tiagabine pharmacokinetics in children ages 2 and older are similar to those in adults, including the effects of concurrent AEDs. Infants have not been studied.

The initial studies of tiagabine were done in patients who were also on other AEDs, primarily enzyme-inducing ones such as carbamazepine. Subsequently, it has been used in conjunction with AEDs that are not enzyme inducing, as well as in monotherapy. The effect of enzyme-inducing AEDs is clearly much stronger than had been appreciated. It appears that the dose of tiagabine for someone who is not on enzyme-inducing AEDs is less than half that for someone who is. Failure to appreciate this difference when tiagabine is used in conjunction with the newer AEDs that are not enzyme inducers can result in significant toxicity.

## DATA ON HUMAN ADULT EFFICACY

### Add-On Therapy in Adults with Partial Seizures

The clinical data regarding the efficacy of tiagabine as add-on therapy come from five placebo-controlled clinical trials in patients with intractable partial seizures. In all five trials, tiagabine was statistically significantly more effective than placebo in the treatment of one or more partial seizure types (53). Two of the studies were crossover and three were parallel group. Most of the patients were adults ages 18–75; however, adolescents

starting at age 12 were also included. Thus, efficacy data are available in this age group, although in a relatively small number of patients. Pediatric trials in younger children are in progress, and the available data are discussed separately.

The first Phase II multicenter study was a crossover design performed in Europe with 94 patients ages 18–65 with refractory complex partial seizures (14). The study had an “enrichment” design. Patients started with a dose of 8 mg/day of tiagabine and titrated the dose to either reduce seizures sufficiently or produce unacceptable adverse events with a maximum dose of 52 mg/day. Patients who improved in this phase were then enrolled in a double-blind trial. Of the 94 patients enrolled, 20 discontinued participation during the open-label phase, and another 28 failed to qualify for the double-blind phase for lack of sufficient reduction in seizures. The average total daily dose of tiagabine in the 42 patients in the double-blind phase was 33 mg/day, and most were taking a concomitant enzyme-inducing AED. Even with this relatively small sample size, the frequency of complex partial seizures only and partial seizures with secondary generalization was significantly reduced when the tiagabine and placebo phases were compared. Details of the second crossover trial have not yet been published, but the results were similar to the first study (53).

The three randomized Phase III multicenter, placebo-controlled, double-blind, parallel-group studies in adults included two studies in the United States and one in Europe. All of these studies showed that tiagabine was significantly superior to placebo as adjunctive treatment of partial seizures.

The first U.S. study (15) was a dose-response study, with patients receiving placebo, or 16, 32 or 56 mg/day of tiagabine in addition to their regular stable AED regimen. Tiagabine was significantly better than placebo at both 32 and 56 mg for median change from baseline and proportion of patients achieving at least 50% reduction in complex partial seizures (in both,  $P < 0.03$ ). Tiagabine was effective for both median change from baseline and proportion with  $>50\%$  reduction in the groups receiving 16, 32, and 56 mg for simple partial seizures.

Partial seizures with secondary generalization were reduced compared to placebo, but this reduction did not reach significance, possibly because of fewer patients and numbers of seizures. A clear dose response was present in this study. The minimum effective dose of tiagabine necessary to achieve a reduction of 50% in complex partial seizure frequency was 32 mg/day, with the group at 56 mg/day showing a better response. Doses greater than 56 mg were not studied in this trial. Note that the patients in this study and in the other two randomized studies were all taking one to three concurrent AEDs, at least one of which was required to be an inducer of the cytochrome P450 enzyme system. Thus, as discussed

in the metabolism section, the doses required in monotherapy, or with a single concomitant noninducer such as valproate, are substantially smaller than when used together with an enzyme-inducing AED such as carbamazepine. The patients in this study were, by and large, a very refractory group with a median duration of epilepsy of 20 years, who had failed to respond to a median of seven AEDs prior to study entry.

The second U.S. multicenter, randomized, double-blind, placebo-controlled parallel-group trial compared placebo to 32 mg/day of tiagabine as add-on therapy in 318 patients (16). In this dose-frequency trial, the tiagabine patients received a total of 32 mg/day as 16 mg twice a day or as 8 mg four times a day. Both groups were superior to placebo ( $P < 0.001$ ) in the number of patients achieving a reduction greater than 50% in complex partial seizures. Both groups were also superior to placebo for simple partial seizures, for either reduction from baseline or proportion, with a reduction in seizures of at least 50%. Taken together with the prior study, the data suggested that the add-on dose of 32 mg/day was likely to be in the low therapeutic range for enzyme-induced patients.

The multicenter European double-blind, parallel-group study was the only adjunctive trial to evaluate tiagabine given three times daily (TID) (54). Tiagabine was given as 10 mg TID or 8 mg TID if a dose of 30 mg/day was not tolerated. There were 154 patients randomized to tiagabine ( $n = 77$ ) or placebo ( $n = 77$ ). The tiagabine-treated group had a significant reduction in both the number of complex and simple partial seizures.

Tiagabine consistently demonstrated efficacy against partial seizures in these trials, but the dose ranges chosen were probably too low in enzyme-induced patients to establish its upper therapeutic range and maximum efficacy. These trials included 67 adolescents ages 12–18 and therefore can be regarded as demonstrating efficacy and safety for this age group as well.

These placebo-controlled trials showed that tiagabine is superior to placebo. The challenge for the practicing clinician is to determine the role of a new AED in the treatment of patients for whom there are a number of other AEDs to consider. Tiagabine has been compared to add-on carbamazepine or phenytoin in a double-blind multicenter study. Placebo and active drug were given in a double-dummy design of patients on baseline carbamazepine receiving add-on tiagabine or phenytoin, or patients on baseline phenytoin receiving add-on tiagabine or carbamazepine. Patients were allowed to titrate to their best-tolerated dose within a wide range to mimic clinical practice.

Preliminary results of the patients taking baseline carbamazepine were recently reported (55). There was no difference in efficacy between the tiagabine group ( $n = 106$ ) and the phenytoin group ( $n = 100$ ) for any

partial seizure type in the intent-to-treat analysis. However, phenytoin patients had greater discontinuations for adverse events (17%) than those on tiagabine (10%). Overall discontinuation rates also favored tiagabine (31% vs. 22%). However, further studies are needed before the precise role of tiagabine in treating refractory partial seizures can be determined.

### Monotherapy Trials

There have been three studies of tiagabine monotherapy in adults with partial seizures (56, 57). The first was a double-blind randomized pilot study of 11 patients who had their AEDs discontinued while they were in the hospital undergoing monitoring for presurgical evaluation (57). Patients receiving tiagabine had fewer seizures than those receiving placebo during the treatment period. In the second study (56), which was an open-label, dose-ranging study, 19 of 31 patients (61%) successfully converted to tiagabine monotherapy. In the third study, which included 198 randomized patients with partial seizures, patients were randomized to daily doses of tiagabine as either 6 or 36 mg/day. Baseline AEDs were discontinued after tiagabine was added on. Seizure frequency was reduced in both the low- and high-dose groups, with the high-dose group having a significantly higher proportion of patients who experienced a reduction in seizure frequency that was greater than 50% (56). The following open-label pediatric data have also been promising (22).

### Human Pediatric Efficacy Data

In an open-label pilot study (22), 25 children with refractory complex partial seizures from a single-dose pharmacokinetics study (20) were enrolled in an open-label, long-term study. Children were initially taking a dose of 0.1 mg/kg/day of tiagabine. They were also continuing a baseline concomitant AED. The dosage was increased every two weeks by 0.1 mg/kg/day until clinical efficacy or toxicity was reached. The results of this study have been encouraging for the use of tiagabine in children. As of January 1996, 23 of 25 children were still taking tiagabine. Of 21 patients treated for greater than 6 months, 19 (90%) had a reduction in the frequency of complex partial seizures that was greater than 50% compared with historical seizure rates. These children had previously uncontrolled partial seizures. For these children, the median 4-week historical baseline rate for complex partial seizures was 5 (range 1–90) and mean 21.1. Conversion to tiagabine monotherapy had been possible for 16 of the children, and they had been seizure-free at least two months on a mean dose of 0.31 mg/kg/day.

The other pediatric study was a dose-ranging, multicenter, add-on study, conducted at three European sites, of 52 children ages 2–15 with epilepsy with a variety of

seizure types and epilepsy syndromes refractory to other AEDs (21). The results are unfortunately difficult to interpret because of the heterogeneous nature of the epilepsy disorders in the study. Twenty-two of the children had generalized epilepsies, including Lennox-Gastaut syndrome; others had myoclonic seizure disorders, infantile spasms, or childhood absence. Before entry into the trial, the children had been unsuccessfully tried on 3–16 other AEDs, including carbamazepine, valproate, and vigabatrin for more than 80% of them.

This study differed from the U.S. open-label study. After a placebo lead-in period of three weeks, tiagabine was given at more rapid escalating doses than in the U.S. study of 0.25 mg/kg/day up to 1.5 mg/kg/day. Dose escalation in the U.S. study was by 0.1 mg/kg/day at no faster than weekly intervals. Patients who completed this phase either entered a long-term extension study or were withdrawn from tiagabine. Of the 53 patients enrolled, 47 entered the tiagabine-dosing phase. Of these, 20 completed the trial and 20 withdrew for lack of efficacy ( $n = 16$ ), adverse events ( $n = 3$ ), or other reasons ( $n = 1$ ). Seven patients were still in the dosing phase when the preliminary report was published (21). Seventeen of 20 patients completing the study entered the long-term extension.

The drug was generally well tolerated (see the following discussion of safety). The study showed no improvement for children with generalized epilepsy, but those with partial seizures improved at doses ranging from 0.37 to 1.25 mg/kg/day. However, the results of this small-scale trial in a very refractory population did not demonstrate a statistically significant effect. These results suggest even more strongly that a controlled trial is needed to determine the place of tiagabine in treating children with partial seizures. The results from the open-label U.S. experience are encouraging, but they need further confirmation.

## SAFETY

### Animal Safety Data

In the preclinical animal studies of tiagabine, there was a large therapeutic window because doses producing sedation were 2.5- to 30-fold greater than the doses treating seizures (58). Other studies in animals have shown no evidence of abnormalities relevant to humans or of carcinogenicity, mutagenicity, or teratogenicity (9).

### Adult Data

Phase I studies in healthy volunteers showed that multiple doses of tiagabine were well tolerated up to 10 mg/day (39) and that side effects greater than those with placebo were noted when the initial dose reached 12 mg/day (59). The side effects included difficulty concentrating, lightheadedness,

impaired visual perception, and confusion. The side effects increased at higher initial doses. These doses may be lower than what might be tolerated by patients taking enzyme-inducing concomitant AEDs, in whom the clearance of tiagabine is greater.

Clinical trials of tiagabine therapy in patients with epilepsy have shown an adverse-events profile that was favorable and comparable to many of the current AEDs. The most common adverse events involved the central nervous system and were usually mild to moderate and transient. In the U.S. multicenter dose-response trial, adverse events sufficient to require discontinuation of the drug occurred twice as often in the groups receiving 32 mg/day (15%) and 56 mg/day (16%) of tiagabine as in the groups receiving placebo (8%) or 16 mg (7%) of tiagabine (15). The side effects with significantly higher incidence in tiagabine-treated patients were dizziness, tremor, and difficulty concentrating or mental lethargy. Adverse events in the second U.S. study, which used a dosage regimen of 32 mg/day (either twice or four times per day), were similar to those in the first study but milder (16). Again, the percentage of patients withdrawn from the study as a result of adverse events was higher in the combined tiagabine groups (10%) than in the placebo group (7%). Nervousness, difficulty with immediate recall (amnesia), and emotional lability were other events of the central nervous system (CNS) that were significantly greater with tiagabine. Abdominal pain, vomiting, and other pain were also significantly increased, but they were usually not attributed to tiagabine. Myalgia was increased with placebo compared to tiagabine given four times per day.

Three monotherapy studies again showed that CNS-related adverse events were the most common (56). These studies may have used higher doses of tiagabine than necessary for clinical practice. One study was a small, inpatient presurgical population; one was an open-label pilot study titrating to the maximally tolerated dose; the third was a controlled high- vs. low-dose conversion-to-monotherapy study. The conversion study enabled an evaluation of dose-related side effects, in which dizziness, trouble concentrating, nervousness, and paresthesia were significantly increased in the high-dose group (36 mg/day). A key finding for safety in the open-label pilot study was that patients converting to monotherapy from enzyme-inducing AEDs demonstrated deinduction of tiagabine clearance. The dose of tiagabine may need to be reduced when monotherapy is reached because tiagabine concentrations rise without an increase in dose when the inducing AED is discontinued. This does not occur if the concomitant AED is a single noninducer such as valproate.

Neuropsychologic testing has been performed in add-on studies and in the controlled conversion-to-monotherapy study (18, 19, 60). Compared with placebo,

tiagabine had no adverse effects on neuropsychologic test scores in both an add-on Finnish study using 30 mg/day (18) and in the multicenter U.S. dose-response study using 16, 32, and 56 mg/day (19). The multicenter U.S. high- vs. low-dose conversion to monotherapy study showed results related to both dose and whether monotherapy was attained (60). Patients achieving monotherapy improved in mood in the low-dose group, whereas abilities improved in the high-dose group. There was worse performance for mood in the high-dose group if monotherapy was not reached. The reasons for improvement did not correlate with control of seizures and may have been from benefits of withdrawing the baseline concomitant AED, better tolerance of tiagabine, or both.

Long-term safety data from the open-label studies have also been reassuring. There have been no clinically relevant changes in laboratory values for hematological or hepatic function. The most commonly reported adverse events were dizziness, somnolence, accidental injury, asthenia (lack of energy), and headache, which are similar to those in the randomized studies (17). Accidental injury and headache are common in populations with severe epilepsy. These adverse events were usually mild and transient and did not require discontinuation of tiagabine therapy. In the long-term open-label clinical trials of tiagabine in the United States, 220 of 1437 patients (15%) have discontinued therapy for adverse events (61).

Recently, loss in the peripheral visual field has been reported in patients treated with vigabatrin (62). Theoretically, this is a concern for all GABAergic drugs, including tiagabine. However, the mechanism of action of tiagabine is different than that of vigabatrin. Tiagabine does not cause total GABA levels in the brain to rise and is only associated with a transient rise in extracellular GABA concentrations (41). Review of the database on tiagabine safety and a study of visual fields by Novo Nordisk have found no comparable visual abnormalities that are attributable to tiagabine therapy to date (K Sommerville, MD, personal communication).

Safety data have also been published on tiagabine overdose (63, 64). There were 22 overdoses in clinical trials as of the end of 1996, with the highest single dose of 800 mg. The most common symptoms were ataxia, confusion, somnolence, agitation, hostility, speech difficulty, weakness, impaired consciousness, and myoclonus. All patients completely recovered. One adolescent had generalized tonic-clonic status epilepticus from a 400-mg overdose but recovered after treatment with phenobarbital. Only supportive care is generally recommended. These findings suggest that the margin of safety with tiagabine is large.

The experience in pregnancy is limited to 21 cases from clinical trials as of October 1996 (65): 9 fetuses were carried to term; 8 were healthy, and 1 had a hip

displacement attributed to a breech presentation. There were 5 elective abortions, 4 women had miscarriages, 1 had a blighted ovum, and another had a salpingectomy for an ectopic pregnancy. The remaining patient drowned in a bathtub during a seizure after discontinuing tiagabine three months earlier. Postmortem examination showed a healthy fetus of 5 months.

## DATA ON PEDIATRIC SAFETY

The safety data in children have also been reassuring. Children in the U.S. open-label pharmacokinetics trial tolerated the drug well in single doses of 0.1 mg/kg (20). Nine of 25 (36%) children reported adverse events, with somnolence being the most common ( $n = 7$ ). One other patient reported a headache, and another had pain at the site of the heparin lock used for sampling blood. All adverse events were mild in severity and resolved without treatment. These children have also tolerated tiagabine very well in a subsequent open-label, long-term study (22). As of January 1996, 23 children were taking tiagabine on an ongoing basis, without discontinuation for adverse events.

The data from the European pediatric study that used higher doses and a more rapid titration were also comparable to adult data (20). Three of 47 children were withdrawn from tiagabine for adverse events, including ataxia ( $n = 2$ ), somnolence ( $n = 1$ ), and depression ( $n = 1$ ). Two additional children had been hospitalized, but both had complete recoveries and were discharged on the same dose of tiagabine. The common adverse events were CNS related and were similar to those in adults. Most were mild to moderate in severity and resolved without requiring discontinuation of the drug.

## TIAGABINE AND STATUS EPILEPTICUS

Soon after the introduction of tiagabine into clinical use, there were reports of possible nonconvulsive status epilepticus associated with tiagabine therapy (66, 67). One report described two patients with confusion and reduced consciousness and simultaneous generalized spike wave discharges on electroencephalogram (EEG) (67). The authors suggested that this reaction may be from GABA<sub>B</sub> receptor agonism and that frontal lobe foci (present in both patients) may be a risk factor. The reports, however, did not confirm that the patients had nonconvulsive status epilepticus or that tiagabine was the cause. The first patient improved slightly after intravenous diazepam and then spontaneously improved 3 hours later. The second patient deteriorated 5 days after a reduction in tiagabine dose of 25%, suggesting that the possible nonconvulsive status was precipitated by a dose reduction.

An additional 13 cases of possible spike-wave discharges and impaired mental status associated with tiagabine therapy have been intensively reviewed (68). The medical histories and pretreatment EEGs were located and reviewed by an advisory panel. Eight of the cases were thought to have preexisting generalized spike-wave abnormalities that worsened with poorly tolerated increases in tiagabine dose. These patients improved with dose reductions and usually continued on tiagabine at lower doses. Three patients had nonconvulsive status epilepticus that could be attributed to their underlying condition. The remaining two patients either improved with a higher tiagabine dose or did not have spike-wave discharges. The panel concluded that the evidence so far is that, in the majority of reported cases, tiagabine did not cause the spike-wave discharges, but rather exacerbated preexisting spike-wave patterns in association with poorly tolerated doses. At high doses, a confusional state occurs. However, a few of the cases clearly were nonconvulsive status.

With the wider use of tiagabine, as well as its off-label use in psychiatric conditions in patients with no prior history of seizure, additional safety data have accumulated (61, 69). Koepp et al. (69) retrospectively reviewed the records of patients with intractable seizures treated with tiagabine and compared them to those not treated with tiagabine. They found that 7 of 90 subjects (8%) treated with tiagabine had electroclinically confirmed nonconvulsive status epilepticus compared with 32 of 1165 patients (3%) who were not treated with tiagabine. Although this review was retrospective and may have included ascertainment bias, the results are of concern. More recently, there have been reports of frank convulsions in both children and adults who were being prescribed tiagabine off label for psychiatric conditions not associated with seizures, such as anxiety. Although most cases were in the context of a high dosage or a very rapid titration and other signs of toxicity, a few cases

occurred in a low dose in patients without clear risk factors for epilepsy. This has led to a change in the label to reflect that convulsions can be a rare but serious side effect of tiagabine (61).

## CONCLUSIONS

Results in multiple controlled trials have consistently shown tiagabine to be an effective AED for patients with partial seizures. The profile of side effects appears to be favorable. Pediatric data remain limited. The data suggest that tiagabine is effective in partial seizure disorders in adults and children. At this point, it is fairly clear that tiagabine should not be used in generalized seizure disorders because of its potential to exacerbate generalized spike-wave discharges in both primary and secondarily generalized epilepsies. Tiagabine has great theoretical appeal as a “designer drug” that enhances the availability of GABA at the postsynaptic membrane without interfering with overall GABA metabolism and without altering GABA levels in the brain. However, as with other GABA agents, the results to date have been mixed. Tiagabine has a number of favorable characteristics, including a spectrum of efficacy in animal models and a relative lack of sedation or changes in neuropsychologic testing, which make it an exciting new drug. However, this is offset by a tendency at higher doses to exacerbate seizures sometimes and by the potential to actually trigger seizures in select patients. Unlike many other AEDs whose typical clinical usage is to push to efficacy or clinical toxicity, tiagabine is a drug that, with rare exceptions, should not be used at doses exceeding those recommended. Although it is too early to know the precise role of tiagabine, physicians caring for patients with seizures can add tiagabine as one of the therapeutic options in selected patients with partial seizures. The availability of multiple new agents improves our ability to care for children and adults with seizures.

## Topiramate

*Tracy A. Glauser*

**T**opiramate (TPM) is one of the second-generation antiepileptic medications approved in many countries during the 1990s. It has efficacy against a broad spectrum of seizure types, is effective as monotherapy or adjunctive therapy, and is used extensively in both adults and children. Other favorable characteristics include linear pharmacokinetics, few drug-drug interactions, and a well-described adverse-events profile, with recognizable and reversible adverse events. Overall, TPM has emerged as a valuable antiepileptic drug (AED) for a variety of pediatric and adult epilepsies.

### **CHEMISTRY, ANIMAL PHARMACOLOGY, AND MECHANISM OF ACTION**

#### **Chemistry**

Topiramate, 2,3:4,5-bis-*O*-(1-methylethylidene)- $\beta$ -D-fructopyranose sulfamate, a sulfamate-substituted monosaccharide derived from the D-enantiomer of fructose, is structurally distinct from other anticonvulsant drugs (Figure 52-1) (1, 2). TPM is a white crystalline powder with a molecular weight of 339.37; it is soluble in water and organic solvents at physiologic pH (3); and it has a  $pK_a$  of 8.7 at 25°C (4).

#### **Animal Pharmacology**

##### *Efficacy*

TPM was initially tested in two traditional animal models of epilepsy, the maximal electroshock test (MES) and the pentylenetetrazol (PTZ) seizure test. The MES test has been hypothesized to identify agents effective against partial-onset and generalized tonic-clonic (GTC) seizures and those that have the capacity to prevent the spread of seizures (5, 6). In rats and mice, TPM blocked MES seizures with a potency similar to that of phenytoin (PHT), carbamazepine (CBZ), phenobarbital (PB), and acetazolamide (1). In the subcutaneous PTZ test, a chemically induced seizure model hypothesized to identify agents that raise the seizure threshold, TPM, like PHT, was either ineffective or only weakly effective (1). This activity profile suggests that TPM exerts its anticonvulsant effects by blocking the spread of seizures rather than by raising the seizure threshold. However, TPM did increase seizure threshold in response to an intravenous infusion of PTZ in mice (7), suggesting that TPM possessed an even broader spectrum of action than was originally thought.

TPM was effective in blocking seizures in four other rodent models of epilepsy. In rats, TPM inhibited amygdala-kindled seizures, indicating a potential for activity against complex partial seizures (5, 8). In the

FIGURE 52-1

Topiramate; 2,3:4,5-bis-O-(1-methylethylidene)-beta-fructopyranose sulfamate.

DBA/2 mouse, a strain genetically prone to seizures, TPM blocked sound-induced clonic seizures when administered before the auditory stimulus (9). In the spontaneously epileptic rat (SER), a hereditary model of epilepsy, TPM inhibited tonic and absence-like seizures (9). TPM was also effective in a rat model of post-traumatic epilepsy (10).

TPM's profile of activity in experimental models of epilepsy suggests a multifactorial mechanism of action. The MES test in rats was used to study the development of tolerance to the anticonvulsant effects of TPM. No tolerance was noted after 14 days of TPM, administered at nearly twice the effective dose ( $ED_{50}$ ) (1, 11).

### Toxicity

**Acute studies.** TPM was well tolerated following acute administration in mice, rats, and dogs (4, 12). The estimated  $LD_{50}$  after oral TPM administration in mice and rats ranged from 2338 to 3745 mg/kg. Dogs were more sensitive than mice or rats to the acute toxic effects of TPM, which were primarily central nervous system (CNS) related.

**Multiple-dose studies.** Multiple-dose (3- and 12-month) toxicity studies were performed in rats and dogs. In these studies, reversible gastric mucosal hyperplasia changes were seen that were similar to those reported with carbonic anhydrase inhibitors (13–15). No evidence of dysplasia, aplasia, or any change suggesting tumor formation was apparent. In studies of rats and mice, formation of urinary microcalculi, associated with TPM use, was also consistent with carbonic anhydrase inhibition (16).

**Reproductive studies.** Fertility was not affected by TPM in male or female rats (R. Reife, personal communication), and TPM did not affect pup survival at doses up to 100 mg/kg/day (4).

**Teratology studies.** In teratology studies, TPM caused right-sided ectrodactyly (congenital absence of

all or part of a digit) in rats and rib and vertebral malformations in rabbits (R. Reife, personal communication). These effects of TPM are similar to those reported with acetazolamide and other carbonic anhydrase inhibitors (17–19).

**Protective index.** TPM was selected for development as an AED, based on its high protective index (PI) and its potency and duration of action in tests in rodents (1, 2). The PI can be determined from the ratio of the median toxic dose ( $TD_{50}$ ) from a neurotoxicity test, such as the rotarod test or the loss of righting reflex test, to the MES  $ED_{50}$ . A higher, more advantageous ratio was obtained in rats and mice with TPM than with PHT, CBZ, or PB. For example, with oral doses, the PI for TPM in rats was greater than 116, whereas the values for PB, CBZ, and PHT were 3.5, 20.8, and greater than 60.8, respectively (1).

### Mechanisms of Action

In vitro, TPM demonstrates an ability to modulate ionic channels, enhance inhibitory neurotransmission, and reduce excitatory transmission processes involved in the generation of seizures. Preclinical studies indicate that TPM has at least six mechanisms of action that may contribute to its anticonvulsant activity.

1. **Modulation of voltage-dependent sodium channels:** In cultured rat hippocampal neurons displaying spontaneous activity, micromolar concentrations of TPM reduced the duration and frequency of action potentials associated with sustained repetitive firing (20). TPM also blocked action potentials induced by depolarizing electric currents. (20).
2. **Modulation of glutamate-mediation neurotransmission:** TPM produced concentration-dependent decreases in kainate-evoked inward currents (excitatory currents) in cultured hippocampal neurons without affecting the activity of glutamate receptors of the *N*-methyl-D-aspartate (NMDA) subtype (those modulated by benzodiazepines) (20, 21). In cultured rat amygdalar neurons, TPM postsynaptically antagonizes the action of kainate receptors of the GluR5 subtype (22). TPM protects against seizures in mice induced by the convulsant substance ATPA, a GluR5 kainate receptor agonist (23). TPM has no effect on the NMDA-mediated glutamate receptor type (20).
3. **Promotion of gamma-aminobutyric acid (GABA) activity:** In cultured murine cerebellar granule cells, micromolar concentrations of TPM, in combination with GABA, augmented GABA-stimulated chloride flux into chloride-depleted neurons (i.e., enhanced inhibitory neurotransmission) compared with

GABA alone (7, 24). The effect of TPM on GABA<sub>A</sub> receptors was not blocked by the benzodiazepine antagonist flumazenil, suggesting that a novel or nonbenzodiazepine modulatory site may be involved (7, 25). As measured by magnetic resonance spectroscopy in vivo, TPM increases GABA content in the human brain (26, 27).

4. *Enhancement of potassium channel conduction:* In rat neurons, TPM increases potassium channel conductance (28).
5. *Modulation of voltage-dependent calcium channels:* In rat neurons, TPM inhibits L-type high voltage-activated calcium channels, possibly through a second messenger. (29)
6. *Carbonic anhydrase inhibition:* The sulfamate moiety of TPM is structurally similar to that of the carbonic anhydrase inhibitor acetazolamide. However, the potency of TPM as an inhibitor of erythrocyte carbonic anhydrase is much lower than that of acetazolamide (1). In vitro, TPM does not appear to exert an anticonvulsant effect through inhibition of carbonic anhydrase (1).

This broad activity profile in vitro suggests that TPM may be effective against a number of seizure types.

## BIOTRANSFORMATION, PHARMACOKINETICS, AND INTERACTIONS IN HUMANS

### Absorption and Distribution

In adults and children, TPM has linear pharmacokinetics with low intersubject variability. In adult studies, TPM is rapidly absorbed from the gastrointestinal tract after administration of single oral doses ranging from 100 to 1,200 mg (30). Its estimated bioavailability is approximately 80% (31, 32); its absorption is not significantly affected by food (30).

The volume of distribution of TPM ranges from 0.6 to 0.8 L/kg, which is consistent with a distribution in total body water (33). For most patients, 90% of the maximal plasma concentration ( $C_{\max}$ ) is achieved within 2 hours after oral administration (30), although this can range from 1.4 to 4.3 hours (30), depending on the dose. Mean values for  $C_{\max}$  and area under the concentration-time curve (AUC), which are reflections of drug absorption and clearance, increase linearly with respect to dose in adults (34). TPM is not highly bound to plasma proteins (9%–17%) (35).

### Metabolism and Elimination

In monotherapy, TPM is not extensively metabolized (34). Six trace metabolites of TPM were identified that

represented less than 5% of the sample radioactivity (36). The metabolites, formed by hydroxylation, hydrolysis, and glucuronidation, do not display significant antiepileptic activity (34, 36). In adults, the elimination half-life ( $t_{1/2}$ ) values for TPM when used as monotherapy range from 19 to 25 hours (37).

Renal excretion is a major route of TPM elimination (36). In adults, within a dose range of 200 to 1,200 mg, at least 51% of the dose is estimated to be excreted by the kidneys (30). Because TPM's renal clearance is much lower than its glomerular filtration rate (30), it has been proposed that TPM may undergo tubular reabsorption. In adults, the  $t_{1/2}$  values for TPM, calculated from plasma (mean, 21.5 hours) and urine (mean, 18.5 hours) data, appear to be independent of dose (30). In patients with renal failure (creatinine clearance <30 mL/min/1.73 m<sup>2</sup>), an approximately twofold increase in AUC and  $t_{1/2}$  occurs (38). Therefore, adults with renal impairment may require reduced TPM dosages. During hemodialysis, TPM is cleared from plasma roughly nine times faster than in patients with normal renal function, implying that patients may need additional doses after hemodialysis (39).

Information on TPM pharmacokinetics in children and adolescents was determined from a single-center, open-label outpatient trial of 18 patients with epilepsy (12, 40). Patients ages 4–17 years received an oral TPM dose of up to 9 mg/kg/day in addition to their standard regimen of AEDs. As in adults, pharmacokinetics were linear in children, and plasma clearance was not affected by TPM dose. Compared with adults, clearance values were 54% greater in children when TPM was administered in the presence of enzyme-inducing drugs and 44% greater in the absence of enzyme-inducing drugs (40). Because overall TPM clearance was approximately 50% greater in children than in adults, for any given dose based on weight (mg/kg), steady state TPM plasma concentrations would be predicted to be approximately 33% lower in children than in adults.

Two studies have examined TPM pharmacokinetics in young children. TPM's mean plasma clearance, in a study of five children ages 2–2.5 years, was slightly higher than that reported for children and adolescents; the plasma clearance was higher in infants on concomitant enzyme-inducing AEDs than in those on nonenzyme-inducing concomitant AEDs (41). In another study of 22 children (ages 6 months to 4 years), TPM's oral clearance was significantly higher in infants and young children on concomitant enzyme-inducing AEDs ( $85.4 \pm 34.0$  mL/h/kg) compared with those taking valproic acid (VPA) ( $49.6 \pm 13.6$  mL/h/kg) or nonenzyme-inducing AEDs ( $46.5 \pm 12.8$  mL/h/kg) (42).

## Drug Interactions

### TPM and AEDs

In general, administration of TPM does not have major effects on the plasma concentrations of other

AEDs. TPM has no effect on most cytochrome P450 isozymes in in-vitro studies (43, 44). There were no TPM effects detected on concomitant drug levels in add-on clinical trials (45, 46). In one study, PHT levels rose 30% to 50% in three patients when TPM was added at a dose of 400–800 mg/day; these patients had baseline PHT levels of 15 µg/mL or higher, and it is proposed that TPM probably inhibited CYP2C19, the secondary enzyme for PHT metabolism (37).

Effects on other antiepilepsy drugs are negligible (43, 44, 47). When TPM was administered concomitantly with CBZ, there were no significant changes in total or unbound CBZ plasma concentrations (47). Similar results were found for lamotrigine (48). Although TPM has little net influence on VPA clearance, it can shift the proportions of several VPA metabolic pathways, but the clinical significance of this is uncertain. An increase in a potentially toxic metabolite, 4-ene-valproate, has been proposed as a factor in the rare cases of hyperammonemic encephalopathy observed with combination TPM-VPA therapy (49). TPM had no effect on plasma PB concentrations (50). No studies are available on the effects of TPM on felbamate, gabapentin, or tiagabine.

In contrast, studies have shown that administration of concomitant AEDs may affect plasma concentrations of TPM. Conversion of patients to TPM monotherapy from concomitant therapy with TPM and PHT (an enzyme-inducing AED) resulted in appreciably higher mean steady state values for TPM  $C_{max}$  and AUC (51). Similarly, withdrawal of CBZ from patients receiving concomitant TPM and CBZ resulted in an approximately twofold increase in TPM plasma levels (47). Therefore, there is a potential need for TPM dosage adjustment when enzyme-inducing AEDs are either added or discontinued. Barbiturates may have a similar effect but have not been studied. Conversely, simultaneous administration of TPM and VPA (an inhibitor of hepatic enzymes) resulted in slightly (17%) higher values for TPM  $C_{max}$  and AUC (52).

#### **TPM and Non-AEDs**

TPM at doses of 200 mg/day or more reduced serum levels of ethinyl estradiol derived from an oral contraceptive by 30% (53), but, in another series of women, TPM doses of 50, 100, and 200 mg/day had no significant effect (54). This TPM effect on oral contraceptives is less than that of the effect of either CBZ, PHT, or PB; unlike these other antiepileptic medications, TPM does not lower progestin levels (54).

Coadministration of TPM and digoxin in healthy adults results in a small reduction in digoxin  $C_{max}$  (16%) and AUC (12%) (55). The apparent oral clearance of digoxin increased by 13% without a corresponding change in the renal clearance, suggesting that TPM may affect the systemic availability of digoxin.

The clearances for lithium, amitriptyline, and risperidone increase and the levels decrease slightly when they are given with TPM (43). Metformin AUC increased by 25% in healthy volunteers given TPM (44). TPM has no pharmacokinetic effects on concomitant propranolol, sumatriptan, or dihydroergotamine (43).

### **CLINICAL EFFICACY**

A summary of the randomized controlled trials involving TPM across a broad spectrum of seizure types, usages (monotherapy, adjunctive therapy), and ages (adults and children) is shown in Table 52-1.

#### **Monotherapy in Adults and Children with Partial-Onset and Generalized-Onset Seizures**

The efficacy of TPM monotherapy has been assessed in four randomized controlled monotherapy trials (56–61). The first trial was a single-center study in which adult outpatients with refractory partial-onset seizures were randomized to either TPM 100 mg/day (low dose) or TPM 1000 mg/day (high dose), converted over 5 weeks from one or two standard AEDs to TPM monotherapy, and then followed for 11 more weeks (56). The study's primary outcomes of time until study exit and successful completion of 112 study days were significantly better for the high-dose TPM group compared with the low-dose TPM group. During the study, 13% of the high-dose TPM patients, but no low-dose TPM patients, became seizure free (56).

Subsequently, two multicenter randomized, controlled trials of TPM monotherapy in children and adults with recently diagnosed epilepsy employed a similar high-dose versus low-dose design, but both studies used lower TPM dosages (57, 58). The study population included both adults and children with partial-onset seizures and generalized-onset tonic-clonic seizures. The first trial randomized 252 patients (age 3 years and older), with epilepsy for less than three years, to either a low dose (25 mg/day if weight was less than 50 kg; 50 mg/day if weight was greater than 50 kg) or a high dose (200 mg/day if weight was less than 50 kg; 500 mg/day if weight was greater than 50 kg) (58). At baseline, patients were either on no medication (56%) or on one drug that was withdrawn within six weeks. The primary endpoint, a comparison of time to second seizure between these doses, was not statistically significant; however, when the time to first seizure was added as a covariate for the data analysis, the high dose proved superior in efficacy ( $P = 0.01$ ). A secondary outcome variable, the percentage of patients who were seizure free during the six-month trial, favored the high-dose group (54% vs. 39%,  $P = 0.02$ ).

The second randomized controlled trial enrolled 470 patients (age 6 years and older), with untreated epilepsy (two or more lifetime unprovoked seizures, with one or two partial-onset seizures or generalized-onset tonic-clonic seizures in a three-month retrospective baseline), to either TPM 50 mg/day or TPM 400 mg/day (57). The primary endpoint, time to first seizure, was better in the high-dose group ( $P = 0.0002$ ). The treatment arms demonstrated a significant difference ( $P = 0.046$ ) in favor of the high-dose arm by study day 14, when patients were receiving 100 mg/day (high dose) and 25 mg/day (low dose). The seizure-free rates for the high and low doses at 12 months were 76% and 59%, respectively ( $P = 0.001$ ) (57). The trial included a large cohort ( $n = 151$ , 32%) of children and adolescents 6–15 years of age. The primary efficacy endpoint of time to first seizure favored the higher TPM dose in the cohort of children and adolescents ( $P = 0.002$ ). The probability that children and adolescents were seizure-free at six months was 78% in the group given the 50-mg target dose and 90% in the group with the higher dose ( $P = 0.04$ ). At 12 months, the probability of being seizure free was higher in the high-dose group compared to the low-dose group (85% vs. 62%, respectively,  $P = 0.002$ ) (60).

A fourth TPM monotherapy trial used a different design (59). Patients were eligible if their epilepsy was diag-

nosed within the previous three months. Study investigators identified whether CBZ (600 mg/day) or VPA (1250 mg/day) would have been their preferred therapy based on the patient's clinical presentation. A total of 613 study patients were randomized to double-blind treatment with either the investigator's preferred therapy (CBZ or VPA) as the active control drug, TPM 100 mg/day, or TPM 200 mg/day. Designed to detect inferiority, the study found no evidence of it between either TPM dose or the active control (CBZ or VPA) for any of the efficacy measures examined: time to exit, time to first seizure, and the proportion of patients who were seizure free during the last six months of treatment. Because 100 mg/day of TPM proved just as effective as 200 mg/day, the authors suggested 100 mg/day as an initial target dose for patients with new-onset seizures. In the subset of pediatric partial-onset seizure patients, the time to first seizure was similar for patients in the TPM, CBZ, or VPA arms, as were the proportions of seizure-free patients during the last six months of treatment (61).

#### Adjunctive Therapy in Adults and Children with Partial-Onset Seizures

TPM has been extensively studied as adjunctive therapy in adults with refractory partial-onset seizures with or with-

**TABLE 52-1**  
*Summary of Randomized Controlled Trials Involving Topiramate in Patients with Epilepsy*

TYPE OF TPM USE	SEIZURE TYPE	AGE GROUP	NUMBER OF STUDIES	DESIGN*	RESULT	REF
Monotherapy	Partial onset— treatment resistant	Adult	1	High dose vs. low dose	High dose > low dose	56
Monotherapy	Partial onset— recently diagnosed	Adults and children	2	High dose vs. low dose	High dose > low dose	57, 58, 60
Monotherapy	Partial onset— recently diagnosed	Adults and children	1	TPM vs CBZ OR TPM vs VPA	TPM not inferior to CBZ or VPA	59, 61
Adjunctive	Partial onset	Adult	8	Placebo controlled	TPM > placebo	45, 46, 62–67
Adjunctive	Partial onset	Child	1	Placebo controlled	TPM > placebo	70
Adjunctive	Generalized tonic clonic seizures of non-focal origin	Adults and children	1	Placebo controlled	TPM > placebo	72
Adjunctive	Seizure types associated with Lennox–Gastaut syndrome	Adults and children	1	Placebo controlled	TPM > placebo	75

TPM = topiramate, CBZ = carbamazepine, VPA = valproic acid, \* = see text for details

out secondary generalization. Eight multicenter, randomized, placebo-controlled trials of adjunctive TPM therapy for adults with treatment-resistant, partial-onset seizures have documented TPM's efficacy compared to placebo at dosages of 200 mg/day or greater (45, 46, 62–67). Initial clinical trials examined the effects of doses ranging from 200 mg/day to 1600 mg/day. The minimum effective daily dose was 200 mg/day (45); intent-to-treat analyses identified 400 mg/day as the most effective dose (45, 67); and doses from 600 mg/day to 1,000 mg/day provided no additional benefit, but they increased the rate of adverse effects (45, 46, 67). It is possible, however, that individual patients may benefit from higher dosages. An initial target dose of 200 mg/day to 400 mg/day is recommended for adults. Pooled analyses of placebo-controlled studies in adults indicate that TPM is effective regardless of race, gender, baseline seizure rate, or concomitant AEDs (68). Subsequent trials examined slower titration rates (64, 66) or lower target dose (65, 66).

Long-term data are available from some of these controlled trials. In one report, 64% of the 214 adults with refractory partial-onset seizures who decided to take TPM after completion of blinded, controlled trials continued on it for another 30 months. Among the approximately one-third of these patients who converted to TPM monotherapy, 28 (13% of the 214) were seizure free for at least the last three months (69).

The efficacy of adjunctive TPM in children, aged 1–16 years with treatment-resistant, partial-onset seizures with or without secondary generalization, was examined in a multicenter, double-blind, randomized, placebo-controlled trial (70). An 8-week baseline was followed by a 16-week double-blind treatment phase (an 8-week titration period followed by an 8-week stabilization period) with a weight-based target dose of 6 mg/kg/day. Forty-one TPM-treated and 45 placebo-treated children ages 2–16 years completed treatment. The median percentage of reduction from the baseline in the average monthly partial-onset rate in the TPM-treated group was 33%, compared to 11% in the placebo group ( $P = 0.034$ ) (70). For the 83 children with partial-onset seizures, with or without secondary generalization, who continued long-term open-label TPM therapy after the double-blind trial phase, the mean TPM dosage was 9 mg/kg/day. Seizure frequency over the last three months of therapy was reduced by 50% or more in 57% of the children; 14% of children were seizure free for six months or more at the last visit (71).

#### **Adjunctive Therapy in Adults and Children with Generalized-Onset Tonic-Clonic Seizures of Nonfocal Origin**

A double-blind, placebo-controlled, multicenter study demonstrated TPM's efficacy against treatment-resistant, uncontrolled, GTC seizures of nonfocal origin

in 80 children and adults (72). Inclusion and exclusion criteria were that patients were ages 4 years or older, had experienced three or more GTC seizures during an 8-week baseline phase, had electroencephalogram (EEG) findings consistent with generalized epilepsy, and were taking no more than two standard AEDs at study entry. Patients meeting these criteria were randomized to either TPM or placebo adjunctive treatment, titrated to target dosages of 6 mg/kg/day over 8 weeks, and maintained at that dose for 12 weeks.

A total of 80 patients (ages 3–59 years) were randomized; the median baseline average monthly rate of GTC seizures was 5.0 in the TPM group and 4.5 in the placebo group. The mean TPM dosage during the stabilization period was 5.0 mg/kg/day. The median percentage of reduction from baseline in average monthly GTC seizure rate at the end of the 20-week double-blind phase was higher for the TPM group compared with the placebo group (57% vs. 9%,  $P = 0.019$ ). More TPM-treated patients experienced a reduction of 50% or greater in GTC seizures compared to the placebo-treated controls (56% vs. 20%,  $P = 0.001$ ). A similarly designed study was published only in abstract form (73).

In an analysis of long-term follow-up of 131 adults and children from the previously described studies, 63% had a decrease of 50% in seizure frequency during a mean follow-up period of 387 days (range, 14–909 days) and 16% were seizure free for the past six months (74). The cohort's mean TPM dose was 7 mg/kg/day (range, 1–16 mg/kg/day). At the last visit, 82% of the patients ( $n = 107$ ) were still taking TPM (74).

#### **Adjunctive Therapy in Patients with Lennox-Gastaut Syndrome**

TPM's efficacy as adjunctive therapy in patients with Lennox-Gastaut syndrome was established in a multicenter, double-blind placebo-controlled trial (75). Study patients had to have active drop attacks (either tonic or atonic seizures), a history of or active atypical absence seizures, and a prior EEG showing a slow spike wave pattern and be taking one or two concomitant AEDs at the time of study entry. Following a 4-week baseline, eligible patients were randomized to either TPM or placebo adjunctive therapy. Study dosages were increased at weekly intervals over 3 weeks to 6 mg/kg/day and then maintained at that dose for 8 weeks.

A total of 98 patients, ages 2–42 years (an average of 11 years) were randomized. The two groups were evenly matched in the median monthly frequency of drop attacks (90 for the TPM group, 98 in the placebo group) and median monthly frequency of all seizure types (267 for the TPM group and 244 in the placebo group). The median average TPM dosage during the stabilization period was 5.8 mg/kg/day (75).

During blinded treatment, patients in the TPM group had a greater median percentage of reduction from baseline in drop attacks (15%) compared to the placebo group (-5%;  $P = 0.041$ ). TPM-treated patients experienced a larger improvement in seizure severity compared with controls (52% vs. 28%;  $P = 0.040$ ) based on parental global evaluations (75).

In the open-label extension phase of this trial, the mean TPM dose for the 97 patients was 11 mg/kg/day, with a mean duration of 539 days (range, 44–1,225 days). At the last clinic visit, drop attacks were reduced by 50% or greater in 55% of patients; 15% of patients had no drop attacks for six months or more (76).

### **Monotherapy and Adjunctive Therapy in Patients with Infantile Spasms (West Syndrome)**

TPM's efficacy against infantile spasms has been reported in at least 10 open-label trials (77–86). In the first reported study, 11 patients with treatment-resistant infantile spasms documented by 24-hour video EEG, utilized an initial dose of 25 mg TPM, followed by a “rapid-dose” titration schedule of 25-mg increments every 2–3 days over a 4-week period until either a maximal tolerated dose was reached, spasms were controlled, or a maximal dose of 24 mg/kg/day was achieved. A total of five patients (45%) became spasm free, with repeat 24-hour video EEG demonstrating absence of infantile spasms and hypsarrhythmia (77). A majority of the patients (64%, 7 of 11) were able to achieve TPM monotherapy; the others were able to reduce their intake of concomitant AEDs (77).

Four of seven infants with West syndrome became seizure free with TPM therapy, as reported in a retrospective study of TPM in patients with intractable epilepsy (78). A third study reported the efficacy of TPM in 13 infants with West syndrome as part of a multicenter study of 224 unselected patients with a variety of epilepsy types. Two (15%) West syndrome infants became seizure free; seven (54%, 7 of 13) had a reduction greater than 50% in their seizures. TPM was used as initial monotherapy in nine patients, with doses as much as 16 mg/kg/day (79). An open-label, multicenter retrospective study of 28 infants treated with TPM included 8 infants with West syndrome; 88% (7 of 8) improved with TPM therapy, and 3 patients received TPM monotherapy (80). One study of 18 patients with spasms (14 infantile, 4 late-onset) found 6 responders, but none were seizure free (82). In contrast, 19 patients with West syndrome were included in an open, prospective, pragmatic study of TPM in 59 infants with epilepsy. Four of the six patients with cryptogenic West syndrome became seizure free (14-month median follow-up). Among the remaining 13 patients with symptomatic West syndrome, 4 patients were responders, but only one (8%) became seizure free (81). Two of nine patients with

infantile spasms became seizure free, and another two patients experienced a reduction of greater than 50% in seizure frequency in a prospective open-label trial of TPM in 47 children (ages 6–60 months) with refractory epilepsy (83). Following initiation of TPM therapy in 4 infants with infantile spasms (in a retrospective review of TPM use in 13 children ages less than 2 years), 2 infants became spasm free, 1 infant had a reduction greater than 75% in spasms, and the other infant had no response to TPM (84). Twenty patients with infantile spasms were treated with TPM monotherapy, with an initial dose of 1 mg/kg/day up to a maximal dose of 12 mg/kg/day (85). Six patients (30%) became spasm free and hypsarrhythmia free on video EEG; the patients with idiopathic spasms did better (4 of 8, 50% spasm free) compared to those with only symptomatic spasms (2 of 12, 17% spasm free) (85).

The largest study of TPM in children with infantile spasms was a 2006 prospective open-label study using TPM as initial therapy in 54 patients with newly diagnosed infantile spasms (86). Overall, 57% (31 of 54) of patients were seizure free for more than 24 months. Among these patients, 9 were on TPM monotherapy and 22 patients received TPM with nitrazepam, valproic acid, or both. The average dosage applied was 5.2 mg/kg per day (range 1.6–26 mg/kg/day). The authors concluded that TPM was an “effective and safe first-choice drug not only as adjunctive but also as monotherapy of infantile spasms in children younger than 2 years” (86).

### **Adjunctive Therapy in Patients with Severe Myoclonic Epilepsy of Infancy (Dravet Syndrome)**

Four studies have examined TPM's efficacy for children with severe myoclonic epilepsy in infancy (SMEI) (81, 82, 87, 88). A trial examined TPM's effectiveness in 18 patients with SMEI, with a starting dose of 1 mg/kg/day, which was increased every 1–2 weeks, with a maximum dose of 6–8 mg/kg/day. The study showed that 17% (3 of 18) of the patients became seizure free, and 56% (10 of 18) had a reduction greater than 50% in seizure frequency (mean 10.5 months, with a range of 6–18 months) (87). A prospective multicenter, open-label adjunctive therapy study of 18 patients (ages 2–21 years, mean 9 years), with SMEI initiated TPM at 0.5–1 mg/kg/day, used 2-week increments of 1–3 mg/kg/day and a maximum dose of 12 mg/kg/day. Similar to the previous study, 3 patients (3 of 18, 17%) became seizure free, and 10 patients (10 of 18, 56%) had a reduction greater than 50% in seizures (mean 11.9 months, with a range of 2–24 months). No patient experienced worsening of seizures with TPM therapy (88). In a subset of a study with 207 children with refractory epilepsy, 3 of 5 SMEI patients responded to TPM therapy (82). Six patients with SMEI were included in an open, prospective, pragmatic study of TPM in 59

infants with epilepsy; only 2 of the 6 SMEI patients responded, and none became seizure-free (81).

### Adjunctive Therapy in Patients with Juvenile Myoclonic Epilepsy

A posthoc analysis of two multicenter, double-blind, randomized, placebo-controlled, trials of TPM for GTC seizures of nonfocal origin revealed that 22 patients with juvenile myoclonic epilepsy had been randomized to either TPM ( $n = 11$ , target dose, 400 mg/day in adults) or placebo ( $n = 11$ ). A significantly higher number of patients in the TPM-treated arm experienced a reduction of 50% or greater in GTC seizures compared to the placebo arm (8 of 11, 73% vs. 2 of 11, 18%;  $P = 0.03$ ). Although reductions were noted in the number of myoclonic and absence seizures and total number of generalized seizures in the TPM arm, the difference did not reach statistical significance (89).

A second study examined TPM's efficacy in 22 patients with juvenile myoclonic epilepsy (ages 13–53 years). The target TPM dosage was as much as 200 mg/day. Among the 16 patients who completed one year of follow-up, 10 patients (62.5%) were free of GTC seizures, and myoclonia was controlled in 11 patients (90).

### Adjunctive Therapy in Patients with Other Epilepsy Syndromes

There are small studies suggesting that TPM is effective for absence epilepsy (91), Doose syndrome (82), and progressive myoclonic epilepsies (92).

### Adjunctive Long-Term Open-Label Treatment

Prospective open-label series may be more predictive of results in clinical practice because long-term extension studies include only patients who have successfully completed randomized trials (a subset that is probably not reflective of the general population). Among 292 adults with refractory seizures treated with adjunctive, open-label TPM, in dosages of 100–1,600 mg/day, and followed for a mean of 2.2 years (84–804 days), mean reductions greater than 50% in both partial- and generalized-onset seizures were observed, and 10% were seizure free for at least six months (93). Discontinuations were more often due to adverse effects (32%) than to lack of efficacy (19%), a pattern typical for TPM treatment (93–96).

A 6-month Canadian multicenter open-label study of 209 adults given TPM as adjunctive therapy reported that patients had a reduction of 41% in median seizure frequency during the final 8 weeks, with 10% becoming seizure free and with improvements in quality of life measurements (97).

A multicenter, retrospective review of open-label TPM adjunctive therapy in 277 children (average age, 8.4 years; range, 1–16 years) with treatment-resistant epilepsy evaluated TPM's long-term efficacy. Overall, after 27.5 months of treatment (range, 24–61 months), 4% (11 of 277) of children were seizure free and 20% (56 of 277) had a reduction of greater than 50% in seizure frequency. TPM's long-term efficacy was greater in patients with partial-onset epilepsy than in those with generalized-onset epilepsy (98).

## ADVERSE EFFECTS

TPM's profile for adverse events is similar for adults and children. TPM-related adverse events in 199 children participating in double-blind, placebo-controlled trials (the events occurred with a greater frequency of more than 5% in the TPM treatment group than in the placebo group) were somnolence, anorexia, fatigue, nervousness, concentration or attention difficulties, aggression, difficulty with memory, and weight loss (99). The mean TPM dose was 6.2 mg/kg/day for a mean of 107 days (99).

In general, TPM is associated with a lower incidence of adverse events (i.e., better tolerated) when it is used as monotherapy than in adjunctive therapy. A slower titration is better tolerated than a rapid titration. The slower rate of TPM titration (i.e., increases at 2-week intervals) that is used in some of these pediatric studies resulted in a lower frequency of adverse events compared to the higher frequency observed with a more rapid rate of titration that is used in many of the adult studies and the trial in patients with Lennox-Gastaut syndrome (100). During the double-blind portion of the placebo-controlled studies involving children, the use of TPM did not result in any discontinuations due to an adverse event (100).

One framework to examine these adverse events is to group them by system: the most common adverse events involve the CNS (cognitive effects, somnolence, fatigue, effects on mood, psychosis, and, rarely, hyperammonemic encephalopathy and acute bilateral secondary angle-closure glaucoma), gastrointestinal system (anorexia, weight loss), and systemic (paresthesias, metabolic acidosis, renal stones). Some of the adverse events are definitely dose related (e.g., cognitive problems, paresthesias, anorexia, and decreases in serum bicarbonate), some are proposed to be dose related (e.g., gastrointestinal symptoms, renal stones, and psychiatric effects), and others are seen mostly during dose initiation and are thus unrelated to final dose (e.g., dizziness, somnolence, fatigue, and ataxia) (101, 102). Serious adverse effects are rare.

## CNS Adverse Events

In clinical trials, the most commonly reported treatment-emergent adverse events were CNS-related, and most

were rated as mild or moderate in severity. In clinical practice, cognitive adverse events are those most likely to limit TPM therapy (95, 96). Cognitive events are less common with a slow titration and when TPM is used as monotherapy (56–58). In the comparative trial of patients with new-onset seizures treated with either monotherapy CBZ 600 mg/day, monotherapy valproate 1250 mg/day, monotherapy TPM 100, or monotherapy TPM 200 mg/day, no cognitive side effect exceeded 8% in any group, although valproate was slightly better tolerated (59). In an adjunctive TPM therapy trial with a slow upward titration of 25–50 mg/week to a target dose of 200 mg, only 5% of patients experienced “concentration or attention difficulty” (66). In contrast, TPM’s cognitive effects were clearly seen during the early, high-dose, rapid-titration, adjunctive therapy clinical trials; “thinking abnormal” occurred in 13% to 33% of patients, while 15% to 25% had “concentration impaired” (68, 101).

A common misperception is that cognitive effects are universally present; in fact, many patients are completely unaffected, even at higher dosages, and group differences are strongly influenced by a subset of patients who are severely affected (103). Patients with intellectual disabilities do not appear to be at greater risk than other patients for the cognitive effects of TPM (104, 105). In addition to slowing the titration rate and using TPM as monotherapy, another effective strategy is to reduce concomitant medications if adverse cognitive events appear (106).

The specific types of cognitive adverse events associated with TPM appear qualitatively different from those with other AEDs. Examples of TPM-related cognitive adverse events include impaired expressive language function, impaired verbal memory, a general slowing of cognitive processing (without apparent sedation or mood change), mild dysnomia, hesitation in verbal replies, and declines in word fluency (68, 107–111). Nineteen patients withdrawn from polytherapy TPM experienced improvements in verbal fluency, working memory, and other functions associated with the frontal lobe (112). Patients with dominant-hemisphere seizure foci or pathology may be more likely to experience word-finding difficulty (110).

Other TPM-related CNS adverse events included sleepiness and fatigue. Between 15% and 35% of subjects experienced transient, nontherapy-limiting sleepiness during short-term clinical trials (45, 46, 63, 64, 95). Fatigue was reported in approximately 16% of study patients during TPM monotherapy trials using 25–500 mg/day, but there was no relationship to TPM dose (31). In adult adjunctive TPM clinical trials, fatigue was seen in 13% of patients taking placebo, 15% of patients receiving TPM 200–400 mg/day, and 30% of patients taking TPM 600–1000 mg/day (44). In children, fatigue was seen in 16% of patients taking adjunctive TPM and 5% taking placebo (44).

In the first five controlled trials using adjunctive TPM therapy, depression was reported in 15% of participants; this was similar to that in the placebo group (101). In an open-label series, 11.9% of patients were described as having depression, hyperirritability, or aggressiveness (96). In another report, 5% had depression and 5.7% displayed irritability or aggressive behavior (113). In this latter report, patients with psychiatric histories were more likely to experience these adverse events (113).

The incidence of psychosis in TPM clinical trials was 0.8%, which is not significantly different from the psychosis rate in the placebo group or the reported rates of psychosis in patients with treatment-resistant epilepsy (114). However, another study reported the rate of psychotic symptoms in 94 patients treated with TPM as 12% (115). Psychiatric adverse events (such as depression and psychosis) are related to a high starting dose and rapid titration (116).

Hyperammonemic encephalopathy has been reported in a few patients taking concurrent TPM and VPA. These patients developed stupor, worsening of seizures, and focal neurologic signs and had slowing of their EEG background rhythm. Recovery was rapid after either TPM or VPA was removed. (49, 117–119).

TPM-related acute bilateral secondary angle-closure glaucoma has been seen in all ages, from children to elderly (120, 121). Symptoms usually start a week after (mean, 7 days; range, 1–49 days) from initiation of therapy and include blurred vision, eye pain, headache, nausea, vomiting, pupillary changes, and hyperemia (121). Early recognition and immediate cessation of TPM are key to successful management (121).

### Gastrointestinal Adverse Events

Many patients taking TPM lose weight, a result that is probably related to anorexia. The extent and duration of this weight loss is variable. In adults, the average decrease in body weight is 4.6%; this loss usually reaches a plateau by 18 months of therapy (68, 122). Obese adults tend to lose more weight on TPM than nonobese adults (123). Weight loss is not always beneficial and can be therapy limiting. Underweight adults and children who cannot voluntarily increase caloric intake may not tolerate this adverse event. In placebo-controlled TPM trials involving children, weight loss occurred in 9% of the TPM group versus 1% of the placebo group (99).

### Systemic Adverse Effects

TPM’s most common systemic adverse events include paresthesias, metabolic acidosis, hypohydrosis, and renal stones. These effects are associated with TPM’s inhibition of carbonic anhydrase isozymes II and IV (124).

Paresthesias more commonly occur with monotherapy use compared to adjunctive therapy use. It is speculated that this is because of higher serum levels of TPM in the monotherapy trials (56, 58). In contrast to epilepsy studies, in clinical trials for migraine, 35% of subjects had paresthesias at 50 mg/day and 49% at 200 mg/day (44). Tingling or numbness involved hands and feet or sometimes the whole body.

TPM can lower serum bicarbonate levels in a dose-dependent effect. The package insert reports that 32% of adults taking 400 mg/day have serum bicarbonate levels less than 20 mEq/L and that the effect is more prevalent in children (44). Another study reports an average decrease of 5.1 mEq/L (26.8 to 21.7) (125). Most patients are asymptomatic because serum pH can ordinarily compensate. In some circumstances, a patient could experience a clinically significant nonanion-gap hyperchloremic acidosis that would manifest with ketosis, renal or respiratory insufficiency, or status epilepticus (126).

Hypohidrosis and oligohidrosis with TPM therapy can be asymptomatic or appear as heat intolerance (127). One study found that 5% (5 of 102) children taking TPM experienced symptomatic hypohidrosis with hyperthermia (128). The adverse event is reversible with TPM withdrawal (129.) The mechanism is not definite, but it is proposed to relate to carbonic anhydrase inhibition at the level of the sweat gland (129).

An incidence of nephrolithiasis of 1.5% during TPM treatment is similar to that during treatment with another carbonic anhydrase inhibitor, acetazolamide (12, 130). Most cases of nephrolithiasis are resolved by the spontaneous passage of renal stones, and 83% of the 18 patients with stones elected to continue TPM treatment (101). Like acetazolamide, TPM has a sulfamate moiety; however, carbonic anhydrase inhibition by TPM is relatively weak.

One study examined 14 children treated simultaneously with TPM and the ketogenic diet (known to predispose patients to metabolic acidosis) for periods of 33–544 days (131). Nine children experienced a decrease of less than 20% in serum bicarbonate levels, (mean, 7.6 meq/L; range, 5.3–12.3 meq/L). Two children required bicarbonate supplements, but no patient had nephrolithiasis (131).

### Teratogenicity

TPM is rated as Pregnancy Category C by the U.S. Food and Drug Administration (FDA) (44). The Category C label means that animal reproduction studies have shown an adverse effect on the fetus, there are no adequate and well-controlled studies in humans, and the benefits from the use of the drug in pregnant women may be acceptable despite its potential risks (132).

## CLINICAL USE

### FDA Indications

TPM is indicated as initial monotherapy in patients ages 10 years and older, with partial-onset or primary GTC seizures, as adjunctive therapy for adults; for pediatric patients ages 2–16 years with partial-onset seizures or primary GTC seizures; and for patients ages 2 years and older with seizures associated with Lennox-Gastaut syndrome. It is also indicated in adults for the prophylaxis of migraine headache (44).

### Formulations

TPM is available in oral preparations, either as a tablet (25 mg, 50 mg, 100 mg, and 200 mg strengths) or as a sprinkle capsule (15 mg and 25 mg) (44). There is no intravenous preparation commercially available.

### Dosing

Attention to the initial dose of TPM, subsequent titration rates, and the maintenance target dose are important to maximize tolerability and, subsequently, to maximize effectiveness. TPM should be titrated until there is a clear clinical response consisting of either seizure control without intolerable adverse events or persisting seizures with intolerable side effects. In patients showing some seizure reduction without intolerable adverse events, the dose of TPM can be further increased. If adverse experiences do occur, titration can be slowed; on the other hand, titration can be more rapid if the suppression of seizures is urgently needed. A small subset of patients (1% to 3%) appears unable to tolerate even the lowest doses of TPM.

For children with epilepsy, commonly used initial TPM doses range from 0.5 to 1 mg/kg/day. Subsequent weekly increases in dosage are in increments of 0.5–1 mg/kg/day. As monotherapy, typical TPM target doses are in the range of 3 mg/kg/day, whereas in adjunctive therapy TPM target doses range from 6 to 9 mg/kg/day. With these slow rates of titration, it may take 6 to 8 weeks to begin to see efficacy, and it is important to explain this time frame to the parents of the patient to avoid undue anxiety and frustration.

An open-label, naturalistic TPM monotherapy clinical trial involving 114 children (ages less than 12 years) at 127 centers throughout Europe and the Middle East found 3.3 mg/kg/day (range, 1.3–13.0 mg/kg/day) as the median final dose of TPM (133). However, infants and some children may require significantly higher initial and target doses. Some infants and children benefit from TPM doses up to 50 mg/kg/day—particularly in the presence of a concomitant enzyme-inducing AED such as CBZ.

For adults with epilepsy, commonly used initial TPM doses range from 25 to 50 mg/day. Subsequent increments of 25–50 mg/day are done every 1–2 weeks. For initial monotherapy, TPM target doses as low as 100 mg/day may be effective, whereas, in adjunctive therapy, TPM target doses range from 400–600 mg/day. In an open-label, naturalistic TPM monotherapy clinical trial involving 441 adults at 127 centers throughout Europe and the Middle East, the median final TPM dose was 125 mg/day (range, 25–700 mg/day) (133).

### Precautions

Measurement of baseline and periodic bicarbonate levels is recommended (44). Periodic measurements could occur when the initial target dose is reached, after large dose increases, and in circumstances predisposing the patient to metabolic acidosis. Minor decreases in bicarbonate usually do not require any action; in general, clinical judgment should guide whether dose reduction or alkali treatment is needed. No other routine laboratory testing is recommended.

Women taking more than 200 mg/day of TPM along with oral contraceptives should take precautions. The absence of breakthrough bleeding is not a reliable sign of secure birth control, but its occurrence may suggest a need for a higher estrogen dose or a second method.

### Contraindications

The only absolute contraindication is hypersensitivity to components of the compound (44).

### Plasma Concentrations

Most large clinical laboratories (in hospitals or independent laboratories) offer TPM plasma concentrations.

Optimal treatment response is most likely to occur at TPM plasma concentrations ranging from 3.2 to 28.8 µg/mL for children ages 5 and younger (134), 1.5–20.4 µg/mL for older children (ages 6–12 years) on TPM monotherapy (134), and 2–10.5 µg/mL (6–31 µmol/L) for adults with treatment-resistant partial epilepsy (135).

### CONCLUSION

TPM is an antiepileptic medication with efficacy in multiple animal models; it possesses multiple mechanisms of action, demonstrates a favorable pharmacokinetic profile in humans, exhibits efficacy against a variety of seizure types in children and adults in both clinical trials and clinical practice, and has a well-defined profile for adverse events.

TPM has efficacy in the MES and the PTZ seizure tests along with multiple other rodent models of epilepsy. Its multiple mechanisms of action include, but are not limited to, state-dependent blockade of Na<sup>+</sup> channels, potentiation of GABA-mediated (inhibitory) neurotransmission, and antagonism of glutamate (excitatory) receptors of the kainate (non-NMDA) subtype. It exhibits a favorable pharmacokinetic profile, including rapid absorption, long duration of action, and minimal interaction with other AEDs. In clinical trials involving adults and children with epilepsy, TPM exhibited efficacy against partial-onset and generalized-onset seizures. It has demonstrated efficacy in patients with epilepsy, ranging from those with newly diagnosed, untreated epilepsy to patients with long-standing, treatment-resistant epilepsy. TPM has demonstrated efficacy as monotherapy and in adjunctive therapy. TPM has a well-characterized adverse event profile with recognizable and reversible adverse events. Overall, TPM has emerged as a valuable AED for children and adults with epilepsy.

# 53

## Valproate

*Blaise F. D. Bourgeois*

**V**alproic acid, or valproate (VPA), has been used in the treatment of epilepsy for more than 40 years (1). During this time, it undoubtedly has established itself as one of the major antiepileptic drugs (AEDs), mainly because it was the first (and until the 1990s the only) drug with a broad spectrum of activity against different seizure types, and because of its relatively low sedative effect. In addition to being the first drug to be highly effective against several primarily generalized seizure types, such as absences, myoclonic seizures, and generalized tonic-clonic seizures, VPA also was found to have some effectiveness in the treatment of partial seizures, Lennox-Gastaut syndrome, infantile spasms, neonatal seizures, and febrile seizures. Thus, VPA became particularly popular among pediatric neurologists. In addition to its place in the treatment of epilepsy, VPA has gained acceptance in the treatment of affective disorders in psychiatry and in the prophylaxis of migraine headaches. Effectiveness in the treatment of Sydenham's chorea has also been suggested (2), indications that will not be included in this chapter.

### **CHEMISTRY, ANIMAL PHARMACOLOGY, AND MECHANISM OF ACTION**

Valproic acid (Figure 53-1) is a colorless liquid of molecular weight (MW) 144.21 with low solubility in water. Sodium valproate (MW 166.19) is a highly water-soluble and highly hygroscopic, white, crystalline material. Sodium hydrogen divalproate (divalproex sodium) is a mixture of equal parts of valproic acid and sodium valproate. Being a short-chain branched fatty acid, VPA differs chemically from all other known AEDs. The anti-convulsant effect of VPA was discovered serendipitously when it was used as a solvent for compounds being tested in an animal model of seizures (3). The antiepileptic activity of VPA has been well demonstrated in several animal models (4–6). The effects of VPA include protection against maximal electroshock (MES)-induced seizures; seizures induced chemically by pentylenetetrazol (PTZ), bicuculline, glutamic acid, kainic acid, strychnine, ouabain, nicotine, and intramuscular penicillin; and seizures induced by kindling (7). This broad spectrum of efficacy of VPA in animal models suggests that it is effective in

FIGURE 53-1

Structural formula of valproic acid (N-dipropylacetic acid).

both preventing the spread and lowering the threshold of seizures, and this is consistent with the broad spectrum of antiepileptic activity of VPA in humans.

Extensive studies have been carried out to elucidate the mechanism of action of VPA. Several effects of VPA have been demonstrated at the cellular level, but the precise mechanism underlying the antiepileptic effect of VPA has not been identified, more than one mechanism may be involved, and none of the identified actions has been widely accepted as the predominant relevant mechanism (8). VPA raises brain levels of the inhibitory neurotransmitter gamma-aminobutyric acid (GABA) (5, 9). This increase may be due to the inhibition of GABA-transaminase, the first step in GABA deactivation (10); inhibition of succinic semialdehyde dehydrogenase, the second step in GABA deactivation (11); or an increase in activity of glutamic acid decarboxylase, an enzyme involved in the synthesis of GABA (9). However, because it occurs at much higher than usual therapeutic doses and because its time course lags behind the anticonvulsant effect (12), elevation of GABA is unlikely to be the predominant mechanism of the antiepileptic effect of VPA. In addition to its effect on GABA levels, VPA reduces sustained repetitive high-frequency firing by blocking voltage-sensitive sodium channels (13) or by activating calcium-dependent potassium conductance (14). It was also demonstrated in mice that VPA can decrease brain levels of the excitatory amino acid aspartate (15), as well as decreased expression of the glutamate transporter-1 in rat hippocampus (16). It is not known to what extent these actions contribute to the clinical effect of VPA.

## BIOTRANSFORMATION, PHARMACOKINETICS, AND INTERACTIONS

### Biotransformation

The main pathways of VPA biotransformation in humans include glucuronidation of VPA itself, beta-oxidation, hydroxylation, ketone formation, and desaturation (Figure 53-2). Both beta-oxidation and desaturation can result in the formation of double bonds. By far the most abundant metabolites are VPA glucuronide and 3-oxo-VPA, which represent about 40% and 33%, respectively,

of the urinary excretion of a VPA dose (17). Two desaturated metabolites of VPA, 2-ene-VPA and 4-ene-VPA, have anticonvulsant activity that is similar in potency to that of VPA itself (18). Because there is delayed but significant accumulation of 2-ene-VPA in the brain and it is cleared more slowly than VPA itself (19), the formation of 2-ene-VPA may provide a possible explanation for the discrepancy between the time courses of VPA concentrations and the antiepileptic activity of VPA (20). It appears that 2-ene-VPA does not possess the pronounced embryotoxicity (21) and hepatotoxicity (22) of 4-ene-VPA, and it may thus represent a better AED than VPA itself. The strongly hepatotoxic 4-ene-VPA is produced under the action of cytochrome P450 enzymes. These enzymes are induced by other AEDs such as phenobarbital, phenytoin, and carbamazepine (17, 23), and this may explain the increased risk of hepatotoxicity in patients receiving these drugs together with VPA (24). However, elevation of 4-ene-VPA levels has not yet been documented in patients with VPA hepatotoxicity or in conjunction with short-term adverse effects or hyperammonemia (25).

### Pharmacokinetics

The main pharmacokinetic parameters of VPA are summarized in Table 53-1.

The bioavailability of oral preparations of VPA is virtually complete when compared with the intravenous route (26). The purpose of the enteric coating of tablets is to prevent the gastric irritation associated with release of valproic acid in the stomach. When VPA syrup was administered rectally, it was found to have the same bioavailability as the oral preparation (27, 28). Compared with oral syrup, the bioavailability of VPA suppositories was found to be 80% in volunteers (29). The time to peak level was longer for the suppositories than for the syrup (3.1 hours vs. 1.0 hour). In a study in patients treated chronically with VPA, administration of VPA suppositories was well tolerated for several days, and the bioavailability was the same as for the oral preparations (30). The available evidence suggests that there is no need for a dosage change or a change in regimen when oral VPA administration is transiently replaced by rectal administration. The bioavailability of the divalproex extended-release preparation is 8% to 20% lower than that of other divalproex preparations (31, 32).

The rate of absorption of VPA after oral administration is quite variable depending on the formulation. Administration of syrup and uncoated regular tablets or capsules is followed by rapid absorption, and peak levels are achieved within 2 hours. Absorption from enteric-coated tablets is delayed, but once absorption begins, it is rapid. The onset of absorption varies as a function of the state of gastric emptying at the time of ingestion, and

FIGURE 53-2

Main biotransformation pathways of valproate. (Courtesy of Dr. Raman Sankar)

**TABLE 53-1**  
*Pharmacokinetic Parameters of Valproate*

Bioavailability	>90%
Time to peak level <sup>a</sup>	1–8 hours
Volume of distribution	0.16 L/kg
Serum protein binding <sup>b</sup>	70–93%
Elimination half-life <sup>c</sup>	5–15 hours
Therapeutic range	50–100 (–150) mg/L 350–700 (–1,000) μmol/L

<sup>a</sup>The longer values are for enteric-coated and slow-release preparations.

<sup>b</sup>Concentration dependent; lower at higher total concentrations.

<sup>c</sup>Shorter values are for comedication with inducing drugs.

peak levels may be reached only 3 to 8 hours after oral ingestion of enteric-coated tablets (33–35). Figure 53-3 shows the serum levels of a patient who received a first oral dose of 500 mg of enteric-coated divalproex sodium. No VPA was detectable in serum until 8 hours after the oral intake, and this was followed by a rapid rise of serum levels (36).

Because of this delayed absorption, serum levels of VPA in patients taking VPA chronically (twice or three times daily) continue to decrease for 2 or more hours after drug ingestion. Therefore, the lowest VPA levels of a 24-hour cycle are not the assumed “trough levels” before the morning dose, but actually occur in the late morning or early afternoon (30). The absorption of enteric-coated sprinkles was compared with the absorption of VPA syrup in 12 children, and no difference in overall bioavailability was found between the two formulations. However,

**FIGURE 53-3**

Valproate serum concentrations after a 500-mg single first oral dose of enteric-coated divalproex sodium in a 60.4-kg woman. Reproduced with permission from (36).

the absorption of VPA was slower from the sprinkles, with an average time to maximal VPA concentrations of 4.2 hours after ingestion of sprinkles, as compared with 0.9 hours after ingestion of syrup (37).

The volume of distribution of VPA is relatively small (0.13–0.19 L/kg in adults and 0.20–0.30 L/kg in children). This suggests that VPA has a relatively lower affinity for binding outside the blood compartment than for binding to serum proteins. Indeed, VPA is highly bound to serum proteins. This binding appears to be saturable at therapeutic concentrations, and the free fraction of VPA increases as the total concentration increases. For instance, Cramer et al (38) found that the average free serum fraction of VPA in adults was only 7% at 50 mg/L and 9% at 75 mg/L, increasing to 15% at 100 mg/L, 22% at 125 mg/L, and 30% at 150 mg/L. Based on these values, with a threefold increase in the total concentration of VPA from 50 to 150 mg/L, the free level of VPA would increase more than 10 times from 3.5 mg/L to 45 mg/L. Because the clearance of VPA is related to the free concentration, there is a linear relationship between the daily maintenance dose of VPA and steady-state free levels. But, as expected on the basis of saturable binding, a curvilinear relationship between VPA maintenance dose and total steady-state concentrations was found by Gram and coworkers (39), with relatively smaller increases in concentrations at higher doses.

The elimination half-life of VPA varies as a function of comedication. In the absence of inducing drugs, the half-life in adults is 13 to 16 hours (34, 40), whereas the half-life in adults receiving polytherapy with inducing drugs averaged 9 hours (26); half-lives in children

are slightly shorter. Cloyd and coworkers (41) found an average half-life of 11.6 hours in children receiving monotherapy and 7.0 hours with polytherapy. Hall and coworkers (42) determined that VPA half-lives were significantly related to age, but volume of distribution and clearance were not. Newborns eliminate VPA slowly, with half-lives that are longer than 20 hours (43).

**Interactions.** Pharmacokinetic interactions involving VPA fall into three categories, based on the fact that (1) the metabolism of VPA is sensitive to enzymatic induction, (2) VPA itself can inhibit the metabolism of other drugs, and (3) VPA has a high affinity for serum proteins and can displace other drugs. Pharmacokinetic interactions with VPA have been reviewed previously (44). Concomitant administration of enzyme-inducing AEDs such as carbamazepine, phenytoin, phenobarbital, and primidone has been repeatedly shown to result in lower VPA levels in relation to the maintenance dose (45). The addition of both carbamazepine (46, 47) and phenytoin (47) significantly lowers VPA levels, usually by at least one-third to one-half. These interactions are particularly pronounced in children, resulting in VPA level reductions of 50% or more (48, 49). When children receiving polytherapy had other drugs discontinued, VPA levels rose 122% after withdrawal of phenytoin, 67% after withdrawal of phenobarbital, and 50% after withdrawal of carbamazepine (50). The antibiotic meropenem can decrease VPA levels to a clinically relevant degree (51). In general, when an inducing drug is added or withdrawn in a patient taking VPA, the dose of VPA must be increased or decreased, respectively, by a factor of about 2, if the same level is to be maintained. Inversely, levels of VPA are raised by felbamate (52, 53). The increase in VPA levels was found to be 28% at a felbamate dose of 1,200 mg/day and 54% at a dose of 2,400 mg/day. In addition to felbamate, clobazam has also been found to reduce the clearance and elevate the levels of VPA (54).

When VPA affects the kinetics of other drugs, the interaction is either an enzymatic inhibition or a displacement from serum proteins. Levels of phenobarbital have been found to increase by 57% (55) to 81% (56) after the addition of VPA. Levels of ethosuximide can also be raised by the addition of VPA, mostly in the presence of additional AEDs (57). Although VPA does not raise levels of carbamazepine itself, levels of the active metabolite, carbamazepine-10,11-epoxide may double (58, 59). The elimination of lamotrigine is markedly inhibited by VPA, with a twofold to threefold prolongation of the lamotrigine half-life (60). This interaction is competitive and rapidly reversible, but it seems to persist at low VPA concentrations (61, 62). Lamotrigine must be introduced at lower doses in patients taking VPA.

A pharmacokinetic interaction occurs between VPA and phenytoin because both drugs have a high affinity for

serum proteins. VPA increases the free fraction of phenytoin (63, 64). Because the free serum level of phenytoin determines the brain concentration, total phenytoin concentrations in the usual therapeutic range may, in the presence of VPA, be associated with clinical toxicity. In contrast to inducing AEDs, VPA is not associated with failure of oral contraceptives (65). Acetylsalicylic acid can both displace VPA from serum proteins and alter its metabolism (66). It appears that this interaction can be sufficient to cause clinical VPA toxicity (67).

## CLINICAL EFFICACY

### Absence Seizures

Valproate is a prime example of a broad-spectrum antiepileptic drug, with at least some degree of efficacy against most seizure types (68). During the first years of routine clinical use of VPA, it soon became apparent that it is a highly effective drug in the treatment of primarily generalized idiopathic seizures such as absence seizures, generalized tonic-clonic seizures, and myoclonic seizures (69). The primary indication of VPA when it was first released in North America in 1978 was the treatment of absence seizures. When VPA was administered to patients with typical and atypical absence seizures, a reduction of spike-and-wave discharges was repeatedly demonstrated (70–75). Comparison of the efficacy of VPA and ethosuximide in the treatment of absence seizures revealed equal efficacy in at least two studies (76, 77). Sixteen patients not previously treated for absence seizures and 29 refractory patients were enrolled in a double-blind crossover study of VPA and ethosuximide, in which the measure of efficacy was the frequency and duration of generalized spike wave bursts on electroencephalogram (EEG) telemetry (77). Ethosuximide and VPA were equally effective in previously untreated patients. An open randomized comparison of VPA and lamotrigine revealed that VPA achieved seizure control much faster than lamotrigine, but the overall seizure freedom at 1 year did not differ (78). According to other reports, simple absence seizures could be completely controlled by VPA monotherapy in 11 of 12 patients (79), in 10 of 12 patients (50), in 14 of 17 patients (80), and in 20 of 21 patients (81). Overall review of the available evidence cannot demonstrate a difference in efficacy between VPA, lamotrigine, and ethosuximide against absence seizures, possibly because of the methodological quality or statistical power of the studies (82). It appears that absence seizures are more likely to be fully controlled if they occur alone than if they are mixed with another seizure type (50, 81). Overall, treatment with VPA appears to be less effective against atypical or “complex” absences than against simple absences (79, 83). VPA can also be used effectively in patients with recurrent absence status (84).

### Generalized Tonic-Clonic Seizures

In addition to establishing itself as a first-line drug in the treatment of absence seizures, VPA was found to be highly effective in the treatment of certain generalized convulsive seizures (85–88). In 36 patients with primarily generalized tonic-clonic seizures, of whom 24 had been treated previously with other AEDs, VPA was used in monotherapy (79). In 33 of these patients, seizures were fully controlled. Among 42 patients with intractable seizures, the generalized tonic-clonic seizures were fully controlled by add-on VPA in 14 patients (07). VPA was compared with phenytoin in 61 previously untreated patients with generalized tonic-clonic, clonic, or tonic seizures (89). The seizures came under control during the time of observation in 73% of patients receiving VPA and in 47% of patients treated with phenytoin. Discounting seizures that occurred before therapeutic plasma drug levels had been reached, this response increased to 82% for VPA and 76% for phenytoin. In another randomized study comparing valproate and phenytoin in patients with previously untreated tonic-clonic seizures, a 2-year remission was achieved in 27 of 37 patients with VPA and in 22 of 39 patients with phenytoin (86). Monotherapy with VPA was assessed in two studies of patients with primary (or idiopathic) generalized epilepsies (81, 82). Among patients who had only generalized tonic-clonic seizures, complete seizure control was achieved in 51 of 70 patients (82) and in 39 of 44 patients (81), respectively. Monotherapy with VPA in children with generalized tonic-clonic seizures was also found to be highly effective (90).

### Myoclonic Seizures

VPA is currently a drug of first choice for most myoclonic seizures, particularly those occurring in patients with primary or idiopathic generalized epilepsies (79–81). In a group of 23 patients with myoclonic epilepsy of adolescence, 16 came under full control with VPA monotherapy (79). In the same study, 22 patients with myoclonic epilepsy of adolescence and abnormality on intermittent photic stimulation, of whom 17 had failed to respond to previous medications, full seizure control was achieved in 17 patients. Photosensitivity on the EEG is easily suppressed by VPA, regardless of the associated clinical seizure type (91). Among a group of patients with primary generalized epilepsies treated with VPA monotherapy, 22 patients had myoclonic seizures and 20 of those had at least one other seizure type, either absence or tonic-clonic seizures. The myoclonic seizures were controlled by VPA monotherapy in 18 of these 22 patients (81). Patients with juvenile myoclonic epilepsy have an excellent response to VPA (92), which still remains a drug of first choice for this condition in most patients, at least in

terms of efficacy. Benign myoclonic epilepsy of infancy, which belongs to the group of primary or idiopathic generalized epilepsies, also responds well to treatment with VPA (90). Postanoxic intention myoclonus is usually refractory to treatment, but some success has been achieved with VPA (93–95). A combination of VPA and clonazepam was advocated in the treatment of the myoclonic and tonic-clonic seizures in patients with severe progressive myoclonus epilepsy (96).

### **Infantile Spasms and Lennox-Gastaut Syndrome**

The available information on the use of VPA in the treatment of generalized encephalopathic epilepsies of infancy and childhood, such as West syndrome and Lennox-Gastaut syndrome, is much less extensive than for the more benign idiopathic primary generalized epilepsies. Like all other antiepileptic medications, VPA is less effective in the treatment of these severe forms of generalized epilepsy. In a larger series of patients treated with VPA, 38 had myoclonic astatic epilepsy, a term used by the authors synonymously with Lennox-Gastaut syndrome (79). Of these patients, seven became and remained seizure free with VPA. In addition, a 50% to 80% improvement was achieved after the addition of VPA in one-third of these patients, and other AEDs were withdrawn or reduced. In the same series, seizures were fully controlled in three of six patients with myoclonic absence epilepsy, all of them on combination therapy. In another series involving 100 children treated with VPA (50), seizure control was achieved in 12 of 27 children with “absences and other seizures” and in 9 of 39 children with atonic seizures.

The majority of reports on the use of VPA for the treatment of infantile spasms include small numbers of patients (97–99), or they include patients receiving corticotropin and VPA simultaneously (100, 101). VPA was used without corticotropin in one series of 19 infants with infantile spasms (102). With VPA as their first drug, 8 of these 19 infants experienced good seizure control and did not require corticotropin. These patients received VPA doses ranging from 20 to 60 mg/kg/day. The patients who experienced an initial failure with either VPA or corticotropin were subsequently switched to the other drug. Comparison of the two groups revealed a tendency toward a better response to corticotropin, but the incidence and severity of side effects was lower with VPA. A low dose of 20 mg/kg/day of VPA was used in a series of 18 infants with infantile spasms not previously treated with corticotropin (103). In 12 of these patients, the short-term results were described as good to excellent. On follow-up, 7 patients had residual seizure activity, and moderate to severe mental retardation was diagnosed in 16. The authors concluded that the efficacy of VPA was similar to the efficacy of corticotropin and that VPA was associated with fewer side effects.

### **Partial Seizures**

Systematic assessment of the efficacy of VPA against partial seizures began only after its role in the treatment of generalized seizures had been established. Preliminary information had been provided by subgroups of patients in studies not dealing primarily with partial seizures, all of which suggested some benefit (50, 79, 104). The first direct comparison of VPA with carbamazepine in the treatment of partial seizures was an open study in 31 previously untreated adults (105). Eleven patients receiving VPA and 8 patients receiving carbamazepine were controlled, but follow-up was less than 1 year in 12 of the 31 patients. Comparison between carbamazepine, phenytoin, and VPA in monotherapy in a prospective study of 79 patients with previously untreated simple partial or complex partial seizures revealed no difference in efficacy among the three drugs (106). A group of 140 adults with previously untreated seizures were randomized to monotherapy with phenytoin or VPA (107). The seizures were tonic-clonic in 76 patients and predominantly complex partial in 64. Determination of 2-year remission rate or time to first seizure revealed no difference between the two drugs in either subgroup. A retrospective study of VPA monotherapy in 30 patients with simple partial and complex partial seizures in whom previous drugs had failed revealed a remarkable response (108). Seizure control was achieved in 12 patients, a more than 50% seizure reduction occurred in 10 patients, and only 9 patients were not improved.

Mattson and coworkers (109) carried out the most comprehensive controlled comparison of VPA and carbamazepine monotherapy in the treatment of partial and secondarily generalized seizures. This multicenter, double-blind, randomized trial included 480 adult patients in whom several seizure indicators, as well as neurotoxicity and systemic toxicity, were assessed quantitatively. Four of five efficacy indicators were significantly in favor of carbamazepine against complex partial seizures, and a combined composite score for efficacy and toxicity was higher for carbamazepine than for VPA at 12 months, but not at 24 months. Outcomes for secondarily generalized seizures did not differ between the two drugs. Two comparative studies of VPA were carried out specifically in children (110, 111). A total of 260 children with newly diagnosed primary generalized or partial epilepsy were randomized to VPA or carbamazepine and followed for 3 years (110). The doses were titrated as needed and as tolerated according to clinical response. Equal efficacy was found for the two drugs against generalized and partial seizures, and adverse events were mostly mild for both drugs. The four drugs, phenobarbital, phenytoin, carbamazepine, and VPA, were compared in 167 children with untreated tonic-clonic or partial seizures entered into a randomized, unblinded study (111). Based on time to first

seizure and to 1-year remission, there was no difference in efficacy at 1, 2, or 3 years. Unacceptable side effects necessitating withdrawal occurred in 6 of 10 patients on phenobarbital, which was prematurely eliminated from the study, in 9% of children taking phenytoin, and in 4% each of children taking carbamazepine or VPA. When trials comparing VPA and carbamazepine were subjected to a meta-analysis, carbamazepine was more effective than VPA for time to first seizure and for time to 12 months of remission (112). Valproate therapy was evaluated in 143 adult patients with poorly controlled partial epilepsy randomized to monotherapy with VPA at low levels (25–50 mg/L) or high levels (80–150 mg/L) (113). The reduction in the frequency of both complex partial and secondarily generalized tonic-clonic seizures was significantly higher among patients in the high-level group.

### Other Uses of Valproate in the Treatment of Seizures

Several studies have assessed the efficacy of VPA in the prevention of febrile seizures (114–120). In some studies VPA was found to be as effective as phenobarbital, and in other studies it was more effective than phenobarbital, placebo, or no treatment in reducing seizure recurrence. Nevertheless, based on risk-versus-benefit ratio considerations, VPA cannot be recommended for the prophylaxis of febrile seizures. Treatment with intermittent diazepam during febrile episodes was as effective as prophylactic VPA in children with a high risk of recurrence of febrile seizures (121). A small group of newborns with seizures have also been treated with VPA either rectally (122) or orally (43). Overall results were favorable. A loading dose of 20 to 25 mg/kg was followed by a maintenance dose of 5 to 10 mg/kg every 12 hours (43). Newborns treated with VPA were found to have a longer elimination half-life (26.4 hours) and higher levels of ammonia.

### ADVERSE EFFECTS

Although adverse effects of AEDs are commonly divided into those that are dose related and those that are idiosyncratic, the distinction is not always easy, particularly with VPA. Some reactions, such as tremor, are indeed fairly predictable and dose related. However, certain adverse events that only occur in a small fraction of patients, and therefore appear to be idiosyncratic, may be more likely to occur at high doses or levels of VPA, such as thrombocytopenia, certain cases of confusion or stupor, and neural tube defects. Finally, certain side effects that are too common to be considered idiosyncratic could never be clearly shown to be dose related, such as hair changes and weight gain. The main adverse effects of VPA are summarized in Table 53-2.

**TABLE 53-2**  
*Adverse Effects of Valproate*

#### NEUROLOGIC

Tremor, drowsiness, lethargy, confusion, reversible dementia, brain atrophy, encephalopathy

#### GASTROINTESTINAL

Nausea, vomiting, anorexia  
Gastrointestinal distress  
Hepatic failure  
Pancreatitis

#### HEMATOLOGIC

Thrombocytopenia  
Decreased platelet aggregation  
Fibrinogen depletion

#### METABOLIC/ENDOCRINOLOGIC

Hyperammonemia  
Hypocarnitinemia  
Hyperinsulinism  
Menstrual irregularities  
Polycystic ovaries

#### TERATOGENICITY

Major malformations, including neural tube defect and possible developmental delay in offspring

#### MISCELLANEOUS

Hair loss  
Edema  
Nocturnal enuresis  
Decreased bone mineral density

### Neurologic Adverse Effects

A tremor with the characteristics of essential tremor is relatively common with VPA (123, 124). It is dose-related and occurs in about 10% of patients. If it does not improve sufficiently with dose reduction, propranolol may be effective (124). Asterixis (125) and reversible parkinsonism (126–128) have also been described. Drowsiness, lethargy, and confusional states are uncommon with VPA, but may occur in some patients, usually at levels greater than 100 mg/L. There have also been well-documented cases of reversible dementia (126, 129, 130) and pseudoatrophy of the brain (130–132). Treatment with VPA has been associated with a rather specific and unique adverse effect characterized by an acute mental

change that can progress to stupor or coma (133, 134). It is usually associated with generalized delta slowing of the EEG tracing. The mechanism is not known with certainty, and hyperammonemia or carnitine deficiency can be associated (135). This encephalopathic picture is more likely to occur when VPA is added to another AED, and it is usually reversible within 2 to 3 days upon discontinuation of VPA or of the other AED. Overall, VPA does not appear to be associated with a high incidence of dose-related effects on cognition or behavior (136–140). A possible psychotropic effect of VPA (141) was not confirmed in a controlled study (142).

### Gastrointestinal Adverse Effects

The most frequent gastrointestinal adverse effects of VPA are nausea, vomiting, gastrointestinal distress, and anorexia. They may be due in part to direct gastric irritation by VPA, and the incidence is lower with enteric-coated tablets. Excessive weight gain is another common problem (143–146). It is not due entirely to increased appetite, and decreased beta-oxidation of fatty acids has been postulated as a mechanism (147). More recently, obese VPA-treated men were found to have higher serum insulin levels than obese control subjects (148, 149). The mechanism for this may be interference with hepatic insulin metabolism rather than increased insulin secretion or insulin resistance (150). In addition, patients who developed obesity while taking VPA had higher leptin levels and lower ghrelin and adiponectin levels (149). Despite recommendations for diet and exercise, weight gain tends to be a bothersome side effect, especially in young women. Excessive weight gain seems to be less of a problem in children, and one study suggests that VPA does not cause more weight gain than carbamazepine in children (151).

Fatal hepatotoxicity remains the most feared adverse effect of VPA (24, 152, 153). The two main risk factors are young age and polytherapy. The risk of fatal hepatotoxicity while receiving polytherapy with VPA was found to be approximately 1 in 600 younger than the age of 3 years, 1 in 8,000 from 3 to 10 years, 1 in 10,000 from 11 to 20 years, 1 in 31,000 between 21 and 40 years, and 1 in 107,000 older than the age of 41 years (24). The risk is much lower for monotherapy and varies between 1 in 16,000 (3–10 years old) and 1 in 230,000 (21–40 years old). No fatalities have been reported for certain age groups. Because a benign elevation of liver enzymes is common with VPA, and the severe hepatotoxicity is usually not preceded by a progressive elevation of liver enzymes, laboratory monitoring is of little value, although it is commonly done routinely. The diagnosis of hepatic failure due to VPA depends mostly on recognition of the clinical features, which include nausea, vomiting, anorexia, lethargy, jaundice, edema, and at times

loss of seizure control. Although increased production of toxic metabolites has been considered as a cause of VPA hepatotoxicity, this has not yet been documented (154, 155). There has also been evidence of a protective effect of carnitine administration (especially intravenously) in cases of severe VPA hepatotoxicity (156). A panel of pediatric neurologists concluded that daily L-carnitine supplementation is strongly suggested in several situations, including certain secondary carnitine deficiency syndromes, symptomatic VPA-associated hyperammonemia, multiple risk factors for VPA hepatotoxicity, or renal-associated syndromes, infants and young children taking VPA, patients with epilepsy using the ketogenic diet who have hypocarnitinemia, patients receiving dialysis, and premature infants who are receiving total parenteral nutrition (157).

Another serious complication of VPA treatment is the development of acute hemorrhagic pancreatitis (158–163). Suspicion should be raised by the occurrence of vomiting and abdominal pain. Serum amylase and lipase are the most helpful diagnostic tests, and abdominal ultrasound may be considered. However, amylase may be elevated in 20% of asymptomatic patients taking VPA (164), and pancreatitis has been described in a patient with normal amylase but elevated lipase (165).

### Hematologic Adverse Effects

Hematologic alterations are relatively common with VPA therapy, but they seldom lead to discontinuation of the drug (166–168). By far the most frequently diagnosed hematologic adverse event is thrombocytopenia (169, 170), which tends to improve with dosage reductions. The thrombocytopenia, in conjunction with other VPA-mediated disturbances of hemostasis, such as impaired platelet function, fibrinogen depletion, and coagulation factor deficiencies (171–174), may cause excessive bleeding. The common practice of discontinuing VPA about 1 month before elective surgery is therefore recommended, especially surgeries considered to be associated with higher blood losses, although several reports have found no objective evidence of excessive operative bleeding during neurosurgical procedures in patients maintained on VPA (175–177). In addition to the described hematologic changes, VPA can also occasionally cause neutropenia (178), bone marrow suppression (179), and systemic lupus erythematosus (180).

### Metabolic and Endocrinologic Changes, Effect on Offspring

Hyperammonemia is a very common finding in asymptomatic patients receiving chronic VPA therapy, and routine monitoring of ammonia is not warranted. Because ammonia levels were initially measured in symptomatic

patients, their elevation was thought to be the cause of the symptoms (181–183). It was later found that hyperammonemia is very common in asymptomatic patients, particularly in those taking VPA together with an enzyme-inducing AED (184, 185). The origin of the excessive ammonium may be renal (186). Although hyperammonemia can be reduced by L-carnitine supplementation (187), there is no documentation that this is necessary or clinically beneficial (188). Chronic treatment with VPA, especially in polytherapy, also tends to lower carnitine levels (189, 190). A role for carnitine deficiency in the development of severe adverse effects of VPA has never been established. One patient who developed an acute encephalopathy and cerebral edema after acute administration of VPA was found to have low carnitine levels (191). A beneficial role of L-carnitine supplementation in acute VPA overdoses has been suggested (192, 193).

VPA can cause menstrual irregularities (194), hormonal changes such as hyperandrogenism and hyperinsulinism (195–199), and pubertal arrest in women (200). Another concern has been the association between VPA therapy and polycystic ovaries (195–197, 201). To what extent these observations are significant and reproducible is an open and debated issue (202–207).

When taken during pregnancy, VPA is associated with an increased of major malformations and of developmental delay in the offspring (208–211). Treatment with VPA during the first trimester of pregnancy is associated with an estimated 1% to 2% risk of neural tube defect in the newborn (212–215). This risk appears to be greater at higher doses of VPA (216) and may also result from a pharmacogenetic susceptibility (217). Folate supplementation seems to reduce the risk (218), and a daily dose of at least 1 mg should be considered in all female patients of childbearing age who are taking VPA (see Chapters 35 and 36). Finally, a more recent concern has been that developmental delay may result from exposure to VPA in utero (219, 220).

### Miscellaneous Adverse Effects

Excessive hair loss may be seen early during treatment with VPA, and, although the hair tends to grow back, it may become different in texture (221) or color (222). Facial or limb edema can occur in the absence of VPA-induced hepatic injury (223). Children may develop secondary nocturnal enuresis during VPA therapy (118, 143, 224–226). Hyponatremia (227) has also been reported in one patient. The occurrence of rashes with VPA is extremely rare (228). Bone mineral density can also be decreased by VPA, with increased risk for fractures (229–233). The precise mechanism has not been elucidated, and VPA, unlike enzyme-inducing drugs, does not cause bone loss through hypovitaminosis D.

### CLINICAL USE

Many different preparations of VPA are available, although not all preparations are available in all countries. Preparations of VPA include valproic acid capsules, tablets, and syrup (immediate release), enteric-coated tablets of sodium valproate or sodium hydrogen divalproate (divalproex sodium) (delayed release), divalproex sodium enteric-coated sprinkles, extended-release oral preparations, magnesium valproate and valpromide (the amide of VPA) for oral administration, valproate suppositories, and a parenteral formulation of sodium valproate for intravenous use. The sprinkles consist of capsules containing enteric-coated particles of divalproex sodium. These capsules can be swallowed as such, or they can be opened and the contents can be sprinkled on food. This is a convenient formulation for younger children.

An initial VPA dose of approximately 15 mg/kg/day is recommended, with subsequent dose increases, as necessary and as tolerated, by 5 to 10 mg/kg/day at weekly intervals. The optimal VPA dose or concentration may vary according to the patient's seizure type (234). Daily doses between 10 and 20 mg/kg are often sufficient for VPA monotherapy in primary generalized epilepsies (50, 80, 81, 89). Children may require higher doses in milligrams per kilogram of body weight per day (56, 79). Doses of 30 to 60 mg/kg/day (in children even more than 100 mg/kg/day) may be necessary to achieve adequate VPA levels in patients who are also taking enzyme-inducing AEDs. If therapeutic levels of VPA are to be achieved rapidly or in patients who are unable to take oral medications, VPA can be administered intravenously (235, 236). This route has also been suggested for the treatment of status epilepticus (237–242), with an initial dose of 15 mg/kg followed by 1 mg/kg/hr (243), but more rapid administration, up to 6 mg/kg/min, has been successfully given (244). In those receiving intravenous replacement therapy or bolus dosing, subsequent administration should be given within 6 hours because of the precipitous fall in levels and return of clinical symptoms. Because of the relatively short elimination half-life of VPA, it is common practice to divide the daily dose into two or three single doses. However, the pharmacodynamic profile of VPA may explain why equally good results were achieved with a single daily dose of VPA (79, 245, 246).

The value of serum levels of VPA is relatively limited. First, there is a considerable fluctuation in VPA levels because of the short half-life, and the reproducibility in a given patient is not good. Second, there seems to be a poor correlation between VPA serum levels and clinical effect at a given time, because the pharmacodynamic effect of VPA may lag significantly behind its blood concentrations (81, 100, 247, 248). Although the recommended therapeutic range for VPA serum levels is usually 50 to 100 mg/L (350–700  $\mu\text{mol/L}$ ), levels up to 150 mg/L are often both necessary and well tolerated.

In selected cases, and particularly during combination therapy with enzyme-inducing drugs, serum VPA levels can be valuable, but the result of a single measurement has limited value and must be interpreted cautiously (249). In patients receiving chronic VPA therapy, it is common practice to monitor routinely liver enzymes

and complete blood count with platelets, at least 1 to 3 months after initiation, and then about every 6 months if results are normal. Severe hepatotoxicity is unlikely to be detected by routine monitoring of liver enzymes, and hematologic abnormalities are more likely to be discovered.

## Vigabatrin

**Günter Krämer**  
**Gabriele Wohlrab**

**G**amma-aminobutyric acid (GABA) is the major inhibitory neurotransmitter in the mammalian brain. Vigabatrin (gamma-vinyl-GABA, 4-amino-5-hexenoic acid; VGB) was synthesized in 1974 as a structural GABA analog with a vinyl appendage. The aim was to achieve an enzyme-activated inhibition of GABA catabolism (1). It has been regarded as a prime example of a drug developed on a rational scientific basis for treatment of a disease (2). VGB was first marketed as an antiepileptic drug (AED) for adults in the United Kingdom in 1989 and thereafter in most European countries (3). The application was extended in 1990 to the use of VGB in children suffering from refractory epilepsy, and later to its use as monotherapy for infantile spasms. Although VGB has been approved in over 65 countries worldwide, its usage has declined after the detection of persistent peripheral visual field defects (VFD) in up to more than 50% of the patients, with restrictions in its approval.

### CHEMISTRY

VGB is a white to off-white crystalline amino acid that is highly water soluble and only slightly soluble in ethanol and methanol. The molecular weight is 129.16, and

the conversion factor is  $7.75 \text{ (mg/L} \times 7.75 = \mu\text{mol/L)}$ . VGB exists as a racemic mixture of S(+)- and R(-)-enantiomers in equal proportions. The S(+)-enantiomer is responsible for the pharmacologic action, whereas the R(-)-enantiomer is inactive (4, 5). The only available forms of VGB are oral formulations (tablets and sachets, containing 500 mg).

### ANIMAL PHARMACOLOGY

The anticonvulsant effect of VGB has been demonstrated in numerous animal models. Whereas it is inactive in models such as maximal electroshock or pentylenetetrazol, it protects against bicuculline-induced myoclonic activity, strychnine-induced tonic seizures, isoniazid-induced generalized seizures, audiogenic seizures in mice, light-induced seizures in the baboon, and amygdala-kindled seizures in the rat (6).

The usual animal preclinical safety studies carried out in rats, mice, dogs, and monkeys demonstrated no significant adverse effects on the liver, kidney, lung, heart, or gastrointestinal tract. Studies revealed no evidence of mutagenic or carcinogenic effects. However, in the brain, microvacuolation has been observed in white matter tracts of rats, mice, and dogs at doses of 30–50 mg/kg/day. In the monkey, these lesions were minimal or equivocal.

This effect is caused by a separation of the outer lamellar sheath of myelinated fibers, a change characteristic of intramyelinic edema. In both rats and dogs the intramyelinic edema was reversible upon discontinuation of VGB, and even with continued treatment histologic regression was observed. In rodents, minor residual changes consisting of swollen axons and mineralized microbodies have been observed (7, 8).

VGB-associated retinotoxicity has been observed in albino rats, but not in pigmented rats, dogs, or monkeys. The retinal changes in albino rats were characterized as focal or multifocal disorganization of the outer nuclear layer with displacement of nuclei into the rod and cone area. The other layers of the retina were not affected. Although the histologic appearance of these lesions was similar to that found in albino rats following excessive exposure to light, the retinal changes may also represent a direct drug-induced effect (7).

Although there is no evidence of intramyelinic edema in humans, the U.S. Food and Drug Administration (FDA) halted clinical studies with VGB in the United States because of these findings for 5 years between 1983 and 1988. Tests done to confirm lack of significant adverse effect on neurologic function include evoked potentials, computed tomography (CT) and magnetic resonance imaging (MRI) scans, cerebrospinal fluid (CSF) analyses, and, in a small number of cases, neuropathologic examinations of brain specimens (8, 9).

Further animal experiments have shown that VGB has no negative influence on fertility or pup development. No teratogenicity was seen in rats at doses up to 150 mg/kg (three times the human dose) or in rabbits in doses up to 100 mg/kg. However, in rabbits, a slight increase in the incidence of cleft palate at doses of 150–200 mg/kg was seen. Therefore, the usage of VGB is not recommended for women with childbearing potential (10).

In neonatal rat brains, the application of VGB (50, 100, or 200 mg/kg twice daily on three consecutive days) elicited apoptotic neurodegeneration in a dose-dependent manner at a threshold dose of 100 mg/kg of body weight. However, the same apoptotic processes have also been shown for other AEDs such as valproate (VPA), phenytoin (PHT), and phenobarbital, which are commonly used AEDs in pediatric epilepsies (11, 12).

## MECHANISM OF ACTION

VGB acts by replacing GABA as a substrate of GABA-transaminase (GABA-T) (13). However, because VGB possesses an inert appendage at the gamma-position, it prevents the transamination of GABA to form succinic acid semialdehyde by irreversible and covalent binding to GABA-T, causing its permanent inactivation (14, 15). This results in prolonged elevation of brain GABA levels

without any major influence on other enzymes involved in GABA synthesis and metabolism. The effect is maximal 3 to 4 hours after administration and maintained for at least 24 hours. Thus, the major pharmacologic effects of VGB are determined not by the half-life of the drug itself but by that of GABA-T. Restoration of normal enzyme activity by resynthesis after withdrawal of VGB takes several days (16). In addition, VGB significantly reduces the activity of the plasma alanine aminotransferase (ALAT) between 20% and 100% (17, 18).

In patients with epilepsy, a dose-related (up to 3 g/day) elevation of free GABA, total GABA, and homocarnosine (a dipeptide of GABA) CSF levels could be demonstrated (19). <sup>1</sup>H-MR spectroscopy has shown that the brain GABA content in the occipital region of patients with epilepsy increased two- to threefold (20–22). Increasing VGB dosage from 3 to 6 g/day did not result in a further increase in brain GABA concentrations, most probably because of a feedback inhibition of glutamic acid decarboxylase (GAD), the GABA-synthesizing enzyme, at high GABA concentrations.

In young children no studies of GABA levels in CSF during VGB treatment have been performed, and GABA levels in brain have not been measured by MR spectroscopy. In a study using <sup>11</sup>C-flumazenil (FMZ)-positron emission tomography (PET) imaging, 15 children (age 1–8 years) with drug-resistant epilepsy were studied to determine whether prolonged treatment with VGB interferes with age-related changes of in-vivo GABA<sub>A</sub>-receptor bindings (23). Seven of these children were treated with VGB (1,000–2,500 mg/day) for at least 3 months, used as add-on therapy with one other AED. Eight age-matched children, treated with one to three other AEDs, were used as a control group. The VGB-treated children were observed to have significantly lower hemispheric FMZ volume of distribution (*V<sub>d</sub>*) in all cortical regions and the cerebellum. This led to the conclusion that VGB induces a decrease in GABA<sub>A</sub>-receptor binding in the cortex and cerebellum of the developing epileptic brain. Further studies of this age-specific drug effect concerning the reversibility and functional consequences are urgently needed because of the important role of the GABAergic system in developmental nervous system plasticity.

## BIOTRANSFORMATION, PHARMACOKINETICS, AND DRUG INTERACTIONS IN HUMANS

### Pharmacokinetics

*Infants and Children.* VGB is rapidly and almost completely absorbed from the gastrointestinal tract. Absorption is faster and more complete in older than in younger

children, and therefore, the bioavailability of the drug is higher. Accordingly, the area under the curve (AUC) values for both isomers are significantly lower in infants than in children, which in turn are lower than in adults. A pharmacokinetic study after a single racemic 50 mg/kg VGB dose in six infants (5–24 months) and six children (4–14 years) with intractable epilepsy showed results comparable to those in adults for the children, mainly with regard to the elimination of the active S(+)-enantiomer, which seems to be age independent (24). In contrast to adults, in whom  $t_{\max}$  of the inactive R(-)-enantiomer is about twice that of the active S(+)-enantiomer, no differences were found for  $t_{\max}$  of the two allosteric forms in children. However, the mean AUC of the R(-)-enantiomer was also significantly greater. Larger apparent volumes of distribution (V/F values) were found for the active S(+)-enantiomer only in younger children. No differences were observed between infants and children aged 4 to 14 years. Smaller V/F values have been measured in adults.

Although the drug-metabolizing capacity is reduced in newborns—particularly in those born prematurely—and increases rapidly during the first weeks of life, the mean values of  $C_{\max}$  and AUC were significantly lower for the active S(+)-enantiomer following single oral doses of 125 mg of VGB racemate in six neonates. No difference was found for the time to reach peak plasma concentrations ( $t_{\max}$ ). Repeated administration of 125 mg twice daily over 4 days showed no evidence of accumulation of either enantiomer (25).

In children, the renal excretion of unchanged drug is the main route of elimination; no metabolites of VGB have been identified. The mean  $t_{1/2}$  of the S(+)-enantiomer is significantly longer than that of the inactive R(-)-enantiomer, but only in younger children (26). The  $t_{1/2}$  and clearance (CL/F) values are shorter and higher in young children.

In conclusion, despite lower AUC values in children, pharmacokinetics of VGB appeared to be little influenced by age, and VGB accumulation during multiple dose administration (5 days) did not occur (24). These findings support the use of similar doses per kilogram according to age between 1 month and 15 years of age.

**Adults.** Food does not influence absorption (27), and peak plasma concentrations ( $C_{\max}$ ) are reached within 0.5 to 2 hours after single doses (28). Areas under the plasma concentration time curve (AUC) as well as  $C_{\max}$  indicate linear pharmacokinetics over the dose range of 0.5 to 4 g. VGB is widely distributed in the body with a volume of distribution of 0.8 L/kg; levels in the cerebrospinal fluid (CSF) are approximately 10% of those in the blood (29).

VGB is neither bound to proteins nor does it influence the protein binding of other drugs or cytochrome P450-dependent enzymes. Elimination is primarily renal

with a renal clearance of unchanged drug accounting for 60% to 70% of the total clearance, which indicates an oral bioavailability of at least that magnitude. The elimination half-life ( $t_{1/2}$ ) is between 5 and 7 hours, but in patients taking hepatic enzyme-inducing drugs, slightly shorter half-life values of 4–6 hours have been observed (29, 30).

Because about 60% of the drug is removed from the blood during hemodialysis, VGB should be administered thereafter (31). The passage of both enantiomers of VGB across the human placenta is slow, and the concentration ratio in breast milk compared to plasma for the active S(+)-enantiomer is below 0.5 (32).

### Drug Interactions

VGB has no effect on the plasma concentrations of VPA (33) and felbamate (FBM) (34). Usually there is also no effect on carbamazepine (CBZ) levels, but an increase of up to 27% has been described by two authors (35, 36), who studied pediatric and adult patients. A decrease of up to 50% was observed by other investigators (37, 38). After a latency of some weeks VGB reduces PHT levels about 25% without altered absorption (39) or plasma protein binding (40). In children with epilepsy, the drop of PHT levels can be even more pronounced (41). Serum levels of phenobarbital and primidone can also be slightly reduced by VGB (30). VPA has no effect on VGB plasma levels (33), and this has also been described for the other established AEDs (42), although a shorter half-life of VGB in patients on enzyme-inducing drugs has been observed (29, 30). FBM leads to a slight increase of the active S(+)-enantiomer (34). Regarding other drugs than AEDs, VGB has no effect on oral steroid contraceptives (43), and there is no information on effects of other drugs on VGB (44).

### Drug Monitoring

VGB can be determined in biologic fluids by high-performance liquid chromatography (HPLC) and gas chromatography–mass spectroscopy (45). A sensitive HPLC method for the simultaneous determination of VGB and gabapentin (GBP) in serum and urine has been described (46). The value of plasma level determinations for therapeutic drug monitoring of VGB is mainly limited because of its mechanism of action, with irreversible enzyme inhibition resulting in a biologic half-life of several days. Consequently, in a study of 16 children with refractory epilepsy there was no strong correlation between VGB dosages, plasma concentrations, and clinical efficacy. Those patients who responded to VGB showed a good correlation between seizure reduction and VGB dosage, but there was no positive correlation between seizure reduction and either inhibition of platelet

GABA-T activity or plasma concentration (47). This was confirmed by another study in 36 patients with VGB dosages between 1,000 and 4,000 mg/day (48). Correspondingly, a proposed tentative target range for the serum concentration of VGB of between 6 and 278  $\mu\text{mol/L}$  is very broad (49).

## CLINICAL EFFICACY

### Infants and Children

*Partial and Generalized Epilepsies.* Following the “usual clinical procedure” to test new AEDs, VGB has been used in refractory epilepsies as an add-on medication to approved AEDs. In most countries, no randomized, placebo-controlled, double-blind trials (evidence class I) in infants and children were published before approval, which was granted on the basis of compassionate experience and open-label studies. Small open trials (41, 50–59) resulted in a response with >50% reduction in seizure frequency in 23% to 89% of patients. The efficacy was generally similar to that reported in adults. One prospective study (58), encompassing 175 children (neonates, children, and adolescents from age 1 week to 19 years) with partial seizures, led to about 30% of patients becoming seizure free and 70% achieving a >50% reduction in seizure frequency. The highest percentage of responders was found in patients with tuberous sclerosis complex (85%), and the lowest in patients with tumors (45%). VGB was effective against both simple and complex partial seizures and secondary generalization.

A randomized withdrawal study of placebo (VGB blindly stopped) versus VGB (continued) in children who had responded earlier to VGB was published by Chiron et al. (60). The seizure frequency was compared to the prerandomization period. A more than 50% increase in seizure frequency induced drop out. The patients remaining in the study were more numerous (93%) than on placebo (46%) ( $P < 0.01$ ) and seizure frequency was lower on VGB than placebo ( $P < 0.05$ ).

Two dose-response studies performed in a total of 81 children with refractory epilepsy (61, 62) demonstrated an optimal efficacy with a dose between 40 and 80 mg/kg/day (mean, 60 mg/kg/day), which is slightly higher than in adults (35–65 mg/kg/day). Further increase of the dose in nonresponders, although well tolerated, did not result in a higher number of patients being controlled. On the basis of pharmacokinetic and dose-response studies, the following dosage regimen for children was recommended and approved: starting dose: 40 mg/kg/day, increasing to 80 to 100 mg/kg/day, depending on response.

The satisfying results obtained with VGB in children with drug-resistant epilepsy have prompted some

investigators to use it as first-line treatment in partial epilepsy. Three open, prospective and randomized studies with a follow-up of 6 months, and 2 years, respectively (63–65; evidence class III), compared the efficacy of VGB ( $n = 104$ ) and CBZ ( $n = 100$ ) in monotherapy in newly diagnosed children with partial epilepsy. Both therapeutic groups included patients with idiopathic, cryptogenic, and symptomatic partial epilepsy at comparable levels. In these trials the evaluation of the efficacy of VGB and CBZ did not reveal any significant differences. Interictal electroencephalographic (EEG) abnormalities decreased in VGB patients more than in CBZ patients. In conclusion, VGB seemed to be an effective AED as primary monotherapy in partial childhood epilepsy.

Long-term efficacy data of VGB treatment in children up to 10 years of age have also been published. One of these studies investigated a cohort of 196 children with drug-resistant epilepsy and VGB as add-on therapy over a period of 1.5 to 5.5 years (66). The evaluation of the long-term prognosis was focused on the incidence of increased seizure frequency, loss of efficacy, and appearance of new seizure types. Increase of seizure frequency occurred in only 10% of patients, with half occurring during the first month of treatment. Patients with atypical absences had the highest incidence of increase in seizure frequency (38%) compared with less than 8% of those with partial seizures. Nonprogressive myoclonic epilepsy and Lennox-Gastaut syndrome (LGS) showed the greatest increase in seizure frequency, 38% and 29%, respectively. Loss of efficacy was reported in 12% of children who were taking VGB (25–50% of responders, some of whom had been seizure free). Three-quarters of these patients had never had their seizures controlled prior to the introduction of VGB. Loss of efficacy was not connected to any specific seizure type except atypical absences and clonic seizures. The average time reported for loss of efficacy was 7 months. In 38%, the loss of efficacy was simultaneous to an attempt to decrease concomitant antiepileptic medication. Eleven percent of the children developed new seizure types, mainly myoclonic and new partial seizures, after a very variable time lag. Partial seizures were better tolerated than the initial seizure type and had little impact on the patient's overall clinical development.

Based on the long-term study of patients with intractable epilepsies of childhood, a sustained beneficial effect of VGB on seizure frequency can be expected in children with partial rather than with generalized seizures. A comparison of lamotrigine (LTG;  $n = 132$ ), VGB ( $n = 80$ ), and GBP ( $n = 39$ ) as add-on therapy in children with intractable epilepsy was performed in a 10-year follow-up study (67). Thirty-three percent of the children taking LTG were seizure free or had a sustained reduction of seizure frequency of >50%. In contrast, only 19% of the VGB and 15% of the GBP-group still responded to the additional drug. The main difference was found in

patients with generalized epilepsy, respectively, in patients classified as having LGS, myoclonic-astatic epilepsy, or unclassified epilepsies. On the other hand, no significant difference in efficacy was found in children with partial seizures.

The long-term retention rate seems to be lower for VGB than for LTG in children with difficult-to-treat epilepsies (68). Comparing efficacy and retention at 5 years in an open label study, the initial efficacy showed no difference (VGB  $n = 56$ , responder 32%; LTG  $n = 39$ , responder 28%) after 6 weeks, and 4 months, respectively. In contrast, the retention at 5 years was still 25.6% in the LTG group, but was reduced to 8.9% in the VGB group. A loss of efficacy occurred in 10 of the initial 18 responders, usually within the first 9 months after initial response.

Several anecdotal case reports have described favorable effects in neonatal seizures due to Ohtahara syndrome (69), partial seizures in Sturge-Weber syndrome (70), Landau-Kleffner syndrome (71), and infantile spasms in Down syndrome (72) as well as an improved outcome in Aicardi syndrome (73). However, the numbers of patients in these reports are too small for a meaningful analysis.

In conclusion, VGB has proved to be a useful AED for add-on treatment of partial seizures with and without secondary generalization, refractory to first-line AEDs. Loss of efficacy, increase of seizures in specific seizure types, and side effects (see following) must be kept in mind. The following studies allow for a better definition of the profile of activity of VGB in different types of drug-resistant epilepsies, including the epileptic syndromes specific to childhood and for the assessment of the tolerability of VGB in children.

**Infantile Spasms (West Syndrome).** One single randomized placebo-controlled study provided class I evidence for the efficacy of VGB in infantile spasms (IS) (74). This trial, which included children with newly diagnosed IS ( $n = 20$  in each group) showed that at the end of the 5-day double-blind phase, seven (35%) patients treated with VGB were spasm free and five (25%) had resolution of hypsarrhythmia compared with two (10%) and one (5%), respectively, in the placebo-group ( $P = 0.063$ ). Relapse was seen in four (20%) of the VGB-treated patients. At the end of the study 42% of the 36 patients who entered the open phase were spasm free with VGB monotherapy. No patient withdrew from the study because of side effects.

In addition, three randomized controlled studies provide class III evidence. The first class III study (75) compared VGB (100–150 mg/kg/day) with adrenocorticotrophic hormone (ACTH or tetracosactide; 10 IU/day) as first-line therapy in 42 infants with IS. The alternative drug was administered in nonresponders (within 20 days)

or in case of intolerance to the initial therapy. Cessation of IS was observed in 48% (11 of 23) of the VGB-treated patients and 74% (14 of 19) of those treated with ACTH. The response to VGB was seen within 14 days. Follow-up data for up to 44 months showed only one relapse. In the ACTH group six patients showed a relapse 40–45 days after cessation of ACTH and replacement by a benzodiazepine.

In a multicenter study (76) including 142 patients, spasms ceased completely within 2 weeks in 23% of the patients, and this effect increased to 65% by the end of a 3-month open label period. Infants were randomly assigned to receive low-dose (18–36 mg/kg/day) or high-dose (100–148 mg/kg/day) treatment. A marked difference in response in dependency to the VGB dosage was observed. Within the first 2 weeks, 8 of 75 patients (10.6%) of the low-dose and 24 of 67 (35.8%) of the high-dose group responded. The response increased considerably during the follow-up period (42% at 4 weeks, 55% at 2 months, and 65% at 3 months), in the course of which the infants allocated to the high-dose treatment showed an earlier cessation of spasms.

The third class III study was a multicenter, randomized controlled trial comparing VGB with prednisolone or tetracosactide in a 14-day trial and a 14-month follow-up (77, 78). Of 52 patients randomized to the VGB group, 28 (54%) were spasm free within 2 weeks. The efficacy of VGB was lower than for the hormone-treated patients, with 21 of 30 (70%) of the patients receiving prednisolone and 19 of 25 (76%) assigned tetracosactide becoming spasm free. Adverse events were reported in 28 of 52 (54%) infants taking VGB, mainly drowsiness and gastrointestinal complaints. Thirty of 55 (55%) children taking hormonal treatment suffered from side effects, mainly irritability and gastrointestinal problems as well. Of the 55 infants allocated to hormonal treatment, 27 received VGB after day 14 because of failure to achieve cessation of spasms (12 of 27), seizure relapse (14 of 27), and one for treatment of focal seizures, respectively. Of the 52 primarily given VGB, 22 received a hormone therapy, 3 due to a relapse. The response rate was 9 of 12 (75%) for VGB and 14 of 19 for hormone treatment, respectively. There were five deaths during the follow-up period. One child died of *Staphylococcus aureus* septicemia on day 15 of treatment with prednisolone. The deaths of the other four children were related to their underlying disease.

Except for the low dose option performed by the U.S. Infantile Spasms Vigabatrin Study Group (76), all prospective studies used cessation of IS by caregiver observation as the primary efficacy endpoint. Initial doses of VGB varied between 50 and 150 mg/kg/day, but in all studies dose was titrated up to 150 mg/kg/day. The relapse rate in these four randomized controlled studies ranged from 8% to 20%.

In addition to these controlled studies, there have been many reports on VGB treatment in newly diagnosed or refractory IS. They included different patient groups regarding symptomatic or cryptogenic etiology. In six open label uncontrolled prospective (class IV) observations (79–84) with between 23 and 116 enrolled patients, the overall response rate varied between 26% and 66.7%. For cryptogenic cases the response ranged from 50% to 100%, and for infants with symptomatic West syndrome from 19% to 57%. The relapse rate was low, ranging from a single case to 14%. The percentage of complete cessation of IS without relapse was comparable for newly diagnosed patients, 43% (81) and 45% (80), and refractory patients, 43% (85) and 48% (79).

In a retrospective survey of the safety and efficacy data from IS patients treated initially with VGB monotherapy at 59 European centers (86), the dosage varied from 20 to 400 mg/kg/day (mean dose, 99 mg/kg/day) and the duration of therapy ranged from 0.2 to 28.6 months. Complete disappearance of IS was reported in 131 of 192 (68%) of the patients. Treatment with VGB did not result in any improvement in 24 (12.5%) of the patients and 1 patient deteriorated. Of the subgroups of IS types, patients with tuberous sclerosis had the highest response rate (27 of 28 = 97%), followed by patients with cryptogenic IS (69.4%) and symptomatic IS of other causes (59.7%). Infants younger than 3 months at the onset responded better (18 of 20 infants, 90%) than those with a later seizure onset (65%). Of the 131 patients with complete initial response to VGB, 28 (21.3%) relapsed at a mean period of 4 months. There were few adverse events reported, and they were generally mild (somnolence, insomnia, hypotonia, hyperkinesia). Therefore drug withdrawal was necessary only in a few patients (~1%).

In all studies the time from initiation of therapy to cessation of spasms ranged from 2 to a maximum of 35 days, and sometimes was observed after only 1 or 2 doses. The placebo-controlled studies performed by Vigeveno and Eltermann (75, 76) as well as several different open-label studies (81, 82) proposed a 2-week cutoff for qualifying responders. The time to EEG response was 7 to 35 days and 11% to 83% of the children had resolution of hypsarrhythmia.

The prospective studies cited used VGB in dosages between 18 and 200 mg/kg/day. Mitchell and Shah (87) presumed a dose-independent response to VGB in infantile spasms. They reported a complete cessation of infantile spasms and resolution of hypsarrhythmia at doses ranging from 25 to 135 mg/kg/day in 12 of 20 patients. In contrast an Asian study (88) mentioned a relapse rate of 56% within 6 months, in all patients who received a reduced dosage (average, 59 mg/kg/day) in comparison to the initial dose. It was concluded that at least 70 mg/kg/day will be necessary to achieve adequate seizure control.

*Tuberous Sclerosis Complex.* VGB has been found most effective in the treatment of IS due to tuberous sclerosis complex (TSC). This has been shown in a multicenter retrospective survey (86), which showed a response rate of 96% (27 of 28 children obtained a complete cessation of spasms). These results were confirmed by a prospective randomized trial comparing VGB and hydrocortisone (89). The monotherapy study in 22 newly diagnosed patients with IS and confirmed diagnosis of tuberous sclerosis was performed with an optional crossover for nonresponders. It showed a highly significant difference between oral hydrocortisone (15 mg/kg/day) and VGB (150 mg/kg/day) both before and after crossover. In patients taking VGB the efficacy was 100% (11 of 11), whereas it was less than half (5 of 11) for patients taking hydrocortisone. All 7 patients who crossed from hydrocortisone to VGB (6 for inefficacy, 1 for adverse events) also became completely seizure free. In addition, there was a statistically significant difference for the mean time to disappearance of IS favoring VGB (3.5 days vs. 13 days), and side effects were less common.

Hancock and Osborne (90) reviewed 16 studies with 77 patients with TCS investigating the use of VGB in IS. Of the 313 patients without TCS, 170 (54%) had complete cessation of their IS; of the 77 patients with TCS, 73 (95%) had complete cessation. They concluded that VGB should be considered as first-line monotherapy for the treatment of IS in infants with either a confirmed diagnosis of TCS or those at high risk, that is, those with a first-degree relative with TCS. In a later review the same authors (91) concluded that they found no single treatment to be proven to be more efficacious in treating IS than any of the others, with the exception of VGB in the treatment of IS in TCS in one underpowered study. Other researchers found that the VGB-induced cessation of the spasms was associated with a marked improvement of behavior and mental development (92). They hypothesized that the complete cessation of the generalized epileptic phenomena of IS seems to be a key factor for the mental outcome, even when partial seizures persist.

The particular efficacy of VGB in TSC suggests that the epileptogenesis in TSC may be related to the impairment of GABAergic transmission. However, the mechanisms underlying this etiology-related efficacy are still unknown (93). In TSC, seizures have a focal or a multifocal origin. IS might represent the secondary generalization of partial seizures and VGB may be especially able to control this secondary generalization (85). Summarizing the relevant data, Riikonen (94), who prefers steroid therapy in IS of other etiology, suggests VGB as the treatment of choice in IS caused by TSC. This opinion is shared by some other authors (95) but not by all. Recent U.S. practice parameters for the medical treatment of IS include the following two recommendations (96): (1) Vigabatrin is possibly effective for the

short-term treatment of infantile spasms (level C, class III and IV evidence); (2) vigabatrin is also possibly effective for the short-term treatment of infantile spasms in the majority of children with tuberous sclerosis (level C, class III and IV evidence).

**Lennox-Gastaut Syndrome.** In the treatment of children with Lennox-Gastaut syndrome (LGS), study results have been controversial and the interpretation of the results has been difficult. LGS is characterized by multiple seizure types that are frequently not analyzed individually in terms of VGB response. In the first European open, add-on, noncontrolled clinical study, 26 children with LGS were included. Good seizure response was observed in less than 30% (6 of 26), and 13 of 26 were unchanged or even worse (50). Only a small number of children with LGS has been included in other studies, and most of them have not been regarded as treatment successes: In a single-blind, placebo-controlled trial (62), 2 of 7 showed a greater than 50% seizure reduction, but 2 showed increases in seizure frequency. Other small studies reported a good response in 3 of 6 (51), or none of 6 patients (97).

A good response rate to VGB in LGS was observed in only one open add-on study (98). Twenty children aged 2 to 20 years with refractory LGS were first treated with high-level VPA monotherapy, and afterwards for 12 months with add-on VGB. Eighty-five percent experienced a more than 50% reduction in seizures and 40% became seizure free under VGB. A decrease of at least 50% was observed in all seizure types (tonic, atonic, atypical absences, tonic-clonic, and complex partial seizures), except myoclonic seizures, which increased by 5%. VGB may therefore have a limited role as add-on treatment in the management of LGS but not in case of myoclonic seizures as the main seizure type.

## Adults

Clinical studies with VGB have included more than 2,000 adult patients. After initial open and single-blind dose-finding studies, several randomized, double-blind, placebo-controlled crossover studies in adult patients with refractory partial epilepsies and add-on therapy with VGB were conducted.

An early Australian study in 97 patients with uncontrolled partial seizures comparing 2 and 3 g/day showed a similar efficacy, with 42% of the patients experiencing a 50% or greater reduction of their seizure frequency in comparison to placebo (=responders). In addition, the number of seizure-free days and longest seizure-free period were significantly longer during VGB and more patients had less severe and shorter seizures (99).

In addition to crossover studies, several double-blind, placebo-controlled parallel group studies were carried out. The therapeutic efficacy of VGB add-on in treatment-resistant epilepsy, as assessed as the percentage of patients having at least a 50% reduction in seizure frequency, was quite similar across the studies, with about 40% of patients being responders (for review of the earlier studies see references 100–102). In the first of more recent studies from the United States, 92 patients received VGB 3 g/day add-on and were compared to 90 patients in the placebo group (103). Significantly more patients receiving VGB were responders with 50% to 99% reduction of seizure frequency (37% vs. 18%) or seizure freedom (6% vs. 1%). The second study examined three different VGB daily doses (1, 3, or 6 g) in a total of 174 patients (104). Whereas only 7% in the placebo group were responders, the corresponding figures for the VGB groups were 24%, 51%, and 54%.

A double-blind, double-dummy substitution trial comparing add-on VGB (2–4 g daily) and VPA (1–2 g daily) in CBZ-resistant partial epilepsy allowing withdrawal of CBZ in responders showed similar percentages of responders (53% vs. 51%) and maintenance of alternative monotherapy (27% vs. 31%) (105).

Two open, single-center randomized monotherapy studies using CBZ as comparator included 100 (106) and 51 patients (107), respectively. Both studies failed to show differences in efficacy but demonstrated a more favorable side-effect profile of VGB (prior to the knowledge of VFD related to VGB). In addition, several open, long-term studies on the add-on use of VGB in adult patients with treatment-resistant partial epilepsy have been reported. The length of the follow-up varied between 9 and 78 weeks. Most of the patients included had a favorable initial response to VGB, which was maintained in 22% to 75% of the patients.

More recently, two larger randomized, double-blind, parallel-group studies have been carried out to compare the efficacy of VGB as monotherapy with CBZ and VPA in newly diagnosed epilepsy. In the VGB/CBZ study, 53% of the 229 patients receiving 2 g of VGB daily and 57% of the 230 patients receiving 600 mg of CBZ daily achieved a 6-month period of remission. However, significantly more patients receiving VGB withdrew due to lack of efficacy than with CBZ, and time to first seizure after the first 6 weeks from randomization also showed CBZ to be more effective. It was concluded that VGB cannot be recommended as a first-line drug for monotherapy of newly diagnosed partial epilepsies (108).

In the VGB/VPA study in a total of 215 patients (age range, 12–76 years), an initial open monotherapy with CBZ was followed by a blinded add-on of VGB (1–4 g/day) or VPA (0.5–2 g/day), and polytherapy in those patients resistant to optimal CBZ monotherapy before CBZ was withdrawn and monotherapy with VGB

or VPA was maintained in the final study phase. The therapeutic efficacy was similar for the two study drugs (109).

In most double-blind trials in adults, the daily dose of VGB was 2 to 3 g. Initial studies suggested that 1 g might also have some therapeutic efficacy, and there are patients who benefit from doses of 4 g or more. In the U.S. study comparing daily doses of 1, 3, and 6 g, no improvement in efficacy was observed in patients given 6 g versus 3 g, but side effects increased substantially (104). Although VGB is usually administered twice daily, a double-blind pilot study in 50 patients comparing once-daily versus twice-daily add-on administration demonstrated no statistical difference (110).

During long-term treatment with VGB, development of tolerance after an initially beneficial effect is observed in about one-third (111) of the patients.

### ADVERSE EFFECTS

In humans, based on histopathologic findings from autopsies and surgical brain samples of patients with an estimated 350,000 patient-years of VGB exposure, no definite case of VGB-induced intramyelinic edema corresponding to the animal data (presented in the section on animal pharmacology) has been identified (112). A single observation reported about normal ophthalmologic and neurologic findings in two children, investigated at the age of 6.10 and 7.9 years, who were exposed to VGB prenatally (113).

Most side effects during VGB treatment are usually mild and well tolerated even with high doses. In adults and older children, fatigue, drowsiness, dizziness, nystagmus, agitation, amnesia, abnormal vision, ataxia, weight increase, confusion, depression, and diarrhea were most often reported (104). In children and infants receiving VGB, drowsiness, somnolence, insomnia, hyperexcitability and agitation, weight gain, and hypertonia or hypotonia were the most frequently reported adverse events (9, 51, 114). A VGB-induced encephalopathy with stupor, confusion, and EEG slowing has been described in single cases (115–117), one of them suffering from an underlying leukodystrophy (Morbus Alexander).

An adverse event possibly related to the GABAergic mechanism of action is an increased incidence of psychosis (118), sometimes as forced normalization. A retrospective survey of behavior disorders in 81 patients described 50 cases meeting the criteria for either psychosis ( $n = 28$ ) or depression ( $n = 22$ ). A comparison with psychotic events in epilepsy patients never treated with VGB described an increased risk for more severe epilepsies, right-sided EEG focus, and suppression of seizures (119). A formal testing of mood disturbances in 73 adult patients with refractory epilepsy before and under treatment with VGB revealed

that mood problems were the main reason for discontinuation (120). Repeated testing with a series of eight cognitive measures in a double-blind, placebo-controlled, parallel group dose-response study in patients with difficult to control focal seizures detected a decreased performance in only one cognitive test (Digit Cancellation Test) (121).

A review of U.S. and non-U.S. double-blind, placebo-controlled trials of VGB as add-on therapy for refractory partial epilepsy in a total of 717 patients revealed a significantly higher incidence of depression and psychosis without differences between treatment groups for aggressive reactions, manic symptoms, agitation, emotional lability, anxiety, or suicide attempt (122). Depression and psychosis were usually observed during the first 3 months. Depression was usually mild, and psychosis was reported to respond to reduction or discontinuation of VGB or to treatment with neuroleptics.

As a secondary effect of treatment with VGB a significant increase of alpha-aminoadipic acid in plasma and urine occurs that may mimic alpha-aminoadipic aciduria, a known rare metabolic disease. Therefore, when a genetic metabolic disease is suspected, amino acid chromatography should be performed before initiation of VGB treatment (123). In addition, VGB can interfere with urinary amino acid analysis through inhibition of catabolism of beta-alanine (124).

In 1997, three patients with severe, symptomatic, persistent visual field constriction (VFC) associated with the use of VGB were described (125). In the meantime it has been demonstrated that VFC is a very common side effect of VGB, at least in adults, and is associated with retinal cone system dysfunction (126). The most important data for adult patients are from a randomized monotherapy trial in newly diagnosed patients comparing VGB and CBZ (127). Of 32 patients receiving long-term VGB monotherapy, 13 (40%) had concentric VFC. The main reason it took almost a decade to detect this severe neurotoxicity has been that the vast majority of even severe defects were asymptomatic. However, in the meantime, it could be demonstrated that in the absence of spontaneous complaints about VFC, symptoms can be elicited by structured questioning, at least in adult patients (128).

Because VGB is often administered during different developmental stages at even higher doses (related to the body weight) and formal visual field testing is often difficult or even impossible, the risk of VGB-induced VFC is a major challenge for pediatric patients with epilepsy. Several case reports have confirmed the possibility of their occurrence in childhood. Based on an observation of 2 patients (129), Vanhatalo et al (130) performed Goldman kinetic perimetry tests on 91 visually asymptomatic Finnish children (age 5.6 to 17.9 years) with a history of VGB treatment at any level. Visual field constriction

(VFC), defined as visual field extent <70 degrees in the temporal median, was considered abnormal. This finding was observed in repeated test sessions in 17 of 91 children (18.7%). A significant inverse correlation was emphasized between the temporal extent of the visual fields and the total dose and the duration of VGB treatment. The shortest duration of VGB treatment associated with VFC was 15 months, the lowest total dosage 914 g. There was no correlation found with age at treatment onset or with total duration of the treatment.

Comparable results were reported in case reports using the same investigation procedure but encompassing smaller patient numbers. Ianetti et al (131) reported 4 of 21 children with VFC, prevailing in the nasal hemifield. One child showed a greater improvement after drug discontinuation. In further reports the range of abnormal findings was 5 of 12 children (41.6%) (132) and 10 of 14 children (71.4%) (133). In 4 of these cases, there was a preexisting visual pathway damage, and in 2 of these, optic disc pallor increased in association with constricted visual fields (133). A prospective long-term follow-up study investigated 29 children before VGB treatment and at 6-month periods up to 6.5 years and reported a variation of ocular pathology (retinal pigmentation, hypopigmented retinal spots, vascular sheathing, and optic atrophy) in 4 of 29 patients (19%) during the follow-up period. Perimetry was not performed (134). In addition to retinotoxic effects of VGB, a reduced ocular blood flow has been described (135).

In an interventional case series report, 138 patients, mainly infants, were evaluated regularly for evidence of possible VGB toxicity (136). Sequential clinical and electroretinographic (ERG) evaluations were performed every 6 months. Three children showed definite clinical findings of peripheral retinal nerve fiber layer atrophy, with relative sparing of the central or macular portion of the retina and relative nasal optic nerve atrophic changes. Some macular wrinkling was evident in one case. Progressive ERG changes showing decreased responses, especially the 30-Hz flicker response, supported the presence of decreased retinal function. The authors concluded that a recognizable and characteristic form of peripheral retinal atrophy and nasal or "inverse" optic disc atrophy can occur in a small number of children being treated with VGB. Because these changes are accompanied by electrophysiologic evidence of retinal dysfunction, discontinuation of VGB should be strongly considered.

Reversibility of VFC has been described in a few pediatric and adult patients, verified by repeated examinations (137–140). Versino and Veggiotti described a 10-year-old girl, developing clinical symptoms ("bumping into objects") 2 years after starting VGB treatment. Symptoms ceased 5 months after VGB discontinuation and perimetry significantly improved. On the other hand, due to the difficulties in testing children, improvement in perimetry examinations

might be an artifact of a learning effect. Nevertheless, from a cognitive age of 9 years on, perimetry seems to be the most sensitive modality for identifying VGB toxicity (141). Abnormal ERG (142) and field-specific visual-evoked potentials (VEP), as described by Spencer and Harding (143), may be useful in monitoring children who are too young to cooperate for perimetry or who are handicapped.

Currently the minimum duration and doses of VGB treatment that can produce side effects are unknown. Short-course therapy, for instance of 6 months in children with IS (72), might reduce the risk of developing visual field constriction. However, today there are no clear data about the incidence of VFC in children treated with VGB for IS during infancy and early childhood. If VGB treatment is continued in spite of the establishment of VFC, there seems to be no progression in the majority of patients, which led to the hypothesis that VGB-associated VFC may be an idiosyncratic rather than dose-dependent toxic side effect (144). Recent U.S. practice parameters for the medical treatment of IS recommend serial ophthalmologic screening. However, data are insufficient to make recommendations regarding the frequency or type of screening that would be of value in reducing the prevalence of this complication in children (level U, class IV studies) (96).

In addition to the persistent VFC, discrete nonhemorrhagic focal lesions in the splenium of the corpus callosum have been described in six patients with epilepsy and treatment with VGB or PHTor both. In two of the patients, the lesions disappeared on follow-up MRI after withdrawal of VGB, PHT, or both (145).

The precipitation or exacerbation of myoclonic seizures, absence seizures, and nonconvulsive status have been reported (146, 147). Therefore, the prescription of VGB in idiopathic generalized epilepsies is not recommended and has been mentioned as a contraindication in some countries. The main mechanism of aggravation of epilepsy is the occurrence of an inverse pharmacodynamic effect. Children treated for epilepsy are particularly likely to suffer from paradoxical aggravation as a result of medical intervention (148). Comparable to CBZ, VGB therapy in patients with idiopathic generalized epilepsies (IGE), for instance in typical or atypical absence seizures, can result in an increase in absence seizure frequency and in absence status (66, 149). Myoclonic seizures are generally aggravated by the same drugs that aggravate IGEs. Induction and increase of myoclonic seizures, myoclonic-astatic seizures, and absence seizures are described particularly in children with Angelman syndrome (150).

## CONCLUSION

VGB shows good pharmacokinetic properties with rapid onset of action and mostly tolerable side effects, especially in infancy. VGB is a very efficient AED in infants

with IS, especially caused by TSC. In infants with IS, who responded to VGB, the drug could be withdrawn without a relapse after a spasm-free period of 6 months (limited data). In addition, VGB has proved to be an efficacious AED for partial seizures with and without secondary generalization, previously drug resistant to first-line AEDs. VGB is still a therapeutic option when other AEDs have failed or were poorly tolerated. However, the concern of severe of concentric VFC requires a careful risk-benefit analysis and some recent authors have omitted VGB as a treatment option in children with partial epilepsies (151).

Guidelines for prescribing VGB in children (152) may help in deciding whether to prescribe the drug. They, along with others, recommend performing visual field

examination with a Goldman perimeter or a Humphrey field analyzer in children with a cognitive age of >9 years before prescribing VGB and, ideally, every 6 months while they continue to take the drug.

A clear statement concerning the indication for VGB in children is made by Wallace (153). She declared that “in clinical use, VGB should be prescribed only in very strictly defined circumstances: partial seizures refractory to other medications, and infantile spasms. Particular caution is necessary, when VGB is being considered in a young child who either is known to have, or is at risk of having, a visual defect due to other causes. Though, obviously, those who already have no vision would not be excluded from treatment with VGB.”

## Vitamins, Herbs, and Other Alternative Therapies

*Orrin Devinsky  
Daniel Miles  
Josiane LaJoie*

**C**omplementary and alternative medicine (CAM) is increasing in popularity. In 1997, CAM costs in the United States were close to \$50 billion (1). In a 2002 survey of more than 30,000 U.S. adults, 62% reported using CAM therapy in the past year (2). The most common were prayer, natural products, deep breathing exercises, meditation, chiropractic care, yoga, massage, and diet-based therapies. CAM is used by 20% to 25% of parents for their children (3–5), with common forms being vitamin supplements, other nutritional supplements or elimination diets, herbs, homeopathy, prayer, massage, and aromatherapy (3, 5–7).

In a Canadian pediatric neurology clinic, CAM was used by 44% of the children (8). The most common CAM therapies were chiropractic manipulations (15%), dietary therapy (12%), herbal remedies (8%), homeopathy (8%), and prayer or faith healing (8%). Caregivers' sociodemographic variables or pediatric health-related quality of life was not significantly associated with CAM use. Parents reported benefits in 59% of CAM-treated children. Side effects were reported in 1 of 46 patients. Its use in children with certain chronic illnesses is 50% to 70% (9). A survey of parents of children with cerebral palsy showed that 56% used one or more CAMs (10). Notably, an increased severity of cerebral palsy correlated with the increased use of CAM. CAM is used in an

estimated 14% to 32% of children with epilepsy (11). As with other pediatric groups, we have observed higher rates of CAM use in children with refractory epilepsy.

As CAM use rises in both pediatric and adult patients, a large communication gap exists between lay persons and traditional health care providers. Although pediatricians and pediatric subspecialists recognize that many patients use or are interested in CAM therapies, many do not feel comfortable discussing or recommending them (12, 13). Fewer than 40% of parents report CAM use to pediatricians (4). The exact frequency of alternative medicine use among children is difficult to ascertain largely because the majority of parents do not disclose their use of these substances to their children's medical providers. Individuals may feel that their complaints will not be taken seriously or that they will be made to feel that their actions are irrational in regard to alternative medicine. Parents are also concerned that others may think they are harming their children. The decision to use alternative medicine also depends on the cultural or religious beliefs of the families.

In this chapter we review some of the many complementary and alternative therapies used for epilepsy (Table 55-1). A recent, multiauthored volume on CAM in epilepsy summarizes many of the relevant findings (6). Many studies focus on adult patients, making extrapolation to pediatric populations problematic. In any case,

reliable information on specific CAMs in epilepsy is lacking, making refutations difficult or clear recommendations impossible. Claims for efficacy often outstrip the available data.

## STRESS

Stress is associated with a diverse set of conditions that can cause or aggravate many disorders. Stress is reported as a provocative factor for seizures by both patients and physicians (14). In self-report studies, stress is a leading seizure precipitant (15, 16). Both emotional and physical stressors may be involved. However, the scientific study of stress and seizures is difficult because stress is subjective and difficult to quantify, can indirectly affect seizure activity (e.g., hyperventilation, sleep deprivation,

and medication noncompliance), and can be induced by seizures and the social-emotional consequences of epilepsy. Further, electroencephalograms (EEGs) recorded while the patient is under stress do not show increased epileptic activity (17).

Stress affects individuals to different degrees, ranging from clinically significant anxiety disorders to problems of everyday life that seem overwhelming. Epilepsy patients with clinical anxiety disorders should be referred for psychologic or psychiatric care. A psychologist, social worker, or other mental health professional can use behavioral strategies to reduce stress and improve emotional well-being and adjustment (6 pp. 25–32). Anxiolytic or antidepressant agents are underused in epilepsy patients owing to underdiagnosis and inflated fear of seizure exacerbation with selective serotonin reuptake inhibitors or other agents (e.g., buspirone) (18). Benzodiazepines can be valuable short-term agents, but withdrawal seizures are a concern in patients with epilepsy. For all epilepsy patients with anxiety symptoms, however, nonpharmacologic approaches are worth pursuing.

Many CAM therapies for epilepsy focus on stress reduction. Reducing stress and its physiologic effects can be achieved through a variety of techniques, such as exercise (19), yoga (6, 20), and specific relaxation techniques, such as progressive muscle relaxation (21). Few controlled studies exist to demonstrate the efficacy of these therapies. In small, uncontrolled studies, exercise either reduced seizure frequency (19, 22, 23) or had no significant effect on it (24, 25). However, exercise may also induce seizures (26–28). A nonblinded study showed that epilepsy patients who performed Sahaja yoga reduced their seizure frequency by 86% and showed fewer signs of stress, whereas those who did simulated yoga or had no intervention had no significant reductions (29). This study has not been replicated. Given the high frequency with which patients report stress as a provocative factor for seizures, stress reduction is a reasonable goal for patients.

## PSYCHOTHERAPY

Psychotherapy can help manage specific psychologic problems as well as reveal how social interactions and self-perception contribute to stress. Group psychoeducational therapy (30–32), interpersonal psychotherapy (6, 33), and cognitive behavioral therapy (34–36) are used in adult and pediatric patients with epilepsy. Small studies with limited data support their effectiveness in reducing seizure frequency (37). In one uncontrolled study (38), 16 patients with refractory epilepsy learned behavioral techniques to interrupt the beginning of a seizure and to “neutralize provoking factors.” Self-reported seizure reductions of at least 60% were reported by 80% of the participants. Psychotherapy is also used to treat

psychogenic, nonepileptic seizures (39, 40). Cognitive-behavioral interventions may help epileptic patients with anxiety and depression (35).

## FEEDBACK THERAPY

### Andrews-Reiter Method

The Andrews-Reiter method, developed by Donna Andrews and Joel Reiter, was a new comprehensive neurobehavioral approach for using biofeedback to treat epilepsy. Their initial positive results from six patients with refractory complex partial seizures (41) were replicated at the Victoria Epilepsy Center (MacKinnon J, personal communication, 2002) and others (42, 43). The Andrews-Reiter method was developed to treat patients with refractory epilepsy and antiepileptic drug (AED) side effects who declined surgery or were not good candidates for it. This approach targets the onset of seizures in developing preventive techniques (44).

An essential part of the Andrews-Reiter treatment is to change the patient's response to pre-seizure warnings and auras by recognizing them and instituting a new, seizure-preventing response (6). Triggers may be physical (e.g., chemical imbalance, disturbed sleep, and missed medication), external (people, places, or situations that cause pressure or stress), or internal (emotional reactions and stressful states). The Andrews-Reiter treatment program includes cognitive and behavioral counseling to reduce seizure activity through enhanced awareness of premonitory or aura symptoms, identifying emotional, behavioral, physiologic, or environmental mechanisms that trigger seizure activity, progressive relaxation and reinforcement, deep diaphragmatic breathing, and EEG and electromyographic (EMG) biofeedback (44).

### Neurofeedback Therapy

Operant conditioning of the EEG (i.e., neurofeedback or neurotherapy) is a noninvasive treatment for patients with refractory epilepsy. Neurofeedback may increase the seizure threshold through producing EEG changes. Initially, a quantitative EEG assessment is obtained to identify abnormal regions that can be targeted during treatment. Neurofeedback is a learning procedure with the goal of altering recorded EEG patterns. It is based on the law of effect, that is, provide positive reinforcement of EEG patterns that approach a normal configuration, and negative reinforcement of abnormal (epileptic) EEG patterns. In practice, a computer processes the EEG signals, identifies the critical components, and then modifies a display on a screen in front of the patient, which provides an integrated response dependent upon the EEG pattern. This process can be reduced to a simple game involving the

completion of a task followed by the scoring of points. For children, these points can lead to meaningful rewards, such as privileges or money. The ultimate reward is learning to change the underlying circuitry of the brain to raise the seizure threshold. Although a natural consequence of neurofeedback is relaxation, it is not a relaxation technique; on the contrary, neurofeedback is more akin to a "cerebral workout" (6).

In animal studies, increasing the sensorimotor rhythm through operant conditioning eliminated or significantly reduced seizures induced by convulsant chemical compounds (45). In other animal experiments, sensorimotor rhythm training increased sleep spindles and improved sleep organization (46). These findings led to a pilot study of neurofeedback for a boy with refractory tonic-clonic seizures; he became seizure free after 3 months (47).

The clinical data on neurofeedback is based on uncontrolled, nonblinded studies in which operant conditioning reduced seizure frequency by over 50% and also reduced seizure severity (6). There is no relation between AED levels and the outcome of the conditioning (6). Studies using sham feedback, relaxation training, or alternate EEG criteria for reward showed no benefits.

Neurofeedback is an expensive and time-consuming process. It can be administered in 1-hour sessions, one to three times per week for periods ranging from 3 months to more than 1 year. It is usually about \$100 per session and is often covered by health insurance under the "out-patient mental health" benefit (6).

### Craniosacral Therapy

Craniosacral therapy was created by Dr. William Sutherland in the early 1900s to examine, assess, and correct cranial bone movements (6). Current practice focuses on the cranial and sacral bones and the membrane structures that connect them. This system is hypothesized to have a craniosacral rhythm, created by the flow of cerebrospinal fluid through the membrane complex.

A practitioner of craniosacral therapy assesses this rhythm and seeks to treat subtle imbalances in the nervous and skeletomuscular systems to restore health. A minimal amount of force (approximately the weight of a nickel) over a long period of time (30 seconds to several minutes) is used during craniosacral therapy. Widespread regions of the body, including many soft tissue structures, are often treated (6).

Although craniosacral therapy is used to treat epilepsy, there have been no controlled trials. The technique can probably reduce stress and muscular tension, but evidence to support the specific craniosacral rhythm mechanism of action is lacking. The reliability of palpating a craniosacral rhythm is poor between practitioners (48, 49). This fundamental skill is the basis of therapy. In one

study (49), two registered osteopaths with postgraduate training in craniosacral techniques simultaneously palpated the head and sacrum of 11 normal subjects. Intrarater reliability at either the head or the sacrum was fair to good (correlation coefficients, 0.52–0.73). Inter-examiner reliability was poor to nonexistent (correlation coefficients, –0.09–0.31).

## VITAMINS

The use of vitamins, minerals, and other dietary supplements in the care of children with epilepsy takes multiple forms, including treatment of seizures in the case of vitamin-deficient or vitamin-dependent seizure disorders involving, for example, pyridoxine, biotin, and folic acid, the replacement or supplementation of vitamin stores, such as folate and carnitine, depleted by the adverse effects of AEDs, and the use of multivitamins for general health maintenance.

### Biotin

Biotin, a water-soluble B vitamin, was discovered to be an essential nutrient in the 1930s, when animal studies of diets containing large quantities of raw egg whites resulted in toxicity manifested by severe dermatitis, hair loss, and poor motor coordination. Biotin administration reversed the symptoms. Subsequently, avidin, a glycoprotein in egg whites, was found to irreversibly bind biotin, preventing its absorption. Cooking eggs destroys the ability of avidin to bind biotin.

Biotin deficiency, which is rare, can result from eating raw eggs, total parenteral nutrition without biotin supplementation, AED use, and prolonged antibiotic use. Antiepileptic medications associated with biotin deficiency include phenytoin, primidone, and carbamazepine; these agents can inhibit transport across the intestinal mucosa and accelerate the metabolism of biotin. Alteration of intestinal flora results in biotin deficiency with antibiotic use. Human biotin deficiency is manifested by seborrheic dermatitis, fungal infections, a perioral, erythematous, macular rash, fine brittle hair, hair loss, depression, mental status changes, myalgias, and paresthesias.

In addition to biotin therapy to counteract the adverse effects of AEDs, biotin is used to treat seizures secondary to biotinidase deficiency. Biocytin, the product of proteolysis of biotin-containing proteins and peptides, is cleaved by biotinidase into lysine and biotin, which is then free to be absorbed across the intestinal mucosa and used in multiple carboxylation reactions. Mutation of the gene that encodes for biotinidase is localized to chromosome 3p25 and results in seizures, ataxia, neuropathy, auditory dysfunction, breathing irregularities, and optic atrophy, as well as skin rashes, hair loss, and

chronic candidiasis. Seizures are the presenting symptom in 38% of patients with biotinidase deficiency and are found in up to 55% of patients at some time before treatment (50). Generalized seizures (tonic-clonic, clonic, and myoclonic) and infantile spasms can occur (51, 52). Biotinidase deficiency is readily screened for by enzyme assay, and is part of newborn screening in many states and countries around the world. Recommended daily treatment is 5 to 10 mg of biotin.

### Pyridoxine

Pyridoxine, or vitamin B<sub>6</sub>, is a cofactor involved in the metabolism of amino acids and multiple neurotransmitters, including gamma-aminobutyric acid (GABA). Glutamate decarboxylase, the enzyme responsible for the conversion of glutamate to GABA, requires pyridoxine. Insufficient concentrations of pyridoxine or glutamate decarboxylase dysfunction result in diminished production of GABA and increased concentrations of the excitatory neurotransmitter glutamate, producing circumstances favoring seizure activity. Seizures associated with pyridoxine are classified as pyridoxine deficient, pyridoxine dependent, or pyridoxine responsive.

Pyridoxine-deficient seizures were first reported in 1950 when children given a diet lacking in pyridoxine experienced seizures that resolved rapidly with intravenous doses of 50 mg pyridoxine (53). Later case reports were associated with baby formulas containing insufficient levels of pyridoxine. Vitamin B<sub>6</sub>-deficient seizures typically begin in the first 4 months of life. The seizures are refractory to AEDs, and a family history of seizures is unlikely. These seizures typically respond to a single dose of pyridoxine (1–5 mg) and do not recur if dietary intake is adequate.

Neonatal seizures refractory to standard AEDs are the characteristic manifestation of pyridoxine-dependent epilepsy, a rare genetic disorder that can present as late as the second year of life. These neonatal seizures may take the form of partial, atonic, or generalized myoclonic episodes, as well as infantile spasms (54). Status epilepticus or seizures may occur in utero. EEG findings include focal, multifocal, and generalized epileptiform discharges. If seizures in early life are resistant to standard treatment, consider pyridoxine-dependent seizures and give an intravenous dose of 50 to 100 mg of pyridoxine. The response to pyridoxine may be dramatic and rapid; EEG monitoring during administration may reveal an abrupt cessation of seizure activity. Children responding to the intravenous dose of vitamin B<sub>6</sub> should then be maintained on daily supplementation to ensure seizure control and promote normal development. Confirmation of the diagnosis requires cessation of treatment with recurrence of seizure activity, then restarting vitamin B<sub>6</sub> and regaining a seizure-free state. An atypical form of pyridoxine-dependent seizures characterized by later onset may be manifested by

seizures with febrile illness and episodes of status epilepticus. Intravenous pyridoxal phosphate, the active form of vitamin B<sub>6</sub>, may be more effective than the oral form of pyridoxine in treating pyridoxine-dependent seizures (55).

Pyridoxine-responsive seizures were first described in 1968 (56). Pyridoxine is used to treat infantile spasms associated with diminished GABA concentrations in children and evidence of pyridoxine deficiency. There are no randomized, controlled trials of this use, but two prospective, open-label studies of pyridoxine treatment for infantile spasms revealed response rates of 13% to 29% (57, 58), raising the question of whether response to pyridoxine therapy exceeds the spontaneous remission rate. Data are insufficient to determine whether vitamin B<sub>6</sub> is effective in treating infantile spasms (59).

### Folate

Folate is another vitamin that plays an important role in the health care of individuals with epilepsy, primarily in relation to AED side effects and the care of women of childbearing age, but also in the treatment of seizures in rare metabolic disorders. Folate is essential for DNA synthesis, and inadequate concentrations are associated with an increased risk of fetal neural tube defects. Certain AEDs (phenytoin, carbamazepine, and barbiturates) can decrease folate absorption. The American College of Obstetricians and Gynecologists in 1996 and the American Academy of Neurology in 1998 published statements recommending folate supplementation in women with a history of a previous pregnancy affected by a neural tube defect and girls and women of childbearing age with epilepsy. Dosage recommendations range from 0.4 to 4 mg daily. Folate deficiency is also associated with elevated homocysteine levels, which increase the risk of cardiovascular disease in both men and women.

Seizures are associated with two disorders of folate activity, cerebral folate deficiency, and folinic acid-responsive seizures. Folinic acid-responsive seizures are most often noted in the neonatal period. The medically refractory seizures are at times mistakenly thought to be related to perinatal hypoxic-ischemic injury because of the presence of atrophy and abnormalities of the white matter seen on magnetic resonance imaging (MRI) of the brain. Analysis of cerebrospinal fluid with high-performance liquid chromatography revealed an as yet unidentified compound (60). Seizures responded to treatment within 24 hours of folinic acid administration.

## AMINO ACIDS AND SUPPLEMENTS

### Gamma-Aminobutyric Acid

The fact that GABA is an inhibitory neurotransmitter has led to both the development of aids that enhance

the effect of GABA and attempts to increase its cerebral concentrations via oral supplementation. GABA is not well absorbed across the blood-brain barrier, even when nitric oxide and other free radicals thought to increase the permeability of the blood-brain barrier are used simultaneously, and increased brain GABA levels are not known to affect seizure activity (61, 62).

### Carnosine

Research into the use of carnosine in the treatment of epilepsy has led to conflicting results. In one study (63), higher levels of homocarnosine were found in children with refractory epilepsy than in those with medically controlled epilepsy. In other studies (64, 65), greater concentrations of homocarnosine were associated with better seizure control. The usefulness of carnosine in the treatment of epilepsy remains uncertain.

### Taurine

Taurine is an amino acid that acts as an inhibitory neurotransmitter in multiple metabolic pathways, including cell membrane stabilization, regulation of cellular calcium levels, and detoxification. Genetic variations of taurine metabolism occur in some epilepsies (66). Although taurine in higher concentrations is associated with lower seizure susceptibility, and in lower concentrations with increased seizure activity, there is no conclusive evidence that taurine supplementation improves seizure control (67). One unblinded study of 25 children with intractable epilepsy treated with taurine reported complete seizure control in only 1 patient, a greater than 50% decrease of seizure frequency in another, and a less than 50% decrease of seizures in 4 patients, but no effect in 18 patients (68). No more than transient effects were noted in another unblinded study of 9 patients with intractable seizures. Five patients were seizure free for about 2 weeks, seizure frequency was temporarily reduced by 25% in 1 patient, and no effect was noted in the remaining 3 patients (69).

### Carnitine

Treatment of mice with carnitine before exposure to a proconvulsant agent had a protective effect on the brain, with reduced seizure frequency noted, but no human research has shown similar results (70). Carnitine-deficient states can be associated with the use of valproate. Clinically significant carnitine deficiency is not common, but may be associated with fatigue, weakness, cardiomyopathy, hypotonia, poor growth, and hyperammonemia. Carnitine supplementation is recommended for patients with deficiency syndromes, but the use of carnitine prophylactically is not advised (71).

## Glycine

Glycine, another inhibitory neurotransmitter, may reduce seizure frequency at a dose of 200 mg a day (72), and one study showed a reduction of seizures provoked by strychnine in animals (73). However, most reports show no significant anticonvulsant effect of glycine (74, 75).

## HERBS

The use of herbal therapy has dramatically increased during the last decade. Despite their common use, little is known about the efficacy or side effects of these compounds. This is due not only to the paucity of controlled trials and rigorous research, but also to the lack of an oversight agency. Moreover, side effects tend to go unreported, or their incidence can be increased by the lack of knowledge on proper dosing and administration, misidentification of a particular herb, or poor manufacturing and quality control. New studies are in progress, but long-term effects will not be known for many years. The lack of information on these supplements makes it even more difficult for the practitioner to advise patients appropriately. Nevertheless, from increasing experience, knowledge about these substances continues to expand. Most of the available information must be adapted from the adult population, keeping in mind the unique differences in the physiology and underlying conditions of the pediatric population. Extreme caution must be taken when these substances are a component of treatment, because they can have profound side effects, negatively affect other conventional medications, or worsen preexisting conditions. All herbs have potential risks and side effects during pregnancy and, in particular, can negatively affect the unborn fetus; therefore their use during pregnancy and lactation is contraindicated (76).

Many popular herbs have been used in patients with epilepsy, but the mechanisms of their antiseizure activity are often unknown. Some herbs in toxic doses may actually provoke seizures. Comorbid conditions should be taken into account, because many of these supplements may interact with other medications or may be contraindicated in certain individuals. Of note, blue cohosh (*Caulophyllum thalictroides*) is an herb that has some properties similar to those of nicotine and is primarily used to induce labor. Its seeds are bright blue and eye-catching to children, who are at particular risk for poisoning if they ingest larger than recommended quantities (76). It is beyond the scope of this chapter to describe each individual herb in detail. Table 55-2 provides information about some of the more popular herbs.

Kava (*Piper methysticum*) is used for the alleviation of anxiety. It can also be used as an antiepileptic supplement. It potentially exhibits various mechanisms

of action, including the inhibition of L-type calcium channels and sodium channels, increase of K<sup>+</sup> outward current, and enhancement of GABAergic inhibitory neurotransmission in animal studies (77). Although many studies have evaluated its efficacy in anxiety, there are few large studies involving patients with epilepsy. Kava's toxicity is increased when it is combined with alcohol, benzodiazepines, and barbiturates (78). Cases of hepatotoxicity have been reported. Its use is contraindicated in children less than 12 years of age.

Gotu kola (*Centella asiatica*) has a variety of uses. Animal studies suggest that it is protective against seizures via action at D2 receptors and possible cholinergic mechanisms, and it delays pentylentetrazol-induced seizures. Some reports suggest that this herb may also improve children's cognitive status, but the sample sizes were small (76).

More than 30 herbs have been found to block seizures in animal experiments (79). Mistletoe (*Viscum*), for example, is protective against pentylentetrazol- and bicuculline-induced seizures in animal models (80), but has no significant effect in the N-methyl-D-aspartic acid (NMDA) tonic seizure model. Data from human studies, however, are insufficient to recommend its use. It is an extremely toxic substance that may cause cardiac, neurologic, and gastrointestinal side effects.

Some herbs should not be used despite their popularity. Ginkgo biloba has been grown in China for more than 200 years. Typically, it is used in the treatment of cognitive deficits such as in Alzheimer's and multi-infarct dementia. It is believed to act as a free-radical scavenger. It reportedly can reduce the seizure threshold, induce seizures, or both (81). Ginkgo biloba should be avoided in patients with epilepsy because it can decrease the effectiveness of certain AEDs, including carbamazepine, phenytoin, and phenobarbital (81). The herb should not be used in individuals taking tricyclic antidepressants, which can also lower the seizure threshold (81). Ginkgo biloba must be used with caution in patients taking anticoagulants because of possible bleeding (82, 83).

Valerian (*Valeriana officinalis*) is commonly used as an anxiolytic and sleep aid. It is thought to inhibit the degradation and reuptake of GABA. Studies on its efficacy, safety, and potential drug interactions are sparse. Because valerian binds to the same receptors as benzodiazepines and may cause sedation, it should not be combined with benzodiazepines or sedatives such as barbiturates. Tremor, headache, cardiac disturbances, and gastrointestinal upset have been reported in patients using valerian in high doses or for a prolonged period of time (84).

Primrose oil and borage, both used for various conditions, are known to lower the seizure threshold (81). Another widely used herb, St. John's wort, which is used to treat depression, is believed to inhibit GABA and other neurotransmitters. Theoretically, this mechanism

**TABLE 55-2**  
**Common Herbs Used as Adjunctive Treatment in Epilepsy**

HERB	LATIN NAME	COMMON USES	PLACE OF ORIGIN	CHEMISTRY	SYSTEMIC EFFECTS	CNS EFFECTS	PREGNANCY ISSUES
American hellebore	<i>Veratum viride</i>	Antiemetic, neuralgia, pneumonia	United States	Similar to steroids	Blood pressure alteration, gastrointestinal and respiratory problems, seizure salivation; high risk of side effects, narrow therapeutic index	Paresthesias, weakness, paralysis, seizure	Teratogenic
Behen	<i>Moringa oleifera</i>	Antimicrobial, gastrointestinal ailments	India	Contains glucosinolates, fatty acids	Gastrointestinal problems	Dizziness	Possible abortive effect
Betony	<i>Stachys officinalis</i>	Respiratory and gastrointestinal ailments,	Europe, North Africa, Siberia	Part of mint family, related to tannins	Hypotension, gastrointestinal problems, hepatic dysfunction	—	Uterine contractions
Black cohosh	<i>Cimicifuga racemosa</i>	Menstrual pain	North America	Estrogen effect	Hypotension, gastrointestinal problems; not for long-term use	Sedation, headache	Increased risk of spontaneous abortion
Blue cohosh	<i>Caulophyllum thalictroides</i>	Induce labor	Midwest and Eastern United States, Canada	Similar to nicotine	Hypertension, gastrointestinal problems, increases glucose; poisonous to children, cardiotoxic to neonates	Seizures	Uterine contractions, teratogenic
Calotropis	<i>Calotropis procera</i>	Antineoplastic	Asia, India, Africa, Pakistan, Sunda Islands	Related to steroids	Gastrointestinal steroids bradycardia; highly toxic	Seizures	—
European peony	<i>Paeonia officinalis</i>	Pain, headache	Southern Europe, Asia	Contains tannins, flavonoids	Hypotension	No	Uterine contractions
Ginkgo	<i>Ginkgo biloba</i>	Cognitive impairment	China	Platelet-activating factor antagonist	Bleeding	Seizures	—

**TABLE 55-2**  
(Continued)

HERB	LATIN NAME	COMMON USES	PLACE OF ORIGIN	CHEMISTRY	SYSTEMIC EFFECTS	CNS EFFECTS	PREGNANCY ISSUES
Goto kola	<i>Centella asiatica</i>	Antimicrobial, antineoplastic, CNS depressant, wound healing	South East Asia, India, Sri Lanka, China, Madagascar, South Africa, Southeastern United States, Mexico, parts of South America	Consists of triterpene acids and sugar residues; affects D2 receptors and cholinergic system	Contact dermatitis, infertility, hyperglycemia, hyperlipidemia	—	Should not be used in pregnancy
Groundsel	<i>Senecio vulgaris</i>	Worm infestation	Europe, Asia, Africa, Australia, Americas	Contains alkaloids, flavonoids	Hepatic dysfunction, carcinogenic; should not be taken internally	—	—
Kava	<i>Piper methysticum</i>	Anxiety	South Pacific	Inhibits L-type $Ca^{2+}$ and $Na^{+}$ channels, increases $K^{+}$ outward current, enhances GABA transmission; member of black pepper family	Hypertension, gastrointestinal and respiratory problems, hepatic dysfunction, leucopenia, thrombocytopenia, dermatitis; should not be used in children <12 years	Acute dystonic reaction	Loss of uterine tone
Lily of the valley	<i>Convallaria majalis</i>	Arrhythmia, cardiac insufficiency	—	Related to steroids	Gastrointestinal problems, cardiac arrhythmia; many drug interactions, highly toxic, not recommended for use	Headache, stupor, changes in color perception	—
Melatonin*	—	Sleep disorders, jet lag	—	Derivative of serotonin	—	Drowsiness	Should not be used in pregnancy

Mistletoe	<i>Viscum album</i>	Cancer, seizures, heart disease, headache	England, Europe, Asia	Contains choline, histamine, tyramine	Blood pressure alteration, gastrointestinal problems, bradycardia, cardiac arrest; highly toxic	Coma, seizures, sedation, psychosis	Uterine contractions
Mugwort	<i>Artemisia vulgaris</i>	Change of fetal position in utero (breech), menstrual problems, depression	Northern Europe, Asia, North America	Part of daisy family	Dermatitis, allergy; not recommended for use	—	Uterine contractions, increased risk of abortion
Pipsissewa	<i>Chimaphila umbellata</i>	Seizures, antispasmodic, diuretic	Europe, Asia, North America	—	Gastrointestinal problems, rash; not recommended for use	—	Should not be used in pregnancy
Skullcap	<i>Scutellaria laterifolia</i>	Cancer, sedative	North America	Contains flavonoids	Hepatic dysfunction, cardiac arrhythmia	Confusion, seizures	Should not be used in pregnancy
Valerian	<i>Valeriana officinalis</i>	Anxiety, sleep	Europe, Mexico, India, Japan	Inhibits degradation and reuptake of GABA	Gastrointestinal problems, hepatic dysfunction; many drug interactions	Sedation, tremor, headache; should not be used in children <14 years	Uterine contractions
Yew	<i>Taxus baccata</i>	Antimicrobial	Europe	Contains taxines, flavonoids	Cardiotoxic, arrhythmia, severely toxic	—	Causes spontaneous abortion

CNS, Central nervous system; GABA, gamma-aminobutyric acid.

**TABLE 55-3**  
*Herbs That May Cause Seizures*

Bearberry (*Arcostaphylos uva-ursi*)  
 Borage (*Borago officinalis*)  
 Ephedra (*Ephedra sinica*)  
 Ginkgo (*Ginkgo biloba*)  
 Ginseng (*Panax ginseng*)  
 Ma Huang (*Herba ephedra*)  
 Monkshood (*Aconitum* sp.)  
 Primrose (*Oenothera biennis*)  
 Yohimbe (*Pausinystalia yohimbe*)

can make seizures worse (84). Herbs containing thujone, such as wormwood and sage, which are used to treat gastrointestinal disorders, may have proconvulsant effects. Table 55-3 lists some herbs that may cause seizures.

Some herbs can interfere with the hepatic P450 system (Table 55-4) and, when used together with antiepileptic medications, produce toxic side effects or decrease their effectiveness. Other herbs can lower anticonvulsant levels or otherwise interact with AEDs (Table 55-5).

### MELATONIN

Melatonin is an indolamine that is synthesized from tryptophan in the pineal gland. It is released in a circadian pattern, with peak levels in the early morning hours (85). Its apparent main function is to signal the brain to induce sleep. Melatonin is used for a variety of conditions, including sleep disorders, jet lag, and autism. By regulating sleep patterns it appears to be helpful in attaining better seizure control, and from animal models, melatonin is helpful in preventing seizure-related brain

**TABLE 55-4**  
*Herbs That Inhibit the P450 System*

American hellebore  
 Chamomile  
 Echinacea  
 Garlic  
 Licorice  
 Milk thistle  
 Mugwort  
 Pipsissewa  
 Pycnogel  
 St. John's wort\*  
*Trifolium pratense* (red clover)

\*Effect on the P450 system is controversial.

**TABLE 55-5**  
*Herbs and Their Effects on Antiepileptic Drugs*

HERB	DRUG	EFFECT
Septilin	Carbamazepine	Decreases drug level
Sho-seiryu-to	Carbamazepine	Delays drug absorption
Paeoniae radix	Phenytoin	Delays drug absorption
Thujone (wormwood, sage)	Phenobarbital	Reduces drug efficacy
Ginkgo	Phenytoin, phenobarbital, carbamazepine	Reduces drug efficacy

damage. A variety of proposed mechanisms are thought to account for melatonin's antiepileptic effect. It appears to increase GABA's concentration in the brain and protects against seizure-induced brain damage by inhibiting calcium influx into neurons and by free-radical scavenging properties (86–89). When given orally, its blood concentration peaks within 1 hour, and usually returns to baseline within 4 to 8 hours (90).

Melatonin's effectiveness has been shown in animal models. It inhibits kainic acid-induced seizures in rats. It also inhibits lipid peroxidation, is a potent free-radical scavenger, and reduces seizure-induced brain damage (91). Melatonin also blocks potassium cyanide-induced seizures in mice (92). Melatonin stimulates brain glutathione peroxidase activity, which is an antioxidative enzyme that metabolizes the precursor of the hydroxyl and peroxy radicals to water. It also raises the electroconvulsive threshold in animal models and potentiates the anticonvulsive activity of carbamazepine and phenobarbital (93). In addition, melatonin significantly reduces neurobehavioral changes in mice, as well as morphologic changes in association with seizures, mostly in the CA3 region of the rat hippocampus (94).

Most clinical studies have looked at the use of melatonin in a limited number of subjects. Its effectiveness and safety profile in epilepsy patients was supported by several open-label trials. Peled et al (95) found that five of six children with intractable epilepsy had significant improvement not only in seizure control but also in their cognitive function. Bazil et al (96) showed that patients with epilepsy had a peak level of melatonin that was 50% of controls' peak level and that the peak occurred 3 hours before that of controls. Some studies have shown a lack of melatonin's efficacy, which may be related to inadequate dosing or other factors (97, 98).

	<i>Cuprum metallica</i>
	<i>Glonoinum</i>
	<i>Ignatia amara</i>
	<i>Zincum metallicum</i>

### PHYTOTHERAPY

Practitioners of phytotherapy believe that there is an imbalance in the body and that specific herbs may restore this balance. Many plants are known for their anticonvulsant properties. Approximately 150 preparations of plants have been investigated. Individual plants are usually used but can be combined if necessary. In most cases, the active compound has not yet been identified. Studies have shown that some natural plant coumarins and triterpenoids exhibit anticonvulsant properties (99, 100). Several show promise against seizures (see Table 55-6), but further study is needed before their routine use.

*Albizia lebbek* increases levels of GABA in the brain. *Piper nigrum* may have antagonistic actions at NMDA receptors. The efficacy of *Casimiroa edulis* has been shown in animal studies to be similar to that of phenytoin and phenobarbital. *Ipomoea stans* is similar in effectiveness to valproic acid. The action of *Piper guineense* and *Psidium guyanensis* is similar to that of phenobarbital (101). The toxicity or side effects of these plants are largely unknown. Some plants may interact with antiepileptic medications; *Ruta chalepensis*, for example, may increase the hypnotic effects of phenobarbital. More work on the use of phytotherapy in epilepsy is needed.

### ASIAN MEDICINE

Traditional Chinese medicine has been used for thousands of years and has been gaining interest in the Western world for quite some time. It is partly based on the view that the body is closely related to its surrounding outside world. The organs inside of the body are themselves considered to be interconnected via an interlacing network of channels and collaterals (102). Most therapies are composed of several herbs. The use of combination therapy is thought to improve the effectiveness and lessen any possible side effects. From the Chinese perspective, certain types of seizures are considered to be due to an exogenous or endogenous "wind." In children, the pathogenesis is

attributed to the insufficiency of the spleen, stagnation of phlegm, and reversed flow of *qi* (known as the vital forces of the body), and stirring up of the endogenous wind (103). Some open-label studies of traditional Chinese herbal mixtures have shown a reduction in seizures and fewer side effects compared with standard AEDs, but well-controlled double-blind studies are lacking. Numerous combinations of Chinese herbs are used to combat seizures; only a few will be discussed.

Tianma gouteng yin is composed of amino acids, alkaloids, and fatty acids in addition to other compounds. Interestingly, it has been found to act as an NMDA-receptor antagonist. Not only does it have direct influences at the receptor, but it also helps to prevent neuronal injury and death (102). When quingyangsen (root) was given as an adjunct to standard AED treatment, almost 30% of patients had seizure control ranging from 2 to 9 months after initiating therapy (104). This compound has also been shown to block seizures in animal models (105). Zhenxianling contains different flowers, animal parts, and human placenta in addition to other substances. A study using Zhenxianling in 239 patients with refractory epilepsy, of whom 147 were aged 1.5 to 20 years, showed that 66% had a greater than 75% seizure reduction and an additional 30% had a greater than 50% reduction of their seizures (106). These effects were seen 1 to 5 days after treatment. In 15 patients with absence seizures, 11 had their seizure frequency reduced by 50% to 75%. A few studies have been performed using longdanxiegan tang, or a modified version, in absence epilepsy. Approximately 90% of patients taking this herb showed significant clinical or EEG improvement (107, 108).

In a study using capsules composed of a variety of Chinese supplements, a significant improvement was found among children with different types of epilepsy (103). More than 900 children were treated with these capsules, and their response was compared with that of only 160 patients treated with phenobarbital. In children taking the capsules, 57% had their seizures reduced by more than 75%. An additional 26% had a seizure reduction of 50% to 75%. The duration of individual seizures was also significantly diminished. In the control group, 40% of patients achieved a 75% seizure decrease and 12% had a 50% reduction in seizures. Approximately 1% had worsening seizure control. Fifty percent of children with absence and benign rolandic seizures had a 75% decrease in seizures. Two cases of infantile spasms were included in this study. One patient had a 75% reduction of seizures and the other a 50% to 75% decrease. Of those in the treatment group who previously had abnormal EEGs, 54% had normal EEGs at the end of the study period.

In Japan, kampo medicines are herbal remedies used to combat various medical conditions, including epilepsy. Most of these therapies are mixtures of different herbs,

some of which are similar to those used in traditional Chinese medicine. Sho-saiko-to is an herbal formula commonly used to treat liver disorders; it also is recommended as a possible treatment for intractable epilepsy. Another formula similar to this compound, the Chinese bupleurum–cinnamon combination (chai-hu-keui-chi-tang), has shown some preliminary benefit in epilepsy. These formulas contain the same nine herbs with minor variations in their relative amounts. They appear to have equivalent effects (109). Sho-saiko-to has been administered to adults and children. The pediatric dose depends on the child's weight (110). There are no well-designed clinical studies on the benefit of this formula in epilepsy. In one study (111), it was given to 24 patients who were taking multiple drugs for uncontrolled epilepsy. Six of the 24 patients had no seizures within 10 months of the herbal therapy. An additional 13 patients were improved, three had no change, and two did not complete the study. Improvements were seen as soon as 1 month. Tonic-clonic seizures seemed to have the best response rate. Another study (112) revealed possible cognitive improvements with the use of this supplement, but the study was flawed and not optimally designed. Animal studies (113) have shown that it can inhibit pentylenetetrazol-induced seizures as well as cobalt-induced seizures and neuronal damage. Other studies (114, 115) revealed that there were no changes in barbiturate potentiation.

Adverse effects have rarely been reported. The formula has caused pneumonitis or hepatitis, or both, in a number of patients with liver disease, and has caused fatalities. Patients using this supplement must be advised to report coughs and fevers to their health care providers; prompt and careful follow-up is necessary (116, 117). Occasionally, gastrointestinal upset or mild transient symptoms are present. In addition to side effects, some of these supplements have been known to contain toxic ingredients that are not named on the label. These herbal remedies have been found to contain such elements as lead, arsenic, and mercury, which, if consumed in greater than safe amounts, can lead to serious consequences (118, 119). Although some report significant success with the use of these products, extreme caution should be maintained.

## ACUPUNCTURE

Acupuncture has been practiced in Asia for more than two thousand years. In the United States, where it has increased in popularity over the past 30 to 40 years, it is used by approximately one million individuals. This ancient therapy is used mostly for pain management, but also for a number of different conditions, including epilepsy. Up to 70% of people who undergo acupuncture treatments do not inform their health care

providers (120). Acupuncture involves the use of fine needles (now made of stainless steel) that are inserted into the skin at defined points of the body. For epilepsy, points along the scalp are key, as acupuncturists consider the scalp a direct projection of the cerebral cortex. Different points are selected depending on the different types and symptoms of seizures (121).

Acupuncture is presumed to restore balance to the disruption of the natural flow of energy that the body requires to function normally. Acupuncture releases endorphins, adrenocorticotrophic hormone (ACTH), and other neurochemicals, such as GABA (122). Some studies show that afterward there is an increase of the serotonin level, which may lead to improved cognitive function (123). Specific sites are used to combat different conditions. The point naokong (GB19) is located near the occipital protuberance. It is selected for acupuncture in a variety of medical conditions in addition to epilepsy, and has been used in children. It is said to have tranquilizing effects, regulate blood flow, and calm “endopathic wind.”

In terms of efficacy, there is a paucity of well-performed and well-controlled clinical trials for evaluating the usefulness of acupuncture in epilepsy, as well as other medical conditions. This is due in part to the individualization of therapy. Acupuncture differs between individuals, making standardization difficult. Even sham acupuncture is difficult to assess, because nonspecific needling can lead to the stimulation of neurohormonal responses (124).

Kloster et al (125) compared the effects of sham acupuncture and actual acupuncture in patients with intractable epilepsy. There was a small but statistically nonsignificant reduction in seizure frequency in both groups, perhaps due to the small sample size. No significant EEG changes were appreciated. Stavem et al (126) also failed to show that acupuncture significantly reduced seizures or had any effect on the patients' quality of life. Adverse effects are rare, the most common being infection and trauma. Other rare complications such as pneumothorax, cardiac tamponade, hepatitis, and spinal cord injuries have also been reported. The transmission of human immunodeficiency virus (HIV) has rarely been reported. The importance of sterilization and universal precautions cannot be emphasized enough (120).

In a child who had almost continuous simple partial seizures, acupuncture improved the seizures after seven sessions, and almost completely eliminated them by 30 sessions (127). Six months later, the patient was reported to be seizure free. In another study (121) involving almost 100 children and adults, 66% had a greater than 75% reduction in seizures, and an additional 24% had a 50% to 75% reduction. Yang (128) reported the use of acupuncture in eight children with status epilepticus. Different acupoints were used depending on the case. Seizures ceased within 10 minutes in all cases. No

recurrences were reported in three patients for up to 2 years and in one patient for 8 years. Acupuncture may be a useful adjunctive therapy in epilepsy, but better designed studies are needed to fully evaluate its effectiveness.

### HOMEOPATHY

There is little scientific evidence for the efficacy of homeopathy in epilepsy, and even less information is available on its use in children. It has been used for more than 200 years, and more than 500 homeopathic remedies have been used to treat seizures. Homeopathy is based on the principle that substances causing medical conditions can also be used to combat them. Symptoms are believed to represent the body's attempt to restore itself to health, and homeopathy aims to treat the patient's symptoms. It relies on the body's own powers for self-healing; therefore an individual's mental and physical state is important and taken into account prior to the administration of remedies. The identification of imbalances within the person in conjunction with his or her symptoms aids the homeopathist in choosing supplements that will restore the body's ability to heal itself. When dealing with children, choosing the correct treatment is further complicated by the fact that the homeopathist must rely on parental observations instead of directly obtaining information from the child.

The remedies used are derived mainly from plants, minerals, and animals. Remedies derived from toxins that are believed to cause illness are diluted before administration (129). Formulas containing *Aconitum napellus* and *Aethusa cynapium* are thought to be helpful in febrile seizures and other seizures associated with illnesses (Table 55-6). There are supplements that may be helpful in febrile and nonfebrile seizures (130). Reliable

information on the risks associated with homeopathic remedies is lacking.

### NATUROPATHY

Naturopathic medicine was established more than a hundred years ago and uses forms of Western medicine in addition to natural therapies. It uses noninvasive techniques and is based on the principle that natural substances can help the body's intrinsic ability to heal itself. Naturopath practitioners place a large emphasis on attempting to remove the underlying cause of the disease. Consuming the proper foods for sufficient nutrition of the body is one way of using natural substances. Nutritional supplements in the form of vitamins and minerals are often used (6). Certain herbs are prescribed to support the liver and kidneys, through which many AEDs are metabolized. In addition, some vitamins can interfere with certain AEDs. Information on the efficacy of naturopathic medicine in epilepsy is limited.

### CONCLUSION

Alternative medicine is a growing field that comprises several different approaches. Most facets have not been well studied, making recommendations for their use in patients with epilepsy difficult. Side effects and complications are mostly underreported. Open communication between patients and health care professionals is vital in ensuring the well-being of patients. Patients should be encouraged to make their physicians aware of any other treatments they are receiving. They should also be advised not to discontinue their conventional medications without discussing their plans with their primary caregivers. Further research is required to better evaluate the role of alternative medicine in the treatment of epilepsy.

## Zonisamide

*John F. Kerrigan  
John M. Pellock*

**Z**onisamide (ZNS) was first synthesized by Dainippon Pharmaceutical Company in Osaka, Japan, in 1974 (1). ZNS was originally developed in an effort to discover medications for psychiatric illness (2–4). However, screening for anti-convulsant effectiveness in the maximal electroshock seizures (MES) model showed positive results, and ZNS subsequently entered human epilepsy trials, with Phase I studies in Japan in 1979 and Phase II trials in 1985. ZNS was approved for marketing in Japan in 1989. Enthusiasm for ZNS in the United States was dampened by the occurrence of renal calculi in early trials, which was attributed to the mechanism of carbonic anhydrase (CA) inhibition. However, subsequent pivotal trials led to approval for marketing by the U.S. Food and Drug Administration (FDA) in March 2000, with an indication for adjunctive therapy for adults with partial epilepsy. As of 2006, the estimated worldwide exposure to ZNS exceeds 2 million patient-years (5).

Very few controlled trials examining the efficacy of ZNS in children have been performed. However, published open-label reports describing ZNS effectiveness with various seizure types and epilepsy syndromes that occur in the pediatric age range have demonstrated that

ZNS should be included among the broad-spectrum group of antiepileptic drugs (AEDs).

### **CHEMISTRY, ANIMAL PHARMACOLOGY, AND MECHANISMS OF ACTION**

#### **Chemistry**

ZNS (1,2-benzisoxazole-3-methanesulfonamide) is a synthetic amine sulfonamide compound (Figure 56-1(A)) (2). ZNS is the only compound in this chemical class among AEDs. Several features of the chemical structure of ZNS deserve comment. All sulfonamide antibiotic compounds include an arylamine domain at the N4-position, which contributes to allergic reactions in susceptible individuals (Figure 56-1(B)) (6). However, ZNS is a nonarylamine sulfonamide and therefore lacks the chemical domain with the greatest potential to produce hypersensitivity reactions. ZNS shares structural similarity with acetazolamide (Figure 56-1(C)) and likewise shares an ability to inhibit the function of CA. Although the role of CA inhibition has been questioned as a mechanism of anticonvulsant action, there appears to be little debate that it contributes significantly to the side effect profile of ZNS. Lastly, ZNS bears structural similarity to other

inhabiting the intertidal zone; it does not appear to have been reported in any other experimental system.)

ZNS also reduces voltage-dependent calcium currents by blocking the T-type calcium channel in a concentration-dependent fashion (9, 10). A methylated analog of ZNS, shown to be ineffective in blocking MES seizures, was likewise ineffective in blocking calcium currents (9). The relevance of T-type calcium channels as potential therapeutic targets of ZNS is suggested by studies in an animal model that examined the consequences of a single episode of status epilepticus, in which hippocampal CA1 pyramidal cells are converted into an abnormal burst-firing mode by up-regulation of T-type calcium channels (11). In addition, the study of dentate granule cells derived from temporal lobe tissue from patients undergoing surgery for refractory epilepsy has shown the presence of calcium currents mediated by T-type calcium channels (12).

In-vitro and animal studies also suggest that ZNS may modulate synaptic transmission as well. ZNS inhibited potassium-mediated glutamate release in the hippocampus in a microdialysis model in rats (13). Also in microdialysis experiments, ZNS functions to increase extracellular levels of dopamine and serotonin (possibly by enhancing synaptic release) in rat hippocampus and striatum (14–18).

ZNS may affect synaptic transmission by altering gene expression of neurotransmitter transporter proteins. In a rat model of hippocampal seizures elicited by injection of FeCl<sub>3</sub> into the amygdala, ZNS caused (1) up-regulation of excitatory amino-acid carrier-1 (EAAC-1), which has the potential effect of enhancing the removal of excitatory amino acids such as glutamate from the synaptic cleft, and (2) down-regulation of the expression of gamma-aminobutyric acid (GABA) transporter-1 (GAT-1), which could enhance inhibitory neurotransmission by increasing synaptic levels of GABA (19). This change in EAAC-1 and GAT-1 expression was present in both epileptic and control animals.

Although chemically related to acetazolamide, it appears that the mechanism for treating seizures may not be by CA inhibition, because drug concentrations for ZNS needed to be 100- to 1,000-fold higher than that of acetazolamide to reach an equivalent inhibitory effect on CA (20, 21). On the other hand, the profile of side effects of ZNS includes signs and symptoms attributable to CA inhibition.

ZNS has also been studied in seizure and epilepsy models in intact animals (22). ZNS can prevent the tonic extensor components of MES in several different species (3). ZNS inhibited the focal cortical discharge provoked by acute electrical stimulation of the visual cortex in cats (23), as well as seizures provoked by electrical stimulation in cats that have undergone kindling of the visual cortex (24). ZNS also prevents spread from the ictal focus in cats that have undergone focal freezing lesions of the cortex (23).

In addition to antiseizure effects, ZNS may have effectiveness as an antiepileptogenic compound as well

(see also the discussion in the following section on possible neuroprotective effects). ZNS suppressed the kindling process, as well as inhibiting seizures resulting from kindling, in adult rats (25). ZNS also inhibited the development of elevated levels of chemical markers for oxidative damage in iron-induced focal epileptogenic foci in rat brain (26). This finding requires further study, but it raises the possibility that ZNS may help prevent the emergence of seizure foci following traumatic brain injury or intracranial hemorrhage.

### Mechanisms of Action: Neuroprotection

ZNS has also been a subject of investigation for possible neuroprotective effects. In an in vitro model, ZNS demonstrates dose-dependent reductions in hydroxyl and nitric oxide free radicals (27). The same group has also shown that ZNS has reduced nitric oxide synthase activity in the hippocampus of rats exposed to N-methyl-D-aspartate (NMDA) (28). Recent studies have shown that pretreatment with ZNS reduces the half-life of free radicals in the hippocampus of rats. This finding was present in normal animals and in those undergoing an acute episode of status epilepticus induced by kainic acid (29, 30). These results suggest that ZNS has the capacity to protect the brain from free-radical-mediated injury.

ZNS reduces hypoxic-ischemic brain injury in neonatal rats (31). In this model, the carotid artery was ligated on one side, and the animal was then exposed to prolonged hypoxia (8% O<sub>2</sub> for 2.5 hours). ZNS was administered by intraperitoneal injection (75 mg/kg) prior to hypoxemia. Cortical infarction size, as a percentage of volume, was 6% in the ZNS-treated animals compared to 68% in control animals. Neuronal loss in the hippocampus was also reduced in ZNS-treated animals. Seizure recordings showed no significant difference between the two groups, suggesting that the neuroprotective effect was independent of any impact of the drug on seizure activity.

ZNS reduced cerebral infarction in a transient middle cerebral artery occlusion model in adult rats (32). Pretreatment with ZNS has shown neuroprotective effects following transient cerebral ischemia in the adult gerbil, as determined by memory performance with water maze and subsequent histologic study. These findings correlated with reduced extracellular glutamate in the hippocampus of the ZNS-treated animals (33).

### BIOTRANSFORMATION, PHARMACOKINETICS, AND INTERACTIONS

ZNS has several properties that are desirable for an AED. These include a long half-life (making once daily

dosing a feasible option), limited plasma-protein binding (minimizing displacement of other AEDs because of competition for protein binding sites), and an absence of autoinduction of the hepatic enzymes responsible for its metabolism (34).

### Absorption

Absorption of ZNS following oral administration appears to be highly efficient, probably approaching 100%, based on recovery of radiolabeled drug in urine (35, 36). Absorption is rapid, with peak blood levels occurring 2–6 hours following dosage administration (37). When taken with food, peak levels are delayed slightly (4–6 hours), but the bioavailability is no different (37).

### Distribution

The volume of distribution following oral administration is 1.0 to 1.9 L/kg in healthy adult volunteers. ZNS is only approximately 50% noncovalently bound to plasma proteins, which limits competition for binding sites with highly protein-bound medications such as phenytoin and valproic acid (37). Accordingly, drug-drug interaction resulting from alterations of free drug levels because of competition for binding sites is minimized.

On the other hand, ZNS has a particularly high binding affinity to the intracellular compartment of

erythrocytes. The tendency of ZNS to sequester in erythrocytes has potential practical clinical importance, with a risk of false elevations of reported ZNS serum levels in hemolyzed specimens (38).

Distribution in the brain has been studied in rats with autoradiography following injection of  $^{14}\text{C}$ -ZNS), showing preferential uptake in cerebral cortex relative to subcortical structures, including striatum, thalamus, hypothalamus, and cerebellum (39). However, further specificity with respect to binding sites is not yet available.

### Metabolism and Drug-Drug Interactions

Among the drugs used to treat epilepsy, ZNS has a relatively long elimination half-life, with a mean of approximately 60 hours in healthy adult volunteers (range 52 to 69 hours) (40, 41). This favorable serum half-life enables twice-daily or even once-daily dosing schedules, but it also implies a prolonged time to steady state, as much as 10–14 days (22).

Zonisamide is partially metabolized by either acetylation, to produce N-acetyl ZNS, or by reduction to 2-sulfamoylacetylphenol (SMAP), then followed by glucuronidation and urinary excretion (40, 42–45) (see Figure 56-2). Study of the disposition of radio-labeled ZNS in human adult volunteers has shown that 62% of ZNS was recovered in the urine, of which 35% was unmetabolized ZNS, 15% N-acetyl ZNS, and 50% as the glucuronide derivative of SMAP (46).

Percent of Total ZNS Metabolites Recovered in Urine

FIGURE 56-2

ZNS is metabolized by the hepatic cytochrome P450 system, specifically by the 3A subfamily, and predominately by the 3A4 isoenzyme (45, 47). However, ZNS does not induce its own metabolism, nor does it induce or inhibit other elements of the cytochrome P450 system (46). Because of the relatively low plasma-protein binding of ZNS, as well as its lack of hepatic enzyme induction, ZNS has little or no effect on the blood levels of other AEDs (48).

Other AEDs, however, can affect ZNS blood levels by virtue of their cytochrome P450-inducing or -inhibiting features. The elimination half-life of ZNS is decreased to 27 hours in adult patients fully induced by coadministration of phenytoin, to 38 hours in patients taking carbamazepine or phenobarbital, and to 46 hours in patients taking sodium valproate (46, 48–50). Non-AED compounds such as cimetidine can inhibit hepatic metabolism of ZNS (51). Other non-AED compounds, such as erythromycin, midazolam, and nifedipine, are also preferentially metabolized by the 3A4 isoenzyme and can therefore compete with ZNS for metabolism, resulting in increased ZNS blood levels (52). Certain dietary items, such as grapefruit juice, may have this same effect. Dexamethasone can act to induce the P450 reduction pathway for ZNS (47).

Detailed pharmacokinetic studies of ZNS within the pediatric age range have not been performed. However, as the metabolizing capacity of young children generally exceeds that of adults on a per-kilogram basis, higher doses may be required to reach the same target drug level (53). ZNS is likely to have a shorter serum half-life in children compared to adults.

### Serum Levels

The significance of ZNS serum levels with respect to efficacy appear limited (37, 54). However, levels greater than 40  $\mu\text{g/mL}$  were more likely to be associated with dose-related side effects, specifically drowsiness (54). This study also showed relatively small changes between blood levels at the peak (4 hours after once-daily morning dose) and the trough (prior to once-daily morning dose). The ratio of the peak to the trough levels showed a mean of  $1.28 \pm 0.15$  in this sample of 72 children on initial ZNS monotherapy, which is consistent with the relatively long half-life of this AED.

A therapeutic ZNS level of 15 to 40  $\mu\text{g/mL}$  has been suggested (50, 55).

## CLINICAL EFFICACY

### Pivotal Adult Trials

Not unexpectedly, Class I studies demonstrating the efficacy of ZNS for treating epilepsy enrolled predominantly adult subjects with partial seizures. In 2005 Brodie

reported the results of a multicenter, randomized, double-blind, placebo-controlled trial in patients with refractory partial seizures (56). The group consisted of patients aged 12 to 77 years, who were taking one to three preexisting AEDs at the time of enrollment. Subjects were randomized to placebo or ZNS at one of three doses (100 mg/day, 300 mg/day, or 500 mg/day).

Efficacy varied directly with ZNS dose. The median reduction in seizure frequency for complex partial seizures was 51.2% for the study group taking 500 mg/day and 16.3% for the placebo group ( $P < 0.0001$ ). The responder rate (the percentage of patients having at least a 50% improvement in seizure frequency) for complex partial seizures was 52.3% for ZNS at 500 mg/day and 21.3% for the placebo group ( $P < 0.001$ ). The most frequent treatment-emergent adverse events during titration to 500 mg/day were somnolence (14.4%), headache (6.8%), dizziness (11.9%), and nausea (7.6%). The frequency of adverse events was generally lower at lower ZNS doses (and with placebo) and during the fixed-dose phase of the trial.

Additional pivotal studies with ZNS utilizing a randomized, placebo-controlled, add-on design have been performed in adult patients with refractory, partial-onset epilepsy (57–59). Representative results of these four studies are shown in Table 56-1.

Continued observation of these refractory partial-epilepsy patients with open-label extensions of the pivotal trials has provided further evidence that ZNS is effective and well tolerated with long-term follow-up (5, 60, 61).

### Early Pediatric Trials in Japan

The initial observations concerning the use of ZNS in children with epilepsy arises from open-label clinical trials and practice experience in Japan, subsequently published in either Japanese or English, and reviewed by Glauser and Pellock (53). In this detailed meta-analysis examining efficacy and safety of ZNS in children in the Japanese publications, the available studies were broken down into those employing ZNS monotherapy (either newly diagnosed or previously treated cases) (62–67), adjunctive therapy with ZNS for treatment-resistant cases (68–72), or studies with a mixed group of patients receiving either ZNS monotherapy or ZNS adjunctive therapy (73–75). Results were then further analyzed by seizure type (partial-onset or generalized-onset seizures), and the percentage of responders (those with an improvement of at least 50% in seizure frequency) was reported. These results are shown in Table 56-2.

A component of one study included a group of 32 children that was randomized to monotherapy treatment with either ZNS ( $n = 16$ ) or valproate ( $n = 16$ ) (53, 73). These patients had generalized seizures and had previously failed seizure control with one to three AEDs. No significant difference in efficacy was observed. The

**TABLE 56-1**  
*Seizure Efficacy for ZNS in Randomized, Placebo-Controlled, Add-On Trials in Adults with Refractory Partial Epilepsy*

STUDY (FIRST AUTHOR)	NUMBER OF SUBJECTS	AGE RANGE (YEARS)	MAXIMUM ZNS DOSE	MEDIAN REDUCTION IN TOTAL SEIZURE FREQUENCY (% CHANGE FROM BASELINE)	MEDIAN REDUCTION IN TOTAL SEIZURE FREQUENCY (% CHANGE FROM BASELINE)	P VALUE
				ZNS GROUP	PLACEBO GROUP	
Schmidt 1993 (57)	139	18–59	20 mg/kg/day	22.5%	–3.0%	<0.05
Faught 2001 (58)	203	13–68	400 mg/day	40.5%	9.0%	= 0.009
Sackellares 2004 (59)	152	17–67	600 mg/day	25.5%	–6.6%	= 0.0005
Brodie 2005 (60)	351	12–77	500 mg/day	51.3%	18.1%	<0.0001

responder rate was 50% for ZNS treatment (at a mean dose of 7.3 mg/kg/day) and 44% for valproate (at a mean dose of 27.6 mg/kg/day).

#### Recent Studies on ZNS Efficacy in Children

*Initial Monotherapy.* In an uncontrolled trial of initial monotherapy in 72 children (mean age, 8.3 years; range, 3 months to 15 years) with newly diagnosed cryptogenic partial epilepsy, Miura treated patients with ZNS at an initial dose of 2 mg/kg/day, escalating at weekly intervals to a maintenance dose of 8 mg/kg/day (54). Dosing

was provided once daily. At this initial target dose, 49 of 72 cases (68%) were completely controlled. After further dosage adjustment, 57 of 72 cases (79%) were completely controlled. The mean duration of ZNS treatment was 27 months (range, 6 to 43 months). Although a clear relationship between ZNS blood levels and clinical effectiveness was not seen, patients who were symptomatic with dose-related side effects (predominantly drowsiness) had blood levels greater than 40 µg/mL.

Seki and colleagues studied 77 children (ages 8 months to 15 years) with various seizure types, 68 of whom were included for analysis of ZNS efficacy (76). Fifty had

**TABLE 56-2**  
*Anti-Epilepsy Treatment with Zonisamide in Children*

INCLUSION CRITERIA FOR OPEN-LABEL STUDY	PARTIAL-ONSET SEIZURES		GENERALIZED-ONSET SEIZURES	
	RR	N	RR	N
Patients on ZNS Monotherapy Only	78%	209	71%	49
Patients on ZNS as Adjunctive Therapy Only	34%	137	15%	54
Patients on Either Monotherapy or Adjunctive Therapy	60%	718	42%	291

Summary results of open-label trials in Japan as reviewed by Glauser and Pellock 2002 (53), noting the responder rate for children with either partial-onset or generalized-onset seizures according to the inclusion criteria for the study (ZNS monotherapy only, ZNS adjunctive therapy only, or combined ZNS monotherapy and adjunctive therapy).  
n = Number of patients in each summary category. RR = Responder rate.

previously not taken any AEDs. All patients were on ZNS monotherapy. Doses were initiated at 2 mg/kg/day (divided twice daily), and increased by 1–2 mg/kg/day at 1–2 week intervals, up to a dose of 12 mg/kg/day. Forty-eight patients (of 68 patients, 62%) had localization-related epilepsy, and 20 (38%) had generalized epilepsies. Of the patients with localization-related epilepsy, 40 of 48 (83%) showed an “excellent” response (at least 3 months seizure-free); for patients with generalized epilepsy, 18 of 20 (90%) were seizure-free for at least 3 months.

**Follow-up Monotherapy.** Wilfong has described an uncontrolled case series of 131 children and adolescents treated with open-label ZNS monotherapy (77). Patients with both partial and generalized seizure types were included, although limited detail regarding seizure type and epilepsy syndrome was provided. Eighty-nine patients (68%) had previously been treated with at least one AED. When all patients are grouped together, 30% were completely seizure free, and an additional 47% had an improvement of at least 50% in seizure frequency. Forty-three patients (33%) reported at least one adverse effect while on ZNS, but only 3 (2.3%) had to discontinue ZNS therapy (sleeplessness and increased seizures, failure to gain weight, and behavioral changes in one patient each).

**Add-on Polytherapy.** Kim and colleagues have reported an uncontrolled, retrospective study of ZNS use in 68 children and adolescents treated for epilepsy (median age, 6.9; range, 1.9 to 18.1 years) (78). ZNS was used initially as monotherapy in 11.8% and as adjunctive polytherapy in 88.2%. The median ZNS dose was 8.0 mg/kg/day (range, 1.5 to 23.2 mg/kg/day). Of the 68 patients, 69.1% had exclusively generalized seizures, 10.3% exclusively partial seizures, 14.7% both generalized and partial, and 5.9% had seizures of undetermined type. Data to determine efficacy were available in 62 patients: 25.8% were completely seizure free, 21.0% had a reduction of at least 50% in overall seizure frequency, 16.1% were improved in seizure frequency by less than 50%, 22.6% showed no change, and 14.5% were reported as having increased seizure frequency. There were no clear trends with regard to efficacy and seizure type or etiology. Adverse events were reported by 61.8% of patients, predominantly during dose escalation. These were generally central nervous system (CNS) related, with behavioral or psychiatric symptoms (such as aggression, agitation, and decreased attention) reported in 23.5%, cognitive dysfunction in 12.0%, and sedation in 10.3%.

A retrospective study by Santos and Brotherton included 50 patients (range, 9 months to 20 years; mean age, 9.1 years) (79). With one exception, all had previously failed at least one other AED, and 47 subjects

(94%) were taking at least one other AED with ZNS. The study group experienced a wide diversity of seizure types. For the entire population, 16% became seizure free, and an additional 22% had an improvement of at least 50% in seizure frequency. Efficacy was not broken down by seizure type. Adverse events were experienced by 62% of patients, including loss of appetite in 14 (28% of total study population), weight loss in 5 (10%), and kidney stones in 2 (4%). Fourteen patients (28% of total study population) discontinued ZNS because of adverse effects. Mean dosage for ZNS was 15.9 mg/kg/day (range, 3.3 to 35 mg/kg/day).

In another retrospective chart review of ZNS add-on therapy in 35 children with refractory epilepsy, Mandelbaum and colleagues determined that 11% of the study population was completely seizure-free, and 31% had an improvement in seizure frequency of at least 50% (80). When efficacy was analyzed by seizure type (generalized, partial, or mixed), there were no clear trends. The authors conclude that ZNS is a broad-spectrum AED.

### **Efficacy in Specific Seizure Types or Epilepsy Syndromes in Children**

**Partial Seizures.** Miura has reported an uncontrolled series of 72 children (mean age, 8.3 years; range, 0.3–15 years) treated with initial ZNS monotherapy for cryptogenic localization-related epilepsy (54). The initial maintenance dose of ZNS was increased incrementally to 8 mg/kg/day and could be increased thereafter for patients not responding with complete seizure control. At 8 mg/kg/day of ZNS, 49 patients (68.1%) were completely controlled. Of the remaining patients, an additional 8 achieved complete seizure control with an increased dose of ZNS (79.2% of study group completely controlled on ZNS monotherapy). CNS-related side effects (drowsiness) tended to occur with blood levels greater than 40 µg/mL. A therapeutic range of 15–40 µg/mL was suggested.

**Absence.** T-type calcium channels have been implicated as an important mechanistic component of absence seizures (81). The ability of ZNS to functionally block these channels makes ZNS a potentially attractive AED for treating this seizure type (9, 10). Wilfong and Schultz have retrospectively reviewed the charts of 45 patients under 18 years of age treated with ZNS for absence seizures (82). Study subjects included both typical and atypical absence seizures and were not further analyzed according to epilepsy syndrome. However, 88.9% of patients had failed prior AED therapy. The mean ZNS dose was 9.0 mg/kg/day (range, 2–24 mg/kg/day). Twenty-three of 45 patients (51.1%) were 100% seizure-free for absence seizures, and 14 (31.1%) had a reduction in absence seizures of at least 50%. The efficacy with regard to treating other seizure types in this series of patients was not provided.

*Juvenile Myoclonic Epilepsy (JME).* Kothare examined the use of ZNS for seizure control in 15 patients with JME, utilizing a retrospective chart review method (83). There was no control group. ZNS was used as monotherapy in 13 patients (87%) and as add-on therapy in 2 patients. Dosing for ZNS ranged from 200 to 500 mg/day (2.0 to 8.5 mg/kg/day). For patients taking ZNS monotherapy, 80% had a decrease of at least 50% in total seizure frequency. When broken down by the individual seizure types commonly seen with JME, 69% of patients were seizure free for generalized tonic-clonic seizures, 62% were seizure-free for myoclonic seizures, and 38% were seizure free for absence seizures. One patient on monotherapy discontinued ZNS because of lack of efficacy, and 3 patients reported adverse events (weight loss, headache, dizziness), which resolved with continuing therapy.

*West Syndrome or Infantile Spasms (IS).* Several uncontrolled, open-label studies have reported the use of ZNS in patients with IS (West syndrome) (77, 80, 84–90).

Suzuki published a prospective, multicenter, open-label, uncontrolled trial with treatment of 13 infants with newly diagnosed IS (84). By protocol, all patients were initially treated with high-dose pyridoxine. Two responded, and the remaining 11 patients were then treated with ZNS, with a dose escalation program to reach seizure control or a maximum of 10 mg/kg/day. Eight of 11 patients (73%) had symptomatic IS. A positive response was defined as complete cessation of seizures and disappearance of hypsarrhythmia on electroencephalogram (EEG).

Four of 11 patients (36%) were initial responders. Interestingly, all had resolution of spasms within days of taking the initial dose at 3–5 mg/kg/day. However, 2 of these patients later relapsed. There were no adverse events reported during ZNS treatment. Of the 7 nonresponders, 5 of 7 later responded to an intramuscular adrenocorticotropic hormone (ACTH) treatment protocol.

Yanagaki treated 23 infants with West syndrome, ages 4–11 months, as either initial or adjunctive therapy, with a dose-ranging protocol to study an increased titration rate. Initial doses varied from 3 mg/kg/day to 10 mg/kg/day, to achieve a final target dose of 9–11 mg/kg/day for the entire group (90). A positive response (defined as a complete cessation of spasms and disappearance of hypsarrhythmia for at least 3 months) was observed in 7 patients (30%). Of these, 4 were cryptogenic and 3 were symptomatic cases. A mild degree of hyperthermia (temperature above 37.5°C), but without obvious signs of infection, was observed in 3 of the 10 patients in the highest initial dose treatment group, but the medication was continued in all, with simple environmental cooling.

Based on this collective open-label experience, it has been noted that the likelihood of success with

ZNS for IS is higher in patients with cryptogenic IS in comparison to those with symptomatic IS. Notably, those who responded often did so quickly and at relatively low doses of 4–8 mg/kg/day (87).

*Lennox-Gastaut Syndrome (LGS).* In comparison to IS, there is relatively little published information directly addressing the use of ZNS for treating patients with LGS. Some of the retrospective, tertiary clinic-based surveys previously noted contain large numbers of patients with cryptogenic or symptomatic generalized epilepsy, but LGS is not broken out as an identified subgroup (78, 80).

Yamauchi has recently described a large cadre of patients followed prospectively as part of an uncontrolled, multicenter, postmarketing surveillance study consisting of 1,631 patients, including enrollment of 774 children (ages 15 years or less) (91). Within the entire study population, 79 patients are described as having LGS. Details regarding ZNS dosing, including whether ZNS was used as monotherapy or polytherapy, are not broken out for the LGS subgroup. However, in response to ZNS treatment, 27.9% of LGS patients experienced an improvement in total seizure frequency of at least 50%, whereas 51.9% are described as unchanged.

*Myoclonic Seizures and Progressive Myoclonus Epilepsy.* Yamauchi (see preceding discussion) also describes open-label efficacy of ZNS broken down by seizure type in a large postmarketing surveillance study (91). Fifty-six subjects experienced myoclonic seizures. Of these, 19.6% are described as completely free of myoclonic seizures, and an additional 32.2% showed an improvement of at least 50% in myoclonic seizure frequency. Details regarding ZNS dosing are not provided for this subgroup.

Generally favorable results have been described in several small, uncontrolled, open-label reports of ZNS treatment of the refractory seizures associated with progressive myoclonus epilepsies, including Unverricht-Lundborg disease (92, 93) and Lafora disease (93, 94).

Importantly, ZNS is not one of the AEDs that may exacerbate myoclonic seizures, which is a list that includes lamotrigine, carbamazepine, phenytoin, gabapentin, pregabalin, and vigabatrin (95).

## ADVERSE EFFECTS

### Dose-Related Effects

Premarketing Phase II and Phase III trials in Japan in 1,008 patients (of whom, 403 patients [40%], were ages 15 years or less) demonstrated that the most frequent treatment-emergent adverse events were drowsiness (24%), ataxia (13%), decreased appetite (11%),

gastrointestinal symptoms (7%), decrease in spontaneity (6%), and slowing of mental activity (5%) (96).

Ohtahara has described the side effect profile of ZNS in 928 children participating in an open-label post-marketing surveillance study (97). The children had a statistically significant lower likelihood of all adverse events (24.3% of pediatric population) in comparison to adult patients in the study (40.1%;  $P < 0.001$ ).

Not surprisingly, the likelihood of adverse events increased with polypharmacy. In one large multicenter trial of ZNS in Japanese children (72), the incidence of adverse events of any kind was 14% in those taking ZNS monotherapy, 37% in those taking one other AED in addition to ZNS, and 53% in those taking two additional AEDs [reviewed in (53)]. The likelihood of adverse effects appeared to correlate with serum level of ZNS; mean levels of ZNS for symptomatic patients were generally greater than 20  $\mu\text{g/mL}$ . Target doses of 8 mg/kg/day and lower were well tolerated.

### Idiosyncratic Effects

**Hyperthermia and Oligohydrosis.** Decreased sweating and increased core temperature, a potential consequence of CA inhibition, is a recognized adverse event with ZNS therapy. This side effect appears to be more common in children and more likely to occur in hot weather (98). Postmarketing assessment of the likelihood of oligohydrosis, hyperthermia, or both in the United States suggested an incidence of 1 case per 4,590 patient-years (0.02% per patient-year) (98). Surveillance of the Japanese market for 11 years after ZNS approval suggested an incidence of 1 case per 10,000 pediatric-years (0.01% per pediatric-year) (98). Knudsen analyzed the Adverse Events Reporting System of the FDA for cases with oligohydrosis, fever, or both (99). Six cases were identified, all in children or adolescents. The reporting rate was calculated to be 1 case per 769 pediatric-years (0.13% per pediatric-year). Ascertainment of the cases in these reports depends on physician report and is biased in favor of medically serious episodes. Conversely, one Japanese report identified decreased sweating in 12 of 70 patients (17%) taking ZNS, based on historical reports by the patients' parents (100). In summary, the preponderance of data suggests that the incidence of serious episodes of oligohydrosis and hyperthermia is low, but milder instances are encountered during routine clinical practice.

**Renal Calculi.** Renal stones occurred in 1.9% of 700 adult patients treated with ZNS in U.S. and European studies (101). A more recent study, also in adult patients, identified stones in 4% of 750 patients (1.2% symptomatic and 2.8% asymptomatic) (102). The incidence of renal calculi in children taking ZNS is unknown. An increased risk of renal stones is most likely attributable

to the effect of ZNS as a CA inhibitor, resulting in alkalization of the urine and an increased risk of calcium phosphate stones. An increased risk for kidney stones is likely in those with a prior history of stones or in those with a family history of renal calculi.

**Rash.** Although ZNS is a sulfonamide, it does not include the arylamine group that increases risk for hypersensitivity skin reactions (6). Accordingly, the risk of allergic drug rash appears to be substantially lower with the use of ZNS in comparison to the sulfonamide antibiotics, for which hypersensitivity can occur in as much as 6% of the population (6). Postmarketing surveillance reports show an incidence of serious rash associated with ZNS treatment of approximately 0.25% (5). Even so, caution and careful observation with use of ZNS in a patient with a recognized history of hypersensitivity to sulfonamide drugs are warranted.

**Cognitive and Behavioral Side Effects.** There is a lack of research into the potential impact of ZNS on cognition, particularly in children. A pilot study in nine adult patients with refractory partial-onset epilepsy, undergoing psychometric testing prior to and 12 weeks following the addition of ZNS, showed impairments in verbal learning without overt signs of overmedication (103). The degree of impairment correlated directly with ZNS plasma levels, particularly with blood levels greater than 30  $\mu\text{g/mL}$ . However, retesting at 24 weeks failed to show significant changes in cognition function relative to baseline, suggesting a drug tolerance effect.

Adverse effects of ZNS on behavior and psychiatric functioning have been reported. In a retrospective report based on open-label use of ZNS for epilepsy in 68 pediatric patients, Kim and colleagues determined behavioral or psychiatric side effects in 23.5% of patients (78). Difficulties described included aggression, agitation, irritability, poor attention, hallucinations, hyperactivity, dysphoria, paranoia, and psychosis. All of these behavioral side effects resolved with lowering the dose or discontinuing ZNS. Only 5 patients in the entire study population (7.4%) discontinued because of side effects, suggesting that behavioral problems were handled successfully by a reduction in dose in most instances.

A postmarketing surveillance study in Japan of 1,512 patients (including 928 children ages more than 16 years) revealed irritable or excitable behavioral episodes in 45 patients (3.0%), depression in 8 (0.5%), and anxiety or hypochondria in 14 (0.9%) (97).

**Teratogenicity.** There is insufficient data regarding ZNS and any associated risk of fetal malformations (104). A small prospective registry study of pregnant epileptic women taking ZNS examined 26 offspring (105). The 4 children born to mothers taking ZNS monotherapy

were normal. The remaining 22 offspring were exposed to AED polytherapy, including ZNS: 2 had significant malformations, 1 with anencephaly, and 1 with an atrial septal defect. Both of these mothers had low ZNS serum concentrations (6.1  $\mu\text{g/mL}$  and 6.3  $\mu\text{g/mL}$ , respectively) during the first trimester.

### CLINICAL USE

A recent survey of recommendations for AED management by selected pediatric epilepsy specialists in the United States shows that ZNS is favorably regarded as a first-line option for initial monotherapy in children with myoclonic and generalized tonic-clonic seizures and as a second-line option for initial treatment of patients with IS, LGS, symptomatic generalized tonic-clonic seizures, and for children with partial seizures who have failed prior AED treatment (106).

Formulations for ZNS currently available in the United States include 25-mg, 50-mg, and 100-mg capsules. Liquid suspensions can be specially formulated, but there are no data regarding stability and shelf-life.

Initial dosing is usually at 1–2 mg/kg/day, and the conventional recommendation is to increase the dose by 1–2 mg/kg/day every 2 weeks. ZNS is correctly regarded as an AED for which it is suggested to “start low and go slow.” Clinical experience has shown that tolerance is

improved and the likelihood of dose-related side effects is lower with incremental dosing. The maximum dose is determined by patient tolerance and seizure control; however, a total daily dose of 10 mg/kg/day is a reasonable initial target, and doses up to 20 mg/kg/day are commonly used. In light of the long serum half-life, ZNS can be administered once or twice daily.

Anticipatory guidance should include a recommendation about the need for the child to stay well hydrated, in an effort to reduce the likelihood of renal calculi, and the need to be aware of the importance of environmental heat as a possible risk factor for oligohydrosis and hyperthermia.

### SUMMARY

ZNS is properly regarded as a broad-spectrum AED. Although not often chosen as the drug of first choice for the newly diagnosed patient, ZNS is an important option for treating children with epilepsy who have failed initial therapy. It may be a particularly good choice for patients with myoclonic seizures as a component of their epilepsy. Although evidence from open-label trials and practice experience is compelling, controlled studies examining the efficacy of ZNS in children and its impact on cognition and behavior would be most welcome.

## The Ketogenic Diet

*Douglas R. Nordli, Jr.  
Darryl C. De Vivo*

**T**he ketogenic diet (KD) is a high-fat, low-carbohydrate regimen with adequate protein. It has been used for more than 70 years on thousands of patients. It is effective and safe, but, like any medical treatment for epilepsy, it must be judiciously applied and carefully monitored.

There are biblical passages that some regard as referring to the salutary effects of starvation on seizure control, but the earliest scientific reports emerged in the 1920s. Geyelin at the Presbyterian Hospital carefully studied the beneficial effects of starvation on seizures (1). Shortly thereafter, Wilder proposed a high-fat diet to mimic the effects of starvation (2). At the time, it was known that ketone bodies could be found in the urine of patients with diabetes and that they were produced when fatty acids were oxidized. This led to the notion that ketone bodies were metabolic waste products of fatty acid degradation. Because this high-fat diet increased the production of ketone bodies, the regimen became known as a ketogenic diet or “keto.” Its anticonvulsant effect was attributed to a sedative effect of the ketone bodies on the nervous system; this notion is easy to understand because the available anticonvulsants of that era—bromides and phenobarbital—were both sedatives.

In the 1950s, however, it was discovered that a separate pathway synthesized the ketone bodies, acetoacetate

(AcAc) and 3-hydroxybutyrate; in 1961 Krebs suggested that ketone bodies were fuels for respiration. In 1967 Owen and colleagues proved that ketone bodies were the major fuel for brain metabolism during starvation (3). Appleton and De Vivo later showed in experimental animals that the utilization of ketone bodies during starvation altered brain metabolites and increased cerebral energy reserves (4). Huttenlocher showed that the level of ketosis correlated with efficacy (5).

There are several different variations of the KD, but the mostly widely used regimen uses long-chain triglycerides (LCT) in the form of heavy cream, butter, and meat fat. We review the scientific basis, effectiveness, and safety of the LCT diet.

### SCIENTIFIC BASIS OF THE DIET

#### Improved Cerebral Energy Reserves and Increased Gamma-Aminobutyric Acid (GABA) Synthesis

Ketone bodies derive from the metabolism of nonesterified fatty acids. During the fasting state, the fall in blood glucose reduces plasma insulin production, stimulates lipolysis in fatty tissues, and increases the flux of nonesterified fatty acids to the liver. Nonesterified fatty acids can be esterified or metabolized to ketone bodies.

The fate of fatty acids in the liver is determined, at least in part, by the carbohydrate status of the host (6). A critical component of this regulation is malonyl-CoA, an intermediate in the pathway of lipogenesis. (7, 8). Malonyl-CoA inhibits carnitine acyltransferase I, which is needed to shuttle long-chain fatty acyl-CoA into the mitochondria for oxidation. The production of glucose from glycogen provides the carbon source for lipogenesis and, in particular, malonyl-CoA. If glucose is reduced, so is malonyl-CoA. The reduction in malonyl-CoA decreases the inhibition on (or increases the net activity of) carnitine acyltransferase. This allows more movement of fatty acids into the mitochondria, where fatty acyl-CoA is converted to acetyl-CoA, and later acetoacetate. Acetoacetate is in equilibrium with beta-hydroxybutyrate, the major ketone body utilized by the brain.

Passage of ketone bodies into the brain may be the critical factor limiting the rate of brain utilization of ketone bodies. Movement of ketone bodies into the brain relies on the monocarboxylic transport system (MCT-1). This is up-regulated during fasting in adults and during milk feeding in neonates (9, 10). Fasting studies in humans demonstrated that the brain's ability to extract ketone bodies is inversely related to the age of the subject (3). In contrast to glucose, ketone bodies can pass directly into mitochondria without being processed in the cytosol. Also, in contrast to glucose, ketone bodies may be used directly by neurons for metabolism (11).

Once inside the mitochondria, beta-hydroxybutyrate is converted to AcAc, and then to AcAc-CoA. The enzyme that facilitates this is 3-oxoacid-CoA transferase or succinyl-CoA-acetoacetate-CoA transferase. As the name implies, this conversion requires commensurate conversion of succinyl-CoA to succinate. It is possible that reduced blood glucose and increased blood ketone may be needed to induce the activity of this enzyme (12).

Scientific studies of the KD have revealed important biochemical and metabolic observations. Appleton and De Vivo (4) developed an animal model to permit study of the effect of the KD on cerebral metabolism (Figure 57-1). Adult male albino rats were placed on either a high-fat diet containing (by weight) 38% corn oil, 38% lard, 11% vitamin-free casein, 6.8% glucose, 4% U.S. P. salt mixture, and 2.2% vitamin diet fortification mixture, or on a high-carbohydrate diet containing (by weight) 50% glucose, 28.8% vitamin-free casein, 7.5% corn oil, 7.5% lard, 4% U.S. P. salt mixture, and 2.2% vitamin diet fortification mixture. Parallel studies were conducted to evaluate electroconvulsive shock responses and biochemical alterations. These studies revealed that the mean voltage necessary to produce a minimal convulsion remained constant for 12 days before the high-fat diet was started and for about 10 days after beginning the feedings ( $69.75 \pm 1.88$  volts). After the animal was on the high-fat diet for 10–12 days, the intensity of the convulsive response to the established

FIGURE 57-1

The effect in adult rats of dietary manipulation on the electroconvulsive threshold. Abstracted from the original, Appleton DB, De Vivo DC, *Epilepsia* 15:211–227, 1974 (4), with permission.

voltage decreased, necessitating an increase in voltage to reestablish a minimal convulsive response. Approximately 20 days after the animal began the high-fat diet, a new convulsive threshold was achieved ( $81.25 \pm 2.39$  volts) ( $P < 0.01$ ). When the high-fat diet was replaced by the high-carbohydrate diet, a rapid change in response to the voltage was observed. Within 48 hours the animal exhibited a maximal convulsion to the electrical stimulus, which had previously produced only a minimal convulsion, and the mean voltage to produce a minimal convulsion returned to the prestudy value ( $70.75 \pm 1.37$  volts).

Blood concentrations of beta-hydroxybutyrate, acetoacetate, chloride, esterified fatty acids, triglycerides, cholesterol, and total lipids increased in the rats fed on the high-fat diet. Brain levels of beta-hydroxybutyrate and sodium were also significantly increased in the fat-fed rats.

De Vivo et al reported the change in cerebral metabolites in chronically ketotic rats and found no changes in brain water content, electrolytes, or pH (13). As expected, fat-fed rats had significantly lower blood glucose concentrations and higher blood beta-hydroxybutyrate and acetoacetate concentrations. More importantly, brain concentrations of adenosine triphosphate (ATP), glycogen, glucose-6-phosphate, pyruvate, lactate, beta-hydroxybutyrate, citrate, alpha-ketoglutarate, and alanine were higher and the brain concentrations of fructose 1, 6-diphosphate, aspartate, adenosine diphosphate (ADP), creatine, cyclic nucleotides, acid-insoluble CoA, and total CoA were lower in the fat-fed group.

The biochemical implications of these results can be grouped into three major categories:

1. Glycolysis and glucose flux are reduced during ketosis. As Wilder originally postulated, the effects of eating a high-fat, low-carbohydrate diet are similar to the biochemical consequences of starvation (2). In this regard, the reduction in glycolysis makes physiologic sense, because the starving organism wants to make every attempt to preserve the rather meager stores of glycogen and to provide the brain with an alternate, more substantial fuel for metabolism (ketone bodies from fats). Measurements of glucose flux in children and adults during ketosis have confirmed the reduced utilization of glucose. Haymond et al. performed sequential glucose flux studies in 11 children (5 control, 6 with epilepsy) and 10 adult volunteers using tagged glucose (14). All subjects were studied after a fast while consuming either a normal diet or the KD. The authors found that glucose flux and ketonemia were inversely related, particularly when corrected for estimated brain mass. This was consistent with the replacement of glucose by ketone bodies for cerebral metabolism.
2. Tricarboxylic acid (TCA) cycle flux is increased by chronic ketosis. The enzyme alpha-ketoglutarate dehydrogenase is the rate-limiting enzyme in TCA cycle function. The major inhibitor of this enzyme is the concentration of the product of the reaction, succinyl-CoA. This product is relatively reduced in the fat-fed group (down 26%), implying that alpha-ketoglutarate dehydrogenase should be functioning at maximal capacity. Yet concentrations of alpha-ketoglutarate, the substrate for this enzyme, was found to be elevated 11% in the fat-fed group. The most plausible explanation is that the TCA cycle is driven to its maximal capacity and is overwhelming the ability of this rate-limiting enzyme to deal with substrate.
3. Cerebral energy reserves are increased by chronic ketosis.

Cerebral energy reserves were calculated from these measurements using the following equation (15):

$$\text{Energy reserve} = (\text{PCr} + \text{ADP}) + 2(\text{ATP} + \text{glucose}) + 2.9(\text{glycogen}) \quad (1).$$

Applying the values determined for phosphocreatine (PCr), ADP, ATP, glucose, and glycogen enabled the calculation of the reserves. Energy reserves were significantly higher in the fat-fed rats ( $26.4 \pm 0.6$ ) compared to those in the controls ( $23.6 \pm 0.2$ ) ( $P < 0.005$ ).

Ketone bodies are thermodynamically more efficient fuels than glucose because they avoid the less efficient glycolytic pathway (Figure 57-2) (16). Animals fed an

equivalent amount of calories in the form of high-fat diets are therefore expected to have more efficient energy production. Assuming that energy demands do not substantially change during fasting, the increased efficiency of ketone body utilization most likely contributes to higher energy reserves.

Pan et al used  $^{31}\text{P}$  spectroscopic imaging at 4.1T to demonstrate an elevated ratio of phosphocreatine or inorganic phosphorus in patients on the KD and concluded that there was improvement of energy metabolism with use of the diet (17). Seven patients with intractable

FIGURE 57-2

Summary of the relevant metabolic pathways affected by the ketogenic diet. The arrows  $\uparrow$  and  $\downarrow$  indicate significant differences of brain metabolites between ketotic animals and nonketotic animals. (A) phosphofructokinase; (B) pyruvate dehydrogenase; (C) alpha-ketoglutarate dehydrogenase; (D) 3-oxoacid-CoA transferase; TCA, tricarboxylic acid; SSA, succinic semialdehyde. The biochemical observations imply that cerebral energetics is improved by chronic ketosis. These findings also suggest that flux rates through the tricarboxylic acid cycle and the gamma-aminobutyrate (GABA) shunt may be maximized and that GABA effects may be augmented. Used with permission from Nordli and De Vivo, 1997 (16).

**FIGURE 57-3**

Chemical structural similarities of GABA, acetoacetate, gamma-hydroxybutyrate, and beta-hydroxybutyrate.

epilepsy (four with Lennox-Gastaut syndrome, one with absence seizures, one with primary generalized tonic-clonic seizures, and one with partial complex seizures) were studied before and after institution of the KD. Coronal <sup>1</sup>H anatomic imaging was performed to provide a correlate to the <sup>31</sup>P data. Ratios of PCr:ATP were measured at baseline and compared with those obtained after the KD. These showed a small but significant increase from  $0.61 \pm 0.08$  to  $0.69 \pm 0.08$  ( $P < 0.05$ ). The ratio of PCr to inorganic phosphorus also changed from  $2.45 \pm 0.27$  at baseline to  $2.99 \pm 0.44$  during the diet ( $P < 0.05$ ). The authors calculated an increase in the  $\Delta G$  of ATP hydrolysis from 12.5 kcal/mol to 12.85 kcal/mol, or 2.5%.

In summary, the available biochemical data suggest that the KD favorably influences cerebral energetics by increasing cerebral energy reserves. This may be an important mechanism behind the increased resistance to seizures in ketotic brain tissue and the favorable cognitive effect sometimes seen with the KD.

### Direct Anticonvulsant Effects of Ketone Bodies

There are direct anticonvulsant effects of the ketone bodies that perhaps relate to the chemical structural similarities of GABA, beta-hydroxybutyrate, and acetoacetate (Figure 57-3). Rats given intraperitoneal acetone showed reduction in seizures in the maximal electroshock, pentylenetetrazole, generalized-kindled seizures, focal-kindled seizures and AY-9944 models (18). Acetoacetate and acetone also suppressed seizures in Frings audiogenic, seizure-susceptible mice (19).

### Possible Neuroprotective Effects Mediated by Mitochondrial Uncoupling Protein

In a model thought to mimic human idiopathic epilepsy, EL mice were shown to have a delayed development of seizures, implying an antiepileptogenic effect of the KD (20). This and the results of other studies also suggested a possible neuroprotective effect of the KD, perhaps involving inhibition of caspase-3-mediated apoptosis (21, 22). Others have examined the effect of the KD on mitochondrial uncoupling protein in the hippocampi of juvenile mice. Mitochondrial respiration rates were found to be substantially higher, and Western blots showed significant increases in uncoupling protein levels, particularly in the dentate gyrus of KD-fed mice. This, combined with the results of reactive oxygen species studies, suggested that the KD might be neuroprotective by diminishing reactive oxygen species production through activation of mitochondrial uncoupling proteins (23).

### INITIATION OF THERAPY

Prior to the initiation of the KD, a nutrition support team or registered dietitian performs a comprehensive assessment. The nutritionist or dietitian asks whether there have been any gastrointestinal problems, food allergies, or feeding difficulties, such as problems with sucking, swallowing, or chewing. They also note the patient's weight, height, usual weight, weight pattern since birth, and head circumference. Next, weight-for-age and height-for-age are plotted and ideal body weight-for-height is determined. Laboratory data are used other tools for nutritional assessment of the patient, and we routinely obtain serum protein, lipid profile, electrolytes, free and total carnitine, hemoglobin, hematocrit, and red blood indices.

The nutritionist or dietitian reviews the method of delivery of the KD, taking into consideration factors such as the patient's age, stage of development, and expected tolerance of the regimen. In the usual case, the KD is offered in a normal, by-mouth fashion, with the expectation being that the patient will eat and drink as is appropriate for his or her developmental stage. The consistency

of the KD can be altered to adjust for feeding difficulties. In very rare circumstances, the nutritional support team may recommend the use of a feeding tube. If patients are to be fasted, they should be hospitalized for the initiation of the KD. Close observation is important because a child with an occult underlying inborn error of metabolism, particularly one that interferes with utilization of ketone bodies, could quickly decompensate (24). The hospitalization also provides the opportunity for family members to be instructed on the maintenance of the diet.

Although this is the traditional method of starting the KD for many, others argue that a fast is not necessary and that equivalent or superior results can be obtained without fasting (25). In one study, Bergqvist and colleagues randomized children who were starting the KD into two groups: one group began with a 24- to 48-hour fast, and the other had a gradual initiation of the KD without a fast (26). They found no difference in efficacy between the two groups, but those who had a gradual initiation of the KD without fasting had less weight reduction, fewer episodes of hypoglycemia, less treatments for acidosis, and a reduced need for intravenous (IV) fluid treatment for dehydration.

The LCT diet consists of three or four parts fat to one part nonfat (carbohydrate and protein) calculated on the basis of weight. It is computed to provide 75 to 100 kcal/kg per body weight and 1–2 g dietary protein/kg of body weight per day. Caloric requirements are adjusted to minimize weight gain and to maximize ketonemia. If a 3:1 (fat-to-nonfat) ratio is insufficient to produce the required ketosis, a ratio of 4:1 is used.

### THE CONVENTIONAL KD OR LCT DIET

Prior to initiating the conventional KD or LCT diet, a dietary prescription is made. Calculation of this prescription is straightforward. For example, if a 10-kg 2-year-old child is to be started on a 3:1 diet, one begins by estimating the calorie requirements of the child:

$$10 \text{ kg} \times 100 \text{ kcal/kg/day} = 1000 \text{ kcal/day} \quad (2)$$

Alternatively, consulting a table of recommended daily allowances (RDA) may derive this figure. In either case, it may require adjustment based on the child's individual metabolic needs. In general, starting prescriptions should begin with 75–80% of RDA needs, but these figures may need to be modified depending on the child's level of activity.

The 3:1 ratio of the diet stipulates that 4 grams of food must contain 3 grams of fat and 1 gram of nonfat. The nonfat consists of both carbohydrate and protein. One gram of fat has the caloric equivalent of nine calories, whereas 1 gram of protein or carbohydrate has the calorie equivalent of approximately four calories. Four

grams of food (arbitrarily referred to as one unit here) on a 3:1 diet is equal to 31 calories:

$$1 \text{g fat} = 9 \text{ calories} \times 3 = 27 \text{ calories}$$

$$1 \text{g protein and carbohydrate} = 4 \text{ calories} \times 1 = 4 \text{ calories}$$

$$\text{Total calories} = 27 + 4 = 31 \text{ calories per unit} \quad (3)$$

To calculate the daily fat intake, one first divides the daily requirements of calories by this number of 31 calories per unit, which generates the number of units required for the day:

$$1000 \text{ calories/day} / 31 \text{ calories/unit} = 32.25 \text{ units/day} \quad (4)$$

Next, multiplying by 27 calories of fat per unit provides the daily fat requirement:

$$32.26 \text{ units/day} \times 27 \text{ calories of fat per unit} = 871 \text{ calories of fat per day} \quad (5)$$

which is equivalent to 96 grams.

The protein requirement depends on the age of the child: children ages 1–3 years require 1.2 g protein/kg/day, children ages 4–6 years require 1.1 g protein/kg/day, and children ages 7 and up require 1 g protein/kg/day. For this child, the requirement would be  $10 \text{ kg} \times 1.2 \text{ g/kg}$  or 12 g/day (48 calories). Alternatively, one may consult the RDA table to determine the protein requirement.

So far, the combination of 871 calories of fat and 48 calories of protein leaves only 81 calories (i.e.,  $1,000 - 919$ ) that are not accounted for in the daily allowance. The carbohydrate intake is calculated to supply the necessary remaining calories (81 calories), which is approximately 20 g.

The diet prescription for this 10-kg patient on a 3:1 LCT diet is the following:

Fat: 96 grams per day or 32 grams per meal

Protein: 12 grams per day or 4 grams per meal

Carbohydrate: 20 grams per day or 7 grams per meal

### Meal Preparation

Meal preparation is key to the success of the diet for patients who are fed by mouth. The meals can be generated using calculations either by a trained dietitian or utilizing a computerized program. The advantage of involving a dietitian for the KD is that meals are calculated under strict guidelines to ensure that they meet the prescription of the diet and also the child's complete dietary needs. The dietitian may also provide valuable insights into the timing of meals and snacks to help maximize consistent control of ketosis and seizures. If parents utilize a home computer program, a dietitian should oversee these reci-

pes to ensure that the nutritional elements are complete and within the doctor's prescription.

When the diet is begun, the number of meal options should be limited to help eliminate errors. Over time, meal options can be increased to provide variety. Variety is important because it increases satisfaction and thereby helps encourage continuation on the diet. Some institutions use a fruit and vegetable exchange system, which allows these foods to be organized by categories and substituted without the need for arduous recalculations. While on the KD, children need daily supplements of calcium and a multivitamin. Care must be taken so that these supplements (and all medications) are appropriately low in carbohydrates. The diet ratio, total calories, or both may need to be altered with the help of the physician to maximize seizure control. Dietary protein may also need adjustment to ensure proper growth. (27)

### Liquid KD

For infants who are bottle-fed or older children who are tube-fed, the KD can be adapted to a liquid form. The ingredients are available through a pharmacy, and the preparation is simple for parents to learn. There are two regimens that can be prescribed for the liquid KD: KetoCal<sup>®</sup> and the modular formula with a product manufactured by Ross Laboratories, Columbus, Ohio: Ross Carbohydrate Free (RCF<sup>®</sup>). KetoCal<sup>®</sup>, manufactured by Nutricia North America (Rockville, Maryland), is a nutritionally complete formula powder that provides a 4:1 ketogenic ratio. It contains 30 g of protein/L, 144 g of fat/L, and 6 g of carbohydrate/L. This diet regimen has a makeup of 90% fats (all of which are LCT), 1.6% carbohydrates, and 8.4% protein. In addition, each liter provides 1,600 mg of calcium, 600 mg of sodium, 2,160 mg of potassium, and 22 mg of iron. This supplies 100% of the recommended vitamins and minerals, even at 75% of the RDA. No additional vitamin or mineral supplementation is necessary.

As an alternative, Ross Carbohydrate Free (RCF<sup>®</sup>) is a soy-based formula with iron that provides essential proteins and nutrients for the diet. It contains 40 g of protein/L, 72 g of fat/L, and 0.08 g of carbohydrate/L. In addition, each liter supplies 1,400 mg of calcium, 591 mg of sodium, 1,460 mg of potassium, and 24.3 mg of iron. RCF is used in conjunction with Ross Polycose<sup>®</sup> Glucose Polymers for carbohydrate and Microlipid<sup>®</sup> from Sherwood Services AG (St. Louis, MO) to provide the fat portion of the liquid KD. This is an emulsion of 50% fat that contains safflower oil and provides 1 gram of fat per 2 mL. The formula made from the mixture of RCF<sup>®</sup>, Polycose<sup>®</sup>, and Microlipid<sup>®</sup> can be given at scheduled bolus feedings or as a continuous enteral tube feeding. This formula method is utilized less often than the KetoCal<sup>®</sup> formula solely because of the ease

of use of the latter. The RCF<sup>®</sup> regimen is lactose- and gluten-free and therefore is useful in patients with known sensitivities to these substances. When using KetoCal<sup>®</sup> or RCF<sup>®</sup> in combination with food, the formulas should contribute approximately 50% of the patient's total energy needs; the remaining half should come from food sources. The need for supplementation should be considered when a combination of food and liquid forms of the diet is prescribed.

### Maintenance of Therapy

After discharge from the hospital, the child and family are closely monitored. Typically, a dietitian contacts the family, often by telephone, within one week from discharge to assess the patient's tolerance of the diet and the caregiver's comfort level. The call is also used to assess for unforeseen needs related to the KD or new questions that may have arisen in the interim. The first scheduled outpatient visit is typically one month from the initiation of the diet, with return visits every three months thereafter. At each visit, note is made of tolerance, apparent palatability, bowel habits, seizure control, and urinary ketone measures. The patient's height, weight, and head circumference are measured and plotted at each visit.

### Modified Atkins Diet for Seizures

The Atkins diet can be modified for use in patients with intractable epilepsy. It is similar to the KD in that there is a higher proportion of fat and a lower proportion of carbohydrates compared with that in regular diets. Prior to starting on the Atkins Diet, the patient and caregivers read the book, *New Diet Revolution*, by Robert Atkins, MD. The dietitian evaluates a 3- to 7-day log of the patient's habitual diet, paying attention to the amount of carbohydrates. The amount of carbohydrates is halved for 1 week following this assessment. Seizure control is evaluated, and, if appropriate, carbohydrates are again cut by a quarter to a half to improve seizure control. Once the diet is initiated, ketones are checked periodically using a urine dipstick.

The scope of use for the Atkins diet is not well known. In a study of 20 patients with intractable epilepsy, the Atkins diet was effective and well tolerated. On the Atkins diet, all 20 children had at least moderate ketones within 4 days. In the 16 patients who completed the 6-month study, 13 (65%) had a seizure reduction of greater than 59% and 7 (35%) had a seizure reduction of greater than 90%; 4 patients (25%) were seizure-free (28).

## RESULTS

Livingston reported extensive (41-year) experience with the diet in the treatment of myoclonic seizures of child-

hood (29). He stated that it completely controlled seizures in 54% of his patients and markedly improved control in another 26%. Therefore, only 20% of patients did not respond. In Livingston's experience, the diet was ineffective in controlling either true "petit mal" or temporal lobe epilepsy, although others have found the diet helpful in a wide variety of seizure types (30).

Other investigators using both the "classic" diet and its variants have reported results similar to Livingston's. In 63 studies of 55 patients conducted by Schwartz et al., a total of 51 studies (81%) showed a reduction greater than 50% in seizure frequency regardless of the type of diet used (31). Others, however, have found that the MCT diet is slightly less efficacious, with 44% of patients achieving a reduction greater than 50% in the number of seizures (32). A corn oil KD was found to be equally beneficial compared with the MCT diet (33). Seizure control appears to be inconsistently accompanied by electroencephalographic improvement (34).

In a prospective study of the diet, 150 children with intractable seizures were treated. Seizure frequency, adverse effects, and reasons for diet discontinuation were noted. Three months after initiation, 83% of children remained on the diet and 34% had a reduction greater than 90% in seizures. After 1 year, 55% remained on the diet and 27% had a reduction greater than 90% in seizures (35).

Clinical experience suggests that, in addition to improved seizure control, the diet may have a calming effect on behavior and may stabilize mood. Although one study with rodents failed to duplicate this effect, another showed reduction in the Porsolt test scores, interpreted as a reduction in "behavioral despair" (36, 37).

## INDICATIONS FOR USE

### Primary Therapy

The KD is first-line therapy for the treatment of seizures in association with glucose transporter protein deficiency and pyruvate dehydrogenase deficiency. (38–40) (Figure 57-4). In both cases, the diet effectively treats seizures while providing essential fuel for brain metabolic activity. In this manner, the diet is not only an anticonvulsant treatment, but also treats the other nonepileptic manifestations of these diseases.

### Secondary Treatment

The KD may be considered as an alternate treatment, usually after the failure of valproate (VPA), for generalized epilepsies, particularly those with myoclonic seizures, including severe myoclonic epilepsy of infancy and myoclonic absence epilepsy (41, 42). Given the effectiveness

FIGURE 57-4

The EEG of a 5-year-old with glucose transporter protein deficiency. There are bursts of generalized spike-wave activity with a regular repetition rate. These bursts correlated with clinical absence attacks. After several days of the ketogenic diet there was a marked diminution in the frequency of the seizures and epileptiform activity.

of the diet in the treatment of myoclonic epilepsies, it could be considered as first-line treatment for patients with these conditions, but no comparative studies exist. The KD can be beneficial in infants with West syndrome who are refractory to corticosteroids and other medications (43–45). Based on Keith's data and our own experience, the KD may also be useful in the treatment of children with refractory absence epilepsy without myoclonus (46). Additionally, in one study in which a modified Atkins diet was used to treat children with intractable epilepsy, four out of five children with absence had a reduction greater than 50% and three went at least one month without seizures (28).

### Further Possible Indications

**Partial Seizures.** It is very difficult to determine the efficacy of the diet in the treatment of partial seizure disorders. Livingston stated that the diet was not effective in treating patients with partial seizures. Keith did not classify his patients in a manner that allows one to determine the effectiveness in partial seizures. In current use, the diet is usually prescribed for children with other forms of refractory epilepsy. In kindled animals, a model of focal epilepsy, the diet was shown to have at least transient anticonvulsant properties (47). This bolsters the consideration of its use in children with refractory partial epilepsy. Nevertheless, although the diet may be considered in this group, there is no compelling clinical data to favor its use. Therefore, children with refractory partial seizures should be evaluated to deter-

mine if they are candidates for focal resective surgery. If they are, surgery need not be delayed to institute a trial of the KD. On the other hand, if drugs have failed and the patient is deemed to be a poor surgical candidate, the diet should be considered. It would seem inappropriate to treat children with otherwise benign seizure disorders, such as febrile seizures, benign rolandic epilepsy, benign occipital epilepsy, and benign familial neonatal convulsions with the KD.

*Other Possible Indications.* Preliminary experience showing some beneficial effects of the KD have been reported in the following disorders: Lafora body disease (48), partial seizures in children with tuberous sclerosis (49, 50), Rett syndrome (51), glycogenosis type V (52), and subacute sclerosing panencephalitis (53).

### ADVERSE EFFECTS OF THE KD

The diet has several adverse effects that are important to note. In general the KD can cause nausea and vomiting, fatigue, loss of appetite, and hypoglycemia. These tend to be short-term effects that are seen most frequently during the initiation of the diet and usually resolve within the first few weeks of treatment.

A variety of long-term side effects can occur, some of which can be identified by screening, but others only by clinical symptoms. Renal calculi may develop and may be exacerbated by concurrent treatment with carbonic anhydrase inhibitors. Although these medications may be cautiously continued in patients, their use will effectively double the incidence of kidney stone formation, when examined as a function of patient-years exposure (54). Discontinuation or reductions of these medications should be considered, particularly if the patient has a family history of urolithiasis, hematuria, or elevated urine calcium-to-creatinine ratio. Bicarbonate levels have been monitored in patients on the KD concurrently treated with topiramate (55). These were found to decrease markedly at the time of diet initiation. The authors recommended monitoring of bicarbonate levels in these children and supplementation for symptomatic patients. Metabolic acidosis may occur in general in patients on the KD, but the lower limit of safe levels of acidosis is not clearly established. We check for acidosis if there are clinical symptoms (lethargy or fatigue), and, if they are confirmed, we recalculate the dietary prescription. If the patient is on concurrent carbonic anhydrase inhibitors, these are further reduced. It may also be necessary to increase total calories or reduce the ratio of the diet. Elevated blood lipids can occur, and one study found increases at 6 months of treatment with the KD in low-density lipoprotein (LDL),

very low-density lipoproteins (VLDL), non-high-density lipoprotein cholesterol, triglycerides, and total apolipoprotein B. At the same time, mean HDL cholesterol decreased while apoA-I increased. These changes were still significant, but were less pronounced, at 12 months and 2 years (56). The clinical significance of this for atherosclerosis is not yet known.

Osteopenia and slowed growth rates are other possible consequences of the diet (57). Patients on the KD exhibit a significantly reduced quantity of bone mass, which improves in response to vitamin D supplementation. Growth rate is carefully tracked, and calories and protein are altered to ensure proper growth (58). Vitamin deficiency should be evaluated, and supplementation should be consistent throughout treatment on the diet. A low-carbohydrate multivitamin and a calcium supplement are recommended for patients on the diet. Selenium deficiency was reported in nine children on the KD, and cardiomyopathy was attributed to this deficiency in one patient (59). Lipemia retinalis developed in two of Livingston's patients (60). Bilateral optic neuropathy has been reported in two children who were treated with a 4:2 classic KD. These patients were not originally given vitamin B supplements. Vision was restored in both after administration of supplements. Thinning of hair and alopecia may occur.

Constipation occurs in some patients because of the decrease in carbohydrates and bulk. To treat constipation, increase fluids, utilize Group A vegetables. These have fewer carbohydrates and therefore allow for a larger portion size. If constipation continues, suppositories or daily oral stool softeners may be useful.

Severe adverse effects of the KD are pancreatitis, death, and coma. A lethal case of pancreatitis was reported in a patient with gemfibrozil-controlled hypertriglyceridemia that developed after initiation of the diet (61). Kang et al. reported deaths in 3.1% of their patients, caused by sepsis, cardiomyopathy, and lipoid pneumonia (62).

### Precautions

The KD may be lethal in circumstances in which cerebral energy metabolism is deranged. An example of this is pyruvate carboxylase deficiency, a condition in which patients may present early in life with refractory myoclonic seizures (24). Mitochondrial disorders or diseases that involve the respiratory chain, such as myoclonic epilepsy with ragged red fibers (MERRF); syndrome of mitochondrial encephalomyopathy, lactic acidosis, and stroke-like episodes (MELAS); and cytochrome oxidase deficiency, would also probably be contraindications for use of the KD, because of the increased stress on respiratory chain and TCA cycle function. Patients who have problems with fatty acid oxidation would also be

adversely affected by the KD, but such patients do not, as a rule, present with seizures.

### Stopping the KD

The KD should be stopped gradually. A sudden stop of the diet or sudden administration of glucose may aggravate seizures and precipitate status epilepticus. Livingston advocates maintaining the diet at a ratio of 4:1 for 2 years and, if successful, weaning down to a 3:1 diet for 6 months, followed by 6 months of a 2:1 diet. At this point, a regular diet is given. We have not utilized such a rigorous protocol.

### Potential Adverse Drug Interactions

Carbonic anhydrase inhibitors such as acetazolamide, zonisamide, and topiramate should be avoided, particularly in the early stages of treatment with the KD. VPA is an inhibitor of fatty acid oxidation and mitigates hepatic ketone body production. When possible, therefore, we avoid use of this agent, but one retrospective study found no difference in relatively small numbers of patients (total of 71) who were taking (24) or not taking (47) VPA (63). Adrenocorticotrophic hormone (ACTH) is not used while patients are on the KD.

Carnitine supplementation is complex. It is often used to supplement the diet of patients with various metabolic derangements whose defects allow a buildup of undesirable intermediates (64). One study summarized the findings of serial measurements of serum carnitine in patients on the KD. Multiple anticonvulsant medications were found to lower the total serum carnitine level, but actual deficiency was uncommon. Most patients had a gradual improvement in levels with long-term treatment and did not appear to require supplementation with carnitine (65). These factors must be weighed in each patient, and the decision to use the supplementation should be individualized. A measure of the serum carnitine concentration may be helpful in making this decision.

### ILLNESS PROTOCOL

While on the KD, children may have periodic normal childhood illness or periodic interruptions of the feedings for other reasons, such dental procedures. All medications should be evaluated for carbohydrate content, and elixirs should be avoided because they usually contain high levels of sugars.

Children may require an increased amount of liquid during an illness because of increased insensible losses and fluid intake should be adjusted accordingly. Table 57-1 outlines common problems and associated suggestions:

### DURATION OF TREATMENT AND STOPPING THE KD

The KD occasionally shows results immediately, but for many patients it may take several months to achieve optimal effect. While on the diet, patients need adjustments to account for increase caloric needs or ratio. We usually encourage parents to give the KD a trial for at least 3–6 months. If the diet is not sufficiently effective, we wean the diet by decrements of 0.5 over several months. The diet is abruptly stopped only in urgent circumstances.

**TABLE 57-1**  
*Common Ketogenic Diet Issues*

PROBLEM	SUGGESTIONS
Vomiting	Stop ketogenic meals; offer fluids to avoid dehydration, including fluids without glucose; refer to pediatrician for evaluation if vomiting is protracted. If vomiting continues for more than 24 hours and no serious medical illness is found, offer unflavored Pedialyte until patient can tolerate ketogenic foods, starting with lower fat ratio, and increase as child recovers.
Diarrhea	Increase binding foods if possible (bananas, rice, applesauce, toast). Dietitian may be able to add these temporarily. If needed, use a lower ratio until child recovers.
Fever or pain	Acetaminophen suppositories have no carbohydrate; all medications should be checked for carbohydrate content.
Hospitalization	If intravenous fluids are necessary, make sure to use glucose-free solutions. If clinical signs of hypoglycemia are present and stat measurement confirms this, give single bolus of glucose (1 g/kg of body weight). 75 mL of D5 = 3.75 grams of carbohydrate = 20 mL of orange juice.
General anesthesia	Give carbohydrate-free intravenous solutions, monitor serum pH and bicarbonate levels (66).

If there is a complete response and patients are seizure free on the diet, the diet is often continued for 2 years and then weaned over several months, again usually by decrements of 0.5 ratio.

## CONCLUSIONS

It is remarkable that 70 years and scores of drugs later, the KD still retains a role in the modern treatment of children with refractory epilepsy. However, even with our new pharmacologic armamentarium, there remain patients whose epilepsy is resistant to the effects of antiepileptic medications. Indeed, once several antiepileptic drugs (AEDs) with multiple mechanisms of action have failed, it is unlikely that another will demonstrate good efficacy. In a sense, these patients may be declaring that they are not candidates for drugs and that they require alternate forms of treatment, such as the KD or surgery. Yet, it is still difficult to determine who these patients are at the onset, and the only reliable way to determine the refractory nature of

their epilepsy is by trying treatment with various AEDs. Improvements in the classification of epilepsy, animal models, clinical studies, and deeper insights into the basic pathogenesis of refractory epilepsy will most likely provide useful information in this regard. In the meantime, physicians caring for children with epilepsy must still carefully weigh the known risks and benefits of all forms of treatment and use their best clinical judgment in order to arrive at the optimal regimen for their patients.

## ACKNOWLEDGMENTS

The authors would like to thank Sarah Mass Ahlm and Robyn Blackford for a thorough review of the chapter, many useful suggestions, and help with background research. Robyn Blackford is a registered dietitian who works with the KD and had many helpful and practical comments regarding the daily use of the diet. Sarah Ahlm is a registered social worker who has been very involved in the clinical management and counseling of patients on the diet.

## Inflammation, Epilepsy, and Anti-Inflammatory Therapies

*Stéphane Auvin  
Raman Sankar*

**A**n understanding of the etiologic role played by the immune system in the genesis or modification of the human epilepsies is complicated by the paucity of high-quality data based on clinical research. It is reasonable to propose a major role for inflammation in the intractable epilepsy associated with Rasmussen encephalitis, and yet present treatment remains surgical. On the other hand, immunomodulatory therapy involving adrenocorticotrophic hormone (ACTH) or corticosteroids is more convincingly established for the treatment of infantile spasms, a syndrome that is not generally attributed to an inflammatory etiology. The clinical literature abounds with scattered and anecdotal reports on the efficacy of ACTH, corticosteroids, or intravenous immunoglobulin (IVIG) in a variety of difficult-to-treat epilepsy syndromes, but almost always as a treatment of last resort; no randomized, placebo-controlled, and blinded studies are available. The foregoing statements are obvious to most clinicians but are recounted here to describe the challenge facing the writers on this important and rapidly evolving topic. It is clear that the topic requires a review of what has been established by basic scientific inquiry before a description of the clinical data and speculation on future developments.

### BASIC SCIENCE

#### Inflammation and Epilepsy

There is a reciprocal relationship between seizures and inflammatory cytokines (1). In many experimental systems, proinflammatory stimuli exhibit proconvulsant properties. On the other hand, seizure or status epilepticus (SE) that is induced by chemical or electrical stimulation has been demonstrated to enhance the expression of proinflammatory cytokines such as interleukin-1beta (IL-1beta), interleukin-6 (IL-6), and tumor necrosis factor-alpha (TNF-alpha) (1).

The proconvulsant effects of inflammation have been studied in animals using the bacterial endotoxin lipopolysaccharide (LPS), which induces a broad inflammatory response, or by employing specific cytokines. The latter have also been used to study effects on excitability in in-vitro preparations. LPS is a component of the outer membrane of gram-negative bacteria and is recognized by cells of the immune system. The effects of LPS in the central nervous system (CNS) are conceivably related to stimulating production of several microglial cytokines (2, 3), although a direct effect through Toll-like receptor (TLR) is also possible (4). IL-1beta has been the most studied cytokine. IL-1beta is a proinflammatory cytokine involved in immune defense against infection.

**Inflammatory Enhancement of Seizure Susceptibility.** Seizure susceptibility to pentylenetetrazol (PTZ) is enhanced in mice by preadministration of LPS, and this phenomenon is blocked by anti-inflammatory drugs (5, 6). Using LPS from *Shigella*, Yuhás et al first showed that LPS enhanced the sensitivity of mice to PTZ-induced seizures via mechanisms involving TNF- $\alpha$ , IL-1 $\beta$ , and nitric oxide (5). LPS produced a decrease in seizure threshold in a dose- and time-dependent manner. The role of nitric oxide (NO), prostaglandins (PGs), and the endogenous opioid systems in mediating the effect of LPS was suggested by the ability of specific antagonists of those systems to mitigate the effect of LPS (6). Heida et al. (7) showed that the combination of LPS and subconvulsant doses of kainic acid (KA) resulted in convulsions in approximately 50% of animals, with very low mortality in P14 rat pups. In the genetically epileptic Wistar Albino Glaxo/Rijswijk rat strain (WAG/Rij, a rat model for absence epilepsy), the high voltage spike-wave discharges increased in number and duration proportionate to dose of LPS (10–350  $\mu$ g/kg) administered (8). In the same model, repetitive administration of LPS daily for 5 days initially increased the number of spike-wave discharges, but a tolerance was observed on the fifth day. The LPS-induced increase in spike-wave discharges was not directly correlated with the elevation of the core body temperature (8).

**Cytokines and Seizure Activity.** Vezzani et al. (9) demonstrated the reciprocal relationship between IL-1 $\beta$  and seizure activity. Induction of seizures by KA or bicuculline injection resulted in expression of IL-1 $\beta$  and microglial activation. Injection of human recombinant IL-1 $\beta$  into the hippocampus 10 minutes preceding the application of KA prolonged the seizures induced by KA, whereas coinjection of an IL-1 $\beta$  receptor antagonist (IL-1RA) or an N-methyl-D-aspartate (NMDA) antagonist prevented this effect. The IL-1RA demonstrated powerful anticonvulsant effect (10). IL-1 $\beta$  also lowered the threshold for hyperthermic seizures and even produced seizures by itself (11). IL-1 $\beta$  receptor-deficient mice were resistant to experimental hyperthermic seizure model. This resistance appeared to be independent of genetic background and was attributed to lack of IL-1 $\beta$  signaling, because exogenous cytokine reduced seizure threshold in wild-type, but not receptor-deficient, mice independent of strain. In addition, high IL-1 $\beta$  doses induced seizures only in IL-1 $\beta$  receptor-expressing mice (11).

Transgenic mice with glial fibrillary acidic protein (GFAP) promoter-driven astrocyte production of the cytokines IL-6 and TNF- $\alpha$  were studied in terms of their susceptibility to experimentally induced seizures (12). GFAP-IL6, but not GFAP-TNF, mice showed markedly enhanced sensitivity to glutamatergic- but not cholinergic-induced seizures. Consistently,

intrahippocampal injection of TNF- $\alpha$  in mice inhibits seizure (13).

A recent study of surgically resected tissue involving focal cortical dysplasia found a significant number of cells of macrophage and microglia line that were immunocytochemically recognizable as CD68- and human leukocyte antigen (HLA)-DR-positive (14). Another study of brain tissue removed surgically for the treatment of intractable epilepsy found immunocytochemical evidence for IL-1 $\beta$  signaling in a substantial population of neurons and glia surrounding focal cortical dysplasia or glioneuronal tumors (15). Such was not the case in histologically normal perilesional tissue or normal control cortex, suggesting that this signaling probably does not represent seizure-induced activation of cytokines and may, in fact, have a causative role in the epileptogenicity of the dysplastic lesion.

### Potential Mechanisms Underlying Altered Excitability

Several studies have observed a relationship between cytokines and neurotransmitter systems that modulate neuronal excitability. Evidence has been found to support the interaction of cytokines, especially IL-1 $\beta$ , with glutamatergic and gamma-aminobutyric acid (GABA)ergic systems, both directly (at the level of receptors and ion channels) and indirectly (via neuromodulatory systems). Direct mechanisms include effects on glutamate and GABA receptor trafficking that amplify excitatory response and limit inhibitory response.

Direct interaction with the glutamatergic systems can take place by at least two routes: (1) enhancement of extracellular glutamate concentrations and (2) increased function of the NMDA and/or -amino-5-methyl-3-hydroxy-4-isoxazolepropionic acid (AMPA) receptors. IL-1 $\beta$  has been shown to inhibit glutamate reuptake in cultures of rat and human astrocytes (16, 17). IL-1 $\beta$  activates inducible NO synthase, leading to production of NO and subsequent increase in glutamate release (18, 19). In addition, cytokines can enhance substance P release (20), and substance P, in turn, can augment cytokine expression (21). Substance P can also enhance glutamate release and contribute to maintenance of seizure activity in hippocampal networks (22).

The proconvulsant activity of IL-1 $\beta$  via NMDA receptors was first suggested in animal models when IL-1 $\beta$  activity was found to be blocked by a selective competitive antagonist of NMDA receptors (9). The interaction between IL-1 $\beta$  and NMDA receptors was described in further detail in a latter report (23). IL-1 $\beta$  increased NMDA receptor function through activation of tyrosine kinases and subsequent NR2A/B subunit phosphorylation, resulting in an increase of NMDA-induced calcium influx. Furukawa and Mattson (24)

used whole-cell perforated patch-clamp recording of cultured hippocampal neurons to show that treatment with TNF- $\alpha$  caused an increase in calcium current by approximately 30%. Beattie et al. (25) showed that glial interaction of TNF- $\alpha$  causes an increase in surface expression of neuronal AMPA receptors responsible for an increase of synaptic efficacy. The newly expressed AMPA receptors were shown to have lower stoichiometric amounts of GluR2, making the receptors permeable to calcium ions. More recently, TNF- $\alpha$  was considered to regulate neuronal homeostasis. In fact, TNF- $\alpha$  increases excitatory pathway by stoichiometric modification of synaptic AMPA receptor even as it causes GABA<sub>A</sub> receptor endocytosis (26).

Effect of IL-1 $\beta$  and TNF- $\alpha$  in mediating AMPA-induced excitotoxicity has been demonstrated in an organotypic hippocampal slice culture (27). Either potentiation of excitotoxicity or neuroprotection was observed, depending on the concentration of the cytokines and the timing of exposure. Preincubation with low concentrations of IL-1 $\beta$  (1 ng/mL) followed by coexposure with AMPA enhanced the effect of AMPA, whereas a higher concentration (10 ng/mL) afforded neuroprotection. Although IL-1 $\beta$  per se did not produce these effects, the effects caused by IL-1 $\beta$  in combination with AMPA could be blocked by IL-1 $\beta$  antagonism. By using TNF- $\alpha$  receptor knockout mice, it was shown that the potentiation of AMPA-induced toxicity by TNF- $\alpha$  involves TNF receptor-1, whereas the neuroprotective effect is mediated by TNF receptor-2.

*Effects on the GABAergic System.* In an in vitro study, IL-1 $\beta$  produced a decrease in synaptic inhibition by about 30% in CA3 pyramidal cells and dentate granule cells (28). Such an effect was confirmed by Wang et al in a subsequent study (29). Such diminution of GABA-mediated currents by TNF- $\alpha$  may be explained by its enhancement of GABA receptor endocytosis (25, 26).

### **Inflammation, Neuronal Injury, and Epileptogenesis**

The reciprocal relationship between seizures and inflammation was alluded to earlier. Although inflammation may exacerbate seizure activity and possibly excitotoxicity, it can also be induced by many experimental seizure models. A question of considerable translational importance is whether the inflammatory process set in motion by an initial bout of SE (or other epileptogenic insults, such as traumatic brain injury) contributes to the process of epileptogenesis. If this question can be answered affirmatively, novel targets for antiepileptogenic therapy may be identified.

Experimentally induced seizures in rodents trigger a prominent inflammatory response in brain areas recruited

in the onset and propagation of epileptic activity involving microglia, astrocytes, and, in some instances, neurons (1). Seizures induced either chemically (systemic and focal kainate injection, lithium-pilocarpine) or electrically increase cytokines in rodent brain. Proinflammatory cytokines are induced in brain also by audiogenic and kindled seizures (30, 31) and remain up-regulated in the brain for several days. In the lithium-pilocarpine model, the expression of IL-1 $\beta$ , NF- $\kappa$ B, and COX-2 started by 12 hours postinjection, persisted for 24 hours (SE period), and returned to basal levels by 3 and 6 days (during the latent period) (32). The regional distribution of the inflammatory markers occurred mainly in structures prone to develop neuronal damage. The authors suggested that seizure-related IL-1 $\beta$ , NF- $\kappa$ B, and COX-2 expression may contribute to the pathophysiology of epilepsy by inducing neuronal death and astrocytic activation (32). Neuronal COX-2 gene induction has been proposed as a key signaling event during epileptogenesis in the kindling model (33).

The effect of cytokines in modulating glutamatergic excitotoxicity via NMDA (23) and AMPA (27) mechanisms has been alluded to earlier. Work in the author's laboratory has shown that an inflammatory stimulus by systemic LPS preceding SE induced by lithium-pilocarpine resulted in enhancement of neuronal injury without being accompanied by an elevation in temperature or prolongation of the status (34). We have also found an increase in the incidence of spontaneous recurrent seizures in rat pups that received LPS prior to lithium-pilocarpine SE and have also observed that administration of LPS accelerated kindling acquisition and intensified kindled seizures in a rapid kindling protocol (unpublished results). On the other hand, Sayyah et al have reported that both LPS (35) and IL-1 $\beta$  (36) displayed anticonvulsant and antiepileptogenic properties when administered intracerebroventricularly (ICV). The same authors have also documented the ability of systemically administered LPS to enhance seizure susceptibility (6). Thus, with the exception of those studies that involved ICV administration of provocateurs, the likelihood is that inflammatory response contributes to epileptogenesis, and interventions that antagonize different aspects of downstream signaling (COX-2, NOS) tend to be antiepileptogenic.

The role of inflammation as a causative factor in human epileptogenesis is beginning to be explored. An association of prolonged febrile convulsions and temporal lobe epilepsy with hippocampal sclerosis with a polymorphism in the promoter of IL-1 $\beta$  gene (IL-1 $\beta$ -511T) was first reported from a study in Japan by Kanemoto and colleagues (37). Such an association could not be confirmed in populations of European ancestry (38–40). However, an important difference accounting for the discrepancy could be the difference in the prevalence of prolonged febrile convulsions in these populations (41).

## CLINICAL PRACTICE

### Anti-Inflammatory Therapies in Clinical Epilepsy

The treatment of epilepsy with immunomodulatory agents has mainly involved ACTH, glucocorticoids, and IVIG. Use of IVIG has all but replaced plasmapheresis. Indeed, this approach has generally been resorted to for syndromes that are known to respond poorly to anti-epileptic drugs (AEDs), such as infantile spasms or epilepsy with electrical SE during slow-wave sleep (ESES), or in individuals with any type of seizure syndrome that has failed to respond adequately to AEDs. Klein and Livingston first reported the use of ACTH in children with intractable seizures (42). The pharmacology of all these agents (ACTH, glucocorticoids, and IVIG) is so complex and diverse that we cannot be certain that the basis of their efficacy is their immunomodulatory ability. In fact, the response of Rasmussen encephalitis to immunomodulatory approaches has been less than satisfactory and enduring, even though a strong role for inflammation is suspected in this syndrome. We shall present a brief summary of our present state of knowledge regarding the use of immunotherapy in specific epilepsy syndromes. If there is a “bottom line” conclusion, it will be stated early in the discussion so that the reader has the option not to traverse a confusing, contradictory, and occasionally contentious body of literature to arrive at that conclusion. Where possible, we shall bring to the reader’s attention potential mechanisms of action that may or may not rely on immune mechanisms.

#### Infantile Spasms

The strongest tradition to date for the use of immunomodulatory therapy exists for the use of ACTH in this catastrophic epilepsy syndrome of infancy. Even here, the strongest statement made by an august group of clinicians who adopted the methods of evidence-based medicine to evaluate the clinical literature was that ACTH is *probably effective for the short-term treatment* (italics ours) of infantile spasms, but there is insufficient evidence to recommend the optimal dosage and duration of treatment. There is insufficient evidence to determine whether oral corticosteroids are effective (43). The conclusions reflect the difficulty in undertaking the study of a relatively rare and age-specific, but not etiology-specific, disorder of considerable variability in the premorbid state.

Previous studies have attempted to clarify whether ACTH treatment is superior to treatment with corticosteroids, whether a higher dose of ACTH (150 IU/m<sup>2</sup>) is superior to a lower dose (40 IU/m<sup>2</sup>), and whether an optimal duration of therapy can be determined. The practice parameters from the American Academy of Neurology (AAN) and the Child Neurology Society do not endorse

corticosteroids as effective, based on the weight of available evidence. It should be stressed that lack of evidence in support of steroids is not proof of lack of efficacy. However, it may be suggestive of a mode of action for ACTH that is not entirely dependent on its ability to induce steroidogenesis. Many of the available studies are covered in some detail in Chapter 16 and need not be duplicated under this heading.

How does ACTH mitigate infantile spasms? The mechanism(s) remain(s) elusive. A major hypothesis has centered around the ability of ACTH to reduce the endogenous synthesis of corticotropin-releasing hormone, which, when injected, produces severe seizures in immature rats (44, 45). This theory does account for the time course of action of ACTH and for the all-or-none response to treatment, and it is also supported by the findings of reduced ACTH and cortisol levels in the spinal fluids of patients with infantile spasms (46, 47). Could ACTH be functioning, at least in part, by its effect on melanocortin receptors, independent of steroid release? There are peptides that are ACTH fragments and can function as agonists at those receptors without mediating steroidogenesis, but no clinical trials with such compounds have been undertaken yet.

Another attractive idea proposes that ACTH stimulates the synthesis of deoxycorticosterone, which is bioconverted to the tetrahydroxy derivative, a potent agonist at the GABA<sub>A</sub> receptor site (48, 49). This theory is consistent with the known ameliorative action of infantile spasms by vigabatrin and supports the present interest in ganaxalone, a neurosteroid derivative that is a highly selective agonist for the delta subunit containing GABA<sub>A</sub> receptors, which are extrasynaptic and mediate tonic inhibition.

None of the previously discussed mechanisms exclude the possibility that the administration of ACTH mitigates infantile spasms by modifying a wide range of cytokines (immunomodulation), which in turn may also influence brain excitability by interactions with glutamatergic and GABAergic mechanisms as described earlier. Thus, both aspects related to immune function and other aspects of the pharmacology of ACTH (and steroids) may be important in why this approach to the treatment of infantile spasms has endured.

Scattered reports describe the use of IVIG in the treatment of infantile spasms, but the data do not permit conclusions in support of this treatment modality (50, 51). One study reported benefit from a single treatment with IVIG in children with refractory juvenile spasms (52). The practice parameters from the AAN and the Child Neurology Society did not recognize IVIG as a valid therapy for infantile spasms.

#### Lennox-Gastaut Syndrome

The reports describing the use of ACTH (53) and IVIG (51) in the treatment of Lennox-Gastaut syndrome (LGS)

are extremely limited. It is likely that most specialists will consider using the ketogenic diet or vagus nerve stimulation in medically refractory patients with LGS. One report described a favorable response in 7 of 10 patients treated with prednisone (54). It is not clear that the benefit was lasting. The use of corticosteroids in managing medically intractable LGS was likely more common before the availability of new-generation AEDs with demonstrated benefit in this syndrome. Anecdotal series describing the use of IVIG in LGS (55, 56) have reported favorable effects, and the therapy is generally better tolerated than either ACTH or corticosteroids. More details on the treatment options for LGS are available in Chapter 21.

### **Syndromes with Electrical SE During Slow-Wave Sleep: Landau-Kleffner Syndrome, Tassinari Syndrome of Continuous Spike Waves During Slow-Wave Sleep**

A spectrum of clinical disorders have been associated with the electroencephalogram (EEG) signature of electrical SE during slow-wave sleep (ESES); the clinical syndromes include the distinctive Landau-Kleffner syndrome (LKS) and the syndrome of continuous spike waves during slow-wave sleep (CSWS) (57, 58), the latter sometimes also referred to as the Tassinari syndrome (59). LKS exhibits many clinical features that are typically associated with idiopathic epilepsy syndromes, whereas CSWS generally presents in a manner that suggests a symptomatic epilepsy syndrome (60). These syndromes are covered in detail in Chapter 24.

Clinical practice tends to approach the pharmacologic aspects of management of these syndromes in a more or less similar fashion, concentrating on the EEG trait of ESES. In the published literature, the immunologic approach seems to work better in LKS (60). The treatment of LKS with corticosteroids in high doses for a protracted period was advocated by Marescaux and colleagues (61). Sinclair and Snyder (62) reported a favorable outcome in 9 of 10 patients with LKS who were treated with prednisone, which compares favorably to the surgical approach of multiple subpial transections (63, 64). Such a robust response has never been achieved in CSWS. One study (65) reported two patients whose language functions recovered rapidly with the initiation of intravenous corticosteroid therapy, followed by conversion to oral therapy. It is uncertain whether intravenous therapy adds much benefit to the more common oral treatment (61, 62, 66).

Successful therapy of LKS with IVIG (67–69) was reported in isolated cases. In a subsequent review, Mikati, one of the authors who had reported two of the three published cases (67, 69), stated that only 2 of 11 patients with LKS had responded adequately to treatment with IVIG (70).

There is no literature to substantiate the specific use of ACTH, corticosteroids, or IVIG in ESES that

presents as CSWS. The initial report by De Negri and colleagues (71) advocating nightly diazepam treatment has been adopted by many clinicians, and abstracts have been published in support of this approach. There has not been a peer-reviewed publication yet that describes this therapy and its outcome in a manner that moves it toward wider acceptance.

### **Rasmussen Encephalitis**

Rasmussen syndrome probably represents the best example of an epilepsy syndrome with a major component of the histopathology of resected tissue representing an inflammatory encephalopathy. The report suggesting a role for auto antibodies to the GluR3 subunit of the glutamate receptor (72) initially resulted in much anticipation for the development of successful immunomodulating therapy. This initial enthusiasm has diminished considerably since then, with lack of consistent identification of such antibodies in many patients (73) and the less than gratifying sustained clinical response to steroids, plasmapheresis, or IVIG (74). Surgery remains the most effective treatment (see also Chapter 27).

## **CONCLUSIONS**

There is a lack of convergence between our scientific advances thus far in linking inflammatory processes with epilepsy and our ability to translate those findings to clinical practice. There is a paucity of scientific evidence to support the development of sound clinical guidelines for implementing immunomodulatory therapy, whereas the toxicities associated with extended treatment with ACTH or corticosteroids are considerable. Although IVIG is generally better tolerated, there is insufficient evidence to support its logical placement in a therapeutic algorithm for any epilepsy syndrome. Where the weight of evidence in support of efficacy for a treatment is somewhat stronger (e.g., ACTH in infantile spasms), it is still not clear whether it is the immunomodulating effect that is critical or some other aspect of the pharmacology of the treatment that is responsible for the observed benefits. In most cases, we do not know the status of markers of inflammation before and after therapy. It is still not entirely clear which markers of inflammation are especially relevant to our pursuit of ameliorating epilepsy by immunomodulation. Indeed, this is also true to a large extent in terms of our ability to explain what aspect of the effect of a particular AED on a neurotransmitter system or a channel is responsible for its efficacy in a particular epilepsy syndrome. Ultimately, clinical decisions are based on the empiric findings of efficacy and the demonstration of safety (or acceptable risk that is not out of proportion to the benefit). That is the equation that has relegated immune therapy as a late option in most epilepsy syndromes.

What may the future hold? Future research should be directed toward identifying inflammation-related biomarkers that correlate with the epileptic process in humans. In animal models, some immunomodulatory drugs tantalize us with the holy grail of antiepileptogenic therapy (75). In clinical practice, many of these

agents (cyclosporine, tacrolimus) are associated with the potential for encephalopathy, seizures, or both, as well as other risks to the patient in terms of infection and organ toxicity. Improvement in the toxicity profile of this class of agents can do much to stimulate well-designed clinical trials.

## Antiepileptic Drugs in Development

*John R. Pollard*  
*Jacqueline A. French*

**I**n the last decade and a half, nine antiepileptic drugs (AEDs) have been approved for use, more than doubling the available agents for patients with epilepsy (1). There is no doubt that this has enhanced the options for physicians as they attempt to optimize therapy. New drugs tend to be safer, better tolerated, broader in spectrum, and less likely to cause drug-drug interactions than older drugs. Yet, in many people's estimation, the number of children with uncontrolled seizures has not changed. Clearly, there is still a need for newer and better drugs. Fortunately, the pipeline of drugs in development is rich in new compounds. These compounds have come from many sources. One source that has been providing new compounds throughout the history of antiepileptic drug development is the discovery of analogs of existing compounds (2). Examples include brivaracetam and seletacetam (analogs of levetiracetam), eslicarbazepine acetate (an analog of oxcarbazepine), as well as several analogs of valproic acid (VPA). Some compounds have been discovered through focus on novel mechanisms. An example is talampanel, the first antiepileptic drug that works through alpha-amino-5-methyl-3-hydroxy-4-isoxazolepropionic acid (AMPA) antagonism. Other compounds are found through high-throughput screening programs. For these drugs, the mechanism of action may be less clear. This chapter briefly describes the

AEDs currently in development, including information about mechanism of action, if known, as well as early trial data and pharmacokinetics.

### BRIVARACETAM

#### Chemistry, Animal Pharmacology, and Mechanism of Action

Brivaracetam, ((2S)-2-[(4R)-2-oxo-4-propylpyrrolidinyl]butanamide), is a pyrrolidone derivative in the same class as levetiracetam (LEV) and piracetam (3). Brivaracetam has a higher affinity ( $pK_i = 7.1$ ) than LEV ( $pK_i = 6.1$ ) for the synaptic vesicle protein 2A (SV2A). SV2A is a membrane glycoprotein found in synaptic and endocrine vesicles. The cellular physiology that leads to subsequent anticonvulsant effect is under active investigation (4). In addition to binding SV2A, the drug has been shown to inhibit voltage-dependent sodium currents (5).

Presuming that the SV2A binding site is important for antiepileptic efficacy, brivaracetam should be more potent than LEV in suppressing seizures. Indeed, several animal models seem to confirm this. Brivaracetam is more potent in the corneal-kindled mouse model (reduced afterdischarge and seizure severity after suprathreshold stimulation compared to LEV), in the audiogenic seizure model, and also in a rat model that is thought to mimic

absence seizures in humans: Genetic Absence Epilepsy Rats of Strasbourg (GAERS) (6, 7). In this model, almost complete suppression of spike wave discharges is seen at high doses. Unlike LEV, there is some effect in the maximal electroshock (MES) model. Like LEV, brivaracetam potently suppresses the development of kindling. Animal data also indicate that the drug should be well tolerated. Although effective doses in seizure models were in the range of 1.2–2.4 mg/kg when the drug was administered intraperitoneally, doses of as much as 212 mg/kg have been administered safely. The drug is also active in animal models of neuropathic pain and essential tremor (3).

### **Biotransformation, Pharmacokinetics, and Interactions in Humans**

Brivaracetam is well tolerated in humans in Phase I. Doses ranging from 10 to 600 mg demonstrate linear pharmacokinetics. The volume of distribution is close to that of body water. Plasma protein binding is low, and the half-life is approximately 8–10 hours. The extent of absorption is not affected by a high-fat meal, but the rate of absorption is slowed. The drug is extensively metabolized in the liver via hydrolysis and hydroxylation—the latter via cytochrome P450 (CYP) isoenzymes 2C8, 3A4, and 2C19—and the metabolites are predominantly cleared renally.

In vitro, brivaracetam inhibits epoxide hydrolase and CYP 2C19 and is also a weak inducer of CYP3A4. Drug-drug interactions studies were performed at relatively high doses of brivaracetam. When administered to patients on steady doses of carbamazepine (CBZ), the CBZ-epoxide levels increased in a dose-dependent fashion, whereas the CBZ levels were slightly reduced. In healthy male volunteers, the interaction between phenytoin and brivaracetam resulted in a slightly lower phenytoin serum concentration. In addition, serum concentration of brivaracetam was reduced slightly in the presence of CBZ. When tested with concomitant oral contraceptive use, there was a moderate reduction of estrogen and progestin components, but no change in the suppression of ovulation. In hepatically impaired patients, the half-life of the drug is prolonged. Renally impaired and elderly subjects do not need dose adjustment, although one metabolite increased in serum concentration.

### **Clinical Efficacy**

The drug was tested in patients with a photoparoxysmal response. Each patient received a single dose of study medication. Even at the lowest administered dose of 10 mg, there was substantial suppression of the photoparoxysmal response. At doses of 10–80 mg, there was only one nonresponder, with all other patients (3 or 4 per group) having partial or complete suppression of the photosensitive response (and the nonresponder did not

have an adequate predose expression of photosensitivity). The pharmacodynamic half-life against photosensitivity increased with dose. At 10 mg, the first effect was seen at 30 minutes, and the effect lasted for 30 hours, whereas the duration of effect was 60 hours at the highest dose tested (8). A Phase II multicenter, double-blind, randomized, placebo-controlled, dose-ranging trial is in progress at the time of writing, in which brivaracetam is being tested at doses of 150 and 50 mg/day in one study and 5, 20, and 50 mg/day in the other, in both studies against placebo, as twice daily (BID) administration. The U.S. Food and Drug Administration (FDA) approved orphan drug testing status for brivaracetam for the treatment of symptomatic myoclonus. The drug is also in Phase II clinical trials of patients with postherpetic neuralgia. It is being tested at doses of 200 and 400 mg/day in BID administration.

### **Adverse Effects**

To date, adverse events have been central nervous system (CNS)-related, consisting of dizziness, somnolence, and fatigue, and increase with escalating dose.

## **ESLICARBAZEPINE ACETATE**

### **Chemistry, Animal Pharmacology, and Mechanism of Action**

Eslicarbazepine acetate (S-(-)-10-acetoxy-10,11-dihydro-5H-dibenzo(*b,f*)azepine-5-carboxamide) is structurally related to carbamazepine (CBZ) and oxcarbazepine (OXC) (2). This drug is a prodrug of S-10-monohydroxy derivative (S-MHD), with a “simpler” metabolism than CBZ and OXC. The first studies in humans were in 2000, with the first Phase II studies in 2002. Phase III is underway. Eslicarbazepine acetate shares the dibenzazepine nucleus with OXC and CBZ. It is metabolized exclusively via hydrolysis to S-licarbazepine, with minor traces of the R enantiomer. It is therefore not subject to autoinduction. It is active in MES and amygdala kindling, equipotent to CBZ, and more potent than OXC. Like CBZ, it acts as stabilizer of the inactive conformation of voltage-gated sodium channels through interaction with site 2 of the channel. The result is preferential impairment of rapidly firing neurons (9–11).

### **Biotransformation, Pharmacokinetics, and Interactions in Humans**

In humans, the drug is rapidly converted to the active metabolite eslicarbazepine. To a much lesser extent, it is also converted to its R enantiomer as well as OXC. Plasma levels of the parent compound are typically undetectable. Time to maximum concentration ( $T_{max}$ ) is

2–3 hours after dosing. Terminal half-life is 9–17 hours. Steady state is reached in 4–5 days, longer than expected from the half-life because of the biotransformation. The PK is not affected by age, gender, or food. Protein binding is low. In-vitro studies showed no inhibitory effect on cytochrome P450, but there was mild induction of UGT1A1, which may indicate a potential for interaction with the oral contraceptive pill. Studies suggest that there is no clinically significant interaction with warfarin and digoxin (12–14).

### Clinical Efficacy

To date, 1,200 subjects or patients have been exposed to the drug. A Phase II add-on study in adults and another in children have been completed. In the adult studies, doses from 400 to 1,200 mg were given in once-daily (QD) and BID regimens. Of note, patients on CBZ and OXC were not excluded from the trial. Side effects included headache, somnolence, dizziness, and perioral paresthesia. A double-blind study was performed in 143 patients with more than four seizures per month, with doses up to 1,200 mg BID or QD. Significant seizure reduction was demonstrated. There was a low discontinuation rate because of adverse events (15). Three Phase III studies are comparing 400, 800, and 1,200 mg QD. A Phase II study for acute mania and recurrence prevention in bipolar disorder is also underway.

### Clinical Use and Laboratory Monitoring

Important for children, an oral suspension (50mg/ml) has been developed that is bioequivalent to the 200- and 800-mg tablets.

## FLUOROFELBAMATE

### Chemistry, Animal Pharmacology, and Mechanism of Action

Fluorofelbamate (2-phenyl-2-fluoro-1,3 propanediol dicarbamate) is a felbamate analog that was designed to avoid the toxicities of its parent compound (7). Fluorine is substituted for hydrogen in the 2-position of the propanediol moiety of felbamate in an attempt to block production of at least one toxic metabolite, atropaldehyde. Some preclinical data suggest that this was successful.

This drug has a broad spectrum of activity against all models of electrically induced seizures and has activity against picrotoxin-induced seizures in mice and sound-induced seizures in the audiogenic seizure-prone Frings mouse. The ED<sub>50</sub> is between 1 and 8 times that of felbamate in the various models. In a sustained status epilepticus animal model, it was effective even at a late

stage that is usually refractory to anticonvulsants (16). In animals, weight loss was seen, similar to that seen with felbamate.

There is some evidence in cell culture, slice model, and hypoxic rat pups that this drug has some neuroprotective capacity (17).

The mechanism of action is unknown but may be due to interactions at the glutamate receptor sites or sodium channels. Both of these hypotheses are supported by electrophysiological data.

### Biotransformation, Pharmacokinetics, and Interactions in Humans

A Phase I study has been performed in 54 patients. The drug was well tolerated, and the exposure was dose-proportional.  $T_{max}$  was 1 hour, and elimination half-life ( $T_{1/2}$ ) was 17 hours. Kinetics were linear.

## GANAXALONE

### Chemistry, Animal Pharmacology, and Mechanism of Action

Ganaxalone (3alpha-hydroxy-3beta-methyl-5alpha-pregnan-20-one) is a synthetic analogue of allopregnanolone, a metabolite of progesterone that has no progesterone activity. It is an allosteric modulator of the GABA<sub>A</sub> receptor complex (18). The exact binding site is unknown, but binding to the benzodiazepine site has been ruled out. It has activity in both the 6-Hz and pentylenetetrazol (PTZ) models (19, 20).

### Biotransformation, Pharmacokinetics, and Interactions in Humans

Metabolism is via CYP 3A4. Drug interactions have not been seen, but specific interaction studies have not been performed. There are no major metabolites. There is no evidence of induction in human trials, and the half-life is 10–20 hours. BID dosing is expected (21).

### Clinical Efficacy

There have been 14 Phase I studies in 210 healthy volunteers. However, after these studies were completed, there was a change in formulation. Bioavailability with the initial formulation was low, with a significant food effect. There have been 500 patients (79 children) exposed in 11 Phase II studies, including exposures for as long as 4 years. In a 3-month pediatric refractory seizure add-on study, 20 subjects aged 6 months to 7 years were titrated up to 12 mg/kg. Sixteen patients completed the study; 25% showed a > 50% reduction

in seizures, and one patient was seizure free. An additional 25% showed a 25–50% reduction (22). Two other open-label pediatric studies were conducted in 60 patients aged 2–13 years, with about half having a history of infantile spasms. The most common background drugs were valproic acid, CBZ, and clonazepam. A 50% seizure reduction was seen in one-third of the patients; 17 patients were on the drug for more than 1 year, and the most common adverse events were somnolence and agitation. Eight subjects reported increased seizure frequency. One subject had agitation, hostility, and hallucinations. A presurgical trial in adults was performed. There were 24 patients on ganaxalone vs. 28 on placebo. Outcome was completion of the trial without meeting exit criteria. Although there was a trend in favor of ganaxalone, this did not reach statistical significance. One patient discontinued because of agitation (23). Additional studies in infantile spasms and adult partial seizures are planned.

## ISOVALERAMIDE

### Chemistry, Animal Pharmacology, and Mechanism of Action

Isovaleramide (3-methylbutanamide) is a branched-chain aliphatic amide that is structurally similar to valproic acid. This is one of a series of valproate-like compounds that has the potential to be broad spectrum but may avoid some of the issues related to valproate administration, including weight gain, hepatic toxicity, difficult pharmacokinetics, and teratogenicity. As with valproic acid, the mechanism of action is unknown. Studies of neurotransmitter binding and uptake have been negative, so a direct receptor-mediated effect is unlikely.

It is effective in oral doses in multiple models, including MES, PTZ in rodents, bicuculline- and picrotoxin-induced seizures in mice, generalized seizure in corneal-kindled rats, seizure score and afterdischarge duration in amygdala-kindled rats, spontaneous EEG spike wave of absence seizures in rats, and sound-induced audiogenic seizures in Frings mice. It also delays kindling in amygdala-kindled rats. Bialer et al. characterize the spectrum of anticonvulsant activity as comparable to that of valproic acid. There was also activity in models of spasticity, pain, and anxiety.

Adverse effects seen in animal species at high doses include transient ataxia and hypoactivity. Doses that caused these effects were significantly higher than that expected to be used in humans. Notably, reproductive toxicity was lower for isovaleramide than for valproic acid. In addition, unlike valproic acid, isovaleramide did not inhibit mitochondrial beta-oxidation and respiration at concentrations up to 1mM (2, 7).

### Biotransformation, Pharmacokinetics, and Interactions in Humans

In Phase I studies the bioavailability of single doses ranging from 100–1,600 mg was almost 100%. The half-life of the drug is about 30 minutes – 2.4 hours, with a  $T_{max}$  of 40 minutes, but sustained-release formulations are possible. There is no protein binding. Only 2–4% of the drug was excreted unchanged in the urine at 24 hours, so, as with valproic acid, hepatic metabolism predominates. In marked contrast to valproic acid, isovaleramide does not inhibit any of the major human P450 isoforms.

### Clinical Efficacy

In Phase I studies there were no serious adverse events and no changes in any assessed clinical value. A Phase II trial for treatment of migraine in about 300 patients was completed in 2004 and showed no statistically significant activity, but the drug was well tolerated.

## LACOSAMIDE

### Chemistry, Animal Pharmacology, and Mechanism of Action

Lacosamide (formerly harkoseride, 2-acetamido-N-benzyl-3-methoxypropionamide) is a trifunctional amino acid derivative that has activity in epilepsy, neuropathic pain, and stroke. It shows affinity for the glycine strychnine-insensitive receptor site of the NMDA receptor complex, but this is not yet confirmed as the molecular anticonvulsant site of action (4, 24).

This drug is active in the MES model, the 6-Hz refractory seizure model, hippocampal kindling, sound-induced seizures in Frings mice, and self-sustaining status epilepticus. Developmental toxicity occurred in rats only at a maternally toxic dose. No teratogenicity or adverse effects on male or female reproductive function was identified preclinically (7).

### Biotransformation, Pharmacokinetics, and Interactions in Humans

Absorption is rapid and complete and occurs in the gastrointestinal tract. Bioavailability is good and similar in the fed and fasted states. 30–40% of the drug is excreted unchanged by the kidneys, 30% is excreted as an inactive metabolite, and less than 0.5% is recovered in the feces. Peak concentrations are attained at about 1–5 hours after an oral dose. Lacosamide is protein bound by less than 15%, and the half-life is approximately 13 hours. The drug is being developed as an intravenous formulation as well. When an infusion is administered over a 1-hour

period, the kinetics are similar to oral dosing. Formal interaction studies performed in volunteers have shown no drug-drug interactions in either direction with CBZ, valproic acid, levonorgestrel, or ethinylestradiol (7).

### Clinical Efficacy

Three Phase II trials have been completed in epilepsy. Efficacy against partial seizures was demonstrated at doses between 100 and 600 mg/day divided BID (25). Several studies have also been carried out for painful diabetic neuropathy and showed significant reduction in pain scores at 400 and 600 mg/day, compared to placebo.

### Adverse Effects

The most common adverse effects from the trials were seen with increasing frequency at higher doses and led to a moderate dropout incidence at the 600-mg dose. These included dizziness, somnolence, diplopia, fatigue, and headache. The intravenous formulation caused paresthesias as well as the symptoms listed for the oral dosing.

### Clinical Use and Laboratory Monitoring

As previously noted, the drug is being developed in an intravenous formulation as well as an oral formulation. This adds potential for treatment of patients who cannot take medication orally.

## RETIGABINE

### Chemistry, Animal Pharmacology, and Mechanism of Action

Retigabine, N-[2-amino-4-(4-fluorobenzylamino)-phenyl]carbamic acid ethyl ester, is a structurally novel anticonvulsant related to flupirtine (an analgesic and antispastic drug available only in Europe). Although it was discovered by screening in animal models of acute seizures, it was subsequently discovered to have a unique mechanism of action, which has galvanized interest in the compound. It has activity at the KCNQ2/3 and KCNQ3/5 potassium channels and is thought to stabilize hyperexcitable cells by altering steady-state activation of the M-current (26). In addition, it has an ancillary mechanism, potentiating GABA-evoked currents, which may not be relevant in human doses (27, 28). The mechanism may be of particular interest to pediatric neurologists, given the recent discovery that benign familial neonatal convulsions may be associated with mutations in genes encoding these channels.

Retigabine is effective in all three classes of models: electrical induction, chemical induction, and genetic

epilepsy. It is also effective against kindling. It is most effective in the amygdala-kindling model in rats (29, 30).

Potentially this drug also has neuroprotective effect, as it produces protection against electroshock amnesia and learning in a cerebral ischemia model. It is also effective against neuropathic pain in two animal models (31, 32). In animal studies CNS side effects were sedation, accompanied by hyperexcitability, and decreased body temperature.

### Biotransformation, Pharmacokinetics, and Interactions in Humans

Phase I studies to assess pharmacokinetic properties indicated bioavailability of 60% (not affected by food), a  $T_{max}$  of 1.5 hours, and a half-life of 8–9 hours. Clearance is reduced in black subjects by about 25%. The drug has demonstrated linear pharmacokinetics in healthy subjects and patients. The drug is hepatically metabolized via N-glucuronidation and N-acetylation, and metabolites are excreted in the urine. The N-acetyl metabolite is active and shows anticonvulsant effect in animals.

There are several potential minor drug-drug interactions. Concurrent administration with phenobarbital caused an increase of 10% in the area under the curve for a single dose (33). Lamotrigine (LTG) half-life was slightly reduced after several days of retigabine (34). Neither of these interactions were significant enough to alter Phase II studies. A Phase II study of 60 patients to evaluate drug interactions revealed that retigabine clearance was increased by 30% in the setting of coadministration of phenytoin or CBZ. Higher doses of retigabine would likely be necessary in the setting of enzyme-inducing medications.

### Clinical Efficacy

In five Phase II studies and one Phase IIb study, 600 patients have been studied. In a randomized, double-blind, placebo-controlled, parallel group adjunctive therapy trial in partial epilepsy, doses of 600, 900, and 1,200 mg/day in three daily doses produced a median reduction in seizures of 23%, 29%, and 35% compared to 13% in the placebo group. The responder rate (reduction greater than 50% in seizures) was 23%, 32%, and 33% for these doses, respectively, compared to 16% for placebo. Studies have not been performed in syndromes other than partial, so spectrum of activity is not known.

### Adverse Effects

CNS-related adverse effects were asthenia, dizziness, somnolence, tremor, speech disorder, amnesia, vertigo, and abnormal thinking. Dropout rate was slightly greater than 40% in the highest dosage group (7, 35). At the

time of writing of this chapter, trials in children had not been initiated.

### Clinical Use and Laboratory Monitoring

To date there is only a single preparation, which is tablets.

## RUFINAMIDE

### Chemistry, Animal Pharmacology, and Mechanism of Action

Rufinamide, 1-[(2,6-difluorophenyl)methyl]triazole-4-carboxamide, is a structurally novel agent for which the mechanism of action is unknown. Studies suggest it interacts with the inactivated state of the voltage-gated sodium channel, limiting high-frequency firing of action potentials in neurons (4).

It is active in models such as MES, PTZ, picrotoxin, and bicuculline, with an oral  $ED_{50}$  of 5–17 mg/kg. It is also effective in delaying kindling. It is not mutagenic or teratogenic in animal models.

### Biotransformation, Pharmacokinetics, and Interactions in Humans

The drug has undergone extensive investigation: 1,965 epilepsy patients have been exposed to rufinamide in clinical studies. Population pharmacokinetic (PK) analysis has been performed on 1,072 patients. There is a moderate increase in exposure when the drug is administered with food (36). However, at steady state, food does not seem to influence bioavailability. Absorption is reduced slightly as doses increase. Intrasubject variability is low.

The bioavailability of tablets is approximately 85%, and  $T_{max}$  is reached at 3–4 hours after ingestion. It is bound to plasma proteins by about 34% and has a half-life of 6–10 hours. It is almost completely metabolized, and very little is excreted unchanged. The metabolism is via hydrolysis via a non-P450-mediated interaction. The breakdown products are nonactive and mostly excreted in the urine. Children and elderly patients do not have different pharmacokinetic parameters. Renal function has no impact on clearance.

There is no autoinduction. In population PK analysis, valproic acid decreased apparent oral clearance of rufinamide by 22%, possibly by a greater percentage in children. Any combination of phenytoin, phenobarbital, and primidone increased clearance of rufinamide by 25%, again possibly more so in children. Rufinamide can cause the clearance of phenytoin to decrease slightly, but this may be significant only at higher starting serum concentrations of phenytoin. Rufinamide is a slight inducer of CYP 3A4, leading to slightly increased clearance of ethinyl estradiol and norethindrone.

### Clinical Efficacy

There have been two Phase II trials in refractory partial epilepsy. Both were in adults, but patients above age 15 years in one trial and 16 in the other were included. In one study, 3,200 mg/day led to a median reduction of 20.4% in seizures vs. a median increase of 1.6% for placebo. The dose ranges in these studies was 400–3,200 mg/day (37, 38). A study in refractory primary generalized tonic-clonic convulsions did not show a difference from placebo.

Rufinamide was shown to have clinical benefit in the treatment of seizures associated with the Lennox-Gastaut syndrome in a randomized, double-blind, placebo-controlled trial that enrolled 139 patients aged 4–30 years, who were taking up to three background AEDs. A dose of 45 mg/kg/day was used. Inclusion criteria included presence of drop attacks (tonic or atonic), more than 90 seizures per month, and an EEG demonstrating slow spike-wave activity. Reduction from baseline monthly tonic-atonic seizure frequency was 42.5% in the rufinamide group compared to 1.4% increase in the placebo group ( $P < 0.0001$ ). There was a dropout rate of 14% in the rufinamide-treated patients vs. 8% for placebo, with the most common treatment-related adverse events leading to discontinuation being vomiting, somnolence, and rash (39). There did not appear to be an impact of rufinamide on weight.

### Adverse Effects

In trials, headache, dizziness, fatigue, somnolence, and nausea were the most common side effects. In the Lennox-Gastaut patients, rash was a rare side effect.

### Clinical Use and Laboratory Monitoring

There is a liquid formulation as well as a tablet formulation of the drug.

At the time of writing of this chapter, Eisai had received an “approvable” letter from the FDA both for adjunctive treatment of partial-onset seizures with and without secondary generalization in adults and adolescents aged 12 years and older and for adjunctive treatment of seizures associated with Lennox-Gastaut syndrome in children aged 4 years and older and in adults.

## RWJ-333369 (CARISBAMATE)

### Chemistry, Animal Pharmacology, and Mechanism of Action

Carisbamate, or RWJ 333369, is a carbamate with the chemical formula (S)-2-O-carbamoyl-1-*o*-chlorophenylethanol. The drug is highly potent in MES and various chemical models, including bicuculline and PTZ, and is active in genetic epilepsy models (4, 40).

### **Biotransformation, Pharmacokinetics, and Interactions in Humans**

Phase I explored doses from 200 to 1,500 mg/day. Pharmacokinetics are linear with a 12-hour half-life. There is a mild food effect. After food,  $C_{\max}$  was reduced by about 11%. The drug is metabolized by a non-CYP-dependent route (UGT). There are virtually no circulating metabolites. CBZ induces the compound by about 40%, but carisbamate does not impact CBZ. There is an increase of 20% in LTG and VPA metabolism, but neither of these impacts the metabolism of carisbamate.

### **Clinical Efficacy**

A Phase II add-on study in refractory patients is complete, at doses up to 1,600 mg/day: 537 subjects were randomized; up to three background AEDs were permitted. This study showed a statistically significant reduction in seizures. Dropout rate from adverse events was dose dependent and up to 20% at the highest dose. The most common adverse events were primarily CNS related events, including dizziness, somnolence, nausea, vertigo, and diplopia. Headache increased at the highest dose only.

## **SELETRACETAM**

### **Chemistry, Animal Pharmacology, and Mechanism of Action**

Seletracetam is one of two SV2A ligands currently in development at the pharmaceutical firm UCB. Seletracetam has a 10-fold higher affinity to the SV2A binding site than LEV and a 50-fold greater potency in inhibiting high-voltage-activated calcium channels (6, 41). There is minor inhibition of the plateau phase of NMDA currents (42). Indirect suppression of glycine inhibition is also seen and is significantly greater than that observed with LEV. Seletracetam has no effect on sodium channels (43).

Seletracetam is more potent than LEV in corneal-kindling, hippocampal-kindling, and audiogenic seizures. There is no effect in the acute screening tests, MES and PTZ. There is also efficacy in the GAERS model at relevant human concentrations. Interestingly, the protective index is substantially higher than that seen for LEV, using the corneal-kindling and the GAERS model (44).

### **Biotransformation, Pharmacokinetics, and Interactions in Humans**

The pharmacokinetic parameters are favorable, and like those of LEV, they are linear and dose-proportional. Absorption is rapid and nearly complete, and there is a slight decrease in rate but not extent of absorption with food. The volume of distribution is close to that of body water.

Seletracetam undergoes hydrolysis and is eliminated in the urine, 60% as metabolite and 40% as parent compound. There is no hepatic metabolism, and drug interactions are not expected. The half-life is 8 hours, and there is less than 10% protein binding.

In Phase I, seletracetam was well tolerated. Treatment-emergent adverse events were CNS related, not dose related. The maximum tolerated dose was not reached in a single, rising-dose study, so the maximum tolerated dose is estimated to be greater than 600 mg.

### **Clinical Efficacy**

A Phase IIa study was done in patients with photoparoxysmal response. There were 4–8 patients per dosing group, although some were tested at two doses. Doses of 0.5–20 mg were explored, and all doses produced some suppression. Modeling of the dose effect showed an increasing effect as doses increased, with a plateau effect reached at 10–20 mg. Subsequently, two exploratory, open-label, dose-exploration studies were performed. One study enrolled 30 patients who could be taking as many as three background AEDs, not including LEV. The second study enrolled 60 patients, all of whom were receiving LEV in addition to up to two additional AEDs. Doses up to 160 mg were tested, and assessments of efficacy, safety, and tolerability were made. Unfortunately, results were not available at the time of writing of this chapter.

In addition to the oral formulation, both intravenous and intramuscular dosing are currently under discussion.

## **STIRIPENTOL**

Stiripentol, 4,4-dimethyl-1-[(3,4-methylenedioxy)phenyl]-1-penten-3-ol, is an antiepileptic compound that has been used in France and Canada for more than 10 years in catastrophic pediatric epilepsy syndromes. Meanwhile, broader development and availability have been hampered by the fact that the drug causes significant inhibition of the metabolism of several commonly prescribed AEDs. This has caused two problems. The first is potential toxicity related to elevated serum concentrations of the inhibited drugs. The second is difficulty in discriminating direct antiepileptic effects of stiripentol vs. seizure reduction because drug-drug interactions lead to higher serum concentrations of other concomitantly prescribed medications. Nonetheless, several investigators believe that stiripentol may have an important place in management of these patients, who are very difficult to treat.

### **Chemistry, Animal Pharmacology, and Mechanism of Action**

There are multiple proposed mechanisms of action for stiripentol (7, 45). It inhibits synaptosomal uptake of

GABA and glycine and inhibits GABA transaminase (46). It also enhances beta-hydroxybutyrate dehydrogenase activity. It is said to increase duration of GABAergic currents in a dose-related fashion, with the duration of channel opening increased, similar to the mechanism of action of barbiturates (47).

The drug is active in PTZ and MES models in mice and in the alumina gel Rhesus monkey (48, 49).

### **Biotransformation, Pharmacokinetics, and Interactions in Humans**

The drug reaches  $T_{max}$  within 2 hours. It is 99% protein bound and, as the dose increases in patients on other AEDs, the serum concentration increases in an exponential fashion (50–52).

As previously noted, development has been complicated by multiple drug interactions. Stiripentol inhibits cytochrome P450 isoenzymes 3A4, 1A2, and 2C19. This results in the plasma concentrations of many concurrent AEDs being potentiated, but with better tolerability than would be expected by giving the parent compound. For example, CBZ is better tolerated, because the ratio of CBZ epoxide to CBZ is reduced in a dose-dependent fashion (53–55). For clobazam, addition of stiripentol leads to significantly higher concentration of the metabolite norclobazam, which is also better tolerated, and a lower concentration of hydroxyl norclobazam, a less well-tolerated metabolite. This is because there is more inhibition of 2C19, which is involved in the nor-to-hydroxy reaction (56). Clearance of stiripentol is increased in the presence of enzyme-inducing medications.

### **Clinical Efficacy**

There have been 1,000 patients treated over 11 years. Clinical studies were discontinued in adults but continued in children, and stiripentol is used currently in Canada and France.

In an open-label trial of 212 children, there were 49% responders, with long-term data up to 2.5 years. The better responders were those with partial epilepsy who were also receiving CBZ, and children with severe myoclonic epilepsy of infancy (SMEI) who were also receiving VPA and CBZ. Subsequently, a randomized, controlled trial was performed, but, as previously noted, it was difficult to separate the effect of stiripentol directly from the effect of potentiation of concomitant AEDs.

The double-blind study started with open add-on treatment of 67 patients with stiripentol. The responders were then randomized to withdrawal to placebo or continuation of stiripentol. The primary endpoint, the number of discontinuations, was not significantly

different, but there was a reduction in seizure frequency. The CBZ dose was increased in the placebo arm in order to mimic the effects of stiripentol, but this was not well tolerated.

Another study in SMEI randomized 41 patients to placebo or stiripentol, in patients on valproic acid and clobazam. Nine patients on stiripentol became seizure free, vs. none of the placebo patients (57). A long-term study followed. The best effect was not on frequency, but on duration of seizures. Efficacy was best for patients under 2 years old. Currently, 200 patients with SMEI receive stiripentol as compassionate use in France. and the drug has been designated as an orphan drug by the European Agency for the Evaluation of Medicinal Products (EMA). A subsequent trial is under way as a European Integrated project.

## **TALAMPANEL**

### **Chemistry, Animal Pharmacology, and Mechanism of Action**

Talampanel, R(-)-enantiomer of 7-acetyl-5-(4-amino-phenyl)-8,9-dihydro-8-methyl-7H-1,3-dioxolo(4,5H)-2,3-benzodiazepine (58), is a novel AED whose mechanism of action involves noncompetitive AMPA antagonism (59, 60). This and similar compounds, unlike other benzodiazepines, are highly selective for the AMPA receptor and have no activity at the GABA<sub>A</sub> receptor. There is also no evidence of activity at other common AED targets. Talampanel is effective in a broad range of animal models such as MES and PTZ and against seizures induced by excitatory amino acids that are agonists at the kainate and AMPA sites of the NMDA receptor (61). It also is protective against fully kindled seizures but does not retard the development of kindling (62). There is no evidence of effect in the WAG/Rij spike wave rat model. In animal models, the therapeutic window is small.

### **Biotransformation, Pharmacokinetics, and Interactions in Humans**

After an oral dose, peak plasma concentration is achieved in 2.5 hours. Protein binding ranges from 67% to 88%. At dosages that cause the plasma concentration to exceed 200 ng/ml, the half-life is approximately 7–8 hours. Elimination is by biotransformation, including acetylation (63). An N-acetyl metabolite is produced, which is active, and may contribute both to efficacy and side effects. Patients may have different genotypes in respect to acetylation. Those who are slow acetylators may have reduced clearance of talampanel; conversely, fast acetylators may need a higher dose.

This drug may have a slight effect on metabolism of CBZ. Conversely, inducing medications reduce the serum concentration of talampanel.

### Clinical Efficacy

Two clinical trials have investigated the efficacy of talampanel in epilepsy. The first study was a crossover design, which randomized 49 patients. Talampanel serum concentrations were very variable and depended on concomitant AEDs. The mean seizure reduction was 21% over the placebo period. CBZ levels rose slightly during talampanel treatment (64). The second study investigated doses up to 50 mg three times per day (TID), as add-on therapy in patients experiencing at least three seizures per month. Patients were stratified according to their AED (inducers vs. noninducers), and doses were escalated to either 35 mg TID or a maximum of 50 mg TID or placebo. Results are not published.

The drug was relatively well tolerated, but dizziness and ataxia were seen.

## VALROCEMIDE

### Chemistry, Animal Pharmacology, and Mechanism of Action

Valroceamide (valproyl glycinamide) is a VPA analog that combines valproic acid and glycine derivatives (65). The mechanism of action has not been established. The molecule was synthesized to improve brain penetration and eliminate the inhibition of beta-oxidative metabolism seen with valproic acid.

Valroceamide is effective in a wide variety of animal models of epilepsy, with a good protective index and low neurotoxicity in the rotarod test. It is effective in MES, PTZ, corneal kindling, and the 6-Hz model. It is either equipotent to or more potent than VPA in all of these models (59, 66–69). Studies in mice strains susceptible to VPA teratogenicity imply a lower potential for teratogenicity. The typical teratogenicity studies in rats and rabbits were also negative (2). Importantly, it is also effective in animal models of neuropathic pain and

bipolar disorders. In addition, the brain:plasma ratio is about four times higher than that for VPA, indicating better penetration.

### Biotransformation, Pharmacokinetics, and Interactions in Humans

Phase I doses of as much as 4 g were explored. It was safe and well tolerated. Pharmacokinetics are linear. About 10–20% of valroceamide oral dose is excreted unchanged in the urine; 40% is excreted as valproyl glycine. It is also metabolized in small amounts to valproic acid (about 5%). The half-life is 7 hours. When a dose of 3 g/day is given, VPA levels of 15 mg/L may result.  $T_{max}$  is about 1.2 hours. Metabolism appears to be induced by enzyme-inducing AEDs. In-vitro studies using probes for effect on hepatic isozymes did not predict any effect on CYP 1A2, 2C9, 2C19, or 2D6. However, 3A4 was mildly induced. Unlike valproic acid, valroceamide does not inhibit epoxide hydrolase.

### Clinical Efficacy

In a Phase IIa trial, 22 patients were exposed to the drug in doses up to 2,000 mg BID. Clearance was higher in epilepsy patients, most likely because the drug is inducible. Adverse events were mild to moderate and impacted the CNS and the gastrointestinal system.

A new, controlled-release formulation has been developed.

## CONCLUSION

There are as many new AEDs in the pipeline at this time as at any time in the past. These should serve to improve the management of children with epilepsy into the next decade and beyond. The diverse mechanisms and profiles of the drugs discussed in this chapter represent enormous promise for expanded efficacy, safety, and tolerability. In addition, it is to be hoped that one or several will turn out to be magic bullets for specific difficult epilepsy syndromes encountered in children.

**EPILEPSY SURGERY  
AND VAGUS NERVE  
STIMULATION**

# 60

## Surgical Evaluation

*Michael Duchowny*

**E**pilepsy surgery is an important treatment for children with medically resistant seizures. Successful surgical therapy offers hope for reversing long-standing medical and psychosocial disability and for achieving a more productive and independent life (1).

Identifying appropriate pediatric surgical candidates and evaluating their seizure patterns are rarely straightforward exercises, because children manifest a wide range of seizure types with polymorphous clinical presentations. When electroencephalogram (EEG) findings are nonlocalizing or nonspecific, a comprehensive battery of investigations is often needed to assist in seizure localization. This chapter reviews the indications and special features of epilepsy surgery in the pediatric population, emphasizing currently available procedures for determining surgical candidacy.

### **CANDIDATE IDENTIFICATION AND SELECTION**

#### **Refractory Seizures**

Partial seizures are a common form of epilepsy. Their incidence in the Danish registry is 135 cases per 100,000 unselected patients (2), accounting for 60% of the

cumulative lifetime prevalence of all epileptic seizures (3, 4). Fortunately, most patients are controlled medically, but there remains a large pool of children with recurrent seizures who are at risk for personal injury, diminished quality of life, and, occasionally, death. For the 5% to 10% of chronic epilepsy patients who are disabled by their disorder, surgery is a justifiable option (5).

To establish intractability, it is first necessary to show that appropriate antiepileptic drugs (AEDs) are ineffective. Serum concentrations should optimally be administered to achieve high therapeutic levels, and polytherapy must be chosen judiciously. Although there are many new and investigational AEDs for partial seizure disorders, children who do not respond to traditional agents are unlikely to go into remission.

Special factors in children may compromise the goal of complete remission. Medication noncompliance in the adolescent population and parental anxiety are two common concerns. At the same time, physician factors, such as medication omissions and dosing errors, can undermine otherwise successful treatment efforts and allow seizures to persist indefinitely (6).

Nonepileptic disorders and psychogenic seizures affect approximately 10% of adolescent and adult epilepsy patients and are a common cause of “pseudointractability” (7). Mimickers of epilepsy are particularly common in children and show a diverse clinical spectrum (8). Two

common pitfalls are mistaking complex partial seizures for primary absence epilepsy and failing to identify precipitating factors such as sleep deprivation. More rarely, supplementary motor area seizures may be mistaken for psychogenic nonepileptic seizures because their clinical semiology consists of bilateral motor convulsive movement with preserved awareness. Supplementary motor area seizures are simple partial seizures arising from a discrete and operable focus in the interhemispheric fissure (9). Neurodegenerative disorders, inborn errors of metabolism, and indolent gliomas are occasionally associated with refractory seizures.

Surgical referral is indicated for all children with partial seizures that do not respond to conventional AEDs and the ketogenic diet and that interfere with daily functioning. Family dynamics and perceptions of well-being often influence referral patterns. It has recently been confirmed that children rendered seizure free by excisional procedures achieve enhanced quality of life in multiple functional domains (10).

Gilman and coworkers (6) reexamined the diagnosis of medical intractability in 21 children referred for epilepsy surgery who had significant treatment omissions, such as nonutilization of a first- or second-line AED or lack of therapeutic drug level. Correcting these omissions did not benefit 19 children (90%), whereas 2 children improved on high-dose AED monotherapy. This experience suggests that, although the occasional medically refractory child responds to additional therapeutic intervention, definitive remission is rare.

### **Pediatric Risk Factors**

Several seizure-related factors are associated with medical intractability (11). Frequent seizures (daily or weekly), clustering (12), and early seizure onset (particularly in infancy) favor seizure persistence (13). Infantile hemiconvulsive status epilepticus is linked to later temporal lobe epilepsy in some individuals (14–16). Motor convulsions in nonconvulsive disorders worsen prognosis in direct proportion to the overall number of convulsive episodes (17). Children with brain damage are particularly prone to persistent seizures (12, 18), with the greatest risk in more severely damaged patients (19).

The negative consequences of medically uncontrolled childhood epilepsy were starkly revealed in early prospective cohort studies begun shortly after World War II of 100 children with temporal lobe epilepsy (20). When seizures persisted into adolescence, patients regressed behaviorally and cognitively, and few symptomatic individuals ever led functionally independent lives. Psychosocial disturbance was most troublesome, and less than 5% of the children with significant psychopathology ever functioned normally if their schooling was interrupted (20).

### **Deleterious Effects of Repeated Seizure Activity**

Although psychosocial and intellectual deterioration are not uniformly associated with chronic epilepsy, seizures are deleterious to the developing nervous system. Recurrent seizures induce both transient and long-lasting disruptions of neural circuitry and permanent memory dysfunction (21). Kainic acid exposure increases binding sites in fascia dentata and the CA3 regions of the hippocampus (22), while even brief seizures are capable of inducing mossy fiber sprouting, synaptic reorganization, long-lasting alterations in gene expression, and potentiated neural excitability (23, 24). Similar findings are noted in anterior temporal lobectomy specimens (25, 26), emphasizing that regulatory disturbance of neural excitation and abnormal cellular architecture accompany human epilepsy as well. Hippocampal damage identical to that in chronic temporal lobe epilepsy is also seen in patients with dementia (27).

Other factors predispose children to limbic dysfunction and cellular change. Prolonged early febrile seizures are a recognized antecedent of hippocampal sclerosis (HS) and temporal lobe epilepsy (28). Developmental staging is critical because older individuals are less likely to be damaged (29). Bacterial meningitis and viral encephalitis predispose children to HS after infections only prior to age 4 years (30, 31).

HS, the predominant histopathologic feature of adults with temporal lobe epilepsy, is also prevalent in childhood. In a study of 53 children with chronic temporal lobe seizures who underwent detailed magnetic resonance imaging (MRI) evaluations, 30 children demonstrated either HS or abnormal hippocampal signal without evidence of a mass lesion (16). HS was subsequently confirmed pathologically in 11 of 13 patients treated surgically.

### **SYNDROMES ASSOCIATED WITH MEDICALLY INTRACTABLE EPILEPSY**

Epilepsy syndromes were included in the 1989 International League Against Epilepsy classification (32), and that classification is presently in widespread use to categorize epileptic seizures (33). Identification of specific epilepsy syndromes helps define long-term prognosis, assist genetic analysis, and facilitate surgical referral.

#### **Sturge-Weber Syndrome**

Sturge-Weber syndrome is a neurocutaneous disorder manifested by venous angiomas of the leptomeninges and ipsilateral facial angiomatosis (portwine stain, nevus flammeus), which are associated with varying degrees of mental deficiency; ocular defects, including glaucoma

and buphthalmos; and epilepsy (34). Partial seizures are particularly common (35), and patients often have uncontrolled seizures and deteriorate clinically. Depressed glucose metabolism on positron emission tomography (PET) (36) and decreased regional blood flow on  $^{133}\text{Xe}$  single-photon emission computed tomography (SPECT) (37) confirm severe functional derangement of cerebral cortex underlying the angioma.

### Tuberous Sclerosis Complex

Tuberous sclerosis complex (TSC) is a phakomatous disorder causing multiorgan dysfunction, severe psychomotor delay, hypopigmentary skin lesions, adenoma sebaceum, and shagreen patches. Eighty-five percent of patients have infantile spasms and partial epilepsy (38), a high proportion of which are drug-resistant. Excisional procedures designed to remove cortical tissue in proximity to the epileptogenic tuber successfully induce seizure remission (39). Multiple tubers are not a surgical contraindication, because sustained seizure relief is still possible (40).

Although intractable focal epilepsy is often viewed as being either lesional or nonlesional, TSC patients are more precisely characterized as “multilesional” in that they harbor several potential epileptogenic lesions. However, removal of a single tuber often successfully improves or alleviates seizures. The preoperative evaluation is therefore oriented toward identifying the epileptogenic surgical tuber while simultaneously assessing the epileptogenic potential of other lesions.

The identification and removal of an epileptogenic tuber utilizes standard preoperative investigational and planning protocols. Video-EEG characterizes primary seizure origin and functional spread patterns. Ictal recording is particularly valuable for localizing seizure onset in rapid secondarily generalized tonic spasms (41) and lateralizing apparent bilaterally synchronous discharges (42).

Hyperperfused cortical regions on ictal SPECT are used to corroborate electrographic seizure origin and are highly localizing when the EEG demonstrates sustained rhythmic focal fast discharges or spiking (43, 44). A significant proportion of surgical candidates experience a good outcome if the MRI, EEG, and SPECT findings are convergent, whereas the risk of developing a new focus postoperatively is acceptably small (45–47). Early seizure control reverses profound mental retardation and severe autism (48).

The long-term prognosis for seizure recurrence in TSC patients rendered seizure free by surgery is unknown. Although any of the remaining tubers could activate in later life, similar risks exist for all surgery in patients with malformations of cortical development. Alternatively, it is also possible that removal of the primary epileptogenic region could modify potential secondary epileptogenic

areas, as may occur in other brain lesions (49). Persistent multifocal abnormalities underscore the need for caution and long-term seizure surveillance.

### Cortical Dysplastic Lesions (CDLs)

Dysplasias of the cerebral cortex represent abnormal patterns of neuronal migration and cellular morphogenesis and are an important cause of intractable childhood epilepsy. High-field-strength magnetic resonance (MR) and functional imaging can detect subtle abnormalities in cryptogenic disorders (Figure 60-1). Although the generalized dysplasias, such as lissencephaly and band heterotopia, are rarely amenable to excisional procedures, focal lesions often merit surgical consideration (50, 51).

Very young patients with intractable partial seizures have a high proportion of CDLs and are prone to severe developmental deterioration. Dysplastic changes in infants with catastrophic seizures are often multilobar and show a predilection for the posterior hemispheres (52, 53). Treatment with multilobar excision or hemispherectomy is often required for full seizure control.

### Syndrome of Gelastic Epilepsy and Hypothalamic Hamartoma

The syndrome of gelastic seizures and hypothalamic hamartoma is characterized by laughing seizures in early life in association with a hamartoma of the posterior hypothalamus. The lesion consists of heterotopic and hyperplastic tissues arising in the interpeduncular cistern or within the hypothalamus near the tuber cinereum and mammillary bodies (54). Patients manifest complex partial seizures or tonic, atonic, and clonic motor convulsions (55). Few are controlled by medication. Precocious puberty in some patients indicates a neurosecretory potential for the lesion. Progressive mental decline during the second decade of life is the rule.

Despite the uniform occurrence of the hypothalamic lesion in affected patients, it has been difficult to prove unequivocally that the hamartoma is intrinsically epileptogenic. Supportive evidence has come from several sources. Ictal SPECT during gelastic seizures reveals hyperperfusion within the hamartoma, hypothalamus, and thalamus, but not the cortex (56, 57). Direct EEG recording from the hamartoma reveals focal spiking (57, 58), whereas electrical stimulation of the hamartoma reproduces gelastic seizures (57).

Both surgical excision (59, 60) and radiofrequency lesioning (57) successfully alleviate seizures. Seizure freedom facilitates progressive improvement in the EEG and eventual disappearance of the paroxysmal activity (59). Improved cognitive ability and behavior have also been reported (59).

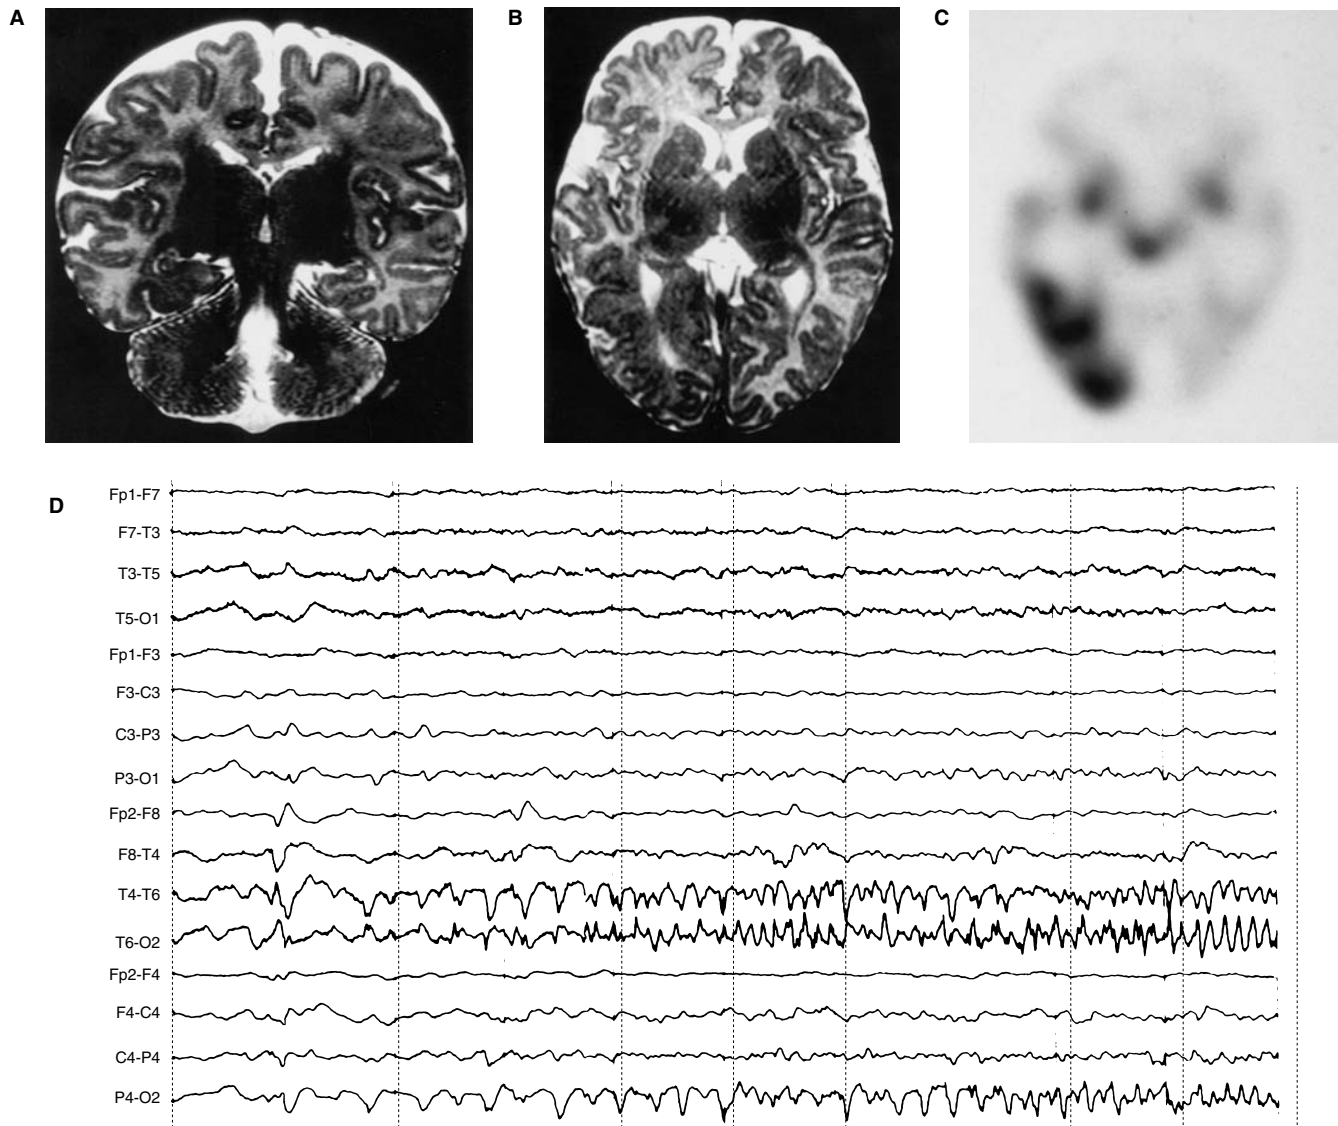

FIGURE 60-1

A 3-month-old male candidate for epilepsy surgery because of neurologic deterioration associated with medically resistant partial seizures and infantile spasms. (A) T2-weighted coronal MR image. There is asymmetric thickening of the cortex in the right parahippocampal and occipitotemporal gyri consistent with cortical dysplasia. (B) T2-weighted axial MR image. There is asymmetric increased myelin deposition in the right occipital and posterior temporal lobes as indicated by the hypointense white matter signal (in comparison to the normal hyperintensity of cerebral white matter in a 3-month-old patient). Areas of hypermyelination are known to occur in conjunction with cortical dysplasia. (C) Axial <sup>99m</sup>Tc HMPAO ictal SPECT. There is increased activity in the right occipital and posterior temporal lobes, corresponding to the regions of abnormality on MR images. (D) Ictal EEG recorded during injection for SPECT study, demonstrating repetitive rhythmic sharp waves in the right temporo-occipital region. The electrographic discharge was accompanied by contraversive eye deviation and facial grimacing.

In contrast, focal resection of epileptogenic cortical regions is rarely beneficial (61). A rationale for corticectomy is rooted in abnormal cortical epileptogenic activity and a belief that ictal laughter and confusion are cortically organized complex partial seizure manifestations. Patients with hypothalamic hamartomas also manifest extralesional abnormalities of gray and white

matter throughout the hemispheres (62), but, although these regions form aberrant intraneuronal networks, their elimination is alone insufficient for seizure freedom.

It should be emphasized that, despite the remarkable advances in surgical technique, removing hypothalamic hamartomas is not without risk. Hypothalamic disturbance and Korsakoff's dementia are potential

consequences of damage to the mammillary bodies, and sessile hamartomas are technically difficult. The Gamma Knife offers a noninvasive alternative for ablating small, deep-seated lesions (63).

### Hemimegalencephaly

Hemimegalencephaly is a rare disorder of brain growth in which one cerebral hemisphere undergoes striking enlargement in conjunction with gyral thickening and accelerated myelination. Histologic analysis reveals bizarre giant neurons and heterotopias similar to those of TSC and high-grade cortical dysplasia (64). Fulminant hemiconvulsive seizures and mental deterioration lead to early death in some affected individuals (65), whereas others experience a more benign course (66).

### Chronic Focal (Rasmussen) Encephalitis

First described by Rasmussen in 1958 (67, 68), chronic focal encephalitis is a rare but striking cause of epilepsy partialis continua and progressive hemiplegia and characteristically is drug-resistant. Serial neuroimaging reveals progressive atrophy associated with nonspecific focal inflammatory changes in brain tissue and cerebral vasculature (69, 70). A viral etiology has not been established despite repeated attempts to culture an agent (67). Acquired autoimmune dysfunction is suggested by the partial resolution of symptoms after immunotherapy and the recent identification of antibodies to the GluR3 receptor in some patients. Hemispherectomy prevents progression in patients with unilateral hemispheric involvement (70).

### West Syndrome

West syndrome, a disorder of brief clonic or tonic spasms, developmental delay, and EEG hypsarrhythmia, is a catastrophic early-onset epilepsy that is often drug resistant. Treatment with corticosteroids and vigabatrin induces remission in approximately half of affected individuals, leaving a sizable proportion with continuing seizures.

The occurrence of spasms in patients with confirmed structural lesions or evidence of localized functional derangement often leads to consideration of excisional surgery (53, 71). The ability to induce surgical remission in an apparently generalized disorder implies that the spasms are a form of secondarily generalized epilepsy. PET abnormalities in dysplastic cortical regions (36) and the cessation of generalized and partial epileptic seizures support this hypothesis (72).

Malformations of cortical developmental and acquired tumors are identified in a high proportion of patients. The restricted region of cortical dysfunction is not inextricably linked to gross structural pathology; many patients with EEG hypsarrhythmia show only

microscopic changes and a normal MRI. The potential preoperative pool thus includes all patients with focal cortical dysfunction, with or without a discrete anatomic abnormality.

The utilization of excisional procedures to treat infants with West syndrome has been facilitated by high-resolution MR imaging of cortical dysplasia and other subtle malformations of cortical development. In nonlesional cases, PET studies may identify focal hypometabolic regions that are subsequently proven to be foci of cortical dysplasia. The ability to identify abnormal metabolic cortex is especially critical in the absence of gross structural lesions (73). Localized cerebral hypoperfusion can also be demonstrated by SPECT (74). For unknown reasons, dysplastic lesions producing infantile spasms show a predilection for the posterior cerebral hemispheres.

Successful excisional surgery to treat patients with West syndrome was first performed in infants with documented spasms and localized hypometabolism on PET. Resections were carried out on patients lacking focal anatomic lesions if there was evidence of localized metabolic abnormality. Resected tissue demonstrated histopathologic findings consistent with cortical dysplasia (73).

More recently, Shewmon et al (75) confirmed the efficacy of surgery in 28 infants who were experiencing active spasms at time of operation. Twenty-six (93%) obtained immediate postoperative seizure relief, and only three relapsed. At long-term follow-up, 11 patients were seizure free, with 5 still taking medication.

There are no universally accepted selection criteria for patients with infantile spasms. Perfectly symmetric spasms are rare, and it is important to document any clinical or electrographic feature suggesting a lateralized process. Apart from clinical signs such as hemiparesis, successful candidates should manifest partial seizures or asymmetric spasms, with or without asymmetry of the hypsarrhythmic EEG (76). Asymmetric spasms and partial seizures can coexist as the principal seizure pattern or occur concurrently (77). Partial seizures trigger spasms in some patients (78).

## SURGERY IN INFANCY

Despite compelling evidence that very young patients can deteriorate rapidly, surgery is often postponed until later childhood or adolescence (79, 80). Rapid deterioration is especially common in infants with exceptionally frequent seizures. Hemispherectomy is indicated when there is hemispheric damage and widespread unilateral epileptic involvement (81). Approximately 85% of hemispherectomy patients achieve seizure freedom. Smaller resections are restricted to patients with localized ictal patterns and convergent neuroimaging findings (82, 83). In an early

report, three of five infants with partial epilepsy undergoing resections became seizure free, two improved significantly, and none deteriorated (84). The favorable experience has been confirmed in larger series of infants undergoing excisional procedures (85, 86).

## SURGICAL CONTRAINDICATIONS

### Degenerative and Metabolic Disorders

Metabolic and degenerative disorders are important surgical contraindications. Most of these disorders present in the first decade of life and are occasionally associated with partial seizures.

### Benign Focal Epilepsies

Syndromes of benign partial epilepsy resolve by the end of the second decade. Benign rolandic epilepsy and benign focal epilepsy of childhood with occipital spikes are relatively common and easily diagnosed by their distinctive clinical and EEG features (87, 88).

### Medication Noncompliance

Noncompliance is usually established by the referring physician and rarely surfaces as an issue during the preoperative evaluation. Noncompliant patients are unsuitable surgical candidates.

### Psychosis

The occurrence of psychotic symptoms in children with partial seizures is controversial and rarely reported. Chronic thought disorders in the adult are rarely improved after surgery, and peri-ictal disturbances generally remit with seizure control (89). It is not known whether psychotic symptoms can be prevented by early surgical intervention.

### Mental Retardation

Patients with chronic epilepsy manifest variable cognitive impairment, but surgery is rarely withheld if patients can comply with the preoperative evaluation. Retarded individuals clearly benefit from seizure freedom.

### Dysfunctional Families

Cooperation with epilepsy surgery team members is fundamental to the success of elective surgery. Psychodynamically dysfunctional families are rarely comfortable during intensive or prolonged hospitalizations and may not be able to evaluate the risks and benefits of surgery

objectively. Dysfunctional families require psychological and social intervention and support before surgical workup.

## PREOPERATIVE EVALUATION

### Neuropathologic Considerations

Disorders of cortical development underlie the majority of intractable seizures in childhood, whereas acquired lesions (i.e., atrophic, sclerotic, or both) are less common. Extensive resections (hemispherectomy or multilobar excision) prove necessary because developmental lesions are associated with widespread anatomic and functional derangement. Although temporal lobectomy is frequently used to treat adults, pediatric patients are more prone to extratemporal seizures and catastrophic presentations (1, 90). Direct comparisons of children and adults with cortical dysplasia and epilepsy reveal that onset of seizure at a younger age is associated with a higher incidence of developmental delay, larger structural lesions, and higher seizure frequency (91).

Not unexpectedly, seizures from a developmentally abnormal cortex are more difficult to characterize by scalp EEG; high-field-strength MR imaging can assist localization by detecting subtle dysplastic lesions. Even so, many low-grade dysplastic lesions and neuronal heterotopias remain undetected (92). Functional localization using PET and SPECT can identify epileptogenic regions through abnormal metabolism or ictal blood flow (93–96).

## CLINICAL SEIZURE SEMIOLOGY

### Frontal Lobe Epilepsy (FLE)

The clinical and electrographic manifestations of FLE are extremely heterogeneous. Frontal lobe seizures are typically brief (<5 minutes) and stereotyped. Clustering and sleep onset are common; prolonged seizure episodes and auras are unusual. Patients may experience brief nonspecific fears or sensations immediately before seizure onset.

Motor seizures of frontal lobe origin may be tonic or clonic, reflecting involvement of Brodmann areas 6 or 4. Seizures arising in motor strip produce contralateral clonic activity, with or without Jacksonian spread to adjacent cortical areas. Very young children are more prone to secondary generalization. Tonic contraversive arm, head, or eye movements suggest involvement of dorsolateral frontal cortex anterior to motor strip. Tonic version is commonly the result of secondary spread of epileptic activity to the frontal cortex.

Ictal head version is a common manifestation of frontal lobe seizure and occurs when the sternocleidomastoid muscle is activated. This muscle has two heads (sternal and clavicular) that rotate the head and neck in opposite trajectories (contralateral turning vs. ipsilateral tilting) (97). Either or both heads may become active, resulting in complex ictal patterns.

Stereotyped psychomotor patterns are more typical of seizures arising in the premotor cortex. Symptoms include bicycling movements, repetitive arm postures and gestures, and disturbances of phonation, including speech arrest and vocalization (98, 99). Activation of anterior and orbitofrontal cortexes are associated with prominent automatisms and complex behavioral sequences. Truncal postural change is not unusual, and patients often appear frightened or agitated. Seizures are typically nocturnal, with frequent arousals that, together with the lack of epileptiform discharges, have suggested paroxysmal nocturnal dystonia.

Supplementary motor area (SMA) seizures often begin in childhood (9); they cause bilateral proximal tonic limb posturing with fully preserved consciousness. The routine EEG may be normal or nondiagnostic, yielding a false impression of psychogenic seizures. Intracortical propagation of SMA discharges may falsely localize seizure onset to the dorsolateral convexity.

### **Temporal Lobe Epilepsy (TLE)**

Seizures of temporal lobe origin are common in childhood. Although they are well characterized in adolescents and adults, the manifestations of TLE are less well documented in infants and children. Many features are seen in adults, but diagnostic pitfalls abound.

Complex partial seizures of temporal lobe origin impair or distort consciousness. Auras are common, although rarely described by the preverbal or nonverbal patient. Automatisms typically consist of gestural or orolimentary movements in infancy, whereas verbal and complex behavioral automatisms are characteristic of older patients (100).

Secondary motor seizures occur frequently in infants and may be the only seizure manifestation. Their incidence declines with advancing age, while behavioral arrest and stereotyped automatisms increasingly predominate. Video-EEG is often required to diagnose secondary motor phenomena (100, 101).

### **Parietal Lobe Epilepsy (PLE)**

Seizures of parietal lobe origin are relatively uncommon, and their true incidence is probably underestimated because symptoms arise only after extraparietal spread. Two clinically distinct propagation patterns are recognized: motor convulsions with spread to the frontal lobes

and complex partial seizures with temporal lobe involvement (102–104). Both patterns may occur in the same patient (104). Panic attacks may be the sole manifestation of right parietal lobe seizures (105).

The EEG is often silent or subtly abnormal. Ictal SPECT may confirm anterior parietal seizure origin in patients with sensorimotor symptoms; psychoparetic symptoms arise posteriorly (104).

### **Occipital Lobe Epilepsy (OLE)**

Occipital seizures produce visual symptomatology, including hallucinations, amaurosis, visual field deficits, and forced eye and eyelid movement (102). Seizure activity may spread frontally or, more rarely, to the temporal lobe and produce regional symptoms. Many children with OLE have benign syndromes that are easily controlled and that remit during adolescence (106, 107).

### **SCALP EEG**

The EEG evaluation remains the single most useful tool for evaluating pediatric epilepsy surgery patients. Experienced pediatric EEG personnel should evaluate the EEG, because the interpretation of pediatric seizure patterns is complex (108). Although patients referred for surgery usually have had extensive EEG evaluations, electroclinical diagnoses should always be reconfirmed by careful review of prior EEG recordings. Video-EEG is essential for documenting seizure manifestations. The appearance of electrographic discharges before clinical seizure onset suggests remote seizure onset (108).

Ictal patterns in the childhood epilepsies are more often regional than localized, and children display a wide variety of artifacts that obscure EEG interpretation. There is a close relationship between ictal and interictal electrographic findings, but less than half of all interictal spikes are detected at the scalp (108). Pediatric surgical candidates often manifest bilaterally synchronous or multifocal discharges. Regionalization serves as a basis for planning further invasive studies. MR and functional imaging often help confirm equivocal electrophysiologic data.

### **STRUCTURAL IMAGING**

Magnetic resonance imaging is the modality of choice for evaluating pediatric epilepsy surgery candidates. Its high specificity and sensitivity provide clues to the pathologic basis of many developmental disorders, including CDLs, migrational disturbances, and developmental tumors (e.g., dysembryoplastic neuroepithelial tumors or gangliogliomas).

MRI presently detects pathologic substrates in more than 80% of children with intractable partial epilepsy (92). Thirty of 98 children and adolescents with partial epilepsy undergoing both computed tomography (CT) and MRI investigations had lesions responsible for their epilepsy that were detected by MRI, but not by CT (109).

MRI studies also reveal a high incidence of HS in childhood. In a study of 53 children with TLE undergoing detailed MRI investigations, 30 children showed either HS or regions of abnormal signal in the absence of a mass lesion (110). Hippocampal volume loss can also be documented (111). One developmentally delayed infant with a normal MRI reportedly developed a unilaterally increased signal in the hippocampus within 24 hours of an episode of status epilepticus (112). Cortical dysgenesis was identified in the temporal lobe specimen.

Neuroimaging of pediatric epilepsy surgery candidates should employ techniques to maximize yield. T1-weighted data are optimally acquired in an oblique coronal orientation, orthogonal to the long axis of the hippocampi (113). Sequencing should include thin (1- to 1.5-mm) images without gaps, especially through the hippocampal regions. Further sequences, such as fluid attenuated inversion recovery (FLAIR), help detect subtle abnormalities. We routinely perform MRI after video-EEG monitoring to facilitate more detailed examination of the candidate seizure region.

## FUNCTIONAL IMAGING

Functional imaging of the epileptogenic region may help define the seizure focus, especially when other modalities yield equivocal or divergent findings. Several techniques are presently available.

### PET

PET utilizes radioactive tracers with short half-lives linked to cerebral blood flow. <sup>18</sup>Fluorodeoxyglucose (FDG) is a marker of the interictal focus, correlating with the epileptogenic region (usually the temporal lobe) in approximately 80% of adult cases (114). Ictal capture is unlikely and should not be induced by convulsant agents because of technical limitations of the scanning process.

The requirement for sedation and the higher proportion of extratemporal seizures limit the clinical utility of PET in children. Newer isotopes that bind to receptor-specific compounds such as <sup>11</sup>C-flumazenil, which is linked to the benzodiazepine receptor, hold promise for enhanced localization (115).

Although less widely employed in the pediatric setting, PET studies have also been employed successfully to localize seizure origin in cases of West syndrome (73)

and other epileptic encephalopathies (116), Sturge-Weber syndrome (117), TSC (118), frontal lobe epilepsy (119), and generalized tonic-clonic seizures (120). PET studies are particularly useful in children with extratemporal epilepsy and childhood syndromes with apparently generalized epileptic discharges.

PET has also been utilized successfully for presurgical localization of eloquent cortex in children with seizures. PET mapping of eloquent language, motor, and visual areas was accomplished in 15 children by coregistering PET images of task-activated cerebral blood flow onto MR images (121). All patients had lesional epilepsy. PET mapping was well tolerated in all cases.

The absolute reliability of PET as a stand-alone localizing tool in the pediatric epilepsy surgical evaluation has been questioned (122). Whereas FDG-PET studies in older children and adolescents have produced results similar to those in adults (123), with one exception (116), there are no longitudinal studies of PET in younger children. It has also been shown that [<sup>11</sup>C]flumazenil PET is significantly more sensitive than 2-deoxy-2-[<sup>18</sup>F] fluoro-D-glucose for detecting cortical regions of seizure onset and frequent spiking in children with extratemporal epilepsy, and that both radioisotopes have low sensitivity when there is rapid seizure spread (124).

### Single-Photon Emission Computerized Tomography

Imaging with SPECT utilizes isotopes such as hexylmethylpropylene amine oxime (HMPAO) for qualitative measures of regional cerebral perfusion (rCP). Early studies were performed in the interictal state, but ictal injections are acknowledged to yield more accurate localization of the epileptogenic region (125). The high yield of ictal SPECT has supplanted PET in the functional evaluation of pediatric epilepsy surgery candidates (126).

The widespread availability of SPECT cameras in nuclear medicine facilities, the low cost of gamma-emitting isotopes, and the introduction of more stable radiopharmaceuticals have facilitated SPECT studies at many pediatric epilepsy centers. SPECT has been employed successfully to evaluate a wide spectrum of pediatric epilepsy surgical syndromes including Sturge-Weber syndrome (127), tuberous sclerosis complex (44), Rasmussen syndrome (128), hemimegalencephaly (129) and focal cortical dysplasia (130).

Ictal SPECT studies remain the procedure of choice to localize a high proportion of children with partial epilepsy (131). Ictal SPECT studies revealed hyperperfusion in 14 of 15 children with temporal lobe epilepsy undergoing preoperative evaluation (132). In 4 children, ictal SPECT provided additional localizing information that was absent from ictal EEG recordings. Similarly, Cross et al (133) reported abnormalities on ictal SPECT in 13

of 14 children with both temporal and extra-temporal seizures. The timing of injection was a critical variable, with injections more than 30 seconds postictally being less likely to yield reliable measurements of regional cerebral blood flow. Pediatric ictal SPECT studies have also been shown to reliably colocalize the epileptogenic zone demonstrated by intracranial EEG recording and to correlate with higher rates of surgical success (134).

In contrast, interictal SPECT injections are a significantly less reliable localizing tool in pediatric patients (135). Normal studies or uncertainty regarding regions of hypoperfusion may potentially be misleading and are rarely relied upon for surgical decision making. Ictal SPECT studies may be used to confirm localizing data from EEG and MRI investigations or to define the epileptogenic region in children with normal or discordant EEG and imaging data. SPECT may also play a role in clarifying the extent of the epileptogenic region and assist in placement of intracranial electrodes.

### **Proton Magnetic Resonance Spectroscopy (MRS)**

MRS studies in epilepsy use N-acetyl aspartate (NAA), creatine, and phosphocreatine-containing compounds, as several lines of evidence indicate that NAA is primarily intraneuronal and an indicator of neuronal well-being (136). <sup>1</sup>H-MRS can be added to routine imaging and provides important lateralizing information, especially in temporal lobe epilepsy (137). Recent MRS studies document neuronal dysfunction in neocortical dysplastic lesions, and correction of metabolic derangement at mirror temporal foci improves after successful surgery (138).

### **Functional MR Imaging (fMRI)**

fMRI is based on noninvasive detection of small regions of increased cerebral blood flow through decreases in deoxyhemoglobin concentration. Three applications are especially promising for patients with epilepsy: delineation of ictal events, localization of the primary epileptogenic region, and identification of a functionally critical cortex (139).

At present, pediatric applications of fMRI are limited. Subjects must be awake, fully cooperative, and not easily distracted. In many candidates, who are developmentally delayed or suffer from behavioral and/or motor disabilities, fMRI data are not easily acquired. fMRI is, however, increasingly being incorporated into the preoperative evaluation of children. fMRI has reliably been used to localize language, sensory, motor, and visual functions in children and can influence surgical planning (140).

Language mapping utilizing developmentally appropriate paradigms generates localizing data in children

that is similar to adults. Cooperative children as young as age 5 years have been studied successfully (141). It has been shown that networks for auditory processing are regionally localized and lateralized by age 5 years (142). Receptive language sites are located primarily along the superior temporal sulcus, similar to those of the adult, suggesting that language localization and network formation is established in early life. False lateralization of language cortex to the homologous nondominant hemisphere may occur in children undergoing fMRI in the postictal state (143).

Sensorimotor cortex can be positively identified utilizing paradigms in which the child taps a finger or toe, wiggles the tongue, or has an extremity brushed. All of these paradigms are simple to apply and achieve reliable results, even in very young children. The location of sensorimotor function by fMRI agrees with localization data obtained by direct cortical stimulation.

## **NEUROBEHAVIORAL AND PSYCHOSOCIAL ASSESSMENT**

### **Candidate Selection**

Neurobehavioral and psychosocial disabilities are common in pediatric epilepsy surgical candidates. A high proportion display mental handicap, short attention span, or high activity level (80, 144). There is a clear link between brain damage and the presence of these features, with the most damaged patients showing earlier seizure onset and a higher frequency of recurrence (12). Older children and adolescents with TLE may develop psychotic thought disorders, especially with left-sided seizure origin (89); adults may experience hyposexuality and personality disturbances (145).

The high incidence of psychosocial and behavioral problems makes baseline assessment of these areas of functioning critical to the preoperative evaluation. However, level of cooperation is often poor, and cognitive deficits may not permit standardized testing.

There is also greater difficulty lateralizing and localizing function in the immature nervous system. Whereas neuropsychologic assessment in adults can lateralize dysfunction, similar procedures are rarely successful in children. The frontal lobes are not fully mature until the second decade, and temporal lobe findings are often non-specific. Developmental lesions may produce widespread functional disturbance.

The contribution of psychosocial assessment to pediatric epilepsy surgery is more realistically directed in two ways. First, preoperative baseline level of function can be documented for future comparisons. Second, psychosocial assessment provides a descriptor of overall maturational brain status.

### Testing Protocol

There is no single neurobehavioral protocol for children being worked up for epilepsy surgery. At the Palm Desert II Epilepsy Surgery Conference, 82 centers completed detailed questionnaires about neuropsychologic testing (146). Forty-two (52.4%) included information about pediatrics, although children were often a small minority. Most centers employed adult test batteries with pediatric norms rather than devising their own batteries. There was uniformity of testing for intelligence and certain measures of cognition but a striking diversity in tests of certain verbal skills and nondominant-hemisphere function. The Wisconsin Card Sorting Test and the Controlled Oral Word Association Test (FAS Fluency) were most commonly used. A more complete listing of tests is found elsewhere (147).

## INVASIVE EEG STUDIES

### Intracranial EEG Recording

In children, as anomalous development occurs throughout the neocortex (148) and is frequently in proximity to eloquent cortex, even seizures of temporal lobe origin are rarely evaluated properly by adult evaluation paradigms (149, 150).

Several additional factors in children explain the higher incidence of more complex workups and higher rates of electrode implantation. Electrocorticographic (ECoG) monitoring, the only tool for physiologically assessing seizure foci intraoperatively, is performed under general anesthesia and frequently is nondiagnostic (108). Electrographically active regions may extend beyond known anatomic boundaries (151), are particularly extensive in infants and very young children (148, 152, 153), and are more likely to involve eloquent cortical regions (154, 155). Dysplastic tissue is rarely visible in the operating room, making visually guided surgery problematic.

Depth electrodes, which are used primarily to sample temporolimbic structures, have limited utility for neocortical foci. Subdural electrodes provide more comprehensive coverage and are well tolerated, even in very young children and infants (155, 156).

### Indications for Implanting Electrodes

There are no universal criteria for invasive EEG monitoring in pediatric patients. Invasive monitoring is often indicated for nonlesional cases (157), whereas scalp EEG, in conjunction with imaging and ECoG, is usually sufficient to evaluate seizures associated with gross structural lesions. Excisional procedures have been performed in patients undergoing only intraoperative ECoG monitoring and PET (53).

Possible indications for invasive EEG recording include the following:

1. *Partial seizures with normal or nonlocalizing imaging data.* Nonlesional epilepsy patients become seizure free only if the ictal onset zone and interictal abnormalities are completely resected. Subdural recording helps define the limits of the epileptogenic region, because depth electrodes cannot sample wide regions of epileptogenic cortex.
2. *Epileptogenic zone larger than the structural lesion.* The true physiologic limits of the epileptic focus in patients with developmental lesions require careful documentation (158). Invasive recording assists surgical planning (159). In 42 children with lesional epilepsy, 90 percent were seizure free after complete excision of the lesion and entire epileptogenic region, whereas half were seizure free with lesion removal and incomplete resection of electrophysiologically abnormal tissue (160).
3. *Noncongruence of data.* Defining the epileptogenic zone with noncongruent seizure semiology, interictal-ictal EEG, and imaging data may not be possible. Invasive EEG recording can help resolve incongruities.
4. *Multiple lesions and/or multifocal interictal epileptiform activity.* Children with multiple structural lesions and/or multifocal interictal spike discharges are surgical candidates when seizures arise from a single operable epileptogenic zone (40, 161, 162). Multiple epileptogenic regions can exert complex ictal interactions, rendering localization difficult from scalp EEG data alone.
5. *Involvement of regions subserving eloquent cortical function.* Regions of eloquent cortex that are contiguous to the epileptic focus require mapping with subdural electrodes. Sensory cortex may be identified intraoperatively by median nerve stimulation. In children, language function is optimally defined extraoperatively.

### Functional Cortical Stimulation

The high incidence of extratemporal and multilobar epilepsy in children requires definition of cortical function in many surgical candidates. The standard adult paradigm, whereby baseline stimulation is increased in 0.5- to 1.0-mA steps until an afterdischarge, functional response, or 15-mA ceiling is obtained, is rarely successful in younger patients (163, 164). Electrical responsiveness increases in direct proportion to age, while threshold for functional responsiveness decreases until adolescence (164).

Cortical responses are more reliably elicited in children by increasing both stimulus intensity and duration in a stepwise fashion (164). Increasing both domains rather

than intensity alone causes the stimulus to converge toward the chronaxie on the strength-duration curve. Responses obtained at the chronaxie are elicited at the lowest possible expenditure of energy, a clear advantage when working in immature cortex. In comparison to the adult paradigm, only dual stimulation successfully evokes both afterdischarges and functional responses in patients 4 years of age and younger (164).

### Sensorimotor Mapping

Dual-stimulation mapping of sensorimotor responses in pediatric epilepsy surgery candidates reveals anatomic representation of cortical function similar to that in the adult. Despite the similarities, however, there are several important maturational features (165). Children under the age of 4 years have predominantly tonic rather than clonic movements, and movement of the tongue is unusual. Below the age of 6 years, hand movement but not individual finger movement is observed. As a rule, tonic finger movements appear earlier than clonic movements, a developmental sequence that mirrors the ontogenetic expression of motor seizure patterns in childhood (100, 166).

Below the age of 2 years, facial motor responses may be bilateral (165), resembling a grimace that lasts several seconds. Bilateral facial movement is absent in older children, suggesting that bilateral facial innervation is a postnatal pattern that predates axonal and/or synaptic elimination (167, 168). Ipsilateral lower facial innervation is gradually lost with maturation. Bilateral facial movement is supported by the observation of facial sparing in congenital but not acquired hemiplegia (169).

Patients with aberrant cortical development exhibit unexpected anomalies of the motor homunculus (165). A hand region superior to primary shoulder region and double shoulder region above and below hand and finger cortex have been described. Aberrant cortical motor organization is more common in patients with other anomalies of cortical development (170). Experimental studies in the primate brain indicate that prenatal lesions are capable of inducing anomalous cortical sulci and functional reorganization at remote cortical sites in both cerebral hemispheres (171, 172).

### Language Mapping

Much of our knowledge of the organization of primary language cortex in the child comes from studies of recovery from childhood aphasia (173). Complete or near-complete recovery is possible based on age at which the lesion occurred and size and location of the damage (174). Recovery involves interhemispheric reorganization and a switch to right-hemisphere dominance. Language recovers well after early postnatal lesions, but deficits in

nonlinguistic skills suggest that recovery is rarely complete or predictable (175).

Although postnatal lesions of the dominant hemisphere in early childhood lead to significant reorganization of language cortex, there is little information about language representation in children with partial seizures and anomalous cortical development. Clarification has obvious implications when seizures originate within or adjacent to language cortex (176).

A recent investigation of electrical stimulation of language cortex in 34 predominantly pediatric patients with implanted subdural grid electrodes, identified 28 with MRI and/or histologic evidence of developmental pathology (155). Patients with developmental lesions had language cortex in frontal and temporal sites anatomically similar to those in the adult. The "adult" representation has been documented in an epilepsy patient as young as 4 years old and a 2-year-old being mapped for tumoral surgery. The actual amount of surface area of cortex devoted to language (based on the number of subdural electrodes showing language representation) is also similar to that of the adult (154, 177), which suggests that language sites are designated in early life and conserved anatomically over the lifespan. The increasing language competence of the child is therefore not attributable to increased cortical surface area.

The relatively fixed position of language cortex in children with anomalous disorders of cortical development contrasts sharply with the relocation of language following early peri- or postnatally acquired lesions (178). Relocation of language sites occurs if language cortex is destroyed before the age of 6 years. By contrast, developmental lesions do not ablate language cortex and therefore do not lead to relocation. Epileptic bombardment also does not displace language cortex from predetermined sites.

### PREOPERATIVE PREDICTORS OF SEIZURE OUTCOME

Clinical, EEG, imaging, and neuropsychologic features have been used to predict outcome of adults selected for temporal lobectomy (1), and multivariate algorithms for predicting success have been described (179). Children exhibit more diverse causes for intractable seizures, making extrapolation from the adult experience difficult. Pediatric candidates with a well-circumscribed interictal EEG focus, localized seizure pattern on monitoring, and tumoral epilepsy have a greater likelihood of seizure freedom (180). Although younger age at surgery is not associated with reduced chances of success, younger patients more often manifest poorly localized EEG patterns (180), and completeness of resection of the epileptogenic area (1) may not be possible.

Studies of preoperative factors for pediatric temporal lobectomy have not identified specific predictors of seizure outcome (181). The absence of statistically significant adult variables such as duration of epilepsy, daily seizures, motor convulsions, and mental retardation suggests caution before

excluding potential candidates. The lower predictive power of preoperative variables in pediatric epilepsy surgical candidates, in direct contrast with the adult experience, suggests that all children with surgically amenable intractable seizures are potential surgical candidates.

## Advanced Neuroimaging: PET-MRI Fusion and Diffusion Tensor Imaging

*Noriko Salamon*

**N**euroimaging for presurgical evaluation of pediatric epilepsy has changed in the last 20 years with the development of modern imaging techniques. Magnetic resonance imaging (MRI) is now the recommended study of choice for patients with epilepsy (1–3). More than 70% of epileptogenic lesions are identified by MRI, including mesial temporal sclerosis, severe cortical dysplasia, vascular malformation, and tumors (4). However, subtler types of cortical dysplasia or cortical dysplasia associated with tumors and mesial temporal sclerosis can be overlooked (5). Advanced imaging techniques including positron emission tomography (PET)-MRI fusion and diffusion tensor imaging (DTI) provide additional findings. In this chapter, the examples of PET-MRI fusion and DTI in mesial temporal sclerosis, tumors, various types of cortical dysplasia, and tuberous sclerosis complex (TSC) are discussed.

### PET-MRI FUSION

PET is a well-established tool for presurgical evaluation of epilepsy (6–9). The most commonly used tracers for epilepsy are 2-deoxy-2-[<sup>18</sup>F] fluoro-D-glucose (FDG) and [<sup>11</sup>C] flumazenil (FMZ) (6–10). Other agents, such as [<sup>11</sup>C]methyl-L-tryptophan, can be used to define the

epileptogenic focus in TSC patients (11). One of the weaknesses of PET imaging is the poor delineation of the anatomical structures. Using the fusion technique, the functional information can be superimposed onto the precise anatomical landmark on MRI. This combined modality technique is useful and increases the sensitivity of neuroimaging in patients with epilepsy.

At some institutions, PET-MRI fusion is performed for all patients undergoing evaluation for epilepsy surgery (12). At the University of California at Los Angeles (UCLA), axial DICOM images of the PET and MRI coronal MPRAGE are transferred into a postprocessing program (Vitrea Vital Image). The images are automatically coregistered (Fusion-7-Mirada), and color coding is applied. Red indicates higher and blue indicates lower FDG metabolic regions.

### DTI

DTI is an emerging MRI method that is potentially useful for uncovering subtle changes in the brain, but few studies have linked DTI changes with histopathology in patients with epilepsy (13). Diffusion-weighted images can provide information on the molecular movements in the microstructure, which is not visible by conventional T1- or T2-weighted MRI. There are two

factors that characterize the DTI phenomenon: diffusivity and anisotropy. The mean diffusivity is often referred to as the apparent diffusion coefficient (ADC). Anisotropy decreases in random microstructures, such as the white matter of cortical dysplasia, and under TSC tubers. Eriksson et al (14) found decreased regional anisotropy in 9 of 11 patients with cortical dysplasia. In addition, decreased anisotropy was also found in the areas beyond the signal abnormality or in areas where conventional MRI T1 or T2 signal were normal. In animal studies, changes in DTI measurements have been associated with changes in myelin (15) and during cortical development high anisotropy in neonates followed by rapid decreases have been attributed to dendrite growth (16).

### MESIAL TEMPORAL SCLEROSIS

Hippocampal sclerosis is the most common type of mesial temporal lobe epilepsy amenable to surgery. In the recent literature (17), about 50% of patients with hippocampal sclerosis have dual pathology, with evidence of neocortical microscopic cortical dysplasia in the postsurgical specimen. In MRI, these cases are shown as temporal lobe atrophy or subtle T2-weighted signal abnormality in the temporal lobe. Mitchell et al (18) found temporal pole T2-weighted high signal abnormality in 57% (31 of 57 cases) of pediatric patients with hippocampal sclerosis. This suggests that the developmental cytoarchitecture is disorganized in many children with hippocampal sclerosis. These findings are easily picked up by FDG-PET study as an area of hypometabolism. (Figure 61-1).

Adachi et al. showed anterior temporal lobe hyperintense T2-weighted signal in 54 of 112 patients with temporal lobe epilepsy. Two cases had focal lesion in the contralateral side, but the electroencephalographic (EEG) seizure foci were seen in the same side as temporal pole signal abnormality (18).

DTI adds further structural imaging information in the otherwise normal-appearing gray or white matter regions. Extrahippocampal white matter abnormality was found in the genu of the corpus callosum and external capsule as decreased fractional anisotropy (FA) values in adults with mesial temporal sclerosis (19).

### TUMORS

Approximately 80% of the tumors seen in patients with intractable epilepsy are in the temporal lobe (20). The common tumors include gangliogliomas, dysembryoplastic neuroepithelial tumors (DNT), pilocytic astrocytomas, oligodendrogliomas, and pleomorphic xanthoastrocytomas. These lesions can be associated

**FIGURE 61-1**

Right mesial temporal sclerosis: the patient is a 16-year-old male; complex partial seizure started at age 9. (A) T2-weighted hyperintense signal in the right hippocampus; the right temporal lobe is smaller than the left. (B) Larger area of hypometabolism in PET.

with cortical dysplasia (21). One series showed that DNT was associated with focal cortical dysplasia (FCD) in 83% (22). The identification of associated cortical dysplasia is important for preoperative evaluation, because

this tissue may need to be included in the surgical margin for good results.

In our series, FDG-PET-MRI fusion showed a larger area of hypometabolism in 50% of the patients with ganglioglioma compared with conventional imaging. These lesions are associated with type I cortical dysplasia, and the MRI showed very subtle T2W hyperintense signal in the neighboring tissues.

## CORTICAL DYSPLASIA

Cortical dysplasia is a developmental anomaly characterized by architectural and cellular abnormalities of the cortex. This anomaly is a significant cause of medically intractable pediatric epilepsy. Histopathologically, cortical dysplasia is a spectrum of abnormalities that can be classified into (1) architectural dysplasia, containing cortical dyslamination and heterotopic neurons in the white matter; (2) cytoarchitectural dysplasia, with features of architectural dysplasia in addition to giant neurons or cytomegalic neurons; (3) Taylor's focal cortical dysplasia, with dysmorphic neurons without or with balloon cells, in addition to features of cytoarchitectural dysplasia (23–24). The Taylor-type focal cortical dysplasia is considered the most severe end of the spectrum of histopathologic abnormalities, and the presence of dysmorphic neurons is related to higher epileptogenicity (23). Palmieri et al proposed a classification of cortical dysplasia (25). These different histological types of cortical dysplasia are associated with varied surgical success (25, 27). In addition, conventional MRI is not sensitive enough to detect all types of cortical dysplasia (Table 61-1).

The degree of hypometabolism can correlate with the degree of dysplasia (28). PET-MRI fusion has been helpful to define the extent of the abnormality and correlates well with the preoperative electrocorticography. Because PET is very sensitive for the subtle type of cortical dysplasia, PET-MRI fusion is even more helpful (Figure 61-2).

## TSC

Approximately 80% of patients with TSC have epilepsy (29). To achieve the best developmental outcome, early seizure control is critical (30). The subset of TSC children with normal development before the onset of seizures, with a single seizure type, and with late-onset partial seizures or transient infantile spasms, fared the best of all children with TSC, both in terms of seizure control and functional outcome (31).

For those children with TSC and drug-resistant epilepsy, surgical resection of the epileptogenic tuber in a timely manner should be considered. Surgical resection is now considered a viable option at leading epilepsy centers,

**TABLE 61-1**  
*Various Types of Cortical Dysplasia*

A. Mild MCD (formerly described as microdysgenesis and not detectable by current MRI techniques)

Type I: ectopic neurons in or adjacent to layer I

Type II: microscopic neuronal heterotopias outside layer I

B. FCD

FCD type I (non-Taylor) no dysmorphic neuron or balloon cell and mostly temporal

Type IA isolated architectural abnormalities (dyslamination plus mild MCD)

Type IB isolated architectural abnormalities plus giant or immature, but not dysmorphic neurons (cytoarchitectural dysplasia)

FCD type II (Taylor) mostly extratemporal

Type IIA: architectural abnormalities with dysmorphic neurons without balloon cells

Type IIB: architectural abnormalities with dysmorphic neurons with balloon cells

but the process of selecting the epileptogenic tuber among the many others is daunting. The multicentric nature of epilepsy in TSC has mostly prevented surgical consideration until recent times. The earliest known case report of epilepsy surgery in TSC was reported in 1989 (32), with the first epilepsy surgery series in 1993 (33). Subsequent studies have suggested that early intervention and single-tuber seizure focus lead to better seizure and functional outcome postsurgically (34).

Recent developments in multistaged, often bilateral, invasive monitoring have yielded promising results for some patients with TSC (35). However, by the nature of the invasive, multistaged, and bilateral monitoring, it is clear that these patients have already progressed to multifocal seizures from multiple different tubers. Thus, the ideal situation remains early surgery when medications fail, with noninvasive presurgical studies, and single-stage resection before secondary epileptogenesis occurs, for the best seizure and developmental outcome for children with TSC and epilepsy.

An ideal diagnostic method will not only identify but also localize the epileptogenic tuber for epilepsy surgery noninvasively, to allow for repeat studies to assess any change over time in the dynamic epileptogenic process. PET scan utilizing alpha-[<sup>11</sup>C]methyl-l-tryptophan is reported to define the epileptogenic focus, but it is unfortunately more specific rather than sensitive in selecting the

FIGURE 61-2

epileptogenic tuber (11) and is not available at most centers. Ictal single-photon emission computed tomography (SPECT) can, in theory, identify the ictal zone, but it poses logistic challenges and offers limited spatial resolution. Lastly, because of the quick propagation potential of neocortical epilepsy, seizures often appear nonlateralized on video-EEG.

The UCLA experience using FDG-PET and MRI fusion is shown in Figure 61-3. The epileptogenic tuber has a larger area of hypometabolism than the nonepileptogenic tuber. DTI is another noninvasive tool that increases MRI sensitivity for subtle structural abnormalities in the brain such as epileptogenic TSC tubers. Jansen et al. (36) used DWI methods and successfully localized the epileptogenic tuber in four children, identified as an increase in ADC values. The ability of DWI to provide data on increased ADC, as well as to estimate reductions in anisotropy the two parameters that are felt to be independent (37), may theoretically improve the sensitivity and specificity of this neuroimaging technique.

### CONCLUSION

Neuroimaging will continue to develop, with faster scan time and higher resolution, but these advances alone may

FIGURE 61-3

Volume of PET hypometabolism and MR tubers between epileptogenic vs. nonepileptogenic tubers.

not considerably increase the detection of otherwise cryptic epileptogenic lesions such as subtle cortical dysplasia. Instead, combining various modalities, such as PET-MRI fusion, and utilizing new techniques, such as DTI, will

help identify epileptogenic structural lesions. Whatever modality is used, all imaging findings should be verified with pathology and electrophysiology to understand better the pathophysiology of epileptogenic lesions.

## Surgical Treatment of Therapy-Resistant Epilepsy in Children

**Gary W. Mathern**  
**Olivier Delalande**

**A**s advocated by physicians and patient activist groups, the treatment goal for patients with epilepsy is to eliminate both seizures and adverse side effects of treatment (1). For young children, an additional aim is to eliminate seizures quickly, at the youngest possible age, in order to optimize cognitive development and improve long-term behavior and quality of life (2). Although physicians concede that complete seizure control is not always possible for every child, it has become increasingly recognized that the difference in quality of life is so significantly better without seizures that this therapeutic objective should be as close to the standard of care as possible.

Epilepsy neurosurgery is an important clinical tool used in the treatment of patients whose epilepsy is resistant to antiepileptic drugs (AEDs). Of historical note, epilepsy neurosurgery predates the discovery of electroencephalography (EEG) as well as most of the AEDs used today. For example, Victor Horsley, working with John Hughlings Jackson and David Ferrier, performed resective brain surgery in London in the 1880s (3). Wilder Penfield carried out his first temporal lobectomy around 1928 (4, 5). By comparison, Hans Berger's initial EEG studies were published in 1929 (6), Foerster and Altenburger reported the first electrocorticogram (ECoG) in

1934 (7), and Merritt and Putnam discovered phenytoin in 1938 (8). Thus, epilepsy neurosurgery is not a new treatment. What is relatively new to clinical neurology is the application of epilepsy neurosurgery for infants and children. With the introduction of continuous EEG video-telemetry and modern neuroimaging techniques, such as magnetic resonance imaging (MRI), [<sup>18</sup>F]2-fluoro-2-deoxyglucose (FDG) positron emission tomography (PET), and ictal single-photon emission computed tomography (SPECT), the late 1980s and early 1990s saw the development of multidisciplinary specialty groups involving pediatric neurologists, neurosurgeons, psychologists, and psychiatrists focused on the diagnosis and operative and nonoperative management of children with therapy-resistant epilepsy (9–12). While the initial clinical protocols mirrored those used by adult epilepsy surgery programs, what has evolved over the past 15 years is a unique conceptual approach to the surgical treatment of children with medically refractory epilepsy (13).

The purpose of this chapter is to highlight what constitutes the distinctive elements of epilepsy neurosurgery in children. Covered topics will include the goals of surgery for the developing brain, clinical characteristics of children undergoing surgery, special challenges related to operating on young children, outcomes and complications, and when the pediatrician and neurologist should

consider referral of therapy-resistant patients to a pediatric specialty epilepsy center.

### THErapy-RESISTANT EPILEPSY: INCIDENCE AND NATURAL HISTORY

Population based epidemiology studies classify children with epilepsy into three general etiologic categories that are relevant in understanding which patients are likely to become therapy resistant (14–18). These categories include patients whose epilepsy is from suspected or confirmed genetic etiologies (termed *idiopathic*; e.g., absence seizures, rolandic epilepsy), and these account for about 30% of new-onset cases. Seizures due to structural brain lesions (termed *symptomatic*; e.g., stroke, cortical dysplasia) occur in around 20% of children, and seizures that have unknown or as yet unidentified etiologies (termed *cryptogenic*) constitute nearly 50% of new-onset pediatric epilepsy cases. Seizure control with AEDs differs depending on the epilepsy etiology category. In the first two years of AED treatment, idiopathic pediatric epilepsy patients can expect a 95% chance of near seizure control (less than 1 seizure per month), and the rate for cryptogenic cases is 90%. By comparison, children with symptomatic epilepsy, who are the most common surgical candidates, can expect near seizure control with 50% probability. The type of symptomatic substrate, as identified by neuroimaging, can also provide a guide to the probability of AEDs controlling seizures. Higher rates of seizure control were achieved with AED therapy in patients with epilepsy related to strokes and vascular malformations than in patients with low-grade tumors, cortical dysplasia, or hippocampal atrophy (19–21). In fact, a recent study found that all children with temporal lobe epilepsy and positive MRI scans showing lesions eventually become medically refractory over a follow-up of more than 10 years (22, 23). Hence, it is estimated that in a general pediatric neurology practice the number of new-onset epilepsy patients whose seizures will not be controlled with medications should be about 16% (expected etiologies times AED failure rate). Of those with therapy-resistant epilepsy, the ones that might be potential surgical candidates (i.e., symptomatic epilepsy) should be 9% to 10% of all new-onset epilepsy cases, or just over half of those with refractory epilepsy. Thus, most patients with new-onset epilepsy will be controlled by AEDs, but a small percentage will not. Population studies with follow-up intervals of nearly 40 years indicate that children less than age 16 years with symptomatic epilepsy are the least likely to become seizure free as adults, generally do not complete higher education, and are unemployed (24, 25). In fact, the development of new AEDs has not substantially affected the rate of medical intractability (26). Hence, young children with

symptomatic epilepsy are at greatest risk for not being controlled with currently available drugs and are the group that should be strongly considered for possible epilepsy neurosurgery.

Based on the clinical response to AED treatment, physicians can predict with relative confidence when a child is deemed “therapy-resistant.” Once a child has failed to reach seizure remission after 2 to 3 medications in mono- or polytherapy, the probability that other drugs will stop seizures is less than 5%, and even less if that child has symptomatic epilepsy (26–28). In addition, 5% to 10% of cases with seizure control on AEDs have sufficiently severe adverse side effects that parents discontinue or change to less effective medical therapy (29). Hence, therapy resistance does not mean failure of all AEDs, as that would take many years with all the available drugs. Instead, therapy resistance can be determined by response to a few medications and knowledge of the underlying substrate as determined by neuroimaging (20, 21, 23).

It is important to note that deciding who might be a surgical candidate is not always straightforward in children with severe epilepsy. For example, children, especially infants, with unilateral hemispheric symptomatic substrates may present with what appear to be generalized clinical seizures, including infantile spasms and bihemispheric EEG abnormalities (30, 31). This may confuse practicing physicians into thinking they are dealing with a nonoperative process when in fact the child is an excellent surgical candidate with a high chance of seizure control (Figure 62-1). Likewise, children may begin with focal epilepsy from a cortical abnormality that rapidly (sometimes within days) progresses to status epilepticus with minimal focal features (32). Analysis of video-EEGs in children indicates that ictal behavior is often less lateralizing in young children than in adults (33, 34). Similarly, children may present with focal EEG patterns and an apparent negative MRI (initially diagnosed as cryptogenic), when in fact they harbor focal cortical pathologies, converting them into symptomatic epilepsy that is surgically treatable. This is especially true for cortical dysplasia, which can be very difficult to identify in the young, rapidly growing brain because of cerebral cortical development and white matter myelination (Figure 62-2). Another clinical presentation, often unique to children, consists of those who have multiple lesions of which only one or two may be epileptogenic, as is often the case in children with multiple tubers from tuberous sclerosis complex (35–37). Hence, pediatric patients with surgically treatable conditions can present with generalized seizures with focal pathologies, with focal pathologies and EEG with an apparent negative initial MRI, and with multiple lesions the removal of one or two of which could result in excellent seizure control. Such unique presentations should be considered in considering when to refer a child with therapy-resistant epilepsy to a specialty center.

**FIGURE 62-1**

MRI scans of pediatric patients with different types of cortical dysplasia. Right side of patient for all figures is shown in panel A. (A) This 2.5-month-old began to have seizures shortly after birth, consisting of body twitches and eye deviation. Scalp EEG disclosed interictal abnormalities and ictal onsets over the left hemisphere corresponding to a region of hemimegalencephaly. Notice the enlarged left cerebral hemisphere with multiple areas of thickened cortex (arrows). Histopathology confirmed severe cortical dysplasia with cytomegalic neurons. (B) This 1-year-old began to have seizures within 2 weeks of birth that eventually progressed to infantile spasms, and EEG abnormalities were localized over the right cerebral hemisphere. MRI disclosed cortical abnormalities involving the right posterior temporal and occipital lobes (arrows) representing multilobar disease. Histopathology after surgical resection confirmed severe cortical dysplasia without balloon cells. (C) This 6-month-old began to have seizures shortly after birth, there was motor asymmetry on examination with mild weakness of the right arm and hand, and seizures consisted of right greater than left tonic motor events. MRI revealed a focal region of cortical and subcortical abnormality involving the left frontal and parietal cortex (arrows). Histopathology confirmed severe cortical dysplasia with cytomegalic neurons and balloon cells. (D) This 7.5-year-old began to have seizures at age 4.8 years that involved focal motor onsets of the right body. MRI revealed a focal region of abnormality in the left frontal lobe with a “tail” extending from the cortex into the white matter (arrow). Histopathology confirmed severe cortical dysplasia with balloon cells.

**FIGURE 62-2**

MRI scans of pediatric patients with difficult-to-diagnose regions of cortical dysplasia. Right side of both patients is shown in panel B. (A) This 8-year-old had a long history of refractory complex partial epilepsy and significant behavioral problems. He had previously attacked his family with a knife and tried to set the house on fire, and outside MRI scans had been read as “normal.” Scalp EEG showed bihemispheric abnormalities with more findings referable to the right frontal and temporal regions. Notice the region of thickened cortex in the right orbital frontal region (arrow). Histopathology showed severe cortical dysplasia with balloon cells. There was a 90+% decrease in seizures with surgery; however, he still has persistent, although less severe, behavioral problems at home and school. (B) This 3.5-year-old presented with new-onset seizures that rapidly progressed over a few weeks into status epilepticus. She was hospitalized at an outside facility receiving pharmacologic therapy with two MRI scans read as “normal.” After transfer, EEG abnormalities were found mostly in the left central-parietal region. Re-review of the MRI scans disclosed an area of thickened cortex at the posterior margin of the Sylvian fissure. Histopathology confirmed mild cortical dysplasia, and the child has been seizure free since surgery.

### **RISKS OF THERAPY-RESISTANT EPILEPSY IN CHILDREN**

Severe developmental delay or regression and increased seizure-related mortality are the major recognized risks of therapy-resistant epilepsy in children (38, 39). Clinical studies indicate that there are at least five independent factors that are associated with developmental delay and lower IQ scores in children with early-onset epilepsy. These are (1) seizure type; (2) age at seizure onset; (3) seizure frequency; (4) seizure duration; and (5) number of AEDs. Children with generalized symptomatic epilepsy (e.g., infantile spasms) and partial seizures originating from one or two lobes of the brain are more likely to have significantly lower IQ scores (>2 standard deviations of the mean) than those with idiopathic epilepsy (e.g., absence, rolandic). Likewise, children whose epilepsy begins before age 1 year, have daily or greater seizure frequency, have uncontrolled seizures for more than

2 years, and use more than three AEDs are at increased risk for developing epilepsy-induced encephalopathy (39, 40). Epilepsy-induced encephalopathy is irreversible, and there is consensus among specialists that early therapeutic intervention, such as resective neurosurgery, is especially critical in infants and young children to prevent catastrophic developmental regression (2, 41). There is emerging clinical data in surgical cohorts that early surgery is associated with better cognitive outcomes (38, 42–46). Even adolescents with therapy-resistant epilepsy are less likely to finish high school, find employment, get married, and be productive citizens than are seizure-free patients (24).

Another important consideration in deciding the timing for epilepsy surgery in children is developmental cerebral cortical plasticity. The developing human brain is capable of significant reorganization of neurologic function, including language and motor skills, after insult and surgery (47–50). In most children, developmental cerebral cortical plasticity may reduce the anticipated neurologic deficits following resective surgery, but it should be noted that the amount of plasticity cannot be predicted before surgery (51).

Therapy-resistant epilepsy in children is also associated with significant seizure-related mortality. There is a higher than expected death rate in children with therapy-resistant epilepsy, with a risk of dying that is more than five times greater than that of the general population in the first 15 to 20 years after diagnosis (52, 53). Clinical trials in therapy-resistant cases indicate that the rate of death from seizures is conservatively 0.5% per patient year (1 in 200), and this risk accumulates over time (54). The causes of death related to seizures include status epilepticus, aspiration pneumonia, drowning, falls, or sudden unexplained deaths due to epilepsy (SUDEP). It is the poor natural history of therapy-resistant epilepsy in children, with increased cognitive morbidity and mortality, that prompts physicians and parents to consider alternate therapies, including epilepsy neurosurgery. In addition, the risks of surgery should be weighed against the risk of cognitive problems and seizure-related mortality in deciding surgical candidacy.

### WHEN TO REFER CHILDREN FOR AN EPILEPSY SURGERY EVALUATION

Expert consensus recommends that children with therapy-resistant seizures or disabling medication side effects should be referred to a pediatric epilepsy center that includes surgery as one of the therapeutic options (2). The purpose of the referral is to evaluate children to be sure they have a correct epilepsy diagnosis, and consider optional therapies in an attempt to stop refractory epilepsy. Thus, not all children referred to a pediatric

epilepsy center end up with surgery. Changes in medical management, after a thorough diagnostic evaluation, can often control seizures, and children are returned to their community physicians (37). Likewise, alternate nonsurgical options can be considered, such as the ketogenic diet (55).

The timing of the referral to a pediatric center is important for children, especially infants who are at greatest risk of epilepsy-induced encephalopathy. It is recommended that children with uncontrolled seizures or infantile spasms under age 2 years should be promptly referred to a specialty center regardless of MRI findings (2). An MRI showing a lesion in any child, regardless of seizure control with AEDs, should also be referred to a pediatric epilepsy center, as these substrates often become therapy-resistant, or the lesion itself should be closely followed for signs of progression (56). Also, focal epilepsy in childhood can be from low-incidence etiologies that should be referred to a specialty center with experience in these pathologies. These etiologies may include children with hemimegalencephaly (57), Rasmussen syndrome (58), Sturge-Weber syndrome (59), tuberous sclerosis complex (35, 36), Landau-Kleffner syndrome, hypothalamic hamartomas (60), and polymicrogyria (57, 59–62).

The evaluation of prospective pediatric epilepsy surgery candidates involves EEG, structural and functional imaging, and appropriate psychologic and psychiatric evaluations (63, 64). EEG studies include interictal and ictal scalp and video recordings to capture seizures and their behaviors. MRI with specific epilepsy protocols is recommended as the primary imaging modality to identify subtle cortical abnormalities not appreciated on routine MRI scans (see Figure 62-2). The MRI sequences may include diffusion tensor imaging (DTI) and thin slices using spoiled gradient recalled (SPGR) sequences or surface coils to capture small cortical defects (56). Other MRI sequences may be required in the first two years of life because of immature myelination, and serial scans may be necessary to identify abnormalities during early postnatal brain development when the clinical team suspects a localized pathologic substrate on the basis of seizure semiology and EEG characteristics. Functional imaging studies may include ictal and interictal SPECT, FDG-PET, and magnetoencephalography (MEG) (37, 65–68). Age-appropriate neuropsychologic/developmental assessments are another important aspect of the pre- and post-surgery evaluation (38, 69). In approximately 25% to 30% of children the seizures cannot be adequately localized with noninvasive studies, and they undergo intracranial electrode placement (grid or depth studies) for ictal seizure localization prior to resection (70).

Not all procedures are necessary for all children, and the decision on the elements of the presurgery evaluation will vary by patient based on age and clinical syndrome. The main criteria for assessing the child with

therapy-resistant epilepsy will be a risk/benefit analysis in which the risks of progressive cognitive delay and death from the seizures is weighed against the probability of seizure control with resection of brain tissue (benefit) and any probable neurologic deficits resulting from surgery (risk). Those judgments involve input from all members of the specialty epilepsy clinical team (surgeons and nonsurgeons) in carefully detailed discussions with the child and family. Thus, there are no set paradigms in deciding who is an epilepsy surgery candidate, and the risk-benefit ratio will vary from one family to another. Also, the presurgery evaluation is expected to change as new technologies and methods are introduced and validated in pediatric patients (1, 67). Postsurgery evaluations should include structural MRI scans and neuropsychologic, psychiatric, and behavioral assessments, along with physical, occupational, and speech therapy. It is recommended that children continue to be followed at the pediatric epilepsy center for as long as necessary to assess and treat these children with chronic conditions even if their seizures are controlled (2).

### CLINICAL CHARACTERISTICS OF PEDIATRIC EPILEPSY NEUROSURGERY PATIENTS

To repeat, the goals of surgical treatment are the same as those of medical therapy. They are to stop seizures with minimal or no additional serious neurologic side effects so that the developing brain can reach its greatest cognitive potential (2). This is especially relevant for pediatric epilepsy surgery in that 45% to 50% of children undergoing surgery have their first seizure before age 1 year (70) and thus are at significant risk of epileptic encephalopathy (71). The best chance for stopping symptomatic therapy-resistant epilepsy is with resective neurosurgery. The optimal surgical candidates are those individuals in whom the seizures arise from portions of the brain that are already severely damaged or nonfunctional such that the resulting neurologic outcome is likely to be no worse than their currently existing medical condition. However, in some children the epilepsy can be so early in life and unrelenting that large resections, such as hemispherectomy, with accompanying physical neurologic deficits may be necessary in order to prevent severe cognitive developmental delay. This is especially true for children with hemispheric cortical dysplasia and hemimegalencephaly with infantile spasms, and slightly older children with Rasmussen syndrome.

The clinical characteristics of the symptomatic etiologies in pediatric patients are different from those in adults (Table 62-1). In a recent International League Against Epilepsy (ILAE)-sponsored survey of 20 pediatric epilepsy surgery centers from Europe, North America,

**TABLE 62-1**  
*Incidence of Symptomatic Substrates in Pediatric Epilepsy Surgery*

ETIOLOGY	PERCENT OF CASES
Cortical dysplasia	42%
Tumor	19%
Infection/stroke/trauma	10%
Hippocampal sclerosis	6%
Tuberous sclerosis complex	5%
Hypothalamic hamartoma	4%
Sturge-Weber syndrome	3%
Rasmussen syndrome	3%
Vascular lesions	1%
Other (gliosis, rarer pathology, normal)	7%

ILAE Pediatric Sub-Commission survey of 20 centers in Europe, Australia, and North America for 2004, patients aged less than 18 years ( $n = 543$  patients). From Harvey et al, 2005 (70).

and Australia (70), the most common pathologic finding in over 40% of pediatric surgical patients was cortical dysplasia. This pathology consists, at a minimum, of cortical dyslamination and columnar disorganization that is nearly always coupled with excessive, heterotopic neurons in the subcortical white matter (72, 73). Cortical dysplasia can be mild or severe; in the latter case the tissue contains abnormal, cytomegalic neurons and balloon cells. As shown by MRI, cortical dysplasia can be hemispheric, multilobar, or lobar/focal (see Figures 62-1 and 62-2), with lobar/focal dysplasia in the frontal and temporal lobes the most common (74). Larger areas of cortical dysplasia are associated with younger ages at seizure onset and surgery (75).

The next most frequent etiologies in pediatric epilepsy surgery patients are low-grade tumors (76), and these typically consist of gangliogliomas and dysembryoplastic neuroepithelial tumors (DNETs) in over half the cases (Figure 62-3). Other relatively common etiologies in pediatric epilepsy surgery patients include atrophic pathologies from stroke, infections, and cerebral trauma, hippocampal sclerosis, and patients with tuberous sclerosis complex (Figures 62-3 through 62-5). Hypothalamic hamartomas, Sturge-Weber, Rasmussen syndrome, and vascular lesions are less frequently found pathologies in pediatric epilepsy surgery patients.

In hypothalamic hamartomas, surgical treatment with or without endoscopy leads to favorable results when performed as soon as possible after the diagnosis of therapy-resistant epilepsy has been established (77). Such a precocious approach is recommended in order to avoid the devastating influence that continuous

FIGURE 62-3

MRI examples of other frequently found symptomatic substrates associated with surgically treated pediatric epilepsy cases. (A, B) This 15-year-old began to have complex partial seizures at age 10 years. MRI disclosed a contrast-enhancing mass lesion in the inferior left temporal pole (A, arrow). Examination of the fresh surgical specimen (B) showed a cystic hard mass that was shown by histopathology to be a ganglioglioma. (C) This 2-year-old presented with new-onset seizures from herpes encephalitis at age 9 months that destroyed most of the right cerebral hemisphere (arrows). Seizures were daily before hemispherectomy, which stopped all events. (D) This 12-year-old had a prolonged complex febrile convulsion at 9 months of age. She remained seizure free until age 6 years, when she developed complex partial epilepsy consisting of staring and lip smacking. MRI revealed signal change in the left hippocampus, and hippocampal sclerosis was established at histopathology.

epileptic activity exerts on the developing nervous system. Nonsurgical techniques (such as Gamma Knife, radiofrequency thermocoagulation, or interstitial radiosurgery), have also been proposed in order to avoid surgery-related complications such as hemiplegia, third cranial nerve palsy, visual field deficit, and central insipid diabetes (62, 78, 79).

Types of epilepsy neurosurgical procedures also are quite varied in pediatric patients (Table 62-2). In the 2004 ILAE survey, 81% of operative cases were resective surgeries involving removing portions of the brain for seizure control, compared with 19% for palliative operations (vagal nerve stimulators and corpus callosotomy) (80–83). Of the resective cases, lobar and focal resections were the

FIGURE 62-4

MRI examples of other less frequent symptomatic substrates associated with surgically treated pediatric epilepsy cases. (A) This 2.5-year-old presented at 7 months of age with infantile spasms from multiple tubers associated with tuberous sclerosis complex (arrows). Removal of the left frontal tuber has controlled all seizures for over 3 years. (B) This 14.5-year-old began to have seizures at age 3 years. Despite failing many different AEDs, he never had an MRI scan until age 14 years, when a cystic mass was found in the right posterior temporal region that included cortical changes into the white matter (arrows). The lesion did not enhance with contrast. Histopathology showed signs of old hemorrhage without evidence of tumor or arteriovenous malformation (AVM), most suggestive of an atypical cavernous angioma. (C, D) This 5-year-old began to have seizures 9 months earlier that within weeks evolved to constant motor clonus of the left face and hand. MRI within two weeks of seizure onset showed fluid-attenuated inversion recovery (FLAIR) changes in the right perisylvian region (arrow in C), and this region enlarged two months later (arrow in D). Clinical presentation and histopathology were most consistent with Rasmussen syndrome (58). This child is seizure free 2 years after cerebral hemispherectomy.

most common (48%), and the regions most frequently involved with pathology were the temporal (23%) and frontal (17%) lobes. In other words, in children undergoing epilepsy neurosurgery, 70% of cases involve extratemporal resection, which is a much higher proportion than typically observed in adult epilepsy surgery cohorts (84). Hemispherectomy was the second most common resective

FIGURE 62-5

Examples of less frequently encountered pathologies in children. (A) This child had refractory epilepsy with developmental delay. Evaluation at an outside hospital found EEG evidence of ictal onsets in the left temporal region, and a left temporal lobectomy was performed. Seizure persisted from the hypothalamic hamartoma (arrow) successfully treated with an endoscopic approach. (B) This child presented with a portwine stain over the forehead. MRI with contrast discloses the typical enhancement pattern seen with Sturge-Weber, which was treated by hemispherectomy.

surgical procedure, followed by multilobar resections (85). In order to decrease complication rates, newer surgical procedures are designed to reduce the volume of brain removal and increase the ratio of disconnection to resection. Such techniques reduce the size of the skin incision and bone flap, which offers the advantages of preventing excessive blood loss and avoiding the exposure of large venous sinuses. This concept, for example, has replaced the term *hemispherectomy* with *hemispherotomy*.

The age at surgery was associated with differences in type of etiology and surgical procedures. Children under age 4 years at the time of surgery are more likely to have

hemispherectomy or multilobar cortical resections (50% of all procedures) for cortical dysplasia (60% of all etiologies), and children had daily or greater seizure frequency. From ages 4 to 12 years the more likely operative procedure would be a focal resection (50%) for cortical dysplasia and tumors (60%), and children would have daily or slightly less frequent seizures. From ages 12 to 18 years the operative procedure will most likely be a focal resection (60%) for cortical dysplasia, tumors, or hippocampal sclerosis (67%), and seizure frequency will be several per week. Palliative procedures, such as vagal nerve stimulators and corpus callosotomy, are evenly distributed by age at surgery.

### SPECIAL OPERATIVE CONSIDERATIONS IN CHILDREN

Neurosurgical procedures can pose special challenges for smaller children, and this is especially true for epilepsy surgery, where younger cases undergo larger cortical resections, which are associated with significant perioperative blood loss relative to total vascular volume (85–89). In children, brain weight is proportionally larger compared to body volume than in adults (90, 91). At age 2 years, for example, the brain is approximately 70% of its adult size, whereas body weight is about 12%. At 10 years of age brain weight is 95% of adult value, but body weight is 50%. Infants weigh 6 to 10 kg at 6 months and 8 to 12 kg by 1 year. Estimated total blood volume (at 75 mL/kg) is 450 to 750 mL at 6 months and 600 to 900 mL at 1 year. By comparison, 10-year-olds weigh 23 to 51 kg, and estimated blood volumes range from 1,700 to 3,800 mL. Expected blood loss varies by operation and generally ranges from 200 to 500 mL for a focal or lobar resection, and 1,500 mL or more for anatomic hemispherectomy. Thus, in a 6-month-old, even relatively small epilepsy surgery procedures can result in blood loss equal to half or more of total blood volume, and larger operations, such as anatomic hemispherectomy, will involve more than a total body transfusion of red cells. Moreover, blood loss and other complications appear to be more common in cases of hemimegalencephaly, where the cortex is very vascular and dysmature (44, 92, 93). Anticipating these operative and postsurgery problems requires a dedicated surgical team that includes neuroanesthesiologists and pediatric intensive care physicians who proactively treat problems before they occur, have adequate vascular access, monitor for ongoing blood loss during surgery, and have a surgical approach that minimizes operative blood loss (85).

Waiting for the child to grow larger before performing epilepsy neurosurgery does not reduce operative risks over the first 3 years of life, and significantly

TABLE 62-2  
Types of Surgery in Pediatric Epilepsy

TYPE OF SURGERY	PERCENT
Lobar/focal resections	48%
Hemispherectomy	16%
Multilobar resections	13%
Vagal nerve stimulator implants	16%
Corpus callosotomy	3%
Other: multiple subpial transections (MST), grids no resection, etc.	4%

ILAE Pediatric Sub-Commission survey of 20 centers in Europe, Australia, and North America for 2004, patients aged less than 18 years ( $n = 543$  patients). From Harvey et al, 2005 (70).

increases the probability for poorer cognitive outcomes. Two-year-olds weigh 10 to 15 kg, whereas 3-year-olds from 11.5 to 17.8 kg with calculated vascular volumes of 750 to 1,100 mL for 2-year-olds and 860 to 1,300 mL for 3-year-olds. Thus, hemispherectomy and other larger neurosurgical operations, where blood loss is expected to range from 500 to 1,000 mL with newer disconnection procedures, is still associated with possible operative blood transfusion in young children, especially in those with large cortical dysplasia and hemimegalencephaly. In other words, the risk of surgery is not significantly reduced in a 2- or 3-year-old compared with an infant. Hence, although operating in young children is riskier than in adolescents and adults, the increased operative risks are justified in order to prevent permanent epilepsy-related cognitive and developmental deficits.

## OUTCOME

Depending on the type of surgery and etiology, resective neurosurgery is expected to achieve seizure remission (no seizures) in 60% to 80% of pediatric cases in the first two years after surgery (94–96). This exceeds the 5% or less chance of seizure remission with AED therapies (26, 84, 97, 98). Postsurgery seizure remission is higher in those children with localized lesions and pathologies requiring focal or lobar resections than those with multilobar resections and more diffuse pathologies such as hemimegalencephaly (9, 45). Analysis of the pediatric epilepsy surgery data base from the University of California, Los Angeles (UCLA), for example, found that 73% of children were seizure free after hemispherectomy compared with 65% after multilobar resections (99). So far, there is currently no evidence that seizure control is influenced by duration of seizures before surgery. However, developmental outcomes do appear to be influenced by duration of epilepsy prior to surgery (100). Children that achieve seizure control through surgery with less than 2 years of seizure duration have higher developmental quotients than those with seizure durations over 2 years (44, 45). What is unclear is the impact of epilepsy surgery on quality of life and altering abnormal behaviors, which will require further study in pediatric epilepsy surgery patients (101, 102).

## OPERATIVE COMPLICATIONS

Resective neurosurgery is not without possible complications, but the risk from operative therapy is generally less than from long-term uncontrolled epilepsy. Reported operative mortality varies from 0.24% for temporal lobe surgery to 2.5% for hemispherectomy performed using

older techniques (96). The operative mortality with newer hemispherectomy techniques is under 1%. The reported risk of permanent surgical morbidity varies by type of surgery from 1.1% for temporal lobe surgery to about 5% for frontal lobe resections (26). For temporal lobe epilepsy surgery, the major serious complication is infarct and possible hemiparesis. For frontal lobe resections, corpus callosotomy, and multiple subpial resections, the major serious complications are increased motor or language deficits. Of interest, patients rendered seizure free postsurgery have a risk of epilepsy-related mortality comparable to that of patients who are seizure free with AEDs alone (103, 104). Thus, in correctly identified pediatric patients, the operative morbidity and mortality is less than the risks associated with the natural history of therapy-resistant epilepsy.

## CONCLUSIONS

Epilepsy neurosurgery has a very important role in the treatment of therapy-resistant epilepsy, especially for the young developing brain at risk for seizure induced encephalopathy. The goal of surgical treatment for pediatric patients is to stop seizures as quickly as possible with minimal or acceptable side effects and to optimize cognitive development leading to improved behavior and quality of life. Rational decisions regarding epilepsy surgery in children involve a benefit-and-risk assessment of all treatment alternatives with parents so that they can reach an informed decision. That discussion and decision are best performed at a specialty pediatric epilepsy surgery center with the input of a team of pediatric neurologists and surgeon. Surgery is medically justified because children with refractory seizures have an increased risk of serious neurologic morbidity and mortality related to their epilepsy. Generally, the most refractory cases are those patients with symptomatic substrates, and they are often excellent surgical candidates. Seizure control can be expected in 60% to 70% of patients postsurgery and varies by operative technique and whether the goal of surgery was palliative or curative. Operative morbidity and mortality are generally under 5%, which is less than the mortality expected from 10 years of therapy-resistant epilepsy. There are no age restrictions for epilepsy surgery, nor is epilepsy surgery restricted to a single epilepsy syndrome or type of operation (105, 106).

## Outcome of Epilepsy Surgery in Childhood

*Shekhar Patil*  
*J. Helen Cross*  
*William Harkness*

**T**he primary aim of epilepsy surgery is relief from seizures, and there are various parameters that may predict the likelihood of seizure freedom. In addition, there are various secondary aims that need to be considered in order to outline realistic expectations to the family. This is particularly relevant in children, where the range of abilities and behavioral phenotypes of those coming to surgery is wide. In the past, predictions of outcome were based on adult series, but there is now a growing literature of outcome in children that can be referred to. As longitudinal data become available, outcome can be measured in both the short and the long term.

### COMPLICATIONS OF SURGERY

As a result of advances in neuroimaging, neurosurgical techniques, and neuroanaesthesia, surgical morbidity has been reduced. Nonetheless, no surgical procedure can be carried out without risk, and this truth needs to be clearly communicated to patients and or their families as part of the consent process. Complications (1–5) may occur in the perioperative period (within 30 days of the procedure) or may be delayed. Intraoperative problems (2–5) may

include excessive blood loss, derangement of clotting, fluid and electrolyte imbalance, and resultant neurologic deficits. Postoperatively there may be CSF leakage, subdural or intracerebral hemorrhage, hydrocephalus, wound and bone infection, and meningitis (chemical or bacterial). Hydrocephalus may occur as either an early or a late complication of hemispherectomy. In our experience, however, this has been seen in only 9% of our own series of 91 children (unpublished data) 6 weeks to 6 months following surgery.

Risk of infection, hematoma formation, or cerebral edema may increase with the insertion of subdural grids (6, 7) or depth electrodes for seizure localization. The rate of infection ranges between 10% and 12%, depending on the series, and the rate of hemorrhage between 3% and 10%. In the series by Onal (6) et al, 8 out of 35 children implanted developed a hemorrhage, either a subdural or an intracerebral hemorrhage, removed where necessary at the time of explantation of the grid. Five of the hematomas were evacuated, and the rest managed conservatively. They highlight the fact that occurrence of hematomas is directly proportional to the size of the grid and the extent of the bone flap and the importance in avoiding venous compression by the edges of the grid. Also of note is the delayed occurrence of subdural hematomas.

## SEIZURE OUTCOME

The primary aim of resective surgery for intractable epilepsy is to achieve seizure freedom. Seizure outcome is related to a number of factors including pathologic substrate, the extent of that substrate and the completeness of its resection, and the type of procedure performed. Factors that have usually been attributed to a poor outcome are a longer duration of epilepsy, normal pathology on histologic evaluation, male sex, an extra temporal focus, and incomplete resection. It is likely, however, that it is the completeness of resection (8–10), whether structurally or electrically defined, that is the most important factor for determining whether a child will become seizure free.

In 2001 the first randomized controlled trial in adults (11) conclusively proved the benefit of epilepsy surgery in temporal lobe epilepsy compared to anti-epileptic therapy. Adult studies have demonstrated the greater likelihood of seizure freedom following temporal as opposed to extratemporal resection. Similar results have been demonstrated in pediatric series, although, as yet, no randomized study has taken place (12–14). The seizure-free outcome for temporal lobectomy varies from 60% to 78% depending on the series and the spectrum of operated population (15–32). Foreign tissue lesions may be more common in series with predominantly young patients nearing 5 years of age, whereas hippocampal sclerosis is more common in older populations. Overall, the presence of unilateral EEG abnormalities, extent of resection, and presence of imaging abnormalities predict a good outcome, whereas bilateral or multifocal epileptiform discharges, incomplete resection, and possibly selective resection of mesial temporal structures predict a poor outcome.

A series of children undergoing temporal lobe resection for hippocampal sclerosis revealed similar outcome in those under 12 years of age as in adults, although adult criteria were used for surgical selection (33). A wider series of children with higher degrees of comorbidities appeared to have a lesser chance of seizure freedom (34). Such has previously been attributable to dual pathology, with similar predictors of outcome as seen in adults (antecedent prolonged febrile convulsion, normal IQ). In a more recent series, however, reviewing the outcome in children undergoing temporal lobectomy for a primary diagnosis of hippocampal sclerosis showing a seizure-free rate of 58%, good seizure outcome was unrelated to the preoperative IQ, but predicted by history of febrile status and absence of additional MRI with or without histopathologic abnormalities (32). Low IQ should therefore not be an exclusion criterion for epilepsy surgery (35–37). Other series of a wider range of procedures have agreed with this.

Another group that is being increasingly seen in epilepsy centers consists of children with dual pathology; for

instance, mesial temporal sclerosis in addition to cortical dysplasia or other developmental pathologies within the temporal lobe. From 5% to 30% of patients with temporal lobe epilepsy are reported as having dual pathology (38–41), tending to be more frequent in children (33, 41). Surgery in this population has similar results as in individuals with typical temporal lobe epilepsy, provided that there is complete resection of the hippocampus and the second pathology.

Extratemporal resections account for a greater proportion of resectional surgeries performed in children than in adults. As the outcome of such resections is considered to be poorer, it could be assumed that the global outcome in children would be less favorable than in adults. This is well depicted by the study of Fish et al (42), with good outcome in 29% of children and adolescents following frontal lobe resection, compared to 59% with temporal lobe resection. Pediatric series have reported outcome from frontal lobe resections comparable to the adult series. The difference in outcomes between frontal lobe and temporal lobe resections tends to be multifactorial and is probably reflected by poorly defined localization of the epileptogenic zone, the possibility of incomplete or limited resection because of the proximity the eloquent cortices, and involvement of insular cortex less amenable to resective surgery. With the increasing use of intracranial grids as a part of presurgical evaluation, the rates for seizure freedom are showing an improving trend but, as yet, remain lower than the outcomes in temporal lobe surgery. Even with similar pathology, patients with frontal lobe resections for cortical dysplasia (43–47) tend to have a poor outcome in comparison to other resections. There is also variability according to the grade of cortical dysplasia. Some studies report that children with Taylor-type dysplasia have better outcomes (48), approaching 75% seizure freedom at one-year follow up, as opposed to 45–50% for other types of dysplasia, and even within this group of Taylor-type dysplasia those with balloon cells tend to do better than the nonballoon type of dysplasia (49). Others report a better outcome for mild or type I cortical dysplasia (50). However, although the short term outcome (51–54) is reasonably good, the longer-term (53) view may be quite different.

Apparent seizure outcome may relate to the time elapsed following surgery prior to evaluation. The occurrence of seizures in the acute postoperative period in children undergoing extra temporal resections and hemispherectomy is considered to be a poor prognostic sign, with eventual poor seizure outcome at 24 months (55–57). However, most studies report a very good short-term outcome in the first year. This initial advantage gradually fades with time, with cumulative relapses of around 25% (28). In fact, in the latter study (28), the only predictor of a poor outcome was the latency to remission after surgery. A further study (58) puts the outcome

at the first follow-up at the end of one year following surgery as a reliable indicator of a long-term outcome, meaning that a good outcome at the first follow-up usually translates to eventual better outcome in the longer term with very few relapses, but of note was the group of 93% undergoing temporal resections versus 7% with extratemporal resections in their cohort of 399 patients. A study (59) by Mathern et al compared a group of 64 children with cortical dysplasia and 71 children with other etiologies such as infection and ischemic etiology to a group of 34 children with temporal lobe resections. At early follow-up, the seizure control in all the groups was equal, but in the long term, at 5 years the children with cortical dysplasia had deteriorated. In another long term review (53), at 10 years seizure freedom was seen in 72% children with developmental tumors and 32% of children with cortical dysplasia, although outcome at two years was indicative of outcome at 10 years.

Parietal and occipital lobe resections have not been reported in large numbers, in contrast to temporal and frontal lobe (60–65). The seizure outcome in occipital epilepsy is related to the pathology, with poor outcome in the developmental malformation group. Identification of a clear demarcation of the epileptogenic zone, presence of a localized lesion on MRI, an acquired pathology, and concordance of investigations carried as part of the presurgical evaluation are positive predictors of a good surgical outcome in occipital lobe epilepsy. Most of the series have studied small populations, but in a large series (65) of 81 patients concentrating on posterior epilepsies, the only predictors of good outcome were shorter duration of epilepsy and a normal neurologic examination prior to surgery. All the studies document an overall benefit of surgery over antiepileptic drug (AED) therapy. Comparative data of series (66) with a long-term follow-up show excellent outcome for temporal lobe resections, followed by posterior epilepsies, whereas median long-term seizure freedom in frontal lobe epilepsies was only 27%.

An important consideration is for children with possible multifocal disease such as tuberous sclerosis. These children tend to have a good outcome if the preoperative evaluation localizes a single tuber or area to be epileptogenic; resection may then alleviate the epilepsy, sometimes with seizure freedom (67, 68). Similar good results have been seen of late with multistage procedures and non-localizing scalp EEG; however, the long-term outcome of such procedures has not been evaluated (69). In the only study (70) of long-term follow-up in 22 postsurgical patients of TS followed for 1–14 years, the predictors of favorable outcome were localized and unifocal ictal onset with normal development.

In children undergoing hemispherectomy (71–78), the outcome is related to the completeness of disconnection and the pathology of the substrate. Children with developmental malformations such as hemimegalencephaly

and extensive or hemicortical dysplasia have lower rates of seizure freedom, varying between 37% and 58%, as compared to children with acquired pathologies such as Rasmussen encephalitis and vascular pathologies, who tend to have a good outcome, with seizure-free rates between 67% and 88%. Series with older children have reported a greater proportion of those with acquired pathologies and show a good overall outcome, whereas series with young children, especially infants with early-onset epilepsy, appear to have more developmental malformations and less seizure freedom.

A question often asked by parents preoperatively is the likelihood of surgery allowing the drugs to be either reduced or stopped. There is little data on this aspect of care; however, from adult studies, a seizure recurrence is quoted in nearly a third of patients at the end of five years following complete withdrawal of AEDs (79, 80). The risk of relapse in the study by Schiller et al (79) was higher in face of a normal imaging. In another mixed adult and pediatric cohort of 396 postsurgical patients (81), the risk for seizure recurrence in patients who discontinue AED was not different from the risk in those who continue to take the drugs. Data in children are sparse (82, 83), but suggest that although there are predictive factors with regard to seizure freedom, reduction or withdrawal of anticonvulsants cannot be guaranteed, and such information should be included in the counseling of families preoperatively. Hamiwka et al (53), reporting 10-year outcome for children undergoing surgery for cerebral malformations, reported 71% still to be taking anticonvulsant medication at that time, whereas the group of Mathern et al (59) reported 75% to be on anticonvulsants after 5 years. Another group, however, showed that in 20 of 33 patients the drugs could be either reduced or stopped (84), and thus for each individual patient the decision to reduce or discontinue anticonvulsants should be based on the pathophysiologic substrate identified prior to surgical treatment, the completeness of excision of that substrate, any peri- or postoperative complications, and the seizure outcome. Naturally, the views of the family and child are pivotal to this decision and are likely to depend on psychosocial as well as clinical issues.

A number of children are not suitable candidates for primary resective surgery—for example, children with Lennox-Gastaut syndrome who are incapacitated with drop attacks, children with bihemispheric malformations, and children with Landau-Kleffner syndrome. These children may benefit from palliative surgeries such as corpus callosotomy and multiple subpial transections (MST). Outcome for callosotomy is more favorable in children with atonic and tonic attacks, with approximately 60–80% benefiting from the procedure with more than 50% drop in the seizure frequency (85–87). Studies have shown a seizure freedom rate with callosotomy and on concomitant AED between 10% and 20%. The main

role of multiple transections is in patients with epileptogenic zone within the eloquent cortex. This procedure can be combined with cortical resection. Seizure freedom with isolated MST (88, 89) is highly improbable, but with additional procedure of resection, seizure-free outcome may be seen in 40–50% of patients.

The final group to consider is those patients in whom surgery is either turned down or not deemed to be an option. Natural history data in individuals with medically refractory localization-related epilepsy who do not undergo surgery paint a uniformly dismal picture, quoting the seizure freedom rate of approx 8–11% at one-year follow-up (11, 90), whereas in longer-term follow-up, the study by Selwa et al (91) in predominantly an adult population showed a seizure free outcome ranging from 15% to 21% in their cohort of 34 cases. This was again confirmed in a further study, with seizure freedom that varied between 14% and 21% in unoperated localization-related epilepsy (92). Thus, the true benefit of surgery over best medical therapy may yet be unknown. Another consideration is whether surgery affects the long-term risk of mortality. After epilepsy surgery, patients who have recurrent seizures had a standard mortality ratio of 5.75 as compared to the patients with seizure freedom. This benefit of seizure freedom following surgery tends to counter the negative effect of intractable epilepsy on survival (93). As most of the data from adult studies are used to predict the outcomes in pediatric population, this benefit in survival may be seen in children with intractable epilepsy rendered seizure free following surgery.

## NEURODEVELOPMENTAL OUTCOME

Neuropsychologic evaluation is an important aspect of presurgical evaluation. The neuropsychologic profile can sometimes aid the laterality and localization of seizures, and knowledge of the degree of cognitive impairment serves as a baseline for postoperative assessment and outcome. This is important from the point of postoperative functioning, as the evaluations of mental reserve capacity allows for a predictive postoperative profile that can be used for counseling and advising on the risks of surgery. This can be used as a tool to evaluate the surgical outcome and quality of life-related issues.

It is of prime importance to consider the potential effects of epilepsy surgery on the development and cognition of any child. There is growing evidence that early-onset, poorly controlled epilepsy has an adverse impact on cognition, hampering normal development (94, 95). Vargha-Khadem (96, 97) showed that patients with early cerebral damage show a greater deficit if associated with onset of epilepsy under the age of 5 years, implying a negative effect of epilepsy on the brain development. It could therefore be presumed that early treatment with

epilepsy surgery could give a window of opportunity to allow for more optimal development of the brain, but this has been difficult to quantify. Duchowny et al (98) concluded that cortical resection in very young children with catastrophic epilepsy does not guarantee an optimal or improved neurologic development, and perceptions of accelerated development in patients rendered seizure free was not confirmed on formal developmental assessment. This is not surprising when one considers that IQ is a measure of development relative to peers of normal development, and therefore a maintained, though not increased, IQ indicates maintained progress relative to peers, preferable to the deterioration that could possibly be expected with continuing seizures. Freitag et al (99) proposed early intervention to at least stabilize the developmental velocity. A recent study by Battaglia et al (100) found that the cognitive level is generally unchanged in a majority of cases postsurgery, with very few patients showing either a sustained improvement or impairment. Their study showed a stable cognitive outcome in 71.5% of children, with improvement seen in 13.3%. There is also no consensus as to whether there is an optimal time for intervention. It does seem from studies (99, 101), however, that early intervention does not really impact on the eventual cognitive outcome, although in children with infantile spasms a shorter duration of epilepsy leads to better neurodevelopmental outcome (102).

## Focal Resections

Data to date suggest that temporal lobe resection in carefully selected candidates is unlikely to have a cognitive impact in children. In one of the largest reported multi-center series on outcome of temporal lobectomy (103), approximately 82% of children did not experience any significant change in their presurgical scores for verbal or performance IQ regardless of the side of surgery, but the individual analysis does show an increase in the performance IQ regardless of the laterality of surgery. A significant decline in global IQ following temporal lobectomy is unlikely to occur (104), but in those with a decline in cognition the investigators propose the influence of the underlying pathology on the eventual outcome. There was no correlation between the seizure laterality and verbal or nonverbal cognitive functioning, and temporal lobe seizures had an equal effect on the verbal reasoning and nonverbal problem-solving capacity irrespective of their side of onset. Earlier studies (105–107) had suggested postoperative decline in verbal memory in the short term, but in the long term and, in particular, in the pediatric population, two studies (107, 108), failed to show any change in the memory at 12 and 24 months after surgery from the preoperative scores. That this deficit is clearly reversible has been well demonstrated more recently by a prospective study (109) that showed a greater

recovery of memory deficits in children than in adults undergoing temporal lobectomy. Their data suggest an increased neuronal plasticity in childhood, with a proposal of a strong argument in favor of early surgery.

Literature review shows a dearth of information on other lobar resections. There are very few studies on postsurgical series in children with frontal lobe and posterior epilepsies (100). Preoperative groups with frontal lobe epilepsy have deficits in the domain of executive functioning and motor coordination. Lendt et al (111, 112) compared the one-year postsurgical cognitive profiles in groups of 12 children, one group with temporal and the other with frontal lobe epilepsy. Both groups showed important gains in attention, processing speed, memory, and bimanual coordination. Surgery did not lead to any additional impairment. The neuropsychologic profile in frontal lobe epilepsy (113) is akin to that of adults with frontal lobe lesions. Surgical outcome has no bearing on the postoperative neuropsychologic profile in children with frontal lobe epilepsy in both good- and poor-seizure-outcome groups. Some gains, albeit insignificant, are made in the domain of motor coordination. Data from other studies lend weight to offering surgery to suitable candidates, as the benefits from epilepsy surgery far outweigh the risks of inflicting minor deficits in the form of working memory and visual constructional skills (114, 115).

The posterior epilepsies are relatively rare in children. In terms of cognition, the posterior cortex plays an important role in attention and visuoconstructional abilities (116, 117). In general the group of patients with posterior epilepsies (100) has a low IQ compared to groups of temporal or frontal lobe epilepsy. The deficit is especially in the domain of visuoconstruction performance; also of note is the fact that the effects are even more disabling in children with early-onset damage to the posterior cortex. Sinclair et al (77) studied a group of children undergoing extratemporal resections, and within this group the children with frontal lobe epilepsy were relatively better preserved, with a mean full-scale IQ nine points higher than in the children with posterior epilepsies, and the postsurgical outcome mirrored the preoperative assessment. Postoperatively, except for an improvement in the sphere of verbal learning, there was no change in the intellectual functioning and memory. Similar results of a stable postoperative cognitive profile were seen in a group of 26 children (118). Even though the group is quite small, the data show no impairment or adverse effects of surgery on the intelligence or memory. Mabbott and Smith (119) assessed memory in a series of 44 children and adolescents undergoing temporal or extratemporal resection and found no significant decline in memory in either group of children. Children have variable performance on the tasks used for assessment. Within the surgical groups, some children perform poorly within tasks, while others

perform well on the same tasks. The observed variability may be dependent on several factors, probably including age, duration of epilepsy, nature of material used to test memory, and number of medications. Also of note is the effect of age at onset; children with older age of seizure onset performed better on tasks of verbal memory and face recognition.

### Hemispherectomy

Many children coming to this procedure have developmental malformations as their underlying responsible pathology, such as hemimegalencephaly (120) or widespread hemispheric cortical dysplasia. The remaining patients have other etiologies such as Rasmussen encephalitis or vascular pathology. Both the groups tend to have a low IQ/DQ preoperatively; but the deficit is most marked in the group with developmental malformations (121–23). This is particularly relevant, considering the data suggest that age of onset of epilepsy is likely to have a major impact on ultimate developmental outcome, and the onset tends to be earlier in the group with developmental malformations (124, 125). Most studies do not show any significant longitudinal change with regards to developmental and cognitive outcome following hemispherectomy. There are a few studies that do report some gain (98, 120–122), whereas others have reported loss of skills postoperatively, predominantly in those with acquired pathology (124). In a group of 71 children (124), 11 children showed a decline of more than 15 points in the IQ at follow-up, but eight of the 11 children had Rasmussen syndrome, and the decline may have been a result of the progressive nature of the disease. Even in this study almost 80% of the children had a postoperative neuropsychologic profile similar to or slightly better than the preoperative score.

The majority of children who come to hemispherectomy are developmentally delayed, as verified by data from the literature. This has not been a criterion to exclude them from a surgical program. Evidence to date suggests that, although we aim to optimize neurodevelopment, we are more likely to prevent possible further cognitive damage from ongoing epilepsy. Data to date suggest the final outcome to be usually comparable to the preoperative level of functioning, suggesting a maintenance of the developmental trajectory. Children who are well maintained preoperatively tend to do better than those with poor developmental skills (126). A recent meta-analysis (127) showed a better outcome in children than in adults, and the short-term cognitive outcomes were maintained in the longer term. Overall, children undergoing left hemispherectomy (128) with early-onset epilepsy and developmental malformations have a poor cognitive profile as compared to children with right hemispheric lesions, and this translates to a similar postoperative profile.

## FUNCTIONAL OUTCOME

When deciding on whether resective surgery should be offered, the likelihood of inflicting a possible neurologic deficit should be carefully considered. The presurgical evaluation is undertaken with meticulous care to reduce the chance of causing this deficit, by outlining the eloquent cortices and, if necessary, using invasive monitoring with subdural grids and functional stimulation. Recently, with the advent of functional imaging to complement the presurgical evaluation and mapping of the motor and language cortex, the need for invasive monitoring for delineation of eloquent cortex has been reduced. In each individual case the risk-benefit ratio needs to be carefully considered.

Reorganization (129–132) of the eloquent cortices has a bearing on the eventual area of resection. Early-onset epilepsy may be presumed to lead to a greater chance of relocalization of function, but studies have shown that language and motor function (129–132) may be localized within dysplastic cortex. In such cases the risk of postoperative functional deficit is very high. The majority of children with congenital hemiplegia (associated with a structural brain pathology) and early-onset epilepsy can expect little change between pre- and postoperative functional status, although a visual field defect is inevitable if not present preoperatively. Surgery for right-sided lesions (128) in the acquired pathology group tends to have a better outcome; overall, however, the outcome is poor in the developmental pathologies as compared to the acquired pathologies. Curtiss et al (133) showed a better outcome for right-sided hemispherectomies with underlying acquired pathologies, but even the left hemispherectomies may have better postoperative performance on the subdomains of language function, suggesting that the right hemisphere can support language reorganization, with better receptive language than expressive (134). Also in the study by Curtiss et al (133), postoperative seizure outcome had a positive impact on language development in children with developmental pathologies.

Frank aphasia and major language dysfunction are usually not seen after standard temporal lobe resection. The only deficit seen in patients with dominant temporal lobe resection is in naming and, probably, verbal learning (135). This too usually resolves within 6–12 months of surgery. Verbal fluency is unaffected in both dominant and nondominant resection.

Hemiparesis is an expected effect of hemispherectomy, but focal motor deficits may be seen in focal, lobar, or multilobar resections encroaching upon eloquent cortex. The degree of motor deficit will vary with time, and many deficits improve, suggesting that the cause is reversible, such as edema or ischemia, or that in the longer term some reorganization can take place. In a group (136) of 15 children posthemispherectomy, etiology-specific

differences in reorganization of the remaining cortex were shown. Ambulation is important for independence, and in those undergoing hemispherectomy (137), children who are ambulant prior to surgery continue to remain so after surgery irrespective of developmental and acquired pathologies. In terms of other musculature, they do show slight deterioration in their function within the first few months after surgery, but they usually recover to near the presurgical level of functioning except for finger dexterity and power in the distal upper limb musculature.

Formal discussion with the parents and the child regarding the expected motor, visual, or language deficit will eventually decide the optimum time for surgery. The risk-benefit assessment should be discussed at length before offering surgery. This is particularly true for children with progressive conditions such as Rasmussen encephalitis and Sturge-Weber syndrome.

## BEHAVIORAL AND PSYCHIATRIC OUTCOME

The prevalence of behavioral problems in intractable childhood epilepsy is high (138), and a proportion of these children will enter a surgical program for evaluation. Psychiatric disorder (34) is reported in 29% of children with idiopathic generalized seizures and in 58% of children with seizures and structural brain abnormality. Davies et al (139) showed that the presence of psychiatric disorder and behavioral problems adds to the already significant disability in these children. At times, behavior can be the most challenging aspect of epilepsy management.

Surgery for epilepsy has a variable impact on the psychiatric and behavioral outcome postoperatively. Few of the patients improve, few worsen, and few remain the same, while (140) a further proportion develop new symptoms following surgery for epilepsy (34, 141). Although new symptoms may evolve in previously normal children, it is generally seen that absence of psychiatric disorder preoperatively predicts a good postoperative psychiatric outcome. Thus, epilepsy surgery has a predominantly positive effect on the behavioral outcome in children with intractable epilepsy beginning early in life. Psychiatric and behavioral outcomes in slightly older children are unclear, with variable results, as mentioned previously. Following surgery there appears to be a risk of precipitating new psychiatric disorders with a *Diagnostic and Statistical Manual (DSM) IV* diagnosis in a proportion of these children.

When hemispherectomy was first described by MacKenzie in 1938 and subsequently by Krynau in the 1950s, it was noted that significant improvement in behavior could be achieved. In one study (142) 36 of 50 children had severe behavioral problems that resolved in 54% of the children postsurgery and improved in a

further 40%. White (143), looking at 144 surgeries for infantile hemiplegia and epilepsy, saw behavior improve in 80% of the 108 patients with behavioral dysfunction. Later studies show behavioral difficulty in 33% of children preoperatively, with improvement in all but one child and new symptoms emerging in five children. In the study by Pulsifer et al (124), there was no difference in the pre- and postoperative scores as measured by the Child Behavior Check List (CBCL).

The rate of behavioral disorders in children coming to temporal lobe resection is high (34), with 83% demonstrating a DSM IV diagnosis at any point pre- and postoperatively. Though poor postoperative seizure control heralds a poor outcome in psychiatric symptoms in adults, studies in children fail to confirm this observation, although in the group of McLellan et al (34), 24% of seizure-free children lost the DSM IV diagnosis, whereas only 4% from the poor-seizure-outcome group lost their diagnosis. Szabo et al (141), in their small series of five patients, did not find any significant change between the pre- and postoperative behavior in children with pervasive developmental disorder undergoing temporal lobectomy for the treatment of epilepsy. Whether the natural history of the disorder

may be influenced by early surgery and seizure control remains under debate (144). Lendt et al (145) looked at a cohort of 56 children, with a study group and a control group of 28 children each. The 28 children underwent surgery, and the control group was managed medically. On review of the CBCL scores, there was normalization of behavior in the study group; at the same time, the control group had new emergent behavioral issues. This study highlights the likelihood of impact of surgery on behavioral outcome as opposed to the natural history of the condition.

## CONCLUSIONS

Surgery for epilepsy in childhood can confer considerable benefits, not only with regard to seizure control but also with regard to neurodevelopmental and behavioral outcome. The degree to which the latter can be achieved, however, is difficult to assess in each individual case. Such needs to be considered carefully, and the likely outcome, however uncertain, in all domains should be outlined to the family prior to any final decision. Further prospective data collection is required to enable more accurate preoperative counseling.

## Vagus Nerve Stimulation Therapy in Pediatric Patients: Use and Effectiveness

*James W. Wheless*

**C**hildhood epilepsies are often characterized by a wide range of seizure types and accompanying comorbidities such as mental retardation or developmental delay (MR/DD), autism, and language disorders, often making treatment difficult. However, advances in our understanding of the underlying mechanisms that result in seizures and epilepsy syndromes have also led to advances in epilepsy treatments. Traditionally, the two primary treatment modalities used to control seizures have been mono- and polytherapy with antiepileptic drugs (AEDs) and epilepsy surgery. Among pediatric patients, the ketogenic diet is used among a small number of children.

In 1997, however, the United States (U.S.) Food and Drug Administration (FDA) approved a new, non-pharmacologic treatment—vagus nerve stimulation (VNS) therapy—for adjunctive use among patients aged 12 years and older with partial-onset seizures refractory to standard therapies. Although VNS therapy is not currently approved in the United States for children younger than age 12 years, studies indicate that success with VNS therapy can be achieved independent of patient age and seizure type or syndrome. Reports indicate that VNS therapy may have unique benefits for pediatric patients (aged less than 18 years), including improvements in quality of life resulting from the lack of pharmacologic interactions

known to impair development, and success at reducing seizure frequency and severity among patients with age-related and difficult-to-control syndromes such as Lennox-Gastaut syndrome (LGS). This chapter outlines both the safety and effectiveness of VNS therapy among pediatric patients with epilepsy, as discerned from current treatment practices and reports in the literature.

### THE VAGUS NERVE STIMULATION THERAPY SYSTEM

Vagus nerve stimulation (VNS) was the first nonpharmacologic therapy approved by the FDA for the treatment of seizures. The treatment, which attenuates seizure frequency, severity, and duration by chronic intermittent stimulation of the vagus nerve, is intended for use as an adjunctive treatment with AED therapies. As of March 2006, more than 35,000 patients with epilepsy have been implanted with the VNS therapy system worldwide, with approximately 30% of those patients being younger than age 18 at the time of their first implant. Approximately one-third of patients receiving VNS therapy experience at least a 50% reduction in seizure frequency with no adverse cognitive or systemic effects (1, 2). Moreover, clinical findings indicate that the effectiveness of VNS therapy continues to improve over time (2–8), independent

of changes in AEDs or stimulation parameters (9). Also notable is the fact that tolerance, which is often accompanied by a reduction in efficacy for many treatments, does not appear to be a factor with VNS therapy, even after extended (>10 years) periods of time (2). Response to VNS therapy may be delayed for some patients (8, 10). As a result, the long-term safety and effectiveness seen with this treatment have made VNS therapy a mainstream treatment option for a broad range of epilepsy patients, including children and adolescents. VNS therapy is second only to AED therapy as a treatment category for childhood epilepsy in the United States.

The VNS therapy system consists of the implantable pulse generator and bipolar VNS therapy lead, a programming wand with software, a tunneling tool, and a hand-held magnet. The original systems consisted of the Model 100 and Model 101. However, in June 2002, Cyberonics, Inc. (Houston, Texas), introduced a new generator model, the Model 102 system, which is thinner (6.9 mm), lighter (25 g), and has less volume (52.2 mm in diameter) than the previous models (11). The smaller size of the Model 102 offers children an improved cosmetic appearance and increased comfort. In addition, the Model 102 has a single- rather than a dual-pin lead, making it easier and faster to implant than the previous models. Both the Model 101 and Model 102 are currently being implanted. The average battery life for the generator (Model 101 or 102) is approximately 7 to 10 years with normal use (11). Increases in stimulation intensities or frequency will decrease battery life.

The magnet provided to patients as part of the VNS therapy system allows for on-demand stimulation, which has the potential to abort seizures, either consistently or occasionally, among some patients or caregivers who are able to anticipate the onset of their seizures (12–14). The additional stimulus train that results when the magnet is held over the generator is typically stronger than the programmed stimulus parameters. This added ability of on-demand stimulation provides a greater sense of control for patients and their caregivers over their disorder, which can help improve how they perceive their quality of life. The magnet also allows temporary interruption of stimulation if needed, particularly when singing or playing wind instruments or during speaking engagements. However, stopping the stimulus should be done sparingly and with care, as doing so creates the potential risk of breakthrough seizures.

### Implantation Procedure

The implant surgery is most often performed under general anesthesia and typically lasts about 1 hour (4). The pacemaker-like generator device is generally implanted in the subcutaneous tissues of the upper left pectoral region, with a lead then run from the generator device to the

**FIGURE 64-1**

VNS lead wire prior to placement on the left vagus nerve. Cathode electrode (green suture) placed proximal (right side of picture), then anode electrode (white suture), then anchor tether (green suture; caudal; left side of picture).

left vagus nerve in the neck, where it is attached by a coiled electrode (Figures 64-1, 64-2) (15, 16). Two incisions are made during the procedure: one in the chest to create the generator pocket, and the other along a fold in the neck to expose the vagus nerve for placement of the electrode (Figures 64-3, 64-4). A loop of lead wire is coiled beside the generator to allow for strain relief and patient growth.

**FIGURE 64-2**

Lead wire starting to be placed on the left vagus nerve.

**FIGURE 64-3**

Implantation of the Model 102.

The procedure is well tolerated in both children and adults (17, 18) and is usually performed as outpatient surgery; however, in some cases, patients may be kept in the hospital overnight for observation. The device is often turned on in the operating room or in the office immediately after surgery, generally with a low initial setting of 0.25 mA (Figure 64-5) (19). The programming wand (Figure 64-6) is used at follow-up visits to check and fine-tune the stimulation settings according to patient comfort and level of seizure control. Instructions concerning care of the incision sites, magnet use, and necessary follow-up visits are given to patients and their families before the patient leaves the hospital.

The length of battery life for the VNS generator is dependent on the device model implanted and the stimulation parameters used (20). Often an increase in seizure frequency or intensity suggests clinical end of service (20). Other indications of battery failure include a sudden stop in sensing stimulation or unexpected changes in stimulation. Once a generator reaches end of service, another surgery is required to replace the generator. The entire

generator is replaced rather than just the battery so as to prevent opening the hermetically sealed titanium case of the generator, which could lead to a rejection reaction (21). The generator-replacement surgery typically lasts approximately 10 to 15 minutes and is performed on an outpatient basis. Because the leads remain untouched during a generator replacement, only one incision is needed. Generator replacement is recommended and preferred by patients before the battery is completely depleted so as to prevent an interruption in treatment (20). A 12-year follow-up study showed that multiple device replacement surgeries are well tolerated (2). Often, however, tolerated device currents are lower after reimplantation but are not equated with a reduction in benefit from VNS therapy, which suggests improved battery strength in the newer models of VNS generators; parameter settings other than current are generally the same as with the initial device (20). For patients not obtaining a substantial level of benefit from VNS, it has been suggested that stimulation parameters be tapered down over an extended period of time before end of service to allow for explanation of

**FIGURE 64-4**

Neck incision (right) after final closure with Durabond; chest incision after final closure (bottom left).

the device before clinical signs of generator dysfunction become evident (20).

*Potential Complications.* Although the implant surgery is a relatively simple procedure that is safe and well tolerated by the vast majority of VNS therapy patients, complications can arise. One possible risk resulting from the implant surgery is an infection at the implant site. This risk may be increased in the pediatric population because young children or patients with neurocognitive disorders may tamper with the wound before the incision has had time to heal properly (22–24). Such infections can be treated with antibiotics but typically lead to explantation of the device if antibiotic treatment is not effective or if tampering continues (25, 26). Stimulator pocket infections among the pediatric population have been relatively uncommon, however (25, 27). No infections were observed in a recent study of 36 children aged younger than 18 years who were followed up for an average of 30 months (27).

The routine lead test performed during surgery also has resulted in reports of bradycardia and asystole in a

small number of patients (~0.1%) (28–31). Neither of these cardiac events, however, has occurred after surgery during day-to-day treatment with VNS therapy or in children; these events are usually transient and self-limiting and are rarely of clinical significance (28–31). Vocal cord paresis, although rare, can be caused by manipulation of the vagus nerve during the implant procedure, but such paresis is most often transient (32). On the whole, the surgery required with VNS therapy is much less invasive and generally better tolerated than other traditional epilepsy surgeries. Although side effects associated with the surgery cannot be avoided completely, they can be minimized with a correct technical procedure (27). In addition, the implant surgery is not associated with any performance or cognitive impairments and can be reversed if the treatment is not effective.

*Alternative Generator Placements.* Depending on the circumstances of the patient, alternative generator placements have been reported with successful results. Le et al (22) successfully used an interscapular placement of the generator to reduce the risk of wound tamper-

**FIGURE 64-5**

Intraoperative use of the handheld computer and programming wand to initiate stimulation.

ing among pediatric patients with cognitive delay who may be prone to tampering with the wound. Of the nine patients with an interscapular generator placement, none required explant; no discomfort or changes in daily routine (e.g., sleeping positions) were reported; and the effects of VNS therapy on seizure reduction and quality of life were consistent with the results seen with the traditional generator placement. An infraclavicular placement also has been used for developmentally delayed children, as well as for young women and children with small muscular mass (33, 34). Three children have had a device reimplanted on the right side rather than the left after undergoing explantation of a VNS device owing to infection (35). All three patients had been deriving benefit from the left-sided implant, but reimplantation of another device on the left side was not pursued because of the potential of inflicting nerve damage. The right-sided implantations were effective in once again reducing seizure frequencies, but a difference was noted in the level of seizure control achieved between the right- and left-sided implants. Although right-sided implantations are not recommended by the

device manufacturer because of possible cardiac side effects, no cardiac events presented among these three children; however, two of the three children did experience transient respiratory events.

### **Stimulation Parameters**

VNS therapy “dosing” is defined by five interrelated stimulation parameters (Figure 64-7): output current (measured in mA), signal frequency (Hz), pulse width ( $\mu$ s), signal On time (s), and signal Off time (s/min). The output current, signal frequency, and pulse width define how much energy is delivered to the patient, with the combination of settings for these three parameters being analogous to the size or dose of a pill. The signal On and Off times constitute the duty cycle (i.e., how often the energy is delivered) and are analogous to the dosing schedule for drug therapy. An optimal dose-response relationship for VNS therapy, however, is elusive, in part because of the interindividual variability between patients and in part because of the number of parameters involved in regulating the dose.

FIGURE 64-6

A programming wand is held by the patient over the device while a physician checks and/or adjusts stimulation parameters using a handheld computer.

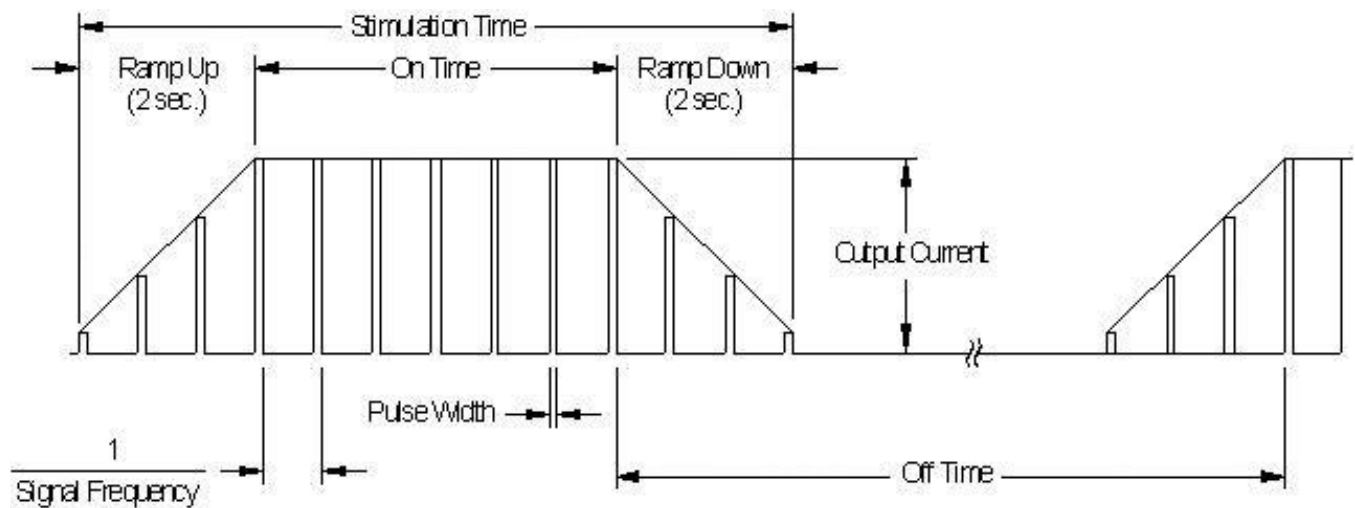

FIGURE 64-7

Stimulation parameters (all duty cycles except low output [ $\leq 10$  Hz]).

**TABLE 64-1**  
*Stimulation Parameter Setting Ranges*

PARAMETER	TYPICAL RANGE	MEDIAN SETTINGS			
		PEDIATRIC ( <i>n</i> = 743)		ADULT ( <i>n</i> = 1,486)	
		3 MONTHS	12 MONTHS	3 MONTHS	12 MONTHS
Output current	0.25–3.5 mA	1.25 mA	1.75 mA	1.00 mA	1.50 mA
Signal frequency	20–30 Hz	30 Hz	30 Hz	30 Hz	30 Hz
Pulse width	250–500 $\mu$ s	500 $\mu$ s	500 $\mu$ s	500 $\mu$ s	250 $\mu$ s
Signal on time	7–270 s	30 s	30 s	30 s	30 s
Signal off time	12 s–180 min	5 min	3 min	5 min	3 min

\*No standard settings have been defined on the basis of patient age or seizure type. The median settings shown here are taken from the VNS therapy patient outcome registry (Cyberonics, Inc; Houston, Texas).

Standard parameter settings, as determined from the clinical trials and outlined by Heck et al (36), range from 20 to 30 Hz at a pulse width of 250 to 500 ms and an output current of 0.25 to 3.5 mA for 30 s On time and 5 min Off time (Table 64-1). Initial stimulation is set at the low end of these ranges and slowly adjusted over time and within the safety limits (Figure 64-8) on the basis of patient tolerance and response. Patients should be closely monitored during the dose adjustment phase

of VNS therapy, typically every 2 to 4 weeks for the first 2 to 8 weeks following generator implantation. Once a patient responds to a tolerated dose, further parameter adjustments are performed only as clinically necessary. However, routine assessment of lead-wire integrity and generator function should be performed.

Response to VNS therapy has been shown to be age dependent and therefore VNS stimulus parameters may need to be adjusted differently for the pediat-

**FIGURE 64-8**

Safety ranges for VNS therapy stimulation parameters.

ric patient (37). Several studies indicate that pediatric patients may require higher output currents (Table 64-1) than those used in adult patients to reach a therapeutic dose (2.0 to 2.5 mA compared with 1.0 to 1.75 mA, respectively), particularly when lower ( $\leq 250$   $\mu$ s) pulse durations are used (33, 36, 38). Additional reports indicate clinically significant responses with low stimulation intensities (1.25 to 1.50 mA) (2, 5, 17). A multicenter, randomized trial looking at device parameter efficacy showed that various duty cycles were equally effective (39). Some reports among children with severe epileptic syndromes showed an increase in seizure frequency and severity at higher output currents (10, 40). Functional magnetic resonance imaging (fMRI) in humans also suggests that pulse width is an important variable in producing brain effects (41). Optimal parameter settings for specific ages and seizure types or syndromes, if they exist, have yet to be defined.

### Mechanisms of Action

The mechanisms of action of VNS therapy are not fully understood, but they are believed to be manifold, owing to the diffuse distribution of vagal afferents throughout the central nervous system, and are distinct from those of traditional AED therapy (42, 43). Studies suggest that altered vagal afferent (not efferent) activities resulting from VNS are responsible for mediating seizures (43, 44). Such altered activities have been recorded in both cerebral hemispheres. Rat studies indicate that VNS activation of the locus coeruleus may be a significant factor for the attenuation of seizures (45–47). Human imaging studies also implicate the thalamus in having an important role in regulating seizure activity (48, 49). The exact antiseizure role of the thalamus is likely to be complex, however, because of the diffuse connections of the thalamus throughout the brain (48). Additionally, the reticular activating system, central autonomic network, limbic system, and noradrenergic projection system all may play a role in the antiseizure mechanisms of VNS therapy (43, 50–53).

Positron emission tomography (PET) imaging studies in humans show that the VNS-induced changes in cerebral blood flow (CBF) and synaptic activity vary over time (53). Widespread alterations in CBF activation during acute VNS was much more restricted after prolonged VNS, indicating that those sites of persisting VNS-induced changes may reflect the antiseizure actions of VNS therapy (53). During chronic VNS, no new sites of CBF alterations that were not also affected acutely were observed (53). Additional human imaging studies using various methods, including functional magnetic resonance imaging (fMRI) and single-photon emission computed tomographic (SPECT) techniques, have produced similar findings in both acute and chronic studies (53). These imaging findings, coupled with the

clinical findings that the effectiveness of VNS therapy continues to improve over time, seem to indicate that rapidly occurring subcortical effects rather than rapidly occurring cortical effects may be more important in the VNS antiseizure mechanism (53). It is believed that rapidly altered intrathalamic synaptic activities as well as other mechanisms likely occurring independently of thalamic activation constitute the therapeutic mechanisms of VNS (53). Electroencephalogram (EEG) observations also suggest that unilateral rather than bilateral abnormalities may show more benefit from VNS (2). Other human studies show that some antiepileptic mechanisms affected by VNS are either modulated by or are the reflection of EEG changes, although the effect of VNS on the EEG background remains uncertain (54). Finally, gamma-aminobutyric acid (GABA) receptor ( $GABA_A$ ) plasticity may contribute to the ability of VNS to modulate the cortical excitability of brain areas associated with epileptogenesis (55). Like medications, many different actions probably contribute to the efficacy of VNS therapy; therefore, determining whether there is a single mechanism that is most important may not be possible.

### Animal Trials

VNS therapy was developed on the basis of early findings of neuroinhibition in the regulation of emesis, and changes in EEG activity resulting from vagal stimulation (56–58). Studies among animals showed that VNS therapy worked both acutely to abort seizures and chronically to control seizures (59, 60). In addition, VNS was effective beyond the period of active stimulation and across a wide range of seizure types and severities, thereby indicating the potential for long-term, phase-dependent seizure control. Tests of VNS therapy in the traditional animal models used to test AED efficacy, including rat, canine, and monkey models (60–64), further indicated that VNS therapy, like AEDs, may be effective for multiple seizure types. The clinical trials that followed proved the safety and efficacy of VNS therapy for controlling seizures, with few and mild side effects that were generally related to stimulation intensities.

A more recent PET imaging study in rats revealed differences between acute and chronic changes in glucose metabolism during VNS, which may reflect cerebral adaptation to VNS (65). These findings are in line with clinical findings and other animal and human studies that show improvements in seizure control and changes in CBF over time (3–5, 65, 66). Other animal studies also have shown that VNS may facilitate the recovery of function following brain damage, both in the rate of recovery and in the final level of performance reached postinjury, as well as enhance memory storage processes (67, 68). This enhancement of neural plasticity is believed to occur by the ability of VNS to enhance norepinephrine release throughout the neuraxis, but further studies are needed to explore the mechanisms

behind these effects more fully (68, 69). Improvements in behavior among rats with induced brain damage also are suggestive of a neuroprotective effect of VNS, which may also help to reduce the behavioral deficits associated with seizures among humans receiving VNS therapy as part of their antiepileptic treatment (67).

## SEIZURE EFFICACY

### Clinical Trials

A series of acute-phase studies with long-term follow-up data proved the safety and efficacy of VNS therapy for the treatment of refractory epilepsy and thereby led to its approval by the FDA in 1997. Results from two randomized, placebo-controlled, double-blind trials (E03 and E05) were pivotal in demonstrating the antiseizure effect of VNS therapy. Patients in the 14-week acute E03 study ( $n = 113$ ) who received therapeutic doses of stimulation (high; 30 Hz, 500  $\mu$ s, up to 3.5 mA for 30 s every 5 min) showed a significantly higher median decrease in seizure frequency of 24.5% compared with only a 6.1% median decrease among patients receiving nontherapeutic levels of stimulation (low; 1 Hz, 130  $\mu$ s,  $\leq$ 3.5 mA for 30 s every 90 min;  $p = 0.01$ ) (70).

Seizure frequency reductions of at least 50% were reported for 31% of patients in the high-stimulation group and for 13% in the low-stimulation group ( $p = 0.02$ ). In the acute E05 study, the median reduction in seizure frequency was 27.9% for the 94 patients in the high-stimulation group and 15.2% for the 102 patients in the low-stimulation group at 3 months ( $p = 0.04$ ) (71).

Long-term follow-up of patients in the acute E03 and E05 studies showed that the effectiveness of VNS therapy was cumulative. After the acute phase of these studies, patients receiving low stimulation had their stimulation levels titrated to therapeutic (high) settings, and all patients were then followed for an additional 12 months of treatment. For the 100 patients in the E03 open-label extension study treated for the additional 12 months, the median reduction in seizure frequency increased to 32% at 12 months from only 20% at 3 months (5). For the 196 patients with evaluable seizure data in the E05 trial, the median reduction in seizure frequency was 45% after an additional 12 months of treatment in the prospective, long-term extension study (4). At this same time point, 35% of patients had at least a 50% reduction in seizure frequency, and 20% had at least a 75% reduction. These seizure frequency reductions were sustained over time.

### Pediatric Outcomes

Although the controlled clinical trials did not focus specifically on the pediatric patient, the children and adolescents

included in one of the five clinical studies (E04) responded at least as favorably as the adults (14, 72). Of the 60 pediatric patients included in the E04 open, prospective study, 16 were younger than age 12 (mean age, 13.5 years). At 3 months, the median reduction in seizure frequency was 23% ( $n = 60$ ); for the 46 patients with follow-up data available at 18 months, the median reduction was 42%. The results, although in a much smaller group, were similar for the patients aged 11 years and younger, indicating that age does not seem to be a factor in the effectiveness of VNS therapy to control seizures. Moreover, data from other pediatric study experiences with VNS therapy indicate that younger patients may have a higher tolerance and more effective response than adult patients (14, 17, 72–75).

The largest study to date to evaluate the effectiveness, tolerability, and safety of VNS therapy among pediatric patients was a six-center, retrospective study of 125 patients aged 18 years or younger (41 patients aged less than 12 years) (19). This study showed greater reductions in seizure frequency than those found in the pediatric subgroup of the E04 clinical trial, with a median reduction in seizure frequency at 3 months of 51.5% (range,  $-100\%$  to  $+312\%$ ;  $n = 95$ ) and 51.0% at 6 months (range,  $-99.9\%$  to  $+100.0\%$ ;  $n = 56$ ). A similar response was reported at 6 months for children aged less than 12 years (median seizure frequency reduction of 51%;  $n = 20$ ). These reductions did not differ between patients with different seizure types.

### Special Patient Populations

Although few prospective or controlled trials have been performed among pediatric epilepsy patients, the number of young patients receiving VNS therapy across the United States and Europe is growing. Observations of pediatric patients with age-related or specialized syndromes receiving VNS therapy indicate that this treatment is safe and effective across a broad range of seizure types and syndromes, independent of age. Table 64-2 (2–5, 7–9, 14, 16, 18, 19, 24, 38, 70–74, 76–85) shows the epilepsy syndromes, seizure types, and associated conditions in which VNS therapy may be helpful. Additionally, VNS therapy also seems to be a palliative treatment option for patients who have failed cranial surgery (Figure 64-9) (83, 86).

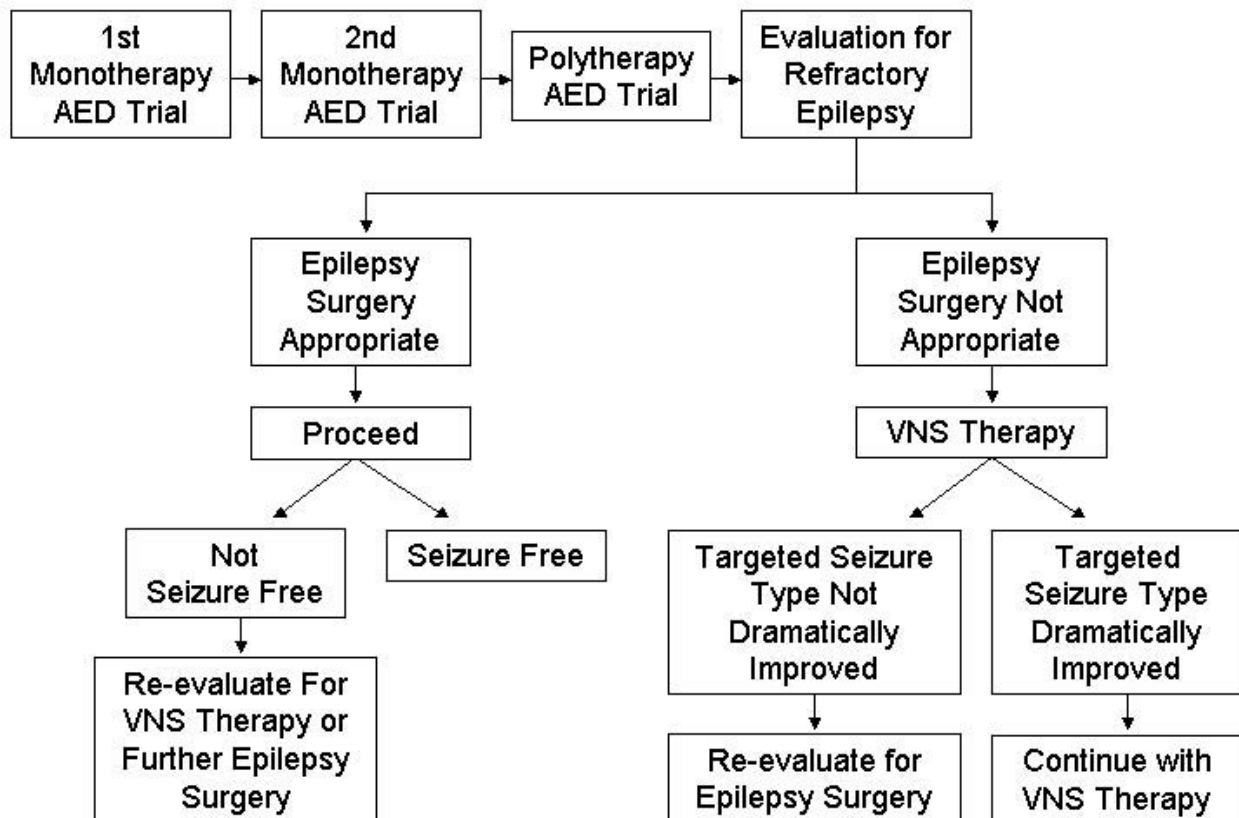

### Lennox-Gastaut Syndrome, Infantile Spasms, and Ring Chromosome 20 Syndrome

Lennox-Gastaut syndrome (LGS) and infantile spasms are rare but difficult-to-treat epileptic disorders. These conditions are also accompanied by neurologic comorbidities that can be exacerbated by the cognitive adverse side effects typically associated with drug therapy. Although

**TABLE 64-2**  
*Epilepsy Syndromes, Seizure Types, and Associated Conditions in which VNS Therapy May Be Helpful*

EPILEPSY SYNDROME, SEIZURE TYPE, AND/OR ASSOCIATED CONDITION	REFERENCES
Simple partial seizures progressing to complex partial seizures or secondary generalization	(2–5, 7–9, 14, 16, 18, 70–72, 74)
Complex partial seizures with or without secondary generalization

Autism with symptomatic epilepsy	(82)
Status epilepticus	(83–85)

### Treatment Sequence for VNS Therapy

**FIGURE 64-9**

Suggested treatment sequence flowchart for patients with epilepsy.

limited data are available for children receiving VNS therapy for the treatment of infantile spasms (87), recent retrospective studies of the efficacy of VNS therapy among patients with LGS have shown some success in reducing seizure frequency without adverse side effects (10, 34, 38, 73, 779).

The largest retrospective study of LGS patients receiving VNS therapy was done by Frost et al (73) on 50 patients from six centers (median age at implant was 13 years; range, 5 to 27 years). This study showed that median reductions in seizure frequency at 1, 3, and 6 months of VNS therapy were 42%, 58.2%, and 57.9%, respectively ( $n = 46$  who had complete seizure data available). Seizure reductions at 6 months by type showed an 88% decrease in drop attacks and an 81% decrease in atypical absence seizures. At 3 months, a 23% decrease was seen in complex partial seizures. In addition, improvements in quality of life with minimal and tolerable side effects from both the surgery and therapy were reported for this patient population. The most notable change in quality of life was an increase in alertness reported for more than half of the patients. Previous corpus callosotomy was not a contraindication for VNS therapy among this patient population, with the five patients who had undergone such surgery showing a 69% reduction in seizure frequency at 6 months. However, the one patient with a previous lobectomy surgery did not show a change in seizure frequency with VNS therapy. Age also was not a contraindication, because those patients aged less than 12 years showed similar response rates to the group as a whole.

A smaller, longer-term study on the behavior of 19 patients with LGS receiving VNS therapy showed no deterioration from baseline in either quality of life or cognitive measures after 24 months of treatment (88). In addition, a positive increase in cognitive measures indicated a gain in mental age of 4.2 months at follow-up. These findings were independent of seizure response to VNS therapy, indicating a potential additional treatment benefit from VNS therapy to patients with LGS. Two-year follow up of 19 children (aged 7 to 18 years) with LGS or Lennox-like types of epilepsy, mental retardation, and multiple seizure types, along with a high seizure frequency, showed that four patients had a seizure frequency reduction of at least 50% (34). One patient remained seizure free 2 years postimplantation. Atypical absence seizures responded better to VNS than other seizure types; moreover, higher baseline seizure frequency, the lowest quantity of interictal epileptic activity, and the highest baseline mental level seemed to predict a higher response rate. A mild improvement in mental age, though modest, and a positive effect on behavior that was independent of seizure control were seen over time. However, unlike some studies that show increased effectiveness over time with VNS therapy,

the duration of treatment in this small study did not appear to increase VNS efficacy among this group of patients.

A case study by Buoni et al (10), however, indicated that the ability of VNS to reduce seizure frequency among patients with LGS may require extended periods of treatment before positive outcomes are observed. A 22-year-old man with LGS reported no reductions in seizure frequency for 1 year of VNS therapy, although improvements in alertness and appetite were achieved. But by 3 years, the patient's seizures abruptly disappeared, and his EEG was borderline normal without any changes in drug therapies or stimulation parameters.

Three separate cases of the use of VNS therapy among patients with ring chromosome 20 have been reported in the literature (40, 89, 90). In 2002, the first report of a girl aged 6 years indicated that VNS may be successfully used to treat the medically refractory generalized clonic epilepsy characteristic of this disorder, which also is marked by developmental delay (90). After receiving VNS therapy, the child became free of seizures and remained seizure free 9 months postimplantation. Moreover, the child was reported to have an increased level of alertness and less lethargy, and, after 4 months of VNS treatment, spontaneous vocalization was reported. The achievement of new developmental milestones after the initiation of VNS therapy was encouraging. A second report of a male implanted with a VNS device at the age of 8 years also showed a good response to VNS therapy (40). Seizures began at the age of 5 years, and the patient was experiencing numerous absence and nocturnal tonic-clonic seizures as well as nonconvulsive status epilepticus at the time of VNS implantation. Following initiation of VNS, seizure frequencies were eventually reduced to only occasional nocturnal episodes and some previously lost skills were reacquired, including ambulation, eye contact, social smiling, and improved mood. The third report was a 14-year-old male with ring chromosome 20 syndrome who was also diagnosed with LGS and experiencing a range of seizure types and severe impairment of cognitive functions. However, he did not show similar results to those reported previously (90). Following implantation of the VNS device at the age of 11 years, the child experienced a 50% reduction in seizure frequency. However, tonic seizures during sleep and secondary generalized seizures continued at a rate of 1 to 3 seizures per day. At age 13 years, a corpus callosotomy was performed with no additional benefit in terms of seizure frequency reduction, but some reduction in seizure severity was achieved. An increase in behavioral problems, fear attacks, and visual hallucinations began after callosotomy. These case reports suggest, therefore, that earlier use of VNS therapy among patients with ring chromosome 20 syndrome may be more beneficial.

### **Mental Retardation/Developmental Delay**

Mental retardation or developmental delay (MR/DD) often co-occur among patients with epilepsy, and the causal relationship between these disorders is complex (91). Both the seizures caused by the epilepsy and the AEDs used to treat the epilepsy are, however, known to potentially exacerbate delays in development, which can complicate treatment among this patient population. The likelihood of additional behavioral and psychiatric disorders, which are estimated to be about sevenfold higher among this population, also further complicates the treatment regimen (91). Moreover, the increased use of polytherapy among this population is indicative of the large number of patients with MR/DD experiencing refractory seizures (92, 93). Therefore, VNS therapy may be an attractive treatment option among patients with developmental and behavioral comorbidities in addition to epilepsy, because VNS therapy may reduce the frequency of seizures without the pharmacologic side effects or interactions of additional drug therapy. Another potential benefit is the fact that VNS therapy is delivered automatically, meaning that compliance and caregiver reliance for treatment are minimized, which is particularly attractive for this patient population because many are unable to care for themselves.

Studies of the effects of VNS therapy among patients with MR/DD show success with VNS therapy (24, 93, 94). A retrospective study by Andriola and Vitale (24) of 21 mildly to severely affected MR/DD patients (age range, 3 to 56 years; 5 patients <16 years) with a range of seizure types and etiologies showed VNS therapy to be both effective and well tolerated. Seventy-one percent (15 of 21) saw some degree of change for the better in seizure frequency or severity. Of the 16 patients who had known pre- and postoperative seizure data available, all of them had some degree of seizure reduction reported, with 11 (68%) having at least a 50% reduction. One patient with secondary generalized seizures became seizure free and remained that way at 3 years postimplant. Improvements also were reported by caregivers for many areas of the patients' functional status, including alertness, mood, and daily task participation. In addition, such improvements were not always associated with decreases in either seizures or AEDs.

Similar findings were found by Gates et al (94) in a retrospective study comparing outcomes of patients receiving VNS therapy living in residential treatment facilities (RTFs) with those not living in RTFs. Despite numerous statistical differences in the demographics and medical histories found between the 86 RTF (age range, 7 to 59 years) and 690 non-RTF (age range, 2 to 79) patients, the 12-month responder rates ( $\geq 50\%$  reduction in seizure frequency) for the two groups were similar at 55% and 56%, respectively. Patients in both groups were

reported to have some degree of improvement in alertness, verbal communication, memory, achievement at school or work, mood, postictal period, and seizure clustering, with more improvements reported at 12 months than at 3 months, thereby indicating a cumulative effect of VNS therapy.

A more recent, prospective study among 40 patients institutionalized with MR/DD and followed for 2 years of VNS therapy confirmed that VNS was an effective treatment option for this population (93). Most patients (34 of 40) had some reduction in seizure frequency. More notable, however, is the fact that this group experienced fewer epilepsy-related hospitalizations after receiving VNS therapy, and postictal recovery periods were reduced among 75% of the patients. Furthermore, the quality of life for these patients was improved by significant improvements at both 1 and 2 years in attention span, word usage, clarity of speech, standing balance, ability to wash dishes, and ability to perform household chores. Other areas of improvement included an increase in their ability to dress themselves, interact with their peers, express themselves nonverbally, and perceive auditory and visual stimuli.

All of these studies to date indicate that VNS therapy was well tolerated and did not introduce the central nervous system or cognitive side effects that commonly occur when a new AED is added to a treatment regimen (24, 93, 94). Reported side effects were minimal and manageable with changes in stimulus parameters. In addition, the surgery was less invasive and thereby more tolerable than other epilepsy surgeries. However, wound tampering can be a potential problem with this patient population. One patient in the Andriola et al (24) study was explanted as a consequence of self-inflicted wound infection. This patient was reimplanted and extra measures (extensive bandages over the implant site and additional barriers) were taken to prevent wound tampering until after the implant incisions had healed. As discussed earlier, a second option to prevent wound tampering would be an interscapular placement of the generator (22).

### **Tuberous Sclerosis Complex, Autism, and Landau-Kleffner Syndrome**

A retrospective, multicenter, open-label study of 10 patients (mean age of 13 years) with tuberous sclerosis complex (TSC) receiving at least 6 months of VNS therapy (with a mean of 22 months) found a high response rate to VNS therapy, with 9 out of 10 patients experiencing at least a 50% reduction in seizure frequency (81). More notably, 5 of the 10 patients experienced a more than 90% reduction in seizure frequency. In addition, three patients were reported to be more alert by their parents and teachers, two were reported to have briefer seizures, and one was reported to have less-intense sei-

zures in addition to the reduction in seizure frequency. A patient diagnosed with an autism spectrum disorder in addition to TSC also was reported to have an 80% reduction in injurious behavior after the start of VNS therapy. These results were not countered by any major complications or side effects. In addition, the high response rate of patients with TSC receiving VNS therapy, compared with patients of similar age and seizure frequencies who were also receiving VNS therapy but did not have TSC, indicated that this patient population may be more responsive to VNS therapy. However, the small number of patients involved in this study was not enough to determine any statistical significance between responses among the TSC and non-TSC groups.

Preliminary data also suggest that VNS therapy may be effective among patients with epilepsy and either autism or Landau-Kleffner syndrome (LKS), which are both childhood disorders known to co-occur with epilepsy (82). Among 6 patients with LKS, 3 experienced a reduction in seizure frequency of at least 50% at 6 months of VNS therapy. Of 59 patients with autism, 58% experienced at least a 50% reduction in seizure frequency at 12 months. More notable, however, were the reported improvements in quality of life, particularly in the area of alertness; 4 of 6 children with LKS and 76% of the children with autism were reported more alert at 6 and 12 months, respectively. Therefore, the benefit of VNS therapy for patients with such disorders may extend beyond or be independent from seizure frequency reductions.

### Hypothalamic Hamartomas

A small study of six pediatric patients ( $\leq 16$  years) with hypothalamic hamartomas and refractory epilepsy indicates that VNS therapy may have the ability to independently improve behavior and, to a lesser extent, decrease seizure frequency or severity in this patient population (95). Three of the six patients experienced some degree of seizure control. However, the immediate and notable improvements in behavior among four of the patients characterized as having severe behavioral problems are of particular interest. Such behavioral improvements were seen independent of seizure control and were dependent on ongoing stimulation. One patient who had the generator turned off for a 2-week period for stereotactic surgery had the injurious and antisocial behavior return in the absence of VNS therapy. Those behaviors once again subsided when stimulation was restarted.

### Status Epilepticus

Four pediatric patients (83, 84) and one adult patient (85) have seen a complete cessation of status epilepticus upon initiation of VNS therapy. As reported in a case report by Winston et al (83), a 13-year-old boy was

implanted with the vagus nerve stimulator 15 days after being admitted to the hospital for pharmacoresistant generalized convulsive status epilepticus. While he was hospitalized, his condition continued to deteriorate despite numerous pharmacologic treatments. The patient also had previously undergone a 90% anterior corpus callosotomy, which had been followed by the return of seizures up to 80% of the preoperative frequency. Immediately following the initiation of stimulation in the operating room, the child's refractory status epilepticus ceased. Over the next year and half, the status epilepticus never reappeared, the rate and severity of seizures significantly decreased with little or no postictal phase, and the patient's neurologic condition, nutritional state, and quality of life all improved.

Another case series presented by Malik et al (94) reports on three children (aged 14 months to 10 years) who also presented with pharmacoresistant status epilepticus and who were emergently implanted with the VNS device. All three children experienced complete resolution of the status epilepticus and continued to have a marked reduction in seizure frequency at their 8-week follow-up visit. The seizure types varied for each of these three patients, with one experiencing atonic, hypomotor, and partial seizures; another atonic, general tonic-clonic, and myoclonic seizures; and the third, multifocal-onset seizures. A 30-year-old man who presented with pharmacoresistant status epilepticus and was placed in a pentobarbital coma also experienced a cessation of seizures and remained seizure free 19 days postimplantation. These preliminary case reports suggest that VNS therapy should be considered as a nonpharmacologic treatment option among children with pharmacoresistant status epilepticus independently of seizure type.

## SAFETY

### Adverse Events

Adverse events reported with VNS therapy are generally transient and mild, and are often related to the duration and intensity of stimulation. Serious adverse events have not been reported with standard therapy, and no patients have died or had a higher mortality risk as a result of VNS therapy (96). The most common adverse events reported during the clinical trials were mild hoarseness or voice alterations, coughing, and paresthesia (primarily at the implant site and decreasing over time) and were not considered clinically significant (4, 18, 70, 71). Other adverse events reported less frequently during these studies include dyspnea, pain, headache, pharyngitis, dyspepsia, nausea, vomiting, fever, infection, depression, and accidental injury (4, 70, 71). Not all of these events were related to VNS therapy. Outside of the clinical trials,

occasional reports of additional adverse events such as shortness of breath (3) and vocal cord paresis (97) have been reported, but did not result in discontinuation of therapy. Many of the side effects initially reported with VNS therapy, such as lower facial weakness and lead breaks, have been resolved. Adverse events associated with the implant surgery are discussed earlier in the chapter in the description of the implantation procedure.

Generally, the side effects associated with VNS therapy are well tolerated and not prohibitive to patients receiving this adjunctive treatment (28). Moreover, many of the side effects tend to diminish or disappear altogether, as patients adjust to the stimulation therapy. If side effects persist or are bothersome to the patient, reductions in stimulation intensity or frequency oftentimes alleviate the side effects, most of which occur only during active stimulation (98). Overall, the mechanisms of action of VNS therapy are different from those of traditional AED therapy and, therefore, produce a unique side effect profile that does not cause the cognitive, sedative, visual, affective, or coordination side effects typically associated with AEDs.

### **Pediatric Safety**

Pediatric patients seem to have a higher tolerance for the treatment. Technical complications (99) and pain at the implant site (17) have been reported among some pediatric patients. However, the smaller and lighter design of the current Model 102 generator has reduced some of these types of complications. Increased salivation (19, 73, 100) and increased hyperactivity (19) have been reported for pediatric patients. Zamponi et al (17) also reported increased salivation and asthenia in one pediatric patient who was switched to rapid-cycling stimulation parameters; these events ceased once standard cycling was resumed. Lundgren et al (100) reported swallowing difficulties among two severely impaired pediatric patients with a history of swallowing difficulties. However, a study of eight patients without a history of swallowing difficulties by Schallert et al (101) showed that VNS therapy did not put patients at an increased risk of aspiration. Overall, the side effects reported for pediatric patients are often mild and transient, and not a contraindication to VNS therapy for this patient population.

### **Device Safety**

Safety features are built into the VNS therapy system to protect patients from stimulation-related nerve injury. The primary safety feature is the “off switch” effect of the magnet. If a patient begins to experience continuous stimulation or uncomfortable side effects as a result of VNS therapy, the magnet can be held or taped over the generator to stop stimulation until the patient can visit the physician. A watchdog timer also is programmed into

the device to monitor the number of pulses a patient receives. If a certain number of pulses is delivered without an Off time, the device will turn itself off to prevent excess stimulation from potentially causing nerve injury.

Procedures such as diathermy and full-body MRI scans, which have the potential to heat the device leads around the vagus nerve and thereby result in either temporary or permanent tissue and nerve damage, are contraindicated among patients receiving VNS therapy. Patients requiring an MRI should have the procedure performed with a head coil, which has been done successfully in VNS therapy patients (102). Of 27 MRI scans performed among 25 patients across 12 centers, 24 scans were performed with the VNS device turned off as recommended by the manufacturer. No stimulation was induced either during these scans or during the three scans performed with the device remaining in the on position. One child (age 11) reported chest pain while experiencing severe claustrophobia during the scan, and one patient had a mild objective voice change lasting several minutes (102). A successful body-coil MRI with the use of an ice pack over the area of the device leads was reported for three patients receiving VNS therapy, but is not recommended by the manufacturer (103). As recommended by the FDA, any instructions for MRI imaging that may be in the labeling for the implant should be followed exactly, and information on the types and/or strengths of MRI equipment that may have been previously tested for interaction with the implanted device should be noted (104). And because leads or portions of leads are sometimes left in the body among patients who have had the pulse generator explanted, it is important to get information regarding previously implanted devices, as the remaining leads could possibly become heated and damage the surrounding tissue (104). A bench study also supported anecdotal evidence that the VNS therapy magnet may inadvertently adjust the settings of programmable shunt valves commonly used to treat hydrocephalus (105). Therefore, physicians should be aware of the possibility of potential device interactions as the development and use of other implantable devices continues to evolve (105).

### **CANDIDATE SELECTION**

Because the mechanisms of action are not well defined, the selection of patients for VNS therapy does not follow a clear set of guidelines. In addition, the clinical trials for VNS therapy could not distinguish any correlation between patient response and seizure type or etiology, age, sex, frequency of seizures, or frequency of interictal spikes on EEG (106) from which to generate any obvious candidate selection criteria. The number of coadministered AEDs or seizure types (78–80) or the type of coadministered AEDs (107) are not predictors of response, either. Therefore, as with AED therapy, there are currently no

markers to predict the success of VNS therapy on a case-by-case basis. The safety and effectiveness of this treatment, achieved without the common adverse side effects associated with traditional AED therapy, and the fact that VNS therapy is reversible if a patient does not respond, make VNS therapy an attractive adjunctive treatment option for patients with refractory epilepsy who are not surgical candidates. VNS therapy is particularly attractive for the pediatric population, given the added benefit of the freedom from compliance issues associated with this therapy (108). Figure 64-9 shows a suggested treatment sequence flowchart that can be helpful in determining which palliative surgical procedures to chose when patients are experiencing refractory seizures.

Patients of any age should be considered for VNS therapy if they experience seizures refractory to other therapies, including AEDs, the ketogenic diet, and epilepsy surgery. Preliminary data suggest that patients treated with VNS therapy earlier in the course of their epilepsy (i.e., when seizures fail to respond to treatment with two or three AEDs within 2 years of epilepsy onset) may have a higher response rate to treatment (109). Early use of VNS therapy in treatment-resistant children would further allow physicians to decrease the negative side effects associated with AED therapy, which are compounded after long-term use and known to hinder development in this population (89, 110). Earlier use may also improve response to VNS therapy among the pediatric population because of a higher degree of neuronal plasticity at an early age that has the potential for permanent damage from long-term epilepsy (78). Earlier use of VNS therapy during the course of pharmacoresistant epilepsy (<6 years) also has been shown to be twice as likely to eliminate seizures than when VNS was initiated among patients who had been experiencing for 6 or more years, which reinforces the view that lesser cumulative seizure loads may improve patients' chances for recovery (111).

Precautions should be taken with patients predisposed to cardiac dysfunction and obstructive sleep apnea (OSA), because stimulation may increase apneic events, and chronic obstructive pulmonary disease may increase the risk of dyspnea (112, 113). A study by Nagarajan et al showed that seven of eight children (aged 4 to 16 years) receiving VNS therapy had respiratory pattern changes during sleep, but these changes were not associated with significant hypoxia or hypercapnia (114). Also, no apnea or hypopnea indexes were in the abnormal range. Although the changes in respiratory patterns during sleep appear to be mild, care should be taken when using VNS therapy among those with sleep apnea syndromes or compromised respiratory function, because vagal afferents influence respiratory control centers (113, 114). Lowering the stimulus frequency or increasing the Off time may prevent exacerbation (112, 114). It is not known whether the effects of VNS on sleep-related breathing diminish over time (113).

The daytime effects of the altered nighttime breathing patterns also are not clear, because VNS has been shown both to facilitate and to inhibit REM sleep (115). A case report by Holmes et al (116) showed that an adult patient began experiencing sleep apneas and arousals associated with the intermittent VNS stimulation patterns, which led to the development of excessive daytime sleepiness. However, reports by Rizzo et al (115, 117) on a broader sample of 10 patients show that sleep modifications induced by VNS therapy among patients with refractory epilepsy actually enhance sleep EEG power, reduce rapid eye movement sleep, and improve daytime alertness. A study by Malow et al (112) among 16 patients receiving VNS therapy also showed an improvement in daytime sleepiness independent of seizure frequency control.

Patients who have undergone a bilateral or left cervical vagotomy are not considered candidates for VNS therapy (11). Evaluation by a cardiologist is recommended for patients with a personal or family history of cardiac dysfunction. If clinically indicated, Holter monitoring and electrocardiograms also should be done before implant.

## COST EFFECTIVENESS

Previous cost analyses for VNS therapy indicate that the initial costs of VNS are offset over time by reductions in health care costs and hospital admissions following implantation (118–121). The reductions in economic burden for both patients and society were seen even among patients with less than a 25% reduction in seizures, indicating that even those without a substantial benefit in terms of seizure frequency reductions receive some benefit from the device (118). Although the efficacy of VNS therapy has been shown to increase over time, a cost analysis study calculated from 18 months before to 18 months after VNS device implantation showed that intensive care unit and ward admissions decreased from the very start of treatment with VNS (118). From a financial standpoint, the economic argument against VNS therapy is weak, particularly considering the potential for meaningful reductions in seizure frequency among patients with refractory epilepsy and the fact that efficacy remains and possibly increases over the long-term (119, 121). Therefore, the decision as to whether to proceed with VNS therapy for a patient population with few options should be made on the basis of clinical judgment rather than short-term costs (119).

## CONCLUSION

VNS is emerging at the forefront of epilepsy treatments as a well-tolerated adjunctive therapy. With its minimal adverse side effects, lack of pharmacokinetic interactions

with drug therapies, negligible compliance issues, residual improvement in quality of life, and improved efficacy over time, VNS therapy may be particularly effective among special patient populations, including pediatric patients and patients with comorbid conditions. Use of VNS therapy, however, must be balanced against the

necessity of surgery, although VNS therapy surgery is well tolerated. As our understanding of what characterizes refractory epilepsy continues to evolve, adjunctive treatments such as VNS therapy will play an increasingly larger role in improving the lives of patients with epilepsy.

## Economics of Pediatric Epilepsy

*Charles E. Begley*

**T**he economic aspects of epilepsy have received considerable attention in recent years. This interest has been generated by the need to contain the cost of medical care, allocate scarce research funds, and justify new therapies and health care services. There are two fundamental types of research on the economics of epilepsy: cost-of-illness and cost-benefit studies.

Cost-of-illness studies attempt to measure the economic burden of epilepsy to society (1). They are used by advocacy groups to promote research and fund services, and by planning and policymaking groups to allocate resources. Such studies measure the amount and distribution of direct cost associated with medical care and social service items, such as drug costs and counseling, and indirect costs from the disability and premature mortality effects of epilepsy, such as lost earnings and productivity. Cost-of-illness studies may also examine the distribution of cost among patients with different types of epilepsy, such as intractable epilepsy versus remitting epilepsy, and in different stages of illness, such as new cases versus prevalent cases.

### **COST OF ILLNESS STUDIES**

In cost-of-illness studies, direct cost includes three broad categories:

1. The cost of medical care, including professional services, laboratory tests, medications, hospital care, medical supplies, and equipment
2. Nonmedical direct cost, including social services and resources related to special education, transportation, and modifications to the residence
3. Imputed costs of patients' and caregivers' time devoted to accessing care or providing care

Indirect costs of illness include the following:

1. Loss of earnings associated with reduced employment
2. Reduced earnings because of illness or reduced productivity on the job
3. The lost value of household production when people are unable to conduct household work
4. The lost earnings because of productive years of life lost from increased mortality attributable to epilepsy; productive years are usually defined as ages 18 through 64; although the pediatric ages are not included, childhood-onset epilepsy may have an impact on the productive years of life as adults

Cost-of-illness studies vary in time perspective. Cross-sectional studies present annual costs for prevalent cases. Longitudinal studies estimate the cost borne throughout

the lifespan for incident cases that occur in a given year. The longitudinal perspective is used to evaluate the long-term effects of a new treatment. For example, to evaluate the economic effects of a new drug, one should estimate the lifetime impact on direct and indirect costs related to relapse seizures, side effects, future employment, and mortality. The cross-sectional perspective is useful for understanding the impact of a change in the healthcare delivery system. For example, the economic impact of managing patients with primary care or specialty physicians can be assessed by comparing the direct and indirect costs of patients in different treatment settings.

### **COST-BENEFIT STUDIES**

In contrast to cost-of-illness studies, which measure the total burden of disease in economic terms, cost-benefit studies are used to evaluate the economic impact of specific interventions in prevention, diagnosis and treatment, or rehabilitation (2). The main objective of cost-benefit studies is to compare specific therapies or systems of health care delivery in terms of their relative benefits and costs. Cost-benefit studies depend on a thorough understanding of the detailed costs of an intervention. In addition, they require data on the outcomes of interventions. The following are examples of cost-benefit questions:

1. A new drug or device is introduced with additional costs, more or less adverse side effects, more or less need for monitoring, but some gain in efficacy. What are the costs and benefits of the new therapy versus the old therapy?
2. In a health care delivery system or network, what is the benefit of a neurologist versus a general practitioner evaluating and treating first-seizure patients and at what additional cost? The cost-benefit evaluation would apply to the accuracy of the diagnostic procedures and resulting patient outcomes, including seizure control and adverse drug affects.
3. What are the costs and benefits of specific tests such as magnetic resonance imaging (MRI) versus computed tomography (CT) scans in improving the accuracy of diagnoses in patients with epilepsy?

Economic studies of epilepsy are methodologically challenging. Cost-of-illness studies face unresolved issues regarding case definition, attribution of costs, and estimation of nonmedical direct and indirect costs. There are standardized methods for conducting cost-benefit studies (3), but data limitations often prevent researchers from following all the recommended procedures. In epilepsy cost-benefit studies lack standardized measures of treatment outcomes.

### **HOW THE COST OF EPILEPSY IS MEASURED**

Because the total direct and indirect costs of illness include many components, one must combine data from several sources to estimate these costs. Direct medical cost typically is determined either from utilization and billing records of patients (4, 5), patient or population surveys (6), or simulated from a disease prognosis models (7, 8). Data collection studies may be prospective or retrospective. Nonmedical direct cost is more difficult to measure but can be obtained for pediatric epilepsy through interviews with caregivers of a representative sample of patients and families. Indirect cost is measured by comparing unemployment rates, lost work due to sick days, reduced productivity at home and at work, and lost work and household production due to premature mortality for people with epilepsy compared with the general population. National age- and sex-specific earnings data, available from the U.S. Bureau of the Census and the Bureau of Labor Statistics, are used to estimate lost earnings. The indirect costs related to differences in employment and wages may have to be inferred from information about the educational achievement of children. Age-specific person years of productive life lost can be determined from studies that measure the excess mortality in individuals with epilepsy.

### **CASE DEFINITION FOR PEDIATRIC COST STUDIES**

Cost-of-illness estimates are strongly influenced by the case definition used. If cases of epilepsy are restricted to patients with recurrent unprovoked seizures that typically are seen in referral centers, then only 1 percent of children will be affected by their eighteenth birthday. However, should single unprovoked seizures, which occur in approximately 0.3 percent of children per year, be included in cost of epilepsy studies? The first seizure, if the patient is identified at that time, is when the major diagnostic workup occurs, and it is a significant direct medical cost. However, many of these children never receive a diagnosis of epilepsy. For this reason, a practical definition would include all cost from the second recognized seizure in the general population.

Cost related to the diagnosis and treatment of febrile convulsions have not been included in the cost of epilepsy. Even though the direct and indirect cost per febrile seizure case usually are low, the large number, four percent of all children, who have such seizures, would greatly increase the pediatric cost of epilepsy if febrile convulsions were included. Approximately 0.5% of all children experience acute symptomatic seizures—seizures related to transient central nervous system insults, the most common of which in children are traumatic brain

injury, encephalitis, and perinatal insults. The cost of these seizures is not included in the cost of epilepsy studies and is more appropriately considered part of the cost of the underlying causes. In addition to children found to have had epilepsy or seizures, there are many who have symptoms suggestive of seizures and incur direct medical cost as a result. Cost of epilepsy studies tend to exclude this sizable population as well.

### SEPARATING THE COST OF EPILEPSY FROM THAT OF OTHER ILLNESSES

Some pediatric epilepsy patients have severe comorbidities, especially cerebral palsy and mental retardation, that contribute to their direct medical and indirect cost because of potential unemployment and excess mortality. If the cost of epilepsy is to be separated from that of other illnesses, one must determine what proportion should be reasonably attributed to epilepsy. In cases of severe neurologic deficits, presumably present from birth (i.e., preceding the epilepsy), only the cost related to the seizure disorder should be attributed to epilepsy. If all the direct and indirect costs in children with severe neurologic deficits and epilepsy are attributed to epilepsy, the total cost of pediatric epilepsy is greatly inflated in the portion of cost incurred by children with neurologic deficit (6).

To avoid this problem, only the direct cost related to the management of seizures in these children should be attributed to epilepsy. Likewise, in cases of postnatal acquired epilepsy—mainly traumatic brain injury, central nervous system infections, and intracranial tumors in children—only those components of direct cost related to seizures should be included. There is a small but, in terms of cost, very important group of children with catastrophic epilepsy of childhood in whom the other disabilities may be a product of epilepsy.

### STUDIES OF THE COST OF EPILEPSY

A number of recent studies have estimated the direct medical care cost of epilepsy in people of all ages (5, 9–12). One study in Italy provided separate cost estimates for children. Table 65-1 indicates a range for annual direct medical care cost of \$126 to almost \$2,000 per person for inactive cases and \$800 to over \$3,000 per year for active cases. The range reflects variation in medical care prices and treatment patterns in epilepsy as well as methodological differences used in the studies. Because of data limitations, most studies do not address the non-medical direct or indirect costs of epilepsy.

Estimates of incidence-based cost come from three studies (13–15) (Table 65-2) and indicate first-year

	\$282 in year 4	\$640 in year 2	\$702 in year 2
	\$254 in year 8		\$471 in year 3
			\$411 in year 4

medical costs ranging from \$917 to over \$3,000 per person and subsequent-year costs 60–70% below first-year cost, reflecting the large number of cases that achieve remission and the lower level of cost for maintenance therapy compared to initial therapy at onset. The most significant cost-driving factor in epilepsy is severity, expressed as seizure frequency. Costs do not appear to vary significantly among different epilepsy syndromes, nor across age groups or by gender.

### THE TOTAL COST OF EPILEPSY

A study was conducted to estimate the total cost of epilepsy in the United States in 1995 (16). A model was constructed that considered the annual number of cases, the variable prognosis of epilepsy for three different groups, the variation in the use of services and medications by prognostic group and time from the diagnosis, and per case estimates of direct cost and indirect cost. The estimated U.S. lifetime cost, based on 1995 incidence cases, was \$11.1 billion; the total annual cost, based on 2.3 million prevalent cases, was \$12.5 billion. Indirect

costs account for 85% of the total and concentrated in people with intractable epilepsy.

The distribution of direct costs of prevalent cases by age and type of epilepsy is presented in Table 65-3 in 1995 dollars. These include the cost of emergency services, inpatient hospitalizations, outpatient visits, diagnostic procedures, laboratory tests, antiepileptic drugs (AEDs), and surgery. The largest direct cost item was AEDs, which accounted for almost 31% of the cost of epilepsy. Hospital admissions were second, accounting for 24% of total costs, and outpatient physician visits were third, with 8% of costs.

### COST-BENEFIT STUDIES OF ANTIEPILEPTIC DRUGS

AED therapy, either monotherapy or polytherapy, is the mainstay of treatment for people with epilepsy. Approximately 60% to 70% of people with epileptic seizures are able to control their seizures quite well with drug therapy. Since 1993, there has been a dramatic increase in the number of new AEDs available in the United States,

Source: Begley 2005 (17).

including felbamate, gabapentin, lamotrigine, levetiracetam, oxcarbazepine, pregabalin, tiagabine, topiramate, and zonisamide.

All second-generation AEDs have been approved as add on therapy for patients with partial epileptic seizures, and three of them have been approved as add-on therapy for patients having generalized epileptic seizures. Most of the second-generation AEDs have been approved for children as well as adults, and four (felbamate, lamotrigine, oxcarbazepine, and topiramate) are approved for monotherapy. Because the new-generation drugs are much more expensive than earlier drugs, the cost-benefit ratio of these agents is a topic of ongoing debate (17) (Table 65-4).

A cost-benefit framework has been applied to evaluate the economic impact of the second-generation AEDs (2). The cost-benefit analysis compares the cost of treatment with one therapy type compared with another intervention, such as a first-generation AED versus a second-generation AED. It then compares the effects, expressed in a clinically relevant outcome measure or patient-based outcome measure, reflecting the benefit of the therapy. To carry out the study in the cost-benefit framework, several versions of analysis can be performed: cost-minimization analysis, cost-effectiveness analysis, and cost-utility analysis. These approaches differ slightly in terms of the data required to perform the economic evaluation of the new therapies.

Cost-benefit studies have compared the first- and second-generation AEDs in monotherapy. These studies indicate that the overall treatment costs for new patients with epilepsy are relatively low compared to the costs of other major chronic diseases. To date, the data also indicate that the first-generation AEDs are more likely to be cost-effective in monotherapy for new patients, but the results are uncertain. The acquisition costs for first-generation AEDs are significantly cheaper, but the cost differences, when considering rates and severity of adverse effects and tolerability, narrow the gap, indicating that payors should take into consideration these treatment cost differences as well as acquisition cost differences (2, 17).

Cost-benefit studies comparing first- and second-generation AEDs as adjunctive therapy illustrate that epilepsy is indeed a costly disorder for people with refractory seizures. They also illustrate that the second-generation AEDs are generally both more effective and more costly as adjunctive therapy—that is, they add cost, but they improve outcomes for refractory patients. Therefore, balancing of the additional cost versus the additional gain or additional benefit of newer AEDs becomes complicated. Patients have fewer adverse effects and drug interactions from the second-generation AEDs, which can significantly lower adverse-effects treatments. Last, second-generation AEDs appeared to be cost effective at a threshold level of about \$40,000 per quality-adjusted life year, which is under the \$50,000 gold standard (17).

Additionally, second-generation AEDs as add-on therapy may be no more expensive than first-generation AEDs as add-on therapy and appear to be cost effective in the long term. This is particularly true when considering the possible reduction in surgical evaluation and surgery. Some second-generation AEDs may be more cost effective than others, and although there are several studies comparing them, the studies are limited and the results are inconclusive (2, 17).

## CONCLUSIONS

The total direct cost of all pediatric epilepsy and unprovoked seizure cases in the United States in 1995 was estimated to be approximately \$230 million, representing 14% of total direct costs for all ages. The cost per case was \$726, but this reflects the cost of cases with inactive as well as active epilepsy. Compared with other

cross-sectional prevalence-based studies, these estimates appear to be conservative. Presumably, this difference is largely due to the inclusion of only those direct costs that can reasonably be attributed to epilepsy rather than comorbidities.

Although the second-generation AEDs tend to be more costly, they also potentially offer cost savings if patients become seizure free, experience fewer adverse effects from their drugs, or require less monitoring of the newer drugs. It appears from the preliminary studies that the second-generation AEDs have most economic value as add-on therapy in refractory patients and therefore need to be carefully evaluated to determine their value as monotherapy in new patients.

## ACKNOWLEDGMENT

The author acknowledges Tom Reynolds and Sharon Coan for their assistance in preparation of this chapter.

## Quality of Life in Children with Epilepsy

*Joan K. Austin  
Nancy Santilli*

**R**ecent changes in health care have led to an increased emphasis on documenting outcomes of care. In childhood epilepsy, the goal of care has traditionally been optimal seizure control. Recently, however, with the increased recognition of the importance of quality-of-life outcomes in the treatment of chronically ill children (1), there has been an impetus to assess the quality of life in children with epilepsy. This chapter provides a general introduction to health-related quality of life (HRQOL) in children and adolescents with epilepsy.

Although references to HRQOL per se are relatively new in the field of pediatric epilepsy, there has been longstanding interest in issues relevant to the quality of life of the child with epilepsy. For example, the emotional, learning, and social problems experienced by children with epilepsy have been a concern to clinicians, and these problems are related to quality of life in these children. Moreover, a clinician's asking "How are you doing?" can be viewed as an attempt, albeit unrefined, to assess quality of life in the clinical setting (2). The recent emphasis on quality-of-life outcomes, however, has led to a need for more formal or systematic approaches to the assessment and treatment of the quality of life of children with epilepsy. A relatively formal approach to HRQOL is the focus in this chapter. Major areas addressed are core domains,

quality-of-life problems, measurement of quality of life in the clinical setting, and clinical interventions.

### HEALTH-RELATED QUALITY OF LIFE

#### Core Domains

Although definitions of health-related quality of life in the literature are inconsistent (3), there is general agreement that it refers to a patient's (and sometimes his or her caregiver's) perceptions of the patient's state of functioning and well-being across multiple areas of concern (4, 5). In children these domains most commonly include those related to physical, psychologic, and social functioning and well-being (4). There also is general consensus that, in the measurement of HRQOL, information should be included that is disease specific or relevant to the child's particular condition and that addresses both the impact of the condition and the effects of treatment. Finally, there is a growing agreement that both subjective perceptions and objective data related to the child's quality of life are important (3, 4). Most studies investigating quality of life in children with epilepsy are consistent with these recommendations in that a multidomain approach is used and information specific to epilepsy is included. For example, Austin and colleagues (6, 7) conceptualized quality of life

around four domains: physical, psychological, social, and school. Information on seizure frequency was included in their measurement of the physical domain (6). In the process of developing a quality-of-life questionnaire for children with epilepsy, Ronen et al used focus groups to identify components of quality of life (8). They conceptualized quality of life in five domains: the epilepsy experience (e.g., how seizures feel), life fulfillment (regular activities), social issues (e.g., stigma), impact of epilepsy (e.g., psychologic), and “attribution” (concerns specific to epilepsy). In a final study Wildrick and colleagues (9) conceptualized quality of life in children with epilepsy in five domains: self-concept, home life (e.g., family relationships), school life, social activities, and medication (e.g., compliance).

For the purposes of this chapter, five domains relevant to health-related quality of life in children with epilepsy are presented in Table 66-1 and described in the next section. The domains presented here are based on the literature on quality of life in epilepsy as well as in other chronic conditions and, although independent, are highly interrelated. The core domains represent a broad-based conceptualization of HRQOL in pediatric epilepsy. The first four domains focus on aspects of child functioning and well-being. Because the family environment is integral to child well-being, the final domain focuses on family adjustment related to the child's epilepsy.

### Epilepsy and Treatment

Assessment in this domain addresses epilepsy-specific information, including neurologic and cognitive functioning and information on the nature of the epilepsy as well as effects of treatment. Information on physical functioning is not generally included in the assessment of quality of life because children with epilepsy should not have physical limitations as a result of their seizure condition. Much of the epilepsy-specific data would be routinely obtained in a clinical setting as a core component of medical care. Assessments made in establishing a diagnosis generally include a complete neurologic examination that provides information about possible neurologic deficits. Moreover, in diagnosing and classifying epileptic syndromes, information on the nature of patients' seizures is collected. Once medications are prescribed, side effects also are regularly assessed. Thus, in the domain of epilepsy and treatment, only the information related to cognitive functioning, such as attention, memory, abstract reasoning, and psychomotor functioning, may not be routinely assessed in all children with epilepsy.

### Psychologic

Two areas are covered in this assessment domain: emotional status and feelings about epilepsy. Emotional status includes common behavioral problems experienced by

**TABLE 66-1**  
*Quality of Life Domains for Pediatric Epilepsy*

#### Epilepsy and Treatment

- Neurologic functioning
- Cognitive functioning
  - Attention, memory, abstract reasoning, psychomotor functioning
- Epilepsy syndrome
- Seizure type, seizure frequency
- Antiepilepsy medication effects
  - Physical, cognitive, and behavioral side effects

#### Psychologic

- Emotional status
  - Happiness and satisfaction
  - Anxiety, depression, behavioral problems, and psychiatric disturbance
  - Self-esteem
- Feelings about epilepsy
  - Concerns and fears
  - Attitude toward having epilepsy
  - Perceptions of stigma

#### Social

- Completion of age-appropriate psychosocial developmental tasks
- Satisfaction with family relationships
- Peer relationships
- Engagement in activities
  - Sports, clubs, hobbies, teams, organizations

#### School

- Academic achievement
- Learning problems
- Adaptive characteristics
  - Works hard, behaves appropriately

#### Family

- Seizure-management skills
- Psychologic adjustment to epilepsy
  - Concerns and fears
  - Attitude toward epilepsy in child
  - Perceptions of stigma
  - Supervision of child's activities
- Leisure activity participation

children who have any chronic physical condition and problems specific to epilepsy. Children with chronic neurologic conditions, such as epilepsy, are more likely to experience emotional problems than are children with non-brain-related physical chronic conditions (10, 11). Therefore, it is critical that this domain include anxiety, depression, behavioral problems, and psychiatric disturbances. Based on Ware's (12) recommendation that the full range of the health state be included in an assessment of quality of life, positive aspects of psychologic well-being (e.g., happiness, satisfaction, and self-esteem) should also be assessed. The second area of this domain relates to the feelings associated with having epilepsy. To what extent are children concerned and fearful about having epilepsy? Do they have negative feelings or a negative attitude about having epilepsy? Do they perceive a stigma associated with epilepsy to the point that it negatively affects their behavior?

### **Social**

Assessment of social functioning and well-being is included because children with neurologic conditions have poorer social competence than children with other chronic conditions (6, 7, 13). An important component of social functioning is the accomplishment of developmental tasks. Because children with epilepsy manifest problems in areas of social competence (14), their assessment is included in this domain. Information on social functioning in both family relationships and peer relationships also is included. The last area included in this domain relates to the child's engagement in age-appropriate activities, including participation in sports, clubs, hobbies, teams, and organizations.

### **School**

Success at school is important precursor of successful employment in adulthood. Functioning at school is especially important to measure in children with epilepsy because they have high rates of learning problems (15), which in some cases predate the onset of epilepsy (16). In addition, these children have poorer academic achievement than would be expected based on intelligence (17) and disproportionately high rates of school failure (18). Because success at school is partially dependent on behaviors such as working hard, school-adaptive characteristics also are included in this domain.

### **Family**

Assessment of the family is important for two major reasons. First, it is the persons in the child's immediate environment who are in a position to exert the most influence on the child's quality of life (19). The family's

adjustment to the epilepsy and the child's psychologic functioning are closely linked. Second, a chronic condition in a child negatively affects the adjustment of other family members, especially the mother (20). Also included in the family domain are factors related to the parents' ability to manage the epilepsy and their psychologic adjustment to the epilepsy. Do parents feel competent in their ability to handle future seizures? Are parents overly concerned and fearful about their child's condition? Are siblings unduly worried? Do family members have an optimistic attitude toward the epilepsy? Are family members unduly concerned about a stigma being associated with epilepsy? Is parents' supervision of the child's activities appropriate for the child's age? Finally, information on the participation of the family in leisure activity is included in this domain because of the importance of such participation in relation to family interaction and cohesion (21). Are family activities being overly restricted because of the epilepsy?

## **QUALITY-OF-LIFE PROBLEMS**

Although a large number of studies have investigated a particular domain of function or well-being in children with epilepsy, far fewer studies have measured multiple quality-of-life domains in this population (22). Austin and colleagues (6) compared differences in four domains of quality of life (physical, psychologic, social, and school) between 136 children with epilepsy and 134 children with asthma age 8 to 13 years. Compared to children with asthma, the children with epilepsy had better functioning in the physical domain and poorer functioning and well-being in the psychologic, social, and school domains. A 4-year follow-up study again comparing quality of life in these same two groups indicated that those with epilepsy were still experiencing a poorer quality of life than those with asthma, even though substantially more of the children with epilepsy had inactive conditions. When the group with epilepsy was grouped by severity (inactive, low severity, and high severity), those with the most severe seizures were faring the worst, especially in the social domain. In the psychologic domain, girls had more anxiety, less happiness, and more negative feelings about having epilepsy than boys did (7). In a Japanese study of the quality of life of children (23), investigators studied quality of life in two environments: home and school. They included the assessment of problems as perceived by the children themselves, by their families, and by their schoolteachers. The children's main concerns were related to medication and seizures. Parents were most concerned about their child's future, their seizures, and their child's school performance. The most common problems the children experienced at school were keeping up with academic work and developing peer friendships.

A review of the literature indicates that functioning in one domain is often related to functioning in other domains. Because information on epilepsy, cognitive, and psychiatric comorbidities is covered in other chapters in this book, the focus here is on the psychologic, social, school, and family quality-of-life domains.

### Psychologic

There is strong evidence that children with epilepsy are at risk for poor psychologic functioning and well-being. Epidemiologic studies indicate that children with epilepsy are up to 4.8 times more likely to have mental health problems than children from the general population (11, 24, 25). Children with epilepsy differ most from normative controls in the areas of internalizing problems (e.g., anxiety or depression), attention problems, and somatic complaints (26). The psychologic problems found in children with epilepsy do not appear to be solely from having a chronic illness, however, because the prevalence rate of problems is higher in children with epilepsy than in children with other chronic conditions (11, 24). For example, Davies et al (25) found that the prevalence of psychiatric disorders among children with uncomplicated epilepsy was approximately 2.5 times higher than among children with diabetes.

Few studies have focused on children's perceptions and coping responses related to having epilepsy. One study investigating the relationship between coping responses and mental health outcomes in youth with epilepsy found that coping responses of competence, optimism, compliance, and seeking support were associated with fewer behavioral problems and a positive self-concept. In contrast, coping responses of irritability, feeling different, and social withdrawal were related to more behavioral problems and a poorer self-concept (27). Austin and Huberty (28) found children's negative attitudes toward epilepsy to be related to poor self-concept and behavioral problems. In another study, children's attitudes or feelings about having epilepsy, an unknown locus of control, and low satisfaction with family relationships were associated with symptoms of depression in youth with epilepsy (29).

Some have hypothesized that mental health problems are caused by underlying neurologic dysfunction that causes both the seizures and the behavioral problems, a hypothesis with some empirical support. Children with epilepsy who also have deficits in neurologic functioning appear to be at an increased risk for mental health problems (30–33). Moreover, the relatively higher rates of psychiatric disorders found in children with chronic conditions involving the brain (10, 11) also provide support for this hypothesis. In addition, studies of children with new-onset seizures found relatively higher rates of behavior problems before the onset of their seizures (34, 35).

For example, in a study of 224 children with a first recognized seizure, approximately 32% of children were in the clinical or at-risk range for behavior problems on a standardized scale (35).

### Social

For optimal social development, children need an environment in which they can develop autonomy and initiative (36). Children with epilepsy have problems with developing independence. For example, Hoare (37) studied child dependency on the mother in four groups: children with newly diagnosed epilepsy, children with chronic epilepsy, children with newly diagnosed diabetes, and children with chronic diabetes. Comparison of these groups with population-based norms indicated that children with either newly diagnosed or chronic epilepsy were more dependent on their mothers in three of four areas. In contrast, no differences were found between the control subjects and children with newly diagnosed diabetes. Finally, children with chronic diabetes differed from norms in only one dependency area.

Studies investigating seizure variables related to social functioning have led to inconsistent results. Austin and colleagues (7) found youth with the most severe epilepsy to be faring the worst socially. In contrast, Camfield and colleagues (18) did not find epilepsy-related variables (e.g., age of onset, seizure type) to be related to social functioning. Furthermore, in that study remission of epilepsy did not predict social functioning.

There is some support in the literature that the social functioning in children might be influenced by parenting behaviors. In an early descriptive study of 12 families, Mulder and Suurmeijer (38) found a relationship between parental control and dependency in children with epilepsy. Long and Moore (39) hypothesized that parents might have different expectations for a child with epilepsy than for a healthy sibling, which might lead to more restrictive parenting practices and subsequently more adaptation problems in the child with epilepsy. In a study of 19 families, Long and Moore (39) found that parents had different expectations for their children with epilepsy than for their healthy children. For example, they expected children with epilepsy to have more emotional problems, to be more unpredictable, and to be more "high-strung" than their siblings. Moreover, in this study parents perceived themselves as being more restrictive in parenting their children with epilepsy than their healthy brothers and sisters. Lothman et al (40) studied parenting behaviors of children with epilepsy through observing mother-child interactions and found praise to be related to child competence and positive affect. In contrast, intrusive and overcontrolling parenting behaviors were related to less autonomy and confidence in these children.

## School

School problems are overrepresented in children with epilepsy. Research comparing academic achievement across different chronic childhood conditions consistently indicates that children with epilepsy are one of the most vulnerable groups. For example, an early comparison study of 270 children with 11 different conditions showed that children with epilepsy, sickle cell disease, or spina bifida were doing the poorest (41). Academic performance in children with epilepsy has consistently been found to be poorer than would be expected by intellectual ability (17). In one study children with uncomplicated epilepsy were, on average, about 1 year delayed in overall reading ability and that approximately 20% demonstrated severe deficits (42). In another study among children with epilepsy and normal intelligence, 39.7% had repeated at least one grade in school (43). When academic achievement on school-administered tests was compared between children with epilepsy and those with asthma, children with epilepsy had significantly lower scores in reading, mathematics, language, and vocabulary (44). In this study boys with the most severe epilepsy fared worst.

The relationship between seizures and academic functioning is unclear. Some studies have found that seizure type and frequency are related to academic achievement (45). In addition, Westbrook and colleagues (46) found that adolescents with mild idiopathic epilepsy had more problems with academic functioning than would be expected. In another study, however, academic underachievement was not related to seizure variables or to medication variables (47). Moreover, newly diagnosed youth with epilepsy who had not been treated already had academic problems, a finding noted by other investigators (16).

Neurologic dysfunction is another potential cause of academic problems in children with epilepsy. It is hypothesized that neurologic deficits lead to cognitive impairments, which in turn lead to academic problems. Even though broad intellectual abilities are stable and normal in the majority of children with epilepsy, these same children often perform below expected levels in the classroom. Although cognitive impairments are related to academic problems, it appears that the family environment can moderate this relationship. For example, cognitive deficits had less of a negative impact on achievement in supportive and organized families than in children with cognitive deficits who lived in unsupportive and disorganized homes (48).

## Family

Few studies have investigated the adjustment of family members of children with epilepsy. Hoare's study of the prevalence of psychiatric disorder in parents and

school-aged siblings of children with either newly diagnosed or chronic epilepsy found that children with newly diagnosed epilepsy were more disturbed than their siblings (49). The siblings' scores, however, did not differ from population norms. In contrast, the siblings of the children with chronic epilepsy were more disturbed than both siblings of children newly diagnosed with epilepsy and population norms. In this study psychiatric disturbance in the child with chronic epilepsy was associated with psychiatric disturbance in their mothers, a relationship that was not present when the child's epilepsy was newly diagnosed. Hoare proposes that chronic epilepsy can lead to stress that can negatively affect the mental health of other family members (49).

Two studies have addressed the concerns of parents whose children have seizures. Ward and Bower (50) studied the parents of 81 children with epilepsy, 30 of whom were newly diagnosed. These parents reported many concerns and fears related to the nature of the seizure, effects of medications, causes of seizures, injury, effects of seizures on intelligence, brain damage, mental health problems, and social problems. Austin and colleagues (51) studied 100 parents of children within 4 months of their first recognized seizure to identify concerns and fears. Concerns and fears focused on two broad areas: epilepsy and treatment (e.g., effect of seizures on the brain, on the child's mental health, and on the child's future life) and management of the epilepsy (e.g., handling future seizures, negative responses of others, lifestyle changes, and preventing mental health problems).

As might be expected based on the high rates of fear, parents have high levels of need for information and help with handling their children's seizure disorder. In a study of the psychosocial care needs of parents of children with seizures, Shore et al (52) found that approximately two-thirds of the mothers still wanted information about their child's seizure condition 6 months after seizure onset. In addition, at the same time 70% still felt the need to discuss their fears about seizures.

It appears that teaching parents about epilepsy can help them parent their children with epilepsy. For example, Suurmeijer (53) found that families imposed fewer restrictions on their child with epilepsy when the parents perceived that the information given to them about their child's condition was adequate. The same investigator reported that parents also indicated that they would more easily accept, be less frightened about, and know better how to deal with the epilepsy if they received adequate information about the condition.

Families of children with epilepsy consistently fare worse than control families in relation to parent-child interaction, maternal negative mood, and overprotection (54). Although fewer studies have explored the relationship between family environment variables and quality-of-life problems in children with epilepsy, most

support a relationship between them, and the most consistent finding is between parent psychologic control and child behavior problems (54). Families of children with epilepsy experience relatively more stress, which has been found to be related to child behavior problems. For example, Pianta and Lothman (55) found family stress to be associated with child behavioral problems even after epilepsy factors and child characteristics were controlled statistically. Finally, the few studies that have explored relationships between family variables and child functioning over time also support a relationship between parenting behaviors and child behavior problems. For example, in a 2-year prospective study an increase in parental emotional support to the child was associated with a decrease in internalizing behavior problems (19).

### MEASURING HEALTH-RELATED QUALITY OF LIFE

Measurement of HRQOL has received less attention in children and adolescents than in adults. One of the reasons instrument development has lagged behind in pediatrics is the changing frame of reference that results from child development and maturation. In deciding how to assess quality of life in children with epilepsy, much depends on the purpose of the assessment. If the goal is research related, measurements should be made that will answer the research questions in the most valid and reliable manner. In a clinical trial, measurement would be targeted to the specific quality-of-life domains most likely to be affected by the treatment under study.

When HRQOL is assessed in the clinical setting, the goal is to select the method that provides the best data to guide treatment decisions. It is these decisions that are the focus of the issues addressed here. The two most common methods used in the clinical setting are structured interview and self-report questionnaire. Advantages of the interview are that the interviewer is available to explain things that are not clear, to answer questions, and to make sure that all questions are answered. Interviews can be conducted either in person or by telephone. Information on quality of life can also be part of the clinician's history taking. Advantages of using self-report questionnaires are scheduling flexibility because an interviewer is not needed. Disadvantages include questions being skipped and the lack of opportunity for children and families to ask questions when something is unclear.

The information that follows focuses on issues related to the use of self-report questionnaires in the clinical setting. When using any instrument, it is important that it be in the respondent's native tongue and be culturally relevant. Criteria for evaluating instruments, practical considerations, selection of respondents, and selection of scales are addressed.

### Selecting Instruments

Criteria for selecting instruments to measure quality of life depend on the conceptualization of health-related quality of life as well the quality of the scale. A good instrument would be conceptually strong in that it would have a sound theoretical underpinning (56) and the domains measured would be consistent with the purpose for doing the assessment. A good instrument should also have robust psychometric properties and meet clinical standards.

Two important psychometric properties are reliability and validity. Reliability refers to the consistency or the extent to which a measuring instrument yields similar results over repeated administrations. Stability reliability is consistency over time, and internal consistency reliability refers to the homogeneity of the items measuring the concept. Validity, which is the extent to which an instrument measures what it is supposed to measure, is commonly of three types: content validity, criterion validity, and construct validity. Content validity answers the question "Do the items measure what they are supposed to?" Criterion validity refers to the extent that the score on an instrument is systematically related to some external criterion. Construct validity refers to the extent that scores on an instrument are logically related to other measures.

An instrument that meets clinical standards differentiates between different levels of severity within the condition. Recently, there has been an emphasis on the extent to which a scale is sensitive or responsive to change. The term *responsiveness* refers to the instrument's ability to detect clinical change over time (57). An instrument must be able to detect even small improvements in a condition if it is going to be used to show effects of treatment.

### Practical Considerations

There also are practical considerations when selecting instruments. Length of time that is required for collecting information must be considered, because time is especially important in the clinical setting. Are the instruments easily administered in the clinical setting? Are there norms based on age and gender? Because of the large differences that occur at various ages, one must use well-developed scales with norms based on age of the child. In addition, because of the different trajectories of boys and girls at different ages, the scales must have norms based on gender.

The complexity of the scoring also is an important practical consideration. Clinical staff may need to assist children and families to complete the instruments. The staff must use instruments that are easily scored and interpreted so the information can be used immediately. Unfortunately, most scales that can be used for a wide age

range because they have norms for age and gender also have complex scoring; however, most of these scales have computer scoring programs that are easy to use.

Staff cooperation and training and an infrastructure for collecting data, scoring instruments, and incorporating the information into treatment are necessary. The assessment must take place in a manner that best fits with the clinical practice. Will children and families be asked to complete instruments before, during, or after clinical visits? More time is available for completion of scales if they are done outside the clinical setting before the clinic visit. The instrument can be sent out with an appointment reminder for the family to bring to the visit. When there is only a short period of time available for measurement or completing a questionnaire (e.g., while in the waiting room), decisions must be made whether to do a comprehensive assessment on a few HRQOL areas or screen in all areas, or a combination of the two. Other questions that must be considered relate to frequency

and timing of assessment. Will all children be screened at every visit? Will more complete assessments be carried out on new patients? Will children who show problems have additional testing? Will different domains be targeted for different age groups? An assessment of HRQOL could also be triggered by critical events that occur in the child's life such as age-related changes (e.g., beginning school, transition into adolescence), health-related changes (e.g., seizures increase, medication change), and social changes (e.g., new school, parent divorce, new sibling).

### Selection of Respondent

An important decision focuses on who should provide the data. Generally, it is ideal to obtain data from multiple sources (e.g., parents, children, and teachers). According to Landraf and Abetz (57), children as young as 5 years can provide reliable information on very concrete concepts such as pain. Austin and colleagues have

**TABLE 66-2**  
*Sample Instruments to Measure Quality of Life in Childhood Epilepsy*

GENERIC SCALES	
Child Health Questionnaire (61)	A generic scale for children ages 5 and older. There are three parent-completed versions of differing lengths that measure 14 concepts and one child-completed version with 12 concepts. The scale has good psychometric properties and norms.
PedsQL™ (62)	A generic scale for children ages 2–18 years. There are child self-report and parent-completed versions that measure physical, mental, social, and school domains. It has a family impact module. The scale showed responsiveness to clinical change over time.
EPILEPSY SCALES	
Quality of Life in Epilepsy—Adolescent (63)	A general epilepsy scale for adolescents 11 to 17 years. The scale has 48 items that measure effects of epilepsy and medicine, stigma, feelings about self, and general HRQOL concepts of family, friends, activities, mood, cognition, and memory.
Health-Related Quality of Life (HRQOL) in Children with Epilepsy (64)	A general epilepsy scale for children ages 8–15 years. There are child-report and parent-completed versions. The 25-item scale evaluates five child domains (social, worries, emotional, secrecy, and normality) and five parent domains (Interpersonal/social, future worries, recent worries, and intrapersonal/emotional, secrecy).

**TABLE 66-3**  
**Questions to Assess HRQOL in the Clinical Setting**

---

**ASSESSMENT QUESTIONS FOR PARENTS**

---

*Epilepsy and treatment*

What concerns do you have about your child's seizure condition or treatment?

What concerns do you have about handling your child's seizures?

*Psychologic*

What concerns do you have about your child's ability to cope with seizures?

Do you think your child is unduly worried or sad about having seizures?

*Social*

Compared to other children, how well does your child get along with others?

Compared to other children, how involved in activities is your child?

*School*

What concerns do you have about handling your child's seizures at school?

Is your child having any learning problems with school?

*Family*

Are any members of your family having problems coping with the seizures?

Is your family avoiding doing any leisure activities because of the seizures?

---

**ASSESSMENT QUESTIONS FOR OLDER CHILDREN AND ADOLESCENTS**

---

*Epilepsy and treatment*

What questions do you have about your seizure condition?

What questions do you have about your medication?

*Psychologic*

Have you been feeling sad or down in the dumps about having seizures?

What kinds of things worry you about having seizures?

*Social*

How well do you get along with other kids your age?

What things are you not doing because of worry about seizures?

*School*

Do you feel you have to work harder on school work than other kids?

Are you having any trouble paying attention in school?

*Family*

Do your brothers and sisters treat you differently because of the seizures?

Do your parents treat you differently because of the seizures?

---

HRQOL, Health-related quality of life.

obtained reliable information on abstract concepts from children with epilepsy as young as 8 years of age (27, 28). As a general rule, parents should provide most of the information when the children are younger than 7 years old. Even for older children, the decision about who should provide information is not an easy one. Cognitive development and the ability to understand abstract concepts must be considered. Children who have had seizures from a very young age may not be able conceptualize what life would be without epilepsy and would have trouble answering questions about their life compared with the best possible life.

When data are collected from different categories of respondents, a number of factors must be considered when interpreting results. For example, mothers tend to report more problems in children than do fathers (57). Moreover, children's ratings of certain areas consistently differ from those of their parents. There tends to be more agreement on concepts related to physical functioning (e.g., activities and chores) and less agreement on behavioral or mental health functioning. For example, adolescents with epilepsy rated themselves to have fewer behavioral problems than their mothers, fathers, and teachers did (58). Parents' reports on children's mental health problems are more valid than children's reports (59). However, the fact that parents, children, and teachers rate things differently does not mean that one viewpoint is better than the other, just that they provide different perspectives. Some information is available only from the child. It also is important to consider that only children can report their emotional feelings, so if this information is desired, it must be obtained from children.

### Selection of Scales

In a comprehensive assessment of HRQOL done for research purposes, it is important to use both general and disease-specific scales (60). General scales allow comparisons across samples, although a disadvantage of using these scales is that they often contain questions irrelevant for epilepsy. Disease-specific scales generate data that can be compared with other samples of children with epilepsy.

In the clinical setting, instruments should be selected that will provide the best data to guide treatment decisions. Foremost, the clinician must consider what to do with the information once it has been collected. For example, a screening survey could be administered first and then followed with more specific information on areas in which problems are identified.

### CLINICAL APPLICATION OF HRQOL ASSESSMENT

Incorporating HRQOL information into the clinical care of children with epilepsy can improve the quality of care provided. Therefore, it is critical that a strategy for HRQOL assessment be developed that can be incorporated into the office routine efficiently. Assessments can identify children who are at risk for problems so that interventions can be initiated at the earliest opportunity. Assessments also can improve clinical decision making by increasing the clinician's understanding of the quality-of-life problems experienced by children with epilepsy and their families. Finally, information from assessment of HRQOL over time can be used to document treatment outcomes (61–64). Table 66-2 describes a few of the available instruments that could be used to measure quality of life.

An alternative to using a formal HRQOL assessment instrument is to ask patients open-ended questions about their care. Table 66-3 includes questions that help to elicit information about quality-of-life issues in the clinical setting.

In the treatment of a chronic condition such as childhood epilepsy, the clinician must be concerned not only about controlling seizures but also about preventing adverse consequences of the condition and optimizing the child's functioning and well-being. When the outcome is narrowly conceptualized to be optimal seizure control, care is based on assessment of seizures and treatment to reduce seizures. When the outcome is conceptualized to include the child's quality of life, it will result in comprehensive care and improved quality-of-life outcomes in the child.

## Epilepsy, Cerebral Palsy, and IQ

*W. Edwin Dodson*

**I**n all cultures children with epilepsy exhibit a disproportionately high share of problems with learning and behavior and are at risk to have poor social outcomes (1–10). As a group, children with epilepsy have an average IQ that is 10 points below normal, resulting in a threefold increased risk of mental retardation (2, 11) (Figure 67-1). Even those children who are not retarded are at increased risk for academic underachievement or school failure and maladjustment in later life (3, 8, 12–14). In one study of Finnish children with epilepsy there was a more than 20-fold increased risk of mental retardation or other handicap (15). Pazzaglia and Frank-Pazzaglia (16) found that among children with epilepsy in Cesena, Italy, only half had normal scholastic records, one-third were in special classes, and 17% were one or more grades behind. Behaviorally, children with epilepsy have an increased risk of psychopathology (10, 17, 18). They also are at risk of being described as fidgety, restless, irritable, inattentive, not liked, worrisome, solitary, disobedient, fussy, or destructive, and they are more likely to tell lies and fight with other children (19). They are also more likely to have temper tantrums, tics, sleep difficulties, poor appetite, loss of bowel control, lisping, stuttering, and headaches.

The specific components of cognitive function that account for the problems of patients with epilepsy are

multiple and not well defined. Studies in children with epilepsy who were not taking medications suggest that perceptual problems and attention are major factors that antedate the onset of both seizures and treatment (20–22). In adults with intractable seizures, verbal and comprehension problems contribute more to variability in their IQs than attention or perceptual issues (23).

Academic underachievement is more prevalent in boys than in girls, a trend that persists among children with epilepsy. In the study summarized in Table 67-1, boys did worse in spelling than girls. Many factors were associated with underachievement in arithmetic. These included older age, generalized versus partial seizures, an earlier age of onset, and more seizures.

It is often difficult to determine the cause when children with epilepsy have academic or behavioral complaints. Parents and teachers tend to blame the epilepsy or the medication for the child's every imperfection. Isolating a cause is always complicated because numerous factors affect learning and behavior simultaneously. These factors include temperament, intrinsic developmental capability, associated brain disease, parent-child interactions, socioeconomic level, seizures, and medication-induced side effects. Some investigators have emphasized the importance of epilepsy or uncontrolled seizures, whereas others have highlighted the importance of other factors, especially drug therapy (24, 25)

FIGURE 67-1

Frequency distribution of IQ in normal children and children with epilepsy. Adapted from Ellenberg et al (11).

(see Chapter 69). Relatively few studies have considered the confounding effects of socioeconomic level. Among the many factors that influence academic achievement in the population overall, socioeconomic status has the most pervasive influence (26, 27). Low socioeconomic status has also been linked to an increased incidence of medical conditions such as cerebral palsy and psychiatric disorders (28, 29).

Do seizures and epilepsy impair global intellectual ability? Usually they do not, but there are rare instances in which high seizure frequency is clearly linked to the stagnation of development and cognitive decline (30–33). Furthermore, children seem to be more vulnerable than adults to developing this consequence (34). A majority of children with epilepsy develop normally and enjoy normal cognitive ability. Aside from immediate ictal and postictal interruptions of awareness, seizures usually do not impair cognition permanently. Relationships between

seizures, motor handicap, and intellectual impairment can, however, be complex. Overall etiology has the most powerful effect on intellectual outcome, but other seizure-related variables are influential as well. And, there are conditions in which childhood epilepsy and cognitive impairment progress simultaneously to result in permanent encephalopathy.

In exploring the relationship between epilepsy and cognitive function, a sequential approach helps to clarify the issues. First, factors that are not related to epilepsy are considered. Next, epilepsy-related factors such as etiology, comorbid conditions, seizure type, frequency, age of onset, and duration are discussed. Not discussed here are degenerative disorders in which neurologic deterioration is the primary feature and cognitive effects of drug treatment. Throughout this chapter it helps to remember that seizures, like mental retardation and cerebral palsy, are symptoms of abnormal brain function.

TERMINOLOGY AND DEFINITIONS

The intelligence quotient (IQ) has been defined as an individual’s mental age divided by chronological age times 100. In determining the IQ, many tests such as the Wechsler Adult Intelligence Scale (WAIS) do not require the actual calculation of a mental age but instead determine IQ based on standardized scale scores. The IQ is normally distributed in the general population with a mean of 100 and a standard deviation of 15 (Figure 67-2). Thus by definition, approximately 2.3% of the population has an IQ that is equal to or less than 70, the IQ value that is 2 standard deviations (SD) below the mean.

TABLE 67-1 Academic Achievement Among Children with Epilepsy		
WRAT SUBTEST	PERCENT UNDERACHIEVING	
	BOYS	GIRLS
Word recognition	10.5	10.1
Spelling	33.3	15.9
Arithmetic	28.1	31.9
Reading comprehension	22.8	13.0

FIGURE 67-2

The distribution of IQ scores showing standard deviations and percent of the population in each group.

Most investigators who have studied the relationship between epilepsy and IQ report IQ values as group means and standard deviations. In these situations it is important to translate these values into terms that allow one to discern the magnitude of increased risk of mental retardation that is shared by group members. For example, if a particular group has an IQ of 90 with a standard deviation of 20, 16.5% of those groups are expected to have an IQ of 70 or less. In this example, even though most group members have normal intellect, the risk of mental retardation is increased sevenfold among group members. Although groups of patients with epilepsy who have been studied with IQ measurements do not necessarily have normally distributed values, for purposes of comparison in this chapter I have assumed that all group values are distributed normally.

The term *mental retardation* implies that an individual's global intellect and adaptation to the problems of living are defective and that these abnormalities have been present during development. Note that this definition encompasses more than an IQ criterion. However, the IQ score is one dimension of adaptive ability that is measured objectively, and it predicts academic performance. The IQ score also carries heavy weight in the diagnosis of mental retardation. Thus, for purposes of this chapter, an IQ score of 70 or less is considered to indicate mental retardation. Although this simplified approach has been adopted here for heuristic purposes, other dysfunctions such as learning disabilities, attention disorders, and disorders of language and communication all can have major adverse effects on learning, development, and socialization (35, 36).

Developmental disabilities are legally defined on a state-by-state basis. Nonetheless, federal legislation defined the condition as functional limitation in three or more major life activities. The major categories of activities include self-care, understanding and use of language, learning, mobility, self-direction, and capacity for independent living (37). The diagnosis of being developmentally disabled has important consequences because it may qualify the child for important educational and rehabilitative benefits. Although disabled children between the ages of 3 and 20 years have federal guarantees of access to educational and rehabilitative services, the authority to determine eligibility and the responsibility for providing services is vested in the states. Disability determinations are not categorical by diagnosis but rather depend on the child's functional ability (see Chapter 68). Thus, seizures may or may not be handicapping depending on their frequency, severity, and time of occurrence.

Cerebral palsy is a group of nonprogressive motor impairment syndromes secondary to lesions or brain abnormalities that arise early in development. The prevalence is 1.5–2.5 per 1,000 live births. The most common forms of cerebral palsy include hemiplegia (right side

twice as frequent as left), spastic diplegia, and spastic quadriplegia. Less common forms include ataxic and athetoid disorders. Cerebral palsy, mental retardation, and epilepsy are often simultaneous manifestations of diffuse brain lesions that were acquired prenatally. The prevalence of various clinical patterns of cerebral palsy has changed, with more cases of spastic diplegia and fewer cases of spastic tetraplegia (quadriplegia). As a result of improvements in obstetrical and neonatal medicine, fewer full-term newborns suffer hypoxic ischemic encephalopathy, and more extremely low-birth-weight premature newborns survive hypoxic ischemic injury. If the latter children develop motor and other neurologic consequences of their encephalopathy, they generally have spastic diplegia and mental retardation, but they are less likely to have epilepsy than are full-term newborns who develop tetraplegia (38, 39).

Definitions of learning disability vary depending on the source, but generally the term implies that an individual's actual performance on measures of academic skills such as reading or arithmetic is substantially inferior to what would be predicted from that individual's global cognitive ability measured by the IQ. Most investigators designate an individual as learning disabled when that individual's IQ and measured academic skills differ by 1 SD or more. School systems in the United States have more complex definitions of learning disability, such that individuals with lower IQ scores require less statistical discrepancy between IQ and measures of scholastic skills to qualify for special remedial help than do individuals with normal or above-average IQ scores.

Studies of learning disabilities are more difficult to compare than studies of global cognitive ability because of the many issues that are involved in learning disabilities, including inconsistent definitions of the condition (40, 41). In studying learning disabilities, various investigators have different theoretical orientations and use different technical approaches. Although the role of factors such as strategic orientation, cognitive style, and motivation have been emphasized in the past, current theory points to defective auditory processing as the seminal abnormality in dyslexia, the most common learning disability (42).

In this chapter the focus will be on IQ scores. Similarly, cognitive functioning is emphasized more than behavior here, because the studies are more homogeneous and allow conclusions to be drawn.

## NON-EPILEPSY-RELATED VARIABLES

Associated disease and social class are important background factors that interact with epilepsy and with antiepileptic therapy to influence behavior and cognitive ability (26, 27). Although many variables affect IQ, most of the determinants of IQ cannot be defined in large-scale

investigations. In these types of studies, the largest determinant of IQ is socioeconomic class.

### Socioeconomic Status

The National Collaborative Perinatal Project (NCPP) evaluated the relationship between various health-related and social factors and IQ measured at age 7 years. Overall, the strongest determinants of intellect were socioeconomic class and related variables such as maternal education. However, considering all predictor variables, the investigators could account for only 25% to 28% of the variance in IQ among whites and 15% to 17% among blacks (43). The highest correlation ( $r = 0.38$ ) was found between socioeconomic index and IQ. This value yields a coefficient of determination of approximately 8%—indicating that 8% of the variability in IQ is linked to socioeconomic class. The correlation between the mother's nonverbal IQ and the child's IQ was lower ( $r = 0.28$ ). The effects of socioeconomic factors are manifest in various ways. For example, 20.2% of children from families in the lowest socioeconomic class failed a test of language comprehension at age 8 years, compared to only a 2% failure rate for those from the highest social class (43).

Studies of epilepsy and IQ from diverse cultures that considered socioeconomic variables have confirmed that the influence of socioeconomic class on IQ is universal (44). Socioeconomic factors also influence many of the determinants and etiologies of epilepsy, cerebral palsy, and mental handicap, with children from the lowest socioeconomic groups faring worst in every outcome (15, 28, 29). Furthermore, sociocultural context plays a major role in the attitudes and behaviors about epilepsy (29, 45) and in the accessibility of educational and treatment opportunities for children challenged by handicaps (46).

The nature and quality of the parent-child interaction is also an important contributor to the child's cognitive development and behavior. Whereas seizure-related variables heavily influence medical outcome, sociocultural differences and the quality of the parent-child interactions exert enduring and pervasive effects on the child's behavioral outcome and statistically have a more far-reaching influence than disease-related factors (45, 47). Furthermore, even after seizures are controlled, flawed early psychosocial development can continue to thwart the maturation of skills necessary for productive, independent functioning (48). Having a child with epilepsy in the family increases the risk of maternal depression, lowers quality of the parent-child relationship, and promotes dissatisfaction with family relationships (18, 46).

### Epilepsy-Related Variables and IQ

The most fundamental elements of neurologic diagnosis are etiologic and anatomic. Where is the lesion, and

what caused it? Thus, it is not surprising that the etiology of a child's epilepsy predicts cognitive functioning best. Unfortunately, in a majority of children with epilepsy the etiology cannot be identified. As a result, the best diagnosis that can be made is usually descriptive, descriptive in terms of the child's seizure type(s) or type of epilepsy or epileptic syndrome. When the diagnosis is predominantly rooted in descriptive phenotypic features of the condition—that is, by seizure type or by epileptic syndrome—the relationship between epileptic variables and IQ is less predictable. Classification by seizure type is the least informative level of descriptive diagnosis. Diagnosis by type of epilepsy or epileptic syndromes provides a more complete description of the disorder and relationships between epileptic variables and IQ are more predictable. In fact, encephalopathy is a criterion for some syndromic categorizations.

### SPECIFIC ETIOLOGIES

When the etiology is identified, the relationship between the epilepsy and intellect is usually clear cut. Among all epilepsy-related variables, the etiology of the epilepsy has the most pervasive effect on cognitive ability (Table 67-2).

**TABLE 67-2**  
*Examples of Etiologies of Symptomatic Epilepsy that also Affect Global Cognitive Function*

Perinatal asphyxia
Symptomatic neonatal hypoglycemia
Neurocutaneous disorders
Tuberous sclerosis

Hypomelanosis of Ito
Chromosomal disorders
Down syndrome
Fragile X syndrome
Microdeletion syndromes
Angelman's syndrome
Prader-Willi syndrome
Inborn errors of metabolism (untreated)
Ion channel disorders
Severe myoclonic epilepsy of infancy (SCNA1 channelopathy)
Rett's syndrome
Progressive myoclonus epilepsies
Unverricht-Lundborg disease
Lafora body disease
Northern epilepsy syndrome
CNS infections
Meningitis
Encephalitis
Human immunodeficiency virus
Subacute sclerosing panencephalitis (SSPE)

**TABLE 67-3**  
*Effect of Epilepsy on IQ at Age 7 years from the National Collaborative Perinatal Project (11)*

	EPILEPSY			CONTROLS		
	<i>n</i>	IQ	(SD)	<i>n</i>	IQ	(SD)
All children	368	90.0	(13)	NA	102.9	(13)
Sibling comparison	98	91.5	(20.9)	98	95.3	(15.1)
Normal early evaluation	59	99.8	(14.9)	59	98.0	(13)

Values shown are means and standard deviations.

In most cases where people with epilepsy are impaired intellectually or behaviorally, underlying brain disease, not recurrent seizures, is the major contributor to the difficulties.

Studies from the NCPP and from many other sources indicate that associated brain disease, not seizures, is the most important contributor to subnormal intellect among children with epilepsy (20). In population-based studies of epilepsy and IQ there is no evidence that epilepsy causes intellectual deficit. Rather, the antecedent conditions that cause epilepsy are associated with lowered group IQ. Among youngsters who began to have seizures between the ages of 4 and 7 years, the group IQ was similar to that of well-matched controls (11) (Table 67-3). By and large, the appearance of seizures in otherwise normal children does not predict reduced IQ.

In comparison to patients with idiopathic epilepsy, patients with symptomatic epilepsy have lower IQs. For example, in a prospective study of children with new-onset epilepsy, the mean IQ for the symptomatic group was 89.1 (SD 29.6) compared to 102.5 (SD 16.1) for the idiopathic group (45) (Figure 67-3). Differences of

**FIGURE 67-3**

IQ distributions for people affected by disorders associated with epilepsy. Developed from information in the publication by Broman et al (43).

this magnitude lead to approximately a 10-fold increased chance of mental retardation among children with symptomatic epilepsy (25.8% vs. 2.3%).

Symptomatic epilepsy due to a cerebral lesion heightens the chance of cognitive impairment even when the cause or precise extent of the lesion is unknown (49, 50). In a sample where 70% of children had symptomatic or presumed symptomatic (cryptogenic) epilepsy, 76% experienced learning problems including more than half of those with normal IQs. Factors that were linked to mental retardation were cerebral palsy, seizure onset before age 6 years, and lack of response to early drug treatment (51). Furthermore, the impact of structural brain abnormalities varies with the location of the lesion and the timing of its intrusion on brain circuitry as well as the intensity and frequency of the seizures that the lesion causes.

Brain malformations are prone to cause both epilepsy and mental impairment. Malformations range from being subtle and localized in the case of focal cortical dysplasia to pervasive and dramatic in the case of lissencephaly. Recently recognized cerebral malformations such as double cortex, frontal opercular syndrome, and congenital bilateral perisylvian syndrome have variably severe adverse effects on cognition (52–54). Despite improvements in imaging, specific brain malformations such as bilateral parasagittal polymicrogyria can still be difficult to detect on imaging tests and can cause a spectrum of cognitive problems plus epilepsy that begins early in life (55). The range of cognitive impairments linked to bilateral parasagittal polymicrogyria extends from normal functioning to mild retardation and includes subtle problems such as normal intelligence with slow mental processing.

In recent years, the proportion of epilepsy that is recognized as symptomatic of brain lesions has increased as a result of vast improvements in imaging techniques. These advances have allowed visualization of subtle, previously inconspicuous brain abnormalities such as heterotopias, areas of abnormal cerebral lamination, or small areas of atrophy (as in mesial temporal sclerosis) that can produce severe epilepsy and cognitive impairment (56). Whereas

contemporary high-resolution magnetic resonance imaging (MRI) techniques allow visualization of mesial temporal lobe and other brain structures that previously were obscure, variations in these structures increasingly are being linked to cognitive differences among people with epilepsy. For example, Strauss et al found that among a group of people with epilepsy, the size of the posterior corpus callosum correlated positively with IQ (57). Similar observations have been made in children who were born prematurely with extremely low birth weights (58) and among mentally retarded men with fragile X syndrome (59). As more neurons connect to each other via the corpus callosum, the corpus callosum enlarges.

Chromosomal disorders illustrate how a particular etiology can produce both seizures and mental retardation independently. Among patients with Down syndrome the average IQ is 43.5 (SD 10.1), resulting in a 99% chance that patients with this disorder will be mentally retarded, independent of epilepsy (60). Angelman ("happy puppet") syndrome and Prader-Willi syndrome are both caused by a microdeletion of a portion of the long arm of chromosome 15 (61). Seizures are an invariable component of Angelman syndrome but occur in only 20% of children with Prader-Willi syndrome. However, subnormal intellect is a major feature of both disorders.

X-linked mental retardation is the most common inherited cause of mental subnormality. Associated with fragile X chromosome in 25% to 50% of cases, mental handicap is a uniform feature of this disorder. Although seizures occur in 20% of patients, they have a negligible relationship to intellect (62, 63).

In some instances of symptomatic seizures, both the etiology and the actual occurrence of seizures affect the cognitive outcome. The various causes of neonatal seizures help to illustrate how these relationships operate. Certain etiologies of neonatal seizures are benign, whereas others have grave consequences for intellectual outcome.

For example, hypocalcemia in the context of late neonatal tetany can cause dramatic and numerous seizures, but it does not increase the risk of mental retardation unless there are additional complications. On the other hand, neonatal hypoglycemia that causes seizures approximately doubles the risk of mental handicap compared to symptomatic neonatal hypoglycemia that does not cause seizures (64). Asymptomatic hypoglycemia only slightly increases the risk of subsequent cognitive impairment. Thus etiology can influence the cognitive consequences of the seizures. Furthermore, in certain etiologies such as hypoglycemia, the actual occurrence of seizures contributes a critical element in the pathogenesis of the adverse intellectual outcome.

In pyridoxine dependency, the number and duration of seizures contributes to the adverse cognitive outcome in children who otherwise would be normal if treated with vitamin B<sub>6</sub>. Mental retardation occurs mainly in

those individuals who have numerous seizures caused by pyridoxine dependency, but usually not in those who have only a few (43, 45, 47, 65). And pyridoxine dependency can be difficult to identify. Initially it was believed that pyridoxine dependency caused only neonatal seizures and neonatal status epilepticus. Subsequently, it was discovered that pyridoxine dependency could cause other types of seizures, including epileptic syndromes that are associated with cognitive decline. Those patients who experience the worst seizures in terms of seizure types, seizure frequency, and the duration of epilepsy have a high risk of irreversible cognitive impairment. And to make the condition all the more difficult to diagnose, the seizures due to pyridoxine dependency are partially responsive to antiepileptic drugs, like other forms of epilepsy.

The symptomatic etiology of epilepsy perinatal asphyxia causes a distinctive combination of cerebral palsy, mental retardation, and epilepsy. Findings from the NCPP revealed that when perinatal asphyxia in full-term newborns caused later epilepsy, it also caused cerebral palsy (60, 66). In the absence of cerebral palsy, no relationship was found between various measures of perinatal asphyxia and the occurrence of epilepsy in later childhood (66), a finding confirmed in a subsequent investigation (67). Among 87 newborns who had Apgar scores of 0–3 at 10 minutes and who did not develop cerebral palsy, none developed epilepsy during the 7-year follow-up period (68).

Similar to the relationship between etiology and cognitive impairment, underlying brain disease, more so than seizure-related variables, increases the risk of behavior disorders. Beran and Flanagan (68) compared adults who had posttraumatic versus idiopathic epilepsy of comparable severity using the Washington Psychosocial Seizure Inventory. There were differences across eight measures that indicated that the extent of brain dysfunction correlated with psychosocial dysfunction more than the severity of the epilepsy. Corbett et al concluded that among children with epilepsy, brain damage and dysfunction were of greater importance in causing behavior problems than medication (69). Deb studied the relationship between epilepsy and psychopathology among mentally retarded people and found that the underlying brain damage was more influential in producing behavioral symptoms than seizures were (70).

Etiology of epilepsy is intertwined with nearly all other epilepsy-related variables because etiology influences seizure type, response to medication, duration of epilepsy, and comorbidities, including cognitive impairment. As a result, etiology has far-reaching impact on global achievements and adjustment of people who are affected by the condition. Symptomatic etiology has adverse consequences for the chance of cessation of seizures, for educational and vocational achievement, for social adaptation, for driving, for employability and for other outcomes (9).

**TABLE 67-4**

*Thirty-Year Outcome of Childhood Onset Epilepsy from a Population of Children 70% of Whom Had Cryptogenic or Symptomatic Epilepsy\**

OUTCOME	EPILEPSY	CONTROLS
Primary education only	49%	23%
No vocational training	69%	52%
Unpartnered	35%	10%
Childless	51%	16%
No driver's license	39%	16%
Unemployed	31%	8%

\*Ongoing recurrent seizures that could not be prevented with medication were linked to the worst social outcomes (9).

Sillanpaa and colleagues reported the long term outcomes of 245 Finnish children with epilepsy that began before age 16 years. This group differed from most other population-based groups in which approximately 80% of cases are idiopathic epilepsy, because among the Finnish children with epilepsy only 28% of cases were idiopathic whereas 72% were either cryptogenic or symptomatic. When followed up after 30 years the adverse outcomes linked to symptomatic etiology and ongoing seizures were dramatic (Table 67-4).

### ASSOCIATED NEUROLOGIC SYMPTOMS—COMORBIDITIES

The linkage between mental retardation, epilepsy, and cerebral palsy is well established. Historically one-third of children with cerebral palsy also have epilepsy. However, as obstetrical and perinatal medical care has improved, the distribution of different forms of cerebral palsy has changed and the incidence of epilepsy in cerebral palsy has changed, too (71). In various series, epilepsy has been most likely to occur in hypotonic, spastic hemiplegic, and tetraplegic forms of cerebral palsy (72, 73), in which the risk of epilepsy is approximately 50% (38, 74). Similarly, the risk of mental retardation is higher in patients with tetraplegia than in patients with spastic diplegia, especially when children with milder degrees of motor dysfunction are considered (75). For example, in one study of children with these disorders, the likelihood of mental retardation (IQ < 70) was 50% lower among children with diplegia than among those with tetraplegia (39). It is less common with spastic diplegia (73), even when the diplegia resulted from the most severe degree of intraventricular hemorrhage, which renders more than 70% of survivors mentally retarded (76). Cerebral palsy has also been linked to the onset of epilepsy in the first year of life,

to neonatal seizures, and to a high incidence of mental retardation (74). In the NCPP, infants with hypotonia that was not further characterized had a mean IQ of 80 (SD 24.9), which translates into a 34.6% risk of mental retardation. In the same study among children with cerebral palsy, the mean IQ was 74.8 (SD 27.2), resulting in a 43.5% risk of mental retardation (43). Among young children, cerebral palsy is the most important single risk factor for severe epilepsy (77, 78).

For newborns with extremely low birth weight, the risk of cognitive and motor impairment is high and increases with increasing degrees of prematurity, with declining birth weight, with shorter gestation, and with more severe degrees of intraventricular hemorrhage when it is present (58, 79, 80). In the presence of periventricular leukomalacia and cognitive impairment, performance IQ was affected worse than verbal IQ. Thinning of the posterior corpus callosum correlated with reduced full-scale and performance IQ but not verbal IQ (58).

In the presence of mental retardation the risk of epilepsy increases with the severity of the mental handicap (Table 67-5). The lower the IQ, the more likely the child will also have epilepsy and the less likely that the seizures will respond to treatment (81). If the IQ is normal and the child has spastic diplegia, the child is more likely to have had a single seizure or to have responded to monotherapy (74). Conversely, among children who are mentally retarded, those who also have epilepsy tend to be more severely affected (82). Chelune et al reported that among people with IQ of 75 or less, the chance that surgical treatment would fail to cure epilepsy was fourfold greater than when the IQ was higher (83). The concurrence of multiple neurologic handicaps has an adverse compounding effect on the child's overall functionality, with the combined deficits having multiplicative rather than additive impact on the child's functioning (84).

A majority of severely retarded children have definable brain abnormalities that are known to heighten the risk of epilepsy. For example, in one series the causes of severe retardation (IQ < 50) included the following: 36%, chromosomal abnormalities; 20%, congenital

**TABLE 67-5**

*Occurrence of Epilepsy Among Various Intellectual Categories*

INTELLECTUAL CATEGORY	PREVALENCE OF EPILEPSY
Normal IQ	1%
Mild mental retardation (IQ 50–70)	15%
Severe mental retardation (IQ < 50)	47%

Adapted from data in Susser et al (60).

malformations; 12%, perinatal complications or infections; and 7%, single-locus genetic diseases. Only 3% had postnatal causes, and the unknown/other category accounted for 22% (60).

Studies conducted since the completion of the NCPP have provided more refined information about the interrelationship between epilepsy, mental retardation, and cerebral palsy (85). Ignoring whether the mental retardation is associated with cerebral palsy, the overall risk of epilepsy among mentally retarded people is 15%. Among mentally retarded children without cerebral palsy, the risk of developing epilepsy by age 22 years is substantially lower, 5.2%. Mental retardation plus cerebral palsy increases the risk of developing epilepsy by age 22 approximately sixfold to 38%. Mental retardation that has been acquired as a result of postnatal causes carries an even higher risk of also developing epilepsy, 66%.

Other manifestations of brain disease and epilepsy are interrelated in children who are neurologically abnormal (Table 67-6). In young infants coincidental congenital disorders that do not seem to affect the nervous system directly nonetheless can be adversely related to IQ. For example, congenital heart disease is associated with a 10-point reduction in mean IQ from 100 to 90.4 (SD 23.5), resulting in a 19.8% risk of having an IQ below 70 (60). The mechanisms by which associated conditions such as this reduce IQ are undefined. Most of these patients have static, nonprogressive intellectual deficits unless additional insults to brain occur.

Thus, among youngsters with congenital neurologic abnormalities, the symptoms of mental retardation, motor disability, and epilepsy are tightly intertwined. These associations notwithstanding, the etiology of the brain dysfunction remains the principal determinant of IQ.

### EPILEPTIC SYNDROMES (TYPES OF EPILEPSY)

A descriptive diagnosis by type of epilepsy or epileptic syndrome provides a more complete picture about the patient's epileptic condition than a diagnosis by seizure type does. Syndromes are nonspecific in regard to etiology and are defined by groups of symptoms that occur together. Several clinical elements define the various syndromes. These include seizure type(s), precipitating factors, electroencephalographic (EEG) patterns (both ictal and interictal), response to various medications, age on onset, natural history, and associated clinical features such as whether the patient has encephalopathy including motor deficits or mental handicap (86). The last two features, natural history, and the presence or absence of encephalopathy are central to this discussion because syndromic groupings usually imply an intellectual prognosis. For example, the encephalopathic epilepsies, such as West syndrome, Lennox-Gastaut syndrome, and Doose syndrome, are regularly associated with cognitive impairment. In other syndromes, such as childhood absence epilepsy, the prognosis is benign including the intellectual outcome (Table 67-7). Some syndromic phenotypes can

*Examples of Epileptic Syndromes and Prognosis for Cognitive Function*

#### Unfavorable Cognitive Development

- West syndrome (infantile spasms)
- Severe myoclonic epilepsy of infancy
- Lennox-Gastaut syndrome
- Doose syndrome
- Landau-Kleffner syndrome
- Rett syndrome

#### Favorable Cognitive Development

- Febrile seizures
- Childhood absence epilepsy (petit mal, pyknolepsy)
- Benign partial epilepsy of childhood (rolandic epilepsy)
- Juvenile myoclonic epilepsy

evolve as the child grows older and as a result of other influences. Examples include the evolution of West syndrome to Lennox-Gastaut syndrome and the emergence of severe myoclonic epilepsy of infancy following febrile seizures.

Some syndromes evolve over time and most have indistinct boundaries (87, 88). A given syndrome can result from many causes and be either symptomatic or be idiopathic (primary). In most instances the idiopathic cases have the better prognosis for control with medication, for eventual remission and for intellectual outcome. Approximately 50% of children who have epilepsy can be categorized into one of the epileptic syndromes.

### Encephalopathic Epilepsies

Epileptic encephalopathy (or encephalopathic epilepsy) is a term that has been used to describe the development of mental impairment that is often associated with a high frequency of seizures that are resistant to medication (89). The usual progression of events is stagnation of development, which causes the affected child to be left behind developmentally by his peers. Less often the child actually regresses developmentally through the loss of previously acquired skills and knowledge.

The mechanisms by which certain epilepsies lead to progressive encephalopathy are poorly understood (90). The major ones—West syndrome, Lennox-Gastaut syndrome, and severe myoclonic epilepsy of infancy (SMEI)—are characterized by early childhood onset, high frequencies of seizure, and multiple types of seizures. Others such as Landau-Kleffner syndrome and the syndrome of electrical status epilepticus during sleep (ESES, also called the syndrome of continuous spikes and waves during slow wave sleep, CSWS) have a low frequency of seizures or, in some cases, no seizures (91). The central elements of these disorders are severe encephalopathy manifested by language impairment. West syndrome and Lennox-Gastaut syndrome are interrelated in that approximately half of the infants who develop infantile spasms later evolve into the clinical pattern of Lennox-Gastaut syndrome (92). West syndrome consists of infantile spasms, an EEG pattern of hypsarrhythmia, and developmental arrest. Lennox-Gastaut syndrome includes multiple seizure types, especially tonic, atonic, partial, and atypical absence seizures, developmental arrest, and a slow spike wave pattern on EEG. In an epidemiological study that did not include mental retardation as a diagnostic criterion, 91% of affected children had IQs of 70 or less (93). Doose syndrome is the idiopathic version of Lennox-Gastaut syndrome. Normal intellect can be preserved if seizures can be controlled in Doose syndrome, but mental impairment accrues if seizures rage on. Although labeled as a syndrome, Rett syndrome is actually an etiologic entity. It is a genetic, progressive,

relentlessly degenerative condition that has its onset in girls in the first or second year of life (94, 95).

### Seizure Type

The ictal behavior that occurs during a seizure determines the seizure type and depends on the area(s) of brain in which the abnormal neuronal discharges are occurring. Any specific type of seizure can have a multiplicity of causes. As a result seizure type is generally a feeble correlate of other aspects of the epileptic condition. Furthermore there is a high rate of error in the clinical diagnosis of seizure types, especially when the behavior in question is epileptic staring.

Generalized seizures and generalized epileptiform patterns on the EEG have been linked to greater degrees of cognitive impairment than partial seizures, but these types of relationships are inconsistent. One comparison of neuropsychologic test results from people with partial seizures to those with partial secondarily generalized seizures found that those with secondarily generalization perform less well on tests of concentration and mental flexibility (96). Moreover, these differences were present before drug therapy was initiated. In another study that looked at the effects of partial versus partial secondary generalized seizures, patients with only partial seizures did better than those with secondary generalization on subtests of arithmetic, digit span, digit symbol, block design, and object assembly (97). Wilkus and Dodrill found that on 11 of 15 Halstead-Reitan measures patients with generalized EEG discharges performed worst, patients with focal EEG discharges had intermediate performances, and patients with no epileptiform EEG discharges performed best (98).

Data from Farwell et al (3) (Table 67-8) and from Bourgeois et al (1) (Figure 67-4) illustrate how the patients' predominant seizure types correlate with IQ overall. For example, generalized absence seizures are a

**TABLE 67-8**  
*Seizure Types and Average IQ Among Children 6–15 Years Old (3)*

SEIZURE TYPE	GROUP AVERAGE IQ
Minor motor	70
Atypical absence	74
Partial and generalized	96
Partial only	98
Generalized tonic-clonic	99

FIGURE 67-4

Frequency distributions of IQ scores among children with various seizure types. The percentage values shown in parentheses indicate the proportion of the group that is expected to have an IQ of 70 or less. The average and standard deviations (SD) for the groups are febrile 100.7 (SD 24.0), mixed 91.2 (SD 22.7), and generalized absence 109.7 (SD 16.4).

feature of many epileptic syndromes, some benign and some ominous. Absence seizures that occur in petit mal epilepsy bear a substantially better prognosis than atypical absence seizures that are coupled with other types of generalized seizures such as atstatic seizures or drop attacks. Atypical absence seizures and atstatic or drop seizures have been labeled collectively as minor motor seizures; these have a poor prognosis for mental development and functioning. Groups of children with classic absence seizures have a mean IQ that is above average. These youngsters probably have childhood absence epilepsy (petit mal epilepsy, pyknolepsy), whereas those patients with classic absence plus generalized tonic-clonic seizures most likely have juvenile myoclonic epilepsy, both of which are genetically determined and are linked to normal or superior intellect. However, absence seizures, especially atypical absence seizures, are linked to some of the worst cognitive outcomes when they occur in children with encephalopathic epilepsy such as infantile spasms or Lennox-Gastaut syndrome. Consistent with these relationships, hospital-based studies of children have found that nonconvulsive absence seizures are associated with lower cognitive scores than convulsive seizures (20).

The major drawback with trying to relate seizure type to intellectual outcome is that the classification of seizure types provides only limited information (99). Seizure types are ictal behavioral phenotypes. Although they provide clues as to the anatomical origin of the epileptic discharges, they are nonspecific in relation to either etiology or epileptic syndrome. Whereas individual seizure types have many causes and occur in many different

syndromes, attempts to correlate seizure types with cognitive ability usually fall short.

### Localization of Partial Seizures

Along with seizure type, seizure frequency, and epileptic syndrome, the localization of partial seizures is sometimes related to cognitive difficulty (20, 50, 100, 101). Fixed cerebral lesions and neurologic deficits produce more consistent clinical pictures than interictal EEG epileptic foci, which tend to wander over time in conditions such as benign partial epilepsy of childhood (BPEC), also known as benign rolandic epilepsy. Compared to children with the transient condition BPEC, children with chronic temporal lobe epilepsy scored lower on reading comprehension and reading speed. Notably, both groups were affected, but children with temporal lobe epilepsy were affected more so (102). Moreover, the types of abnormality found in repeated recordings from the same individuals can fluctuate over time, switching from focal to generalized epileptiform patterns and vice versa (103). Localized discharges also vary in their distant effects on other brain regions that play key roles in cognition. Positron emission tomography (PET) scans have demonstrated depressed cerebral metabolic activity in areas that are remote from EEG-defined epileptic foci (104, 105). These mechanisms of distant neuronal suppression appear to impair cognitive processing more so than memory.

Nonetheless, many investigators have found relationships between the cerebral localization of focal seizures and cognitive and/or behavioral outcomes. The results of this line of research generally support the theory that left-sided abnormalities are prone to interfere with verbal cognitive functions (106). High frequency of seizures has been linked to inattention (107, 108).

Although children with BPEC have normal IQs (109, 110), there are reports of heterogeneous patterns of difficulties with fine motor control, visual learning, and attention (109). No single cognitive profile has been identified, but some investigators have found that school difficulties and transiently weak scores improved after the EEG abnormalities abated (111). Other investigators found spike frequency to have greater impact on cognition than spike localization (112). Among 40 children with benign rolandic epilepsy (BRE), deficits in IQ were linked to spike frequency but not seizure frequency, lateralization of focus, and duration since spike focus was first identified. Perisylvian discharges were linked to learning difficulties at school and with language dysfunction affecting reading, spelling, auditory verbal learning, expressive grammar, and auditory discrimination (113).

Some investigators have drawn attention to the transient adverse effects of nocturnal EEG discharges in BPEC (113). Frequent subclinical nocturnal EEG

discharges were linked to a heterogeneous group of educational, language, and behavioral impairments that, in themselves, were another mixed bag of disorders (114). After epileptic discharges in sleep stopped (remission of interictal discharges), IQ scores improved, as did performances on several subtests including visuomotor coordination attention and picture naming (115). Children with dyslexia and EEG trait of BPEC had attention impairment comparable to those with dyslexia but no BPEC (116). The occurrence of seizures during sleep is a noteworthy feature of the severe epileptic encephalopathies including Lennox-Gastaut syndrome, Doose syndrome, Landau-Kleffner syndrome, and ESES.

In a group of eight children with frontal lobe seizures who were studied in detail, IQ was spared but performance varied with lateralization, frequency, and age of onset (107). Left-sided EEG localization affected verbal long-term memory and visuospatial analysis. Hendriks and colleagues (108) identified verbal memory problems with temporal lobe epilepsy, but deficits also were intensified by high frequency of seizures, early age of onset, and long duration. Compared to children with generalized absence epilepsy or with temporal lobe epilepsy, children with frontal lobe seizures had reduced performance speed and were more distractible (117). Children with idiopathic occipital lobe epilepsy scored lower on attention and memory problems than nonepileptic controls (118).

Early onset of temporal lobe epilepsy can cause speech and language functions to relocate to nontypical cortical regions. These changes may be linked to reduced performance on subtests, but overall measures of intelligence are usually within the range of normal (119). Children with BPEC may relocate language away from the site of originally recorded spike focus (119, 120). Children who have left-sided brain abnormalities and shift language to either extratemporal bilateral or right brain language localization also show so-called crowding effects with nonverbal memory deficits.

Muszkat et al compared test results from 26 children with partial epilepsy to those from 61 control children who did not have epilepsy (121). Overall the children with epilepsy did less well than the control group. Furthermore, right-hemisphere EEG spike lateralization was linked to lower scores on measures of spatial ability and nonverbal attention. Left-hemisphere spike lateralization was linked to low scores on only digit span. Mitchell et al found that children with epilepsy tended to have slower reaction time, more variable performance, and make more errors of omission, but not commission, than normal control children (22). In another study of eight children with frontal lobe epilepsy, left-sided EEG localization affected verbal long-term memory and visuospatial analysis, whereas high frequency of seizures was linked to attention deficit (108).

Left hippocampal atrophy on MRI has been linked to problems with verbal memory (122). Among patients with left versus right mesial temporal sclerosis, those with left hippocampal atrophy had inferior general memory, verbal memory and verbal fluency, and naming (122, 123). Hermann et al compared patients with left versus right temporal lobe EEG foci (124). Subjects with left EEG foci did worse than either patients with right temporal foci or control subjects on verbal learning ability, immediate memory, and retrieval of verbal material from memory. Patients with left temporal lobe foci also had more problems with semantic organization, whereas the group with right temporal abnormalities did as well as controls. In another study, adult patients with left, but not right, temporal lobe EEG foci had reduced recognition of symbols presented tachistoscopically in their right visual fields. However, epileptic patients as a group had worse retention (memory) for the symbols than controls (125). In yet other studies left-sided lateralization of the epileptic focus was linked to loss of verbal abilities, whereas right-sided lateralization was linked to loss of nonverbal cognitive functions (126). Verbal-manual tasks used to assess cerebral organization for language indicate those children with left, but not right, hemisphere EEG foci have atypical patterns of cerebral dominance such as bihemispheric dominance (127). Right-sided temporal lobe epileptiform activity due to BPEC was accompanied by deficits in recognition memory (108, 119, 128). Billingsly and Smith reported lowered performance on both verbal and nonverbal IQ subtests by children with atypical cortical representation of speech (119).

Whereas linkages between cognitive difficulties and the laterality of EEG foci tend to be inconsistent, structural hemispheric lesions that produce hemiplegia have more dependable relationships to cognitive outcome. Sussova et al reported that among children with hemiplegic cerebral palsy, 80% had paroxysmal EEG features, although less than half actually had seizures (129). In these children the presence of epilepsy, not simply EEG abnormalities, was linked to lower IQ scores, an observation that was confirmed subsequently by others (130). Interestingly, in this particular study, right hemisphere lesions were more often linked to low IQ than left hemisphere lesions. In a different study, left hemispheric dysfunction producing right hemiplegia and epilepsy was linked to reduced IQ scores (26).

In children with tuberous sclerosis, the higher the number of lesions on MRI, the lower the IQ, the worse the behavior and the more severe the epilepsy (131). There are also relationships between the age of onset and cognitive outcome in tuberous sclerosis.

Epileptic foci in the left hemisphere have been linked to behavior disturbances, too. Corbett et al found that patients whose seizures originated in the left hemisphere were more likely to have behavior problems including

FIGURE 67-5

Effect of seizure frequency on full-scale IQ among people having seizure frequencies that were low (3 or fewer seizures per year), moderate (4–12 seizures per year), or high (12 or more seizures per year). Data are from Dikmen et al (133).

destruction of property, worrying, irritability, fussiness, and being resentful and aggressive (69).

Overall, however, in comparisons of the influence of various epilepsy-related variables on cognitive outcome, laterality of the epileptic seizure has been a less powerful covariable than age of onset (132).

### Interrelationships of Epilepsy-Related Variables

Epilepsy-related variables that are linked to cognitive ability tend to be interrelated and often occur simultaneously. As will be seen in the sections that follow, age of onset and duration of epilepsy are closely intertwined. Collectively, these variables relate loosely to the overall intensity of the epileptic disorder. Dikman and colleagues evaluated 14 measures from the Halstead-Reitan Battery in adults who were categorized on the basis of seizure

frequency, age of onset, and duration of epilepsy (133). Seizure frequency was directly related to reductions on 7 of 14 measures. Specifically, the average full-scale IQ declined from 95 to 81 as seizure frequency increased from 3 or fewer per year to more than 12 per year (Figure 67-5). When these investigators combined all three risk factors and compared the 12 patients with lowest risk to the 12 who had the highest risk, most cognitive measures were worse in the highest risk group—those patients who had the earliest onset, longest duration, and highest frequency of seizures. Similar findings have been reported by others (134).

### Age of Onset of Epilepsy

Many investigations have found relationships between the age of onset of seizures and IQ (1, 3, 133, 135). In the study by Farwell et al the correlation between age of onset and full-scale IQ was 0.30: the older the age of onset, the higher the IQ (3). Overall, the onset of epilepsy in the first year of life has an ominous prognosis (136, 137). A long-term prospective study of 133 children whose epilepsy began in the first year found that 11% died before reaching age 7 years, 40% were severely retarded, and only 40% had an IQ of greater than 70 (138). The prognosis was the same no matter whether the child had infantile spasms or another type of epilepsy.

In the NCPP, epilepsy in the first year of life was associated with an average IQ of 91.8 (SD 22.0), which would result in 16.7% of this group being mentally retarded (11). In clinic-based studies the variables of age of onset and duration of epilepsy are usually interrelated. For example, Dikmen et al found that among adults with persistent epilepsy that began in childhood, the average group IQ declines in relation to the age of onset, the younger the age of onset the lower the IQ score (133) (Table 67-9). In addition, the early-onset group did worse

TABLE 67-9  
Age of Seizure Onset and IQ Among Adults  
who Had Childhood Onset of Epilepsy that Lasted for 4 or More Years

	AGE OF ONSET

FIGURE 67-6

Relationship of age onset of seizures to IQ scores in children with tuberous sclerosis. Reproduced from Gomez (135) with permission.

on all 10 WAIS subtests, with statistically significant differences occurring on information, comprehension, arithmetic, and object assembly.

Seizure-related variables can interact simultaneously with etiology and the location of cerebral lesions to contribute to the child's cognitive capabilities. For example, in tuberous sclerosis the age of onset of seizures correlates with IQ: the earlier the onset of seizures, the lower the IQ (135) (Figure 67-6). Whereas most people with tuberous sclerosis are mentally retarded, virtually all mentally retarded patients with tuberous sclerosis have epilepsy, too. Finally, the location, number, and extent of cerebral lesions in tuberous sclerosis play central roles in shaping the overall clinical picture (131).

### Seizure Frequency

Seizure control usually results in improved cognitive function (138–141) (Table 67-10.). Farwell et al found that among children whose seizures were controlled, the mean IQ was 99.6 compared to 87.0 for the group with

continuing seizures (3). Among those patients whose seizure frequency declined there were overall improvements in IQ plus improvements on 8 of 11 subtests. By contrast, only the performance IQ and object assembly score improved on repeated testing among those whose seizure frequency remained the same or increased.

Although the severity of the epilepsy has been linked to the degree of mental handicap, severe mental handicap does not preclude good seizure control (141).

In BPEC spike frequency, not seizure frequency or lateralization of the focus, has been linked to reduced IQ and other measures of cognition (112). Compared to control children, children with rolandic spikes tended to suffer from impaired IQ, defective visual perception, short-term memory disturbance, plus deteriorated psychiatric status and fine motor performance. However, after rolandic epilepsy remits, the cognitive impediments usually resolve (142).

Intuitively, seizure frequency would seem to be associated with cognitive impairment because of the extremely high frequency of seizures among children with encephalopathic epilepsies. In practice this association has proven difficult to document, especially when the seizure frequency is moderate to low. For example, among children with febrile seizures, neither the number of seizures nor the duration of individual seizures was associated with a reduction in IQ among patients compared to siblings. In the NCPP, among 36 children who had three or more febrile seizures, the full-scale IQ was 95.9 (SD 10.8) versus 95.9 (SD 11.6) in control siblings (143).

### Duration of Epilepsy

In most studies the duration of epilepsy is related to the age on onset in that an early age of onset tends to be followed by a prolonged duration of the disorder. Thus, both of these factors are associated with reductions in group IQ scores. In some studies the duration of epilepsy has been inversely correlated with IQ in children with a correlation coefficient of  $-0.40$  (3). When adjusted for duration of seizure-free years, the correlation has been even stronger,  $-0.62$ .

Factors that predict persistent seizures are also linked to adverse cognitive outcomes for children with epilepsy. These include frequent seizures, an early age of onset, secondary generalization, symptomatic epilepsy due to structural brain lesions, and abnormal neurologic status (143). When clinic-based groups of children who have partial seizures have been followed for long periods of time, those who have these features are at high risk for cognitive and social morbidity plus seizure-related death (144, 145). Among children with epilepsy due to Sturge-Weber syndrome, those with lower IQs had longer duration of epilepsy and more seizures (105).

Although population-based studies do not provide evidence that cognitive decline occurs in people with

Values shown are means and standard deviations.  
Adapted from Seidenberg et al (153).

epilepsy, studies from institutions and from referral centers indicate that severe epilepsy is occasionally followed by declining IQ scores. Whereas these changes materialize insidiously over years to decades, repeated evaluations over long periods of time are needed to identify when this is occurring (9). Corbett et al found that 15.7% of patients at Lingfield Hospital experienced a reduction in IQ of 15 or more points (69). Factors that were associated with decreased IQ included higher levels of primidone and phenytoin and lower folate levels, but not the severity of EEG abnormalities or the seizure frequency. In a prospective clinic-based study of children with epilepsy, decreasing IQ scores were associated with earlier age of onset, more difficult-to-control seizures, having drug levels in toxic range, and having more drugs that caused toxicity (1). However, the mean IQ for the group as a whole did not decline. Although IQ scores declined in 11.1%, they increased in 16.7%.

Long-term follow-up of children with temporal lobe epilepsy indicates that a high percentage encounter academic failure if seizures continue unabated for years. In the series reported by Lindsay et al, there were 4 seizure-related deaths before age 16 years. A total of 10 of 58 children who were candidates for epilepsy surgery died. Among those whose seizures persisted and who were not treated surgically, only 25 of 45 completed regular school and 16 of 45 experienced early cognitive deterioration (144). Only 4 of the 45 members of this group were employable, and only 6 obtained driver's licenses. In another study (134), compared to healthy controls, people with prolonged temporal lobe epilepsy had reduced performance on tests of intelligence, language, motor speed, and executive function with longer duration associated with declining mental capability. As noted previously, symptomatic etiology can be linked to long-duration epilepsy and poor social adjustment in adult life (9).

### **Epilepsy and Neuropsychiatric Adaption**

Although adults with epilepsy have a greater risk of neuropsychiatric problems, the nature and extent of these problems is difficult to characterize. In the Veterans Administration Collaborative Study 118, patients were compared to normal controls before therapy (146). Patients with epilepsy had significantly worse scores on 14 of 18 neuropsychologic measures before medication was started. However, the risk of neuropsychologic compromise among adult patients with epilepsy seems to be the same as among patients with other chronic neurologic ailments. Hermann et al found no differences due to seizure type or age of onset on Minnesota Multiphasic Personality Inventory (MMPI) measures of psychopathology, but epilepsy per se was associated with a greater risk of problems (147). After an extensive analysis of MMPI profiles from the literature, other investigators have con-

cluded that compared to people without epilepsy, patients with epilepsy are at higher risk for psychopathology, but the risk associated with epilepsy is similar to that associated with chronic disease in general (148). In a later report, Dodrill and Batzel reiterated that patients with epilepsy are at greater risk than normal, but they argued that the risk of psychopathology for people with epilepsy is the same as for people with other neurologic disease; both of the neurologic disease groups, epileptic and non-epileptic, have higher risk than patients with chronic, non-neurologic diseases (149). The excess of psychopathology among people with neurologic disease is manifest primarily as a high prevalence of psychotic MMPI profiles for both epileptic and other neurologic groups.

Studies in adults that relate seizure type to distinctive personality profiles are controversial. Although some investigators have suggested that adults with temporal lobe epilepsy have distinctive personalities, others have been unable to confirm it (148, 149). Thus a majority of investigators conclude that temporal lobe epilepsy is no worse than any other type of epilepsy in this regard. Dodrill and Batzel, in reviewing this issue, also criticized the item content of the MMPI as being inappropriate for patients with epilepsy (149). In general, when adults with epilepsy have psychopathology, it tends to be severe (148). Depression is a particularly common problem (150).

Psychological tests in teenagers do correlate with overall adjustment later in adulthood. Dodrill and Clemmons followed up patients with epilepsy 5.9 (SD 1.86) years after their original evaluations during adolescence. The patients were rated on vocational adjustment (unemployed to full-time employment in four categories) and on daily life functioning (fully dependent to independent in three categories) (151). The MMPI did not predict either vocational or life functioning. Predictive measures of being fully functional (adequate in both vocational and independence measures) included the Halstead Impairment Index, Seashore Rhythm, Aphasia Screening (total errors), and verbal, performance, and full-scale IQ. Discriminant function analysis indicated that vocational adjustment related best to the Halstead Impairment Index, whereas independence in living was predicted by Seashore Rhythm and thematic perception test (TPT) (memory). Language skills were especially important. In a separate study, marital adjustment among adults with epilepsy was more related to emotional adjustment, whereas living independently was related to mental ability (152).

### **CONCLUSIONS**

Although most children with epilepsy are developmentally and behaviorally normal, children with epilepsy as a group have an average IQ that is approximately 10 points

lower than in children without epilepsy. Learning disabilities are also more prevalent among children with epilepsy. Boys are at higher risk than girls. The lower IQ found among groups of epileptic children is largely a consequence of antecedent, etiologically specific neurologic abnormalities rather than a consequence of seizures or antiepileptic drug therapy.

Although seizures do not cause intellectual decline in most cases, certain exceptional encephalopathic epileptic syndromes are associated with abnormal development and intellectual decline. These severe epilepsies are so rare that they are not encountered to a meaningful extent in most population-based studies. Among all epileptic syndromes, childhood absence epilepsy (pykno-

lepsy or petit mal epilepsy) alone is associated with an above average IQ.

Among all epilepsy-associated variables, etiology plus the location and extent of cerebral lesion(s) best predict cognitive abilities in children with epilepsy. The risk of associated mental retardation in patients with epilepsy is increased when there is associated motor impairment, when epilepsy begins at an early age, when the duration of epilepsy is prolonged, when there are multiple seizure types—especially minor motor seizures—and when multiple drugs in high doses are required. Childhood epilepsy with uncontrolled seizures that persists into adulthood can cause dramatic and pervasive disruption of the acquisition of adult social and cognitive skills.

## Academic Deficits and Interventions in Pediatric Epilepsy

*Caroline E. Bailey  
Rochelle Caplan*

**I**n this chapter, we address issues of academic achievement and educational intervention for children with epilepsy. We approach this discussion on two levels. First, we highlight common educational concerns for children with epilepsy. We then review research on educational interventions and teacher attitudes toward epilepsy and discuss the impact this has on classroom education. Likewise, we discuss specific academic deficits in the areas of reading and language that are associated with pediatric epilepsy. We explain what is known about the underlying cognitive correlates of these difficulties, both in epilepsy and in other neurobehavioral disorders with similar symptom profiles. We discuss empirically supported interventions used to treat these academic deficits in other populations and examine their applicability to the pediatric epilepsy population. At the end of the chapter, we address this issue clinically using our experiences as practitioners and advocates working with patients and families. We provide guidelines on how to design an appropriate intervention for a specific child. We discuss the importance of teacher awareness and parent-teacher-student communication and make suggestions for obtaining special education services for children with epilepsy. In conclusion, we stress the importance of the role of the clinician as an educational advocate,

and advocate for empirical investigations of academic interventions for children with epilepsy.

### **ACADEMIC DEFICITS IN PEDIATRIC EPILEPSY**

Academic achievement difficulties are well documented in children with epilepsy (1–7). Yet, comparatively few investigations have examined these deficits in terms of the underlying cognitive and illness-related variables contributing to specific areas of academic weakness. In the linguistic domain, these areas of academic concern include reading and spelling (2, 4, 6, 8), spoken language, vocabulary development, rapid naming, verbal memory, and higher-level discourse deficits (2, 3, 9–11). Whereas important environmental factors such as family support and socioeconomic status affect academic achievement (3, 4), identifying the cognitive and linguistic correlates associated with academic failures in children with epilepsy is a key component in the process of understanding the academic needs of this population. This is particularly germane to the important task of determining appropriate educational interventions for children with epilepsy. Although educational interventions for children with learning disabilities have been

well researched, educational interventions for the academic deficits associated with pediatric epilepsy remain grossly unstudied, in contrast to other conditions such as dyslexia, language impairment, and autism. At this point in time, empirically supported educational interventions for children with epilepsy are sorely lacking, in contrast to the large number of academic interventions geared toward other populations with learning difficulties. Few academic intervention studies have been conducted among children with epilepsy, largely because empirical groundwork is still being laid in terms of identifying the underlying mechanisms associated with academic failure in these patients. From the perspective of the advocate (a role often filled by the pediatric specialist), it is not sufficient to simply identify academic deficits in children with epilepsy without understanding their underlying cognitive mechanisms. Hence, it is timely and appropriate for educational issues in pediatric epilepsy to be addressed.

### EDUCATIONAL CONCERNS

Many parents of children with epilepsy are concerned about finding appropriate school placements for their children. Given that children with epilepsy are at risk for academic failure and poor vocational outcome (12) and have been shown to manifest social, cognitive, and academic difficulties (2, 13), this concern is important and well founded. Of particular importance to parents are issues of special education and access to appropriate educational services. Although savvy parents are able to advocate for the immediate health needs of their children with epilepsy, many caregivers have difficulty accessing appropriate educational interventions. Likewise, some school districts may be hesitant to recognize that children with epilepsy may experience learning difficulties in conjunction with their medical illness. Given the lack of well-controlled studies investigating specific academic interventions with the pediatric epilepsy population, parents and educators are often unable to identify appropriate classroom options. In many cases, educational professionals lack sufficient knowledge of epilepsy to provide expert guidance. When this occurs, the clinician familiar with pediatric epilepsy plays a vital role as an educational advocate.

### TEACHER AWARENESS OF AND ATTITUDES TOWARD EPILEPSY

Teachers report a lack of knowledge of the academic challenges associated with epilepsy (14). Despite evidence that children with pediatric epilepsy use special education services both before and after diagnosis of epilepsy (15), teachers appear unaware of their special education needs.

A recent community-based study of 613 children with newly diagnosed epilepsy indicates that 58% received special education services 5 years after diagnosis (15). Although children with remote symptomatic epilepsies were most likely to be identified for services, approximately 50% of the children in the sample with cryptogenic and idiopathic epilepsy also used special education services.

A common misconception among educators is that academic deficits in children with epilepsy are a result of medication and other illness-related variables and therefore cannot be treated with educational strategies and interventions. However, it is well documented that many children with epilepsy have already begun receiving special education before seizure onset, illustrating that behavioral and neurocognitive processing deficits precede the onset of seizures in many cases (15–17). Given the broad effect of epilepsy-related academic deficits, learning disabilities associated with pediatric epilepsy constitute a unique area of clinical concern, ripe for awareness and development of sound educational interventions.

Historically, in the United States, teachers' attitudes toward students with epilepsy have been negative, in part because of knowledge gaps about epilepsy (14). However, as more information about epilepsy has been disseminated, attitudes have improved, and once commonly held misconceptions such as that "children with epilepsy are insane or prone to criminal activity" have decreased among educators (18). Bishop and Boag found that as a group, teachers hold positive attitudes toward students with epilepsy (14), but teachers' attitudes are influenced by teacher-related factors including their age, level of education, and classroom experience. Happily, teachers with experience working with students with epilepsy demonstrated the most positive attitudes toward epilepsy, supporting the notion that education about epilepsy helps create positive attitudes about the condition. Despite these positive findings, teachers still hold misconceptions and biases such as that "students with epilepsy are more accident prone" and "families of children with epilepsy should not be provided additional social support services"—suggesting that more teacher education is needed.

Teachers generally are aware that they are undereducated about the needs of children with epilepsy. Despite their positive attitudes toward students with epilepsy, as a group teachers report that they lack their knowledge of epilepsy and educational strategies appropriate for teaching children with epilepsy. In the Bishop and Boag study, approximately 70% of teachers reported having below-average knowledge of life circumstances and conditions of students living with epilepsy (14). Teachers felt unprepared to teach students with epilepsy because of lack of knowledge of the disease and its impact on

classroom learning. This is in part because the education curriculum for teachers does not address the learning needs of children with epilepsy. Moreover, the lack of controlled studies of educational intervention for these students is likely a further contributor to educators' unfamiliarity with the learning needs of pediatric epilepsy patients. To date, only one published study has addressed this issue (19). Nonetheless, a majority of teachers want to learn more about management of epilepsy in the classroom.

### **CURRENT EDUCATIONAL INTERVENTIONS FOR CHILDREN WITH EPILEPSY**

In an important step toward implementing evidence-based instruction methods for children with epilepsy and prominent learning disabilities, Humphries et al conducted a pilot study examining the effectiveness of Direct Instruction on a group of 55 students with intractable epilepsy and severe learning difficulties (19). Based on the principles of teacher-directed lessons, Direct Instruction techniques feature highly sequenced and scripted teaching geared toward teaching students to accomplish salient, individualized tasks. Students received instruction in a small classroom setting 3 to 4.5 days per week for up to 16 weeks. At pretest, students were underachieving in both reading and mathematics. At posttest, after the intervention, gains occurred in all areas except word identification. Treatment gains were related to IQ, not to seizure-related variables.

Children with severe epilepsy are receptive to highly structured, sequential learning tasks targeting specific academic areas (19). Given that more severely ill children do well with these techniques, it is likely that structured intervention techniques may benefit less severely affected children, too. Furthermore, many current interventions for learning disabilities use a similar structured approach (20, 21). Although no controlled studies have evaluated specific techniques, these remediation methods merit further clinical research.

### **COGNITIVE AND ACADEMIC DEFICITS ASSOCIATED WITH PEDIATRIC EPILEPSY**

Language and reading deficits are frequently associated with childhood epilepsy. Research on educational interventions used in children with and without epilepsy who demonstrate similar learning deficits provide clinicians with information about options for educational interventions. Although these treatments have not been specifically studied in the pediatric epilepsy population, there is good evidence that they are efficacious in

children demonstrating similar language-based learning difficulties (22, 23).

### **Language Skill Deficits**

How many times have clinicians heard parents report that their child with epilepsy "just doesn't listen," "won't follow directions," or "doesn't express himself well verbally or on paper"? Although comorbid attention deficit hyperactivity disorder (24) and illness-based reasons for difficulty with spoken and written language, such as high frequency of seizures or medication intoxication, should not be overlooked, language disorder is a common problem among children with epilepsy (11, 25). In a recent study 42% of children with epilepsy had some degree of language difficulty. Furthermore, children with focal epilepsies were 30% more likely manifest language disorder than those with other varieties of epilepsy (26).

Many children with complex partial seizures (CPS) have delayed verbal language skills (11, 27, 28). Schoenfeld et al compared a group of children with CPS to a sibling control group and found that the patients had expressive language deficits in the areas of oral vocabulary, oral fluency, and category fluency (27). Fastenau and colleagues found below-average performance on the Stroop naming tasks, suggesting underdeveloped confrontation naming skills and slowed verbal retrieval (3). Caplan et al found deficits in how children with CPS use language to formulate their thoughts. In conversations with CPS children, listeners often experience difficulty following who and what the child is talking about (10). Children with CPS have deficits in expressive language skills and phonological processing (28).

Basic language deficits in children with CPS are related to seizure frequency, to number of antiepileptic drugs (11), and to age of onset (27), suggesting a correlation between the degree of language impairment and the severity of epilepsy. Higher-level discourse skills are associated with verbal IQ, gender, seizure frequency, and age in these children (29). However, in children with intractable epilepsy who were surgical candidates as well as in children who were treated medically, cognitive functioning falls below age expectations across a wide variety of areas including language skill (30). Thus, seizure-related variables account for some but not all of the language difficulty in children with CPS.

Language difficulties are also present in children with benign childhood epilepsy with centrotemporal spikes (BECTS) including problems such as poor articulation, stuttering, and word-finding difficulties (31). Children with active BECTS and those in remission experience difficulty with expressive language, particularly in grammar (32). However, language deficits in these children appear to be strongly associated with atypical seizure characteristics (33).

Research on language skill in other forms of childhood epilepsy indicates problems that are less well documented. Compared to normal peers, children with generalized tonic-clonic seizures and children with absence seizures exhibit different patterns of brain activity when performing semantic processing and phonological tasks (34). Likewise, Caplan et al found that children with absence seizures and children with CPS have similar deficits in their abilities to use language to formulate thoughts (10). In contrast, Pavone et al suggested that language skills in patients with childhood absence epilepsy were relatively intact (35). In yet another study of children with absence seizures, communication deficits were related to duration of illness, male gender, and seizure frequency (36).

In summary, it is clear that many children with pediatric epilepsy struggle with expressive language skills. These skills are an integral to gaining access to their educational curriculum and to scholastic achievement. Although at this time, there are no language interventions designed specifically for children with epilepsy, there are several intervention methods that have been studied in other populations.

### **Language Interventions— Important Considerations**

There are many options for language intervention for children with epilepsy. However, before committing to a specific intervention, parents who suspect their child is experiencing language difficulties should consult with a certified speech and language pathologist and request an assessment. This assessment is designed to identify the child's specific strengths and weaknesses across speech and language domains including vocabulary, phonetics, grammar, pragmatic language, articulation, listening, and comprehension. This information is critical to tailoring interventions to the individual child's needs.

In most areas, a request for a speech and language assessment can be made through the public schools. However, it has been our experience that, even in cases where children are receiving special education services on the basis of their medical illness, parents must ask the school authorities to conduct this testing, rather than relying on the authorities to refer their child for services spontaneously. In cases where school-based assessment is not available (i.e., where a child is attending a private school), many reputable and talented practitioners in private practice are licensed to provide this service. Physicians must make caregivers aware of these resources and must be willing to make referrals themselves to speech and language pathologists.

Wallach recently reviewed important ideas to consider when seeking speech and language intervention (37). Most importantly, interventions should be relevant to the curriculum and should focus on the question "What interventions will facilitate this child's academic success?" Language disorders present on a continuum, resulting in

wide variability in symptom profiles. In most cases spoken language difficulties are related to written language difficulties. As such, written language skill is an important area for assessment. Likewise, reading is a language-based process. Children with language difficulty are prone to developing reading difficulties, a finding that has been supported by a large body of work (21). Hence, assessment must be comprehensive and focus on deeper linguistic skills and language-related difficulties, rather than addressing isolated symptoms.

### **Specific Language Intervention Strategies**

Although there are no treatments that have been studied specifically for application to language disorder in children with epilepsy, there is a great deal of information regarding interventions for children with specific language impairment (SLI). Although these interventions may not have been customized with children with epilepsy in mind, we argue that information from the SLI treatment literature can serve as an important reference when considering treatment for language disability in children with epilepsy. Some of these interventions are described in the following paragraphs.

Verbal and nonverbal deficits in children with specific language impairment not only result in decreased school achievement but also can lead to behavioral problems in school (38). In many cases, grammatical knowledge presents a distinct difficulty for children with SLI. Fey and colleagues listed 10 principles that are fundamental to grammatical intervention in children with SLI (38). Generally speaking, interventions must be developmentally appropriate, with specific goals that are designed to increase the child's fluent use of grammar in conversational language. Furthermore, interventions should take place in environments where social and linguistic context is stressed and where a systematic approach highlights morphological and phonological information.

The narrative-based language intervention has been evaluated as an approach to helping children with SLI improve their conversational skills (39). Poverty of speech content is a problem that plagues children with SLI. This intervention was designed to assist children in developing richer story content, as well as good story form and sentence form. The narrative-based language intervention has enhanced the quality and detail of children's narratives but not grammatically based elements of storytelling.

Fast ForWord® (a product of the Scientific Learning Corporation) is a computerized program designed to assist children with specific language impairment or other expressive language disorders in developing fundamentals of oral language. It offers a variety of programs geared toward developing auditory discrimination, vocabulary, and phonological skills. One appealing component of this program is that it can be implemented both at home

and in an educational setting, providing children with access to resources outside of school. Additionally, Fast ForWord offers a variety of programs geared toward children of different skill levels and ages. It targets both oral language skills and reading development.

Evaluations of the efficacy of Fast ForWord have produced mixed results. Troia and Whitney reported that children with poor expressive oral language improved significantly on a standardized oral language measure after intervention with Fast ForWord in comparison to an untreated control group (40). However, there were no differences between the experimental and control groups on measures of reading and phonological processing skill. Additional studies indicate that Fast ForWord produced gains for children with auditory temporal processing difficulties (41, 42). Cohen et al performed a larger randomized, controlled trial of the effects of Fast ForWord (43). When the Fast ForWord group was compared to two control groups, consisting of a group receiving commercially available language-based computer programs and a no-treatment group, all groups were found to improve, and over time there were no between-group differences. Likewise, in another study that compared the effectiveness of Fast ForWord, Earobics, and LiPS in children with reading and language deficits, no effects on language or reading performance were found (44). Thus, Fast ForWord is neither more nor less effective than other commercially available school-based interventions.

In regard to developing phonological skills, Patricia and Charles Lindamood's Auditory Discrimination in Depth program has been proven to generate both long-term and short-term gains in both phonological awareness and articulation skills in children with reading disability and in children with language disabilities (20). This structured, multisensory phonics approach teaches students core principles of articulation of speech sounds and discrimination of speech sounds. Systematic phonics instruction methods such as the Auditory Discrimination in Depth program help children to master the phonological processing skills required in single-word decoding more effectively than other unstructured methods (45).

### Reading Skill Deficits in Pediatric Epilepsy

Literacy is fundamental to academic achievement. Reading skill is defined broadly by an amalgam of orthographic, phonological, and semantics skills that culminate in fluent single-word decoding and reading comprehension (46). Hence, children need phonological, orthographic, and semantic skills to become fluent, accurate readers (47). Failure to master any one of these key components can result in a disabled reading profile (46, 47). Understanding the specific nature of reading impairment allows for tailored interventions. Despite evidence of reading

difficulties in pediatric epilepsy patients, few studies have examined cognitive correlates of reading disability in epilepsy patients (5, 8, 48). The information we do have regarding reading in children with epilepsy comes largely from patients with partial epilepsies (5, 8, 48).

Children with CPS experienced more reading problems, in particular problems with phonological skill and slow reading rate, than age-matched normal peers after controlling for differences in IQ (49). Children with left-sided CPS had more difficulty reading and experienced a greater degree of delays in phonological decoding, reading comprehension, and word recognition than those with right-sided CPS. Phoneme sequencing was particularly impaired among the left CPS group in comparison to both normal children and those with a right-sided epileptic focus. Children with right-sided CPS demonstrated visual-spatial but not language-based difficulties.

Reading deficits have been reported in children with temporal lobe epilepsy (TLE) (8). Children with TLE performed less well than those with idiopathic generalized epilepsy and those with BECTS on measures of reading speed and comprehension. However, these findings were affected by seizure-related variables, suggesting a relationship between illness severity and decreased reading skills. In the TLE group, children with left-sided epileptic activity (LTLE) demonstrated more reading difficulties than those with right-sided foci (RTLE). Phonological and semantic problems were prominent in the LTLE group compared to the RTLE group, suggesting that phonological processing difficulties may be sensitive to the lateralization of an epileptic focus.

In a study of French-speaking children with epilepsy, children with TLE, frontal lobe epilepsy, and childhood absence epilepsy (CAE) had reading deficits compared to healthy peers (48). Although children with TLE performed significantly less well than control subjects on overall reading ability, they did not demonstrate phonological deficits, as did children with frontal lobe epilepsy. Children with CAE showed deficits only in phonemic segmentation, implying a milder phonological delay. As a group, children with epilepsy did not differ from controls on language tasks, suggesting that reading deficits do not stem from underlying language problems. Children in the epilepsy groups did not differ on seizure frequency, age of onset, or duration of illness. No effect was found for monotherapy versus polytherapy with antiepileptic medications. The authors suggest the difficulty that the frontal lobe epilepsy patients had with single-word decoding may have resulted from decreased attention or reduced executive functioning.

In a study comparing written language skills of Greek-speaking children with benign rolandic epilepsy to normal peers, children with acute symptoms performed worse than controls on reading comprehension, reading aloud, and spelling (5). The Greek version of the Bangor

Dyslexia Test produced significant differences between children with epilepsy and controls.

### **Reading Interventions— Important Considerations**

The majority of research on intervention in reading disability, in particular developmental dyslexia, has been focused around the idea that dyslexic readers have core deficits in phonological processing (21). This phonological deficit limits the individual's ability to manipulate speech sounds within words, to learn spelling to sound correspondences, and to decode single words accurately (50–52). However, phonological deficits can manifest themselves in many ways and are not limited to deficits in single-word decoding. Dyslexics of all reading levels have been shown to perform poorly in comparison to same-age normal control subjects on tasks of phoneme deletion, position analysis, speech perception, letter naming, spelling, lexical access, verbal working memory, and auditory processing of fast temporal stimuli (53–57). The phonological core deficit hypothesis proposes that dyslexics' reading difficulties are related to specific deficits in the representation and use of phonological information (21, 55, 58). Whereas reading deficits such as poor comprehension may not necessarily be phonologically based, the majority of poor readers do demonstrate some degree of phonological impairment (47). This being said, a savvy advocate for a child with epilepsy will want to investigate the variety of phonics-based interventions available.

There are a variety of structured, multisensory phonics programs that emphasize teaching students to understand grapheme-phoneme correspondences and single-word decoding strategies. As mentioned earlier, structured, systematic phonics approaches to instruction are the most effective with poor readers (45). Key components of successful systematic phonics interventions involve intensity of teaching and frequency of instruction (20). Likewise, early phoneme awareness intervention in kindergarten reduces the incidence of reading disability in at-risk children in both short-term and long-term follow-up (58). Moreover, the practitioner must be qualified to administer the intervention. In most cases, teachers must obtain specialized training that results in certification to be able to provide this instruction (i.e., Orton-Gillingham, Slingerland, Wilson Reading). In selecting a teacher or learning specialist it is important to ascertain whether that person is certified in these approaches. Overviews of some of these methods are provided herein.

### **Specific Reading Intervention Strategies**

Orton-Gillingham is a multisensory phonics intervention designed to be delivered on an individualized basis (59). This program uses auditory, visual, and kinesthetic

sensory input to create a total language approach that first emphasizes grapheme-phoneme correspondence rules (e.g., “A” says /a/ as in apple) and moves on to teach phonograms, vowel patterns, and syllable patterns. Written instruction, including letter formation, is taught along with phonological instruction to reinforce multisensory connections and teach spelling patterns. Reading whole words is introduced when the child has mastered simple vowel patterns and phonograms. Later, Beth Slingerland adapted this approach to be used in a classroom setting. Hence, the Slingerland method is the classroom adaptation of Orton-Gillingham and follows the same pedagogical principles (60).

Wilson Reading is also a structured, multisensory approach to reading designed originally for one-to-one instruction and is based on the Orton-Gillingham model (61). Originally designed for adolescents and adult poor readers, this 12-step, sequential program emphasizes awareness of individual speech sounds as well as six syllable types. From a teacher's perspective this system is very accessible because it comes with many premade instruction materials and can be adapted to work in a small group setting.

As described previously, Auditory Discrimination in Depth (20) is an effective method of teaching phonological awareness to children. Since its inception Patricia Lindamood has collaborated with Nancy Bell to form what is now called the Lindamood-Bell approach. Similar in content to Auditory Discrimination in Depth, Lindamood-Bell also incorporates training in orthographic knowledge and reading fluency (62).

Project Read is a school-based approach to reading remediation aimed at delivering phonics instruction to children falling in the lower quartile in reading and spelling skills (63). The curriculum, which is used frequently in school settings, is composed of the following three phases: (1) multisensory phonics instruction using Orton-Gillingham-like techniques, (2) reading comprehension and vocabulary skills, and (3) written language skills (spelling and sentence structure). This program is quite cost-effective and can be administered in a small-group setting. Another strength of the program is that it is designed for any child who is a poor reader, not just for dyslexic children. Hence, this intervention is quite broadly based and may be more suited to “garden variety” poor readers.

### **SUMMARY AND IMPLICATIONS**

Language-based learning disabilities are associated with various types of pediatric epilepsy and often occur independently of epilepsy-related variables. Given that many academic problems such as reading, spelling, and language disabilities have specific underlying cognitive mechanisms (i.e., phonological deficits in the case of reading impairments), the key to intervention lies in pinpointing the

cognitive processing mechanisms interfering with optimal learning. Efficacious intervention is best conducted by implementing appropriate, valid educational methods. Using tools such as a comprehensive neuropsychologic evaluation, we are able to identify a particular child's cognitive strengths and weaknesses and to tailor an appropriate educational strategy. If one considers learning disability as a presenting symptom, following it to its underlying cause facilitates proper treatment. Although no educational interventions are specific for children with epilepsy, much can be learned from existing methods of remediation for reading and language deficits for children with similar learning problems.

### Clinical Implications

Although each child is an individual requiring a tailored educational approach, in our experience there are fundamental areas of concern that affect many children with epilepsy. Based on this, we offer the following guidelines in choosing an appropriate educational intervention.

First, we recommend a comprehensive, psychoeducational or neuropsychologic testing assessing for learning disabilities. Although it is often difficult to ascertain which symptoms (i.e., psychomotor slowing) are illness related and which indicate learning disorder, simply identifying the child's specific cognitive strengths and weaknesses is essential to developing an educational plan. This assessment is highly specialized and should be conducted by a licensed educational psychologist, pediatric neuropsychologist, or clinical psychologist with appropriate training.

Second, close communication between parents, students, and teachers is essential. Developing open lines of communication with the child's primary instructor is crucial to academic success. Knowing that many teachers do not have adequate knowledge of epilepsy, we encourage parents to provide teachers with this information. Succinct resource guides are often quite effective because most busy teachers prefer concise sources of information. Teaching children good coping skills, such as becoming their own advocates how to discuss their illness with peers and adults is also a key factor in academic success (64). One way to do this is to perform role playing exercises with the child, teaching him or her how to explain his or her special needs to an adult.

Third, after specific learning difficulties have been identified, parents should work with educational therapists and school psychologists to develop an intervention

strategy. This should be a collaborative effort between caregivers and educators. In discussing this plan with educational professionals, it is essential to set measurable and appropriate academic goals for the child. These goals should be documented and revisited appropriately. Due to a lack of evidence, we cannot recommend specific educational intervention strategies. However, we encourage parents whose children have reading and language disabilities to explore the array of available methods. Examples of these methods include Lindamood-Bell, Wilson, and Orton-Gillingham for reading difficulties and Fast ForWord for language problems.

Last, we encourage health care professionals to advocate for parents attempting to obtain services from their child's school. Often, parents are unsure of the specific steps necessary to qualify their child for special education services. By becoming familiar with the steps required in the local community, health care professionals can guide parents through this process. This process typically requires submitting to the school district a written request for a special education evaluation and following a predetermined protocol. Frequently, parents will ask their treating physician to document their child's illness and the ways in which it impacts the child's learning. Providing supporting documentation with clearly outlined requests for specific educational services greatly increases the patient's chances of obtaining an optimal educational intervention. It is imperative to request all reasonable academic accommodations and assessments to ensure that proper resources are allocated to the child.

Depending on circumstances, the process of obtaining special education services for a child can be time consuming and frustrating. Parents should be encouraged to be both patient and persistent in their pursuit. Many school districts are not aware that children with epilepsy have both illness-related educational needs and specialized learning needs. Therefore, educational administrators have little knowledge of the sorts of academic accommodations that children with epilepsy and associated learning difficulties require. Educating school professionals about the needs of pediatric epilepsy patients is essential, as is encouraging continued research regarding educational interventions for children with epilepsy. However, what is paramount is supporting our patients in the process of securing appropriate educational interventions and helping them to understand that just learning differently does not mean that they cannot learn.

## Cognitive Side Effects of Antiepileptic Drugs

*David E. Mandelbaum*  
*Christine L. Trask*

**C**ognitive side effects have emerged as a key consideration when an antiepileptic drug (AED) is being selected for the treatment of childhood seizure disorders. In years past, despite concerns about side effects, when the choice of antiepileptic medication was limited to phenobarbital and phenytoin, their adverse effects were accepted as a “necessary evil.” After the Perinatal Collaborative Project demonstrated the generally benign course of recurrent febrile seizures (1), thinking shifted to the view that it might be best to avoid phenobarbital in the treatment of febrile seizures because it appeared that “the cure was worse than the disease” given concerns about adverse cognitive and behavioral effects of phenobarbital. In the early 1970s the emergence of carbamazepine as an alternative to phenytoin for partial seizures generated interest in the cognitive side effects of medications and stimulated debates as to whether carbamazepine had a side effect profile that was preferable to those of phenytoin and phenobarbital. Since then there has been a remarkable increase in options for the pharmacological management of seizures. As treatment options have increased there has been a commensurate increase in the interest in the side effect profiles of these drugs. For the most part, phase III trials reveal that there is little, if any, difference in efficacy among the different drugs. Thus, although the choice of an AED is driven, in part,

by seizure type or epilepsy syndrome, in the final analysis the selection of an AED for a particular patient is heavily influenced by the side effect profile.

When drugs are brought to market, relatively little is known about their cognitive and behavioral side effects. Unfortunately, formal psychometric testing has not routinely been included in the studies done as part of the Food and Drug Administration (FDA) approval process. As a result, the information available regarding cognitive and behavioral side effects is limited and incomplete. Although some phase II and III trials have included quality of life assessments, these are not a substitute for objective, standardized, and quantifiable psychometric measures of the impact of these medications on cognition.

The epilepsy itself is an important confounding factor in assessing the cognitive effects of AEDs. Epilepsy can be associated with cognitive problems by virtue of the intrinsic neuropathology underlying both the mental impairment and the epilepsy. Cognition can also be affected by the seizures themselves, interictal electroencephalographic (EEG) activity, psychosocial problems, familial factors, and, of course, the effects of the AEDs (2). When AEDs suppress epileptiform discharges and decrease seizure frequency, they can improve cognitive function (3). However, the mechanisms by which AEDs suppress seizures may also affect normal neuronal mechanisms such as ion channel permeability, receptors,

neurotransmitter kinetics, and second messengers and interfere with cognitive function. The mechanisms of action of the various anticonvulsant drugs are reviewed in Chapter 30 of this textbook.

Many of the studies assessing the cognitive side effects of AEDs in adults and children suffer from major methodological flaws, limiting the information that can be gleaned. Before reviewing these studies, it is advisable to review these methodological issues.

The first issue in the study of AEDs relates to who is being studied. Studies vary by patient selection criteria, including type of seizures, age of subjects, and duration of exposure to medication. In examining the influence of AEDs on cognition in patients with epilepsy, many studies include patients with any type of epilepsy. This can be problematic because, compared to patients with idiopathic epilepsy, patients with symptomatic epilepsy are more likely to have associated or underlying neurological disorders that directly impair neurological function, including cognition, attention, mood, and behavior (4). People with symptomatic epilepsy may also be more sensitive to the neurological adverse effects of AEDs.

Even within the category of idiopathic epilepsy, different seizure types are associated with varying cognitive impairments. For example, in a study of 43 children with new-onset idiopathic seizures, Mandelbaum and Burack (5) found that cognitive functioning was worse in children with generalized versus partial seizures, and nonconvulsive versus convulsive seizures, a difference that also may have an impact on adverse responses to AEDs.

Another methodological issue in studying the effect of AEDs on cognition is the composition of control groups. Studies may use either an “active” control (e.g., people receiving another medication, or with another medical disorder) or a “healthy” control. In some studies AEDs have been administered to normal adult volunteers. Although these studies have the virtue of isolating the effects of the AEDs from the effects of epilepsy or other medications, they have disadvantages as well. Most of them are limited to a short-term period of observation. None of them could detect a beneficial interaction between the AED and the epileptic brain. Furthermore, there are important differences between the mature, adult brain and the developing child’s brain, which limit the applicability of studies in normal adult volunteers to children.

The use of a medical control group has the potential advantage of controlling for the socioemotional effects of dealing with a health condition. These types of control subjects may include children with other neurological or systemic illnesses. For example, in a study comparing children with newly diagnosed diabetes to children with newly diagnosed seizures before and 6 months after initiation of treatment, Williams and colleagues (6) found no differences over time between the groups on measures

of cognitive or behavioral functioning. In contrast, Seidel et al (7) found that in a repeated-measures design, 14 children with untreated migraine headaches exhibited higher verbal memory scores in comparison to 10 children with benign rolandic epilepsy treated with carbamazepine. In a study by Bourgeois and others (4), the IQ score of the sibling controls of children with symptomatic epilepsy was much lower than the IQ score of the sibling controls of children with idiopathic epilepsy, illustrating the importance of socioeconomically (and, perhaps, genetically) matched controls.

Controlling for practice effects is important when studies follow children over time, with testing done before and after treatment. For this reason a separate control group is of considerable importance to interpreting the significance of changes in scores over time. Normal individuals who undergo repeated cognitive assessment as long as 4 years apart, much longer than is traditionally associated with a test-retest effect, show notable increases in test scores during repeated administrations (8). This raises the possibility that a lack of practice effect, that is, stable scores over time, indicates an adverse effect on learning.

Comparison of different studies is thwarted by significant variability in the measures used by individual researchers. Cochrane and colleagues (9) reviewed 40 randomized, controlled trials and noted a lack of uniform approach to neuropsychological assessment with approximately 87 different measures being used. The most commonly identified measures were the Stroop Color Word and Finger Tapping Test. Nevertheless, these tests were not used or reported uniformly, a lack of consistency that creates significant obstacles for integrating information across different studies. Furthermore, the decision of what is and is not included in the test battery can significantly affect the results. A drug may “look good” or “look bad” depending on the type of testing that was done. For example, in some of the early testing with carbamazepine it was demonstrated that carbamazepine enhanced sitting behavior, yet other studies showed adverse effects on motor tasks.

When reporting test results, it is essential that the nature of the data being used (e.g., raw scores, standardized scores based on manual-provided information, or specific reference to independent normative samples) be identified. Table 69-1 represents a battery of well-developed and widely available measures. This battery is proposed as a more uniform approach to studies of the cognitive effects of AEDs. In this battery the Stroop color word phenomenon is assessed as part of the Delis-Kaplan Executive Function System (D-KEFS), Color Word (10). Completion of comprehensive neuropsychological testing has practical limitations and choices must be made about which tests to administer. For example, the test battery listed in Table 69-1 would take 5 to 6 hours to

administer and another 1 or 2 hours to score. The cost of doing such studies becomes immediately apparent, not to mention the challenge of assuring compliance with serial measures.

Research investigating the cognitive effects of AEDs must control for other potentially confounding variables, including parental intellectual level, family dynamics (e.g., level of disorganization, level of negative affect), and other stressors, including financial limitations. Socioeconomic status is one of the strongest predictors of intelligence in children with epilepsy (27). Ostrom and colleagues (28) found that cognitive and behavioral outcomes in 42 children with idiopathic or cryptogenic, newly diagnosed epilepsy followed over 3.5 years were related to the child's prediagnostic learning history, as well as to the parents' ability to cope effectively with their child's epilepsy. Children from disorganized and unsupportive homes were also more likely to have a poorer academic outcome (29, 30).

As a result of selection bias when subjects are chosen, results from studies of AEDs on cognition may not be generalizable to the population at large. For example, the majority of research in pediatric epilepsy has been conducted at epilepsy centers, where patients are more likely to have associated handicaps and severe forms of epilepsy (31).

There are differences of opinion on how the data on cognitive aspects of AEDs should be collected. A major research design question is whether to use cross-sectional versus prospective approaches. Cross-sectional studies are useful in that they help identify variables that show relationships with the identified area of interest by providing a snapshot of that relationship. Prospective, randomized studies are essential to establish the causal aspect of a relationship. Ideally, an initial neuropsychological assessment should be completed when epilepsy is diagnosed and before initiation of medication, with serial measures after treatment is initiated.

Other factors can also influence cognition among children with epilepsy. Subclinical or subtle seizures can affect test results. Thus, it is optimal to have EEG monitoring done at the time of testing, or at least in close proximity to the time of testing. The effect of AEDs on test performance may be influenced by drug concentrations (32), including whether testing is done at the time of peak or trough levels. Whereas drug concentrations fluctuate throughout the day, testing at a consistent time of day can minimize the confounding influence of this variable.

Finally, in any study comparing two groups, the null hypothesis—that is, that there is no difference between the two groups (treatment vs. placebo, drug A vs. drug B)—has to be disproved to a degree of statistical probability. Usually a two-tailed test with the *P* value set to <0.05 is used when a single outcome is being evaluated. A poorly designed or executed study or a study with

**TABLE 69-2**  
*Methodological Issues*

SUBJECT SELECTION	CONTROL GROUPS	ENVIRONMENTAL FACTORS	OUTCOME VARIABLES	ANALYSES
Idiopathic vs. symptomatic	"Active control" e.g., headaches, diabetes	SES/Parental functioning	Different measures in different studies	Sample size
Focal vs. generalized	Siblings	Investigator and parental bias	Subjective vs. objective measures	Cross-sectional vs. longitudinal studies
Healthy adults	"Internal controls" (practice effect)	Peak vs. trough levels		

SES = socioeconomic status

inadequate power (as with a sample size that is too small) can fail to detect important differences. Many studies on this topic are single-center studies that have a small sample size that may miss important differences between study conditions. Likewise, when many outcomes are considered simultaneously, such as multiple subtest scores in a psychometric test battery, the probability value used to reject the null hypothesis must be made more stringent. If the *P* value is set at 0.05 and 20 dependent variables are evaluated, one or more dependent variables is likely to attain a level of significant difference by chance alone. Setting the *P* value at 0.01 or 0.001 is required to avoid this pitfall in data analysis.

The limitations of the literature notwithstanding (Table 69-2), representative studies that have looked at the question of cognitive effects of AEDs will now be reviewed. The reader is also directed to a supplement of the *Journal of Child Neurology* that was devoted to this topic (33).

### PHENOBARBITAL

Because phenobarbital is the drug that has been used longest to treat epilepsy, there is a fairly extensive body of literature regarding its adverse effects. Phenobarbital is widely considered to have substantial adverse side effects, particularly as it relates to cognition. However, in a comprehensive review of the literature on phenobarbital, Pal stated, "The overall design quality and statistical methodology of clinical trials in this area is poor, especially for those trials conducted in the 1970's and 1980's" (34). Pal reported that blinded studies of childhood epilepsy did not show significant differences of behavioral or cognitive side effects when phenobarbital was compared to other AEDs, in contrast to studies in which the investigators were unblinded, hence subject to observer bias. In his review of the literature, there was one double-blinded,

randomized, placebo-controlled study of phenobarbital for febrile seizures that showed an adverse effect of phenobarbital on IQ after 2 years of treatment that persisted for 6 months after discontinuation of therapy (35). However, this study had several confounding features including the following: Among 638 children eligible to enroll 421 declined, mostly because of parental reluctance to have the child take phenobarbital. The lowest-IQ group showed the greatest decrease in IQ compared to placebo, and it was the low-IQ phenobarbital group that had the greatest number of dropouts, with only 11 of 24 available for testing at 2 years and 13 of 24 at 2.5 years. Furthermore, although the analysis was done on the basis of intention to treat, because of breakthrough seizures and side effects, many participants did not complete the study. For example, approximately 25% of children assigned to placebo were taking phenobarbital by the end of the study, and only about half of the children assigned to phenobarbital were still taking phenobarbital at the end of the study. It is impossible to know how these factors impacted on the outcomes reported, but statistical assumptions had to be made to analyze the results.

Concerns have been raised about behavioral problems from phenobarbital (36). But, as pointed out by Pal, these data represent parental report in an unblinded, nonrandomized, uncontrolled study. A study comparing the efficacy of phenobarbital, valproate, and intermittent rectal diazepam, in which subjects were randomly assigned to treatment group, found that the parents of 8 of 41 children taking phenobarbital discontinued it because of side effects. In contrast, only 3 of 50 parents discontinued valproate (37).

In an effort to use surrogate neurophysiological data to assess the effect of phenobarbital on central nervous system (CNS) function, Chen et al (38) noted a prolongation of P-300 latencies in auditory evoked potentials in children treated with phenobarbital and not in those treated with carbamazepine or valproate monotherapy.

## PHENYTOIN

Aman and colleagues in 1994 (39) investigated the cognitive impact of phenytoin by assessing children at both trough and peak levels and found no effect on cognitive performance, although the drug concentrations studied were rather low. A study of phenytoin compared to placebo in healthy adults found impaired memory, concentration, and mental and motor speed while taking phenytoin (40). An open-label study of cognitive function in children with epilepsy treated with either phenytoin, carbamazepine, or valproate monotherapy found that the phenytoin group did worse than the valproate group on a single measure of processing speed after 1 month, but not after 6 or 12 months of treatment (41).

## CARBAMAZEPINE

Carbamazepine, approved for epilepsy in 1974, provided the first major alternative to phenobarbital and phenytoin for localization-related epilepsies. Studies of the cognitive impact of carbamazepine have shown both beneficial and adverse effects on cognition. Aman and colleagues (42) studied 50 children on carbamazepine monotherapy at trough and peak concentrations and found that the children performed significantly better at peak carbamazepine concentrations on measures of activity, attention span, motor steadiness, and task-specific response times. In a study by Forsythe and colleagues (41), 64 children with newly diagnosed epilepsy were randomly assigned to carbamazepine, phenytoin, or valproate. Cognitive testing was done before initiation of treatment and three times over the first year of treatment. The authors concluded that carbamazepine in moderate doses adversely affected memory, whereas valproate and phenytoin did not. A study by Stores and colleagues (43) compared 63 newly diagnosed children randomly assigned to either carbamazepine or valproate with 47 matched controls. Cognitive testing done before initiation of treatment and at intervals over 1 year revealed modest effects of both carbamazepine and valproate on cognitive abilities. There were no effects on behavioral measures, and there was no difference between carbamazepine and valproate. A study by Berg and colleagues (44) evaluated 64 children newly diagnosed with epilepsy who were randomly assigned to carbamazepine, phenytoin, or valproate. Behavioral measures were done before medication and after 1 and 6 months of treatment. The authors found that carbamazepine and valproate were associated with minor behavioral difficulties after 1 month, but these problems were not present at 6 months. In another study of children with both generalized and focal epilepsy, carbamazepine resulted in impaired reaction time variability that persisted over 12 months of treatment (45). In this group of

patients there were attention problems at baseline, before medication was started. In most measures of cognitive functioning there were no adverse effects after initiating treatment with anticonvulsants.

## VALPROIC ACID

Valproic acid, approved in the United States 4 years after carbamazepine, is useful in localization-related, generalized, convulsive, and nonconvulsive epilepsies. A study of children randomly assigned to valproic acid, carbamazepine, or phenytoin showed valproate to have fewer negative effects than carbamazepine or phenytoin (41). One study of children with newly diagnosed epilepsy found that scores on 4 tests of a total of 30 administered over a 12-month period were significantly worse in the children treated with valproate than in controls; a similar result was found for the carbamazepine group (43). However, it is worth noting that valproate has been used successfully to treat children with explosive temper and mood lability (46).

## NEWER DRUGS

There is less information about the newer AEDs introduced since 1992. Among these drugs, topiramate appears to have more adverse cognitive effects than lamotrigine, oxcarbazepine, and levetiracetam. (47)

### Lamotrigine

Among the newer AEDs, one of the better studied drugs is lamotrigine. Lamotrigine administered to normal adult volunteers caused no adverse effect on cognitive function compared to controls (48, 49); nor did lamotrigine result in any adverse effects in adults with epilepsy (50, 51). A study by Meador et al (52) comparing treatment with lamotrigine and carbamazepine in a double-blinded, randomized, crossover design demonstrated lamotrigine to have a side effect profile preferable to that of carbamazepine. Studies in children have suggested positive effects such as behavioral improvement and increased alertness, even in the absence of seizure reduction (53, 54).

### Gabapentin

Gabapentin has been associated with behavioral problems in children. In a double-blind, placebo-controlled, add-on study among children with refractory partial-onset seizures, gabapentin was associated with an increased incidence of somnolence, hostility, emotional lability, and hyperkinesias compared to placebo (55). Other reports indicate that children with mental retardation are at

greater risk than children with normal IQ for developing aggressive behavior while taking gabapentin (56). Studies in adult volunteers have shown no adverse effect of gabapentin at doses of 2,400 mg/day (57, 58). In the study by Meador et al, of 31 variables assessed there were 6 in which the subjects taking no drug did better than they did while taking gabapentin, as opposed to 15 variables in which the no-drug group did better than those taking carbamazepine. On 8 variables performance while taking gabapentin was superior to that while taking carbamazepine. Carbamazepine was not superior to gabapentin on any variables in this study. Note, however, that although this was a blinded study and the subjects were studied while not taking and while taking the two drugs, there was no placebo group.

### **Tiagabine**

Tiagabine, which acts by increasing the effect of gamma-aminobutyric acid (a mechanism shared by barbiturates), variably causes disturbances in mood and behavior. In placebo-controlled studies, tiagabine, as either monotherapy or add-on in 162 subjects with epilepsy, was reported to cause no adverse cognitive effects (59). However, an open-label study of tiagabine as adjunctive therapy in children with refractory, complex partial seizures reported complaints of somnolence, headache, dizziness, and nervousness. These complaints diminished over time and were less frequent when the drug was used as monotherapy (60).

### **Vigabatrin**

In an open label, randomized study comparing vigabatrin and carbamazepine monotherapy in adults with newly diagnosed epilepsy, there were no adverse effects of vigabatrin on cognitive functions, thus demonstrating a better adverse effect profile than carbamazepine (61). A similar, open label, randomized trial comparing vigabatrin to carbamazepine in children found that 6 of 38 children taking vigabatrin were described as having excessive irritability and excitability, whereas 6 of 32 children taking carbamazepine were excessively sedated (62). Vigabatrin, which is not FDA approved for sale in the United States, is largely limited to treatment of children with infantile spasms, particularly those with tuberous sclerosis. Little data are available on cognitive effects in this severely involved group of patients. Although vigabatrin has been shown to have significant neurotoxic effect in animal models, consisting of intramyelinic edema with microvacuoles in the optic tracts, cerebellum, hippocampus, and columns of the fornix in rodents and dogs (63), no effects on white matter have been found on magnetic resonance imaging (MRI) studies of humans who took vigabatrin. However, vigabatrin causes irreversible visual field constriction in what appears to be

an at least partially dose- or duration-dependent fashion. Of note, in most cases these visual field defects were not overtly symptomatic (64).

### **Topiramate**

Topiramate has been linked to difficulties with word finding and coding on psychometric tests. Meador and colleagues (65) compared the cognitive effects of topiramate to those of valproate or carbamazepine in adults with partial epilepsy. On the symbol-digit modalities test, 20% of the patients taking topiramate had a worsening in their performance of greater than 1 standard deviation, as opposed to none of the patients taking valproate. On a controlled word-association task, about 25% of the topiramate group performed more than 1 standard deviation below their baseline scores compared with about 10% in the valproate group. A double-blind, randomized, placebo-controlled study of topiramate as add-on therapy for children with intractable partial seizures noted increased incidences of emotional lability, fatigue, attention and concentration problems, and forgetfulness, compared to placebo; and this was despite improved seizure control (66). In another study of 42 patients with juvenile myoclonic epilepsy treated with valproate (62%) or topiramate (38%) monotherapy, among 27 items in the psychometric battery, the topiramate group performed significantly worse in 3. Two of the three were measures of memory, attention, and speed processing, and one a measure of verbal fluency (67).

### **Oxcarbazepine**

In general, oxcarbazepine has not been linked to adverse cognitive effects. A study of the cognitive effects of oxcarbazepine, carbamazepine, and valproic acid in adults with newly diagnosed epilepsy showed no deterioration of cognitive function in patients in any of the treatment groups. In fact, there was improvement in learning and memory tests in the oxcarbazepine and carbamazepine groups, but not the valproate group. The patients who were treated with valproate showed improvement in attention and psychomotor speed (68). In studies on healthy volunteers, oxcarbazepine improved attention and writing speed and had no effect on long-term memory (69). One add-on study of oxcarbazepine in children with intractable epilepsy reported a 35% incidence of somnolence in children taking oxcarbazepine compared to a 14% incidence of somnolence in the placebo group (70).

### **Levetiracetam**

Levetiracetam, although chemically related to piracetam, a drug with cognitive enhancing effects including improvement in learning and memory, has not been

shown to have the same nootropic effect (71). A review of the adult literature comparing the behavioral effects of levetiracetam in adults with epilepsy versus adults with cognitive or anxiety disorders showed a greater incidence of depression, nervousness, hostility, anxiety, and emotional lability in epileptic patients treated with levetiracetam compared to placebo (72). A study of the cognitive and neurophysiologic measures in healthy volunteers treated with carbamazepine, oxcarbazepine, and levetiracetam found motor slowing in the volunteers treated with carbamazepine and oxcarbazepine, but not levetiracetam. Attention span increased from baseline levels with all three drugs. Carbamazepine and oxcarbazepine induced changes in some components of the visual evoked potential responses, whereas levetiracetam did not. Similarly, oxcarbazepine and carbamazepine, but not levetiracetam, resulted in slowing of the EEG (73). An open-label, retrospective study of levetiracetam as add-on therapy in children with intractable seizures found that among 41 of 59 children still taking levetiracetam at 12 months, 28% had adverse behavioral effects and 24% were lethargic in a non-dose-dependent fashion (74).

### Zonisamide

Zonisamide, approved in the United States in 2000, was not studied in children before its release. Clinical experience, particularly in Japan, indicates that it is effective in a wide range of seizure types in children and adults (75). An open-label study of cognitive functioning in adults treated with zonisamide as add-on therapy showed effects on the acquisition and consolidation of new information with no effect on previously learned material or psychomotor performance. Verbal learning was affected, whereas visual-perceptual learning was not. There was a correlation between the impairment of cognitive function and the plasma concentration. There was also evidence of the development of tolerance to the adverse effects over time (76). In a retrospective review of their experience with children with intractable epilepsy treated with zonisamide as add-on therapy, Mandelbaum and colleagues (77) reported that at 12 months, among the 19 of 35 children still taking zonisamide, 7 (37%) were described as lethargic, 3 had behavior problems, and 3 had decreased appetite in a non-dose-dependent manner.

### Pregabalin

A study of pregabalin administered to healthy adult volunteers demonstrated an effect of pregabalin on a subset of psychometric tests; specifically, of a total of seven psychometric tests, there was an adverse effect in three and an improvement in one, compared to placebo.

Functions adversely affected included arousal and reaction time, both of which were affected transiently. The test on which there was an improvement on pregabalin was also an assessment of reaction time. The third test in which pregabalin treatment was associated with a worse score was a subjective report of sedation. (78). No studies of children have been reported.

### Clobazam

A drug that has not been approved for sale in the United States, clobazam is one of the few AEDs that have been studied in children using formal psychometric measures. A study comparing clobazam to carbamazepine or phenytoin found that the scores on performance IQ and memory tests were inversely related to clobazam serum concentrations. Whereas practice effects were evident in children on carbamazepine and phenytoin tested after a year of treatment, the children taking clobazam did not have a practice effect (79). As discussed previously, the absence of a practice effect likely indicates impairment of cognitive function (8).

## VAGUS NERVE STIMULATION

A study by Clark et al (80) compared 10 patients with vagus nerve stimulation (VNS) to a control group of patients with sham stimulation and found that VNS stimulation of 0.5 milliamperes administered after reading a paragraph enhanced word recognition; there was no improvement with stimulation intensities of 0.75 to 1.5 mA and no improvement if the stimulation was done before reading the paragraph.

## CONCLUSION

The nature of the data available, coupled with individual variability in response to the various AEDs, make it difficult to predict how an individual child will respond to a specific drug. The newer AEDs have the advantage of requiring less monitoring for medically serious adverse effects such as bone marrow suppression or hepatic dysfunction. For absence seizures, ethosuximide is a safe, effective drug with little in the way of adverse effects (81). For partial seizures and generalized convulsive seizures there are some clues as to which drugs are more or less likely to be problematic (Table 69-3). When administered prudently, lamotrigine, tiagabine, oxcarbazepine, levetiracetam, and zonisamide are effective, safe, and have favorable cognitive side-effect profiles. Topiramate and clobazam appear to be more likely to cause cognitive side effects, and gabapentin has been linked to adverse behavioral effects. It is of interest that a critical review of the

**TABLE 69-3**  
**Summary of Predominant Adverse Cognitive and Behavioral Effects**

DRUG	BEHAVIORAL/COGNITIVE EFFECTS	REFERENCES
Phenobarbital	IQ effects, irritability	34, 35, 36, 37
Phenytoin	Processing speed	39, 40, 41
Carbamazepine	Memory, behavior	41, 42, 43
Valproic acid	(cognitive teratogenic effects)	41, 42
Lamotrigine		53, 54
Gabapentin	Behavior	55, 56
Tiagabine	Somnolence, nervousness	59, 60
Vigabatrin	Irritability, excitability	62
Topiramate	Cognitive	66, 67
Oxcarbazepine	Somnolence	70
Levetiracetam	Behavior	72, 74
Zonisamide	Cognitive, behavior	77
Pregabalin	No childhood studies	
Clobazam	IQ and memory	79

literature on phenobarbital suggests that its reputation for adverse cognitive and behavioral side effects is not fully documented. Hopefully, multicenter, blinded, head-to-head studies of different AEDs using a uniform battery of formal psychometric measures will be done to address

these questions more conclusively. Pharmaceutical company-sponsored studies of new drugs should include objective, quantifiable psychometric testing in addition to the subjective, qualitative adverse effect reports that are currently the norm.
