For organelle analysis, median filtering is performed with a large rank (large filter window) so that all the sharp spikes are removed from the electropherogram. Then, the filtered electropherogram, which contains the wide peaks and background drift, is subtracted from the original to yield an electropherogram with a flat baseline and sharp spikes that represent the detection of individual organelles. As reported, the optimum rank value should generally be equal to, or greater than, the baseline peak width of the widest peak of interest.<sup>95</sup> However, in the analysis of individual organelles, we find that the optimum rank value is much greater than the baseline peak width; that is, typically greater than 10 times the average peak width. When the rank is too low, negative peaks will be observed in the filtered data. Following the median filter procedure, organelle events can be discriminated from noise based on their intensities. Frequently, five times the standard deviation in the background is used as the threshold to identify organelles.

## 20.6 CONCLUDING REMARKS

As shown throughout this chapter, CE is a very versatile and powerful separation technique that has proven useful in subcellular analyses. As in all applications of CE, a trend for subcellular analysis is increasing throughput by using microfluidic devices to reduce separation times. This was recently demonstrated by analyzing fluorescently labeled mitochondria, for the first time, on a microfluidic chip.<sup>96</sup> The analysis allowed a fivefold reduction in analysis time, from 20 to 4 min. To realize the full potential of CE, advances in electrophoretic models must also be made. Models that can accurately predict electrophoretic mobility, as well as explain observed differences, will allow this information to be used more effectively. Finally, as the information that can be gleaned from an electrophoretic

separation is limited, the development of complimentary techniques that can be combined with CE will allow more information about subcellular compartments to be discovered.

## 21.1 INTRODUCTION

The cell is the organizing unit of life, and characterization of the composition of cells is of value in both fundamental research and in clinical applications. Classic analytical methods are often used to characterize cellular homogenates produced from thousands to billions of cells. These methods are

**FIGURE 21.1** Comparison of two cellular populations, one homogeneous, with a key component present at intermediate levels, and the other heterogeneous, with some cells lacking the compound while others have that compound in high abundance.

unable to distinguish between a homogeneous population of intermediate composition and a heterogeneous population made up of a mixture of high- and low-expression cells. Figure 21.1 presents two samples that have the same average composition. In one case, the population is homogeneous and in the other is highly heterogeneous; the responses of these populations to a stimulus are likely to be quite different.

In many cases, it is clearly useful to study single cells, rather than an average of the population. Classically, flow and image cytometry are used to measure physical properties and chemical composition of single cells, and are very important in both clinical and fundamental research. In these methods, affinity reagents are usually used to determine the distribution of a handful of components in a cellular population. While extremely powerful, these methods are limited in the number of components resolved. More importantly, classic cytometry methods can only detect those components for which affinity reagents are available; the unexpected is undetectable.

In contrast, chemical cytometry employs powerful ultrasensitive analytical methods to characterize the composition of single cells. In principle, chemical cytometry can resolve hundreds of components from a single cell.

Our work in this field is motivated by three broad applications. First, this technology will be of value whenever characterizing complex tissues, such as neurons and cells of the immune system, where there is a tremendous cell-to-cell heterogeneity in composition. For example, one can imagine providing a detailed cell-by-cell map of selected brain structures or monitoring the evolution in a T-cell population in response to an infection. Second, this technology will be of value in characterizing the molecular changes associated with the maturation of stem and precursor cells into their differentiated progeny; in an ideal experiment, an organism such as *Caenorhabditis elegans* would be microdissected so that each cell can be analyzed as the organism develops from a single-cell embryo to an adult. Finally, we believe that chemical cytometry may prove of value in improving the accuracy of cancer prognosis and diagnosis; just as cell-to-cell variation in ploidy can have prognostic value, determination of cell-to-cell heterogeneity in other cellular components may improve prognostic accuracy.

## 21.2 BACKGROUND

### 21.2.1 THE CHALLENGE

Chemical cytometry employs modern analytical tools to characterize single cells. Analysis of the content of a single cell requires extremely sensitive instrumentation. Consider a typical mammalian cell that has a 10- $\mu\text{m}$  diameter, 500-fL volume, and 500-pg mass. If that cell is 10% protein by weight, then the cell contains 50 pg of protein. Assuming an average molar mass of 30,000 g/mol, a single cell contains about 2 fmol of protein. The fraction of the proteome expressed by a single cell is unknown; perhaps 10,000 different proteins are present in each cell, with an average of 200 zmol

(1 zmol =  $10^{-21}$  mol = 600 copies) per protein. As we show below, there is a large distribution in protein expression within a cell. In addition, the cell contains  $\sim 15$  fmol of amino acids and other biogenic amines. Chemical cytometry requires exquisite detection sensitivity.

### 21.2.2 CLASSIC CYTOMETRY

Cytometry is the measurement of physical properties and chemical composition of single cells, and a wonderful review of the field is given by Howard Shapiro.<sup>1</sup> Cytometry was pioneered by Caspersson,<sup>2,3</sup> who developed microspectrophotometers that were used to measure ultraviolet (UV) absorbance of single cells at 260 nm to characterize nucleic acids and at 280 nm to characterize protein content. This work was particularly important because it led to the discovery that DNA content of cells doubled during the cell cycle, strengthening the hypothesis that DNA contained genetic material.

Image cytometry had its genesis in Caspersson's instrumentation, where a scanning stage was used to translate a sample through the focal volume of the microspectrophotometer, recording transmission data from a large number of cells. Since then, many technological improvements have been made to measure transmission, scatter, and fluorescence from cells and tissues.

Flow cytometers record optical and electrical signals from single cells flowing in a stream. The earliest instruments were based on light scatter and electrical impedance and were used for cell counting, replacing the hemocytometer. More sophisticated instruments record fluorescence intensity in one or more spectral bands and can characterize perhaps a half-dozen components in a single cell. The most sophisticated instruments are cell sorters that employ an electrical signal to deflect cells of interest from the flowing stream into a receiving reservoir for subsequent culture or analysis. Modern instruments can measure the signal from 200,000 cells/s and sort 50,000 cells/s.<sup>4</sup> Classic cytometry typically employs fluorescence to characterize a few components per cell; by use of several excitation wavelengths and multiple detection channels, instruments can characterize up to a dozen parameters per cell.<sup>5</sup>

Fluorescence-based assays employ reagents to characterize a wide range of cellular components, including nucleic acids, proteins, biogenic amines, carbohydrates, and lipids. These assays are often based on affinity probes, such as oligonucleotides, antibodies, aptamers, and lectins, which are used to characterize a specific component within the cell. In addition, fluorogenic substrates are used to characterize enzyme activity in single cells.

### 21.2.3 CHEMICAL CYTOMETRY

Chemical cytometry employs modern analytical tools to characterize the chemical composition of single cells. As an example, mass spectrometry has been used to monitor hemoglobin in single erythrocytes and neuropeptides in giant neurons. The information content of the mass spectrometer's signal is invaluable in component identification. Caprioli and coworkers has reported the use of matrix-assisted laser desorption/ionization time of flight (MALDI-TOF) to analyze tissue samples.<sup>6</sup> Over 800 components are detected from a tissue section.<sup>7</sup> Li and coworkers has reported the detection of hemoglobin from a single erythrocyte by MALDI-TOF mass spectrometry (MS).<sup>8</sup> Each cell contains about 450 amol of hemoglobin, and only extremely highly expressed proteins are detected and identified in a single cell. Sweedler and coworkers<sup>9</sup> has reported the use of MALDI-TOF to analyze neuropeptides in single cells.

Several separation methods have been developed for chemical cytometry. In an early example, silk fibers were used for the electrophoretic determination of 100 pg of RNA contained within a single cell, employing a UV microscope to detect the components.<sup>10</sup> Kennedy et al.<sup>11</sup> inaugurated the modern era of chemical cytometry by using open tubular capillary chromatography for the analysis of biogenic amines in a single giant neuron from a snail.

## 21.2.4 CHEMICAL CYTOMETRY OF PROTEINS, BIOGENIC AMINES, AND METABOLIC CASCADES BY ONE- AND TWO-DIMENSIONAL CAPILLARY ELECTROPHORESIS

### 21.2.4.1 Introduction

A rich literature has developed for the use of capillary electrophoresis (CE) for chemical cytometry. Wallingford and Ewing<sup>12</sup> reported the use of a capillary to sample the internal contents of a single giant neuron for electrophoresis of biogenic amines. Hogan and Yeung<sup>13</sup> reported the use of a specific label to derivatize thiols in individual erythrocytes; once the derivatization reaction was completed, a single cell was injected into a capillary, lysed, and the contents separated by CE. Gilman and Ewing<sup>14</sup> reported the on-column labeling of amines from a cell that had been injected into and lysed within a capillary; the capillary was used for electrophoretic separation of amines. Allbritton and coworkers<sup>15</sup> reported the use of a pulsed laser to lyse a cell before analysis of kinase activities by CE. Han and Lillard<sup>16</sup> reported the use of cell synchronization based on the shakeoff method for the characterization of RNA synthesis in single cells as a function of cell cycle. Zare and coworkers<sup>17</sup> reported a microfabricated device to automate cell lysis, labeling, and separation.

### 21.2.4.2 High-Sensitivity Electrophoresis

Capillary electrophoresis employing a postcolumn sheath-flow cuvette has produced outstanding detection limits, approaching single molecule levels in favorable cases.<sup>18,19</sup> We have used chemical cytometry based on CE to study proteins and biogenic amines in a wide range of cell types, including the HT29 colon cancer cell line; the MCF7 breast cancer cell line; the AtT20 adrenal gland cancer cell line; the MC3T3 osteoprecursor cell line; the hTERT telomerase-expressing Barrett's esophagus cell line; the A549 lung cancer cell line; the SupT1 T-cell line; RAW 264.7 macrophage cells; *Deinococcus radiodurans* cells; primary neurons, macrophages, and T-cells; and single-cell *C. elegans* and mouse embryos.

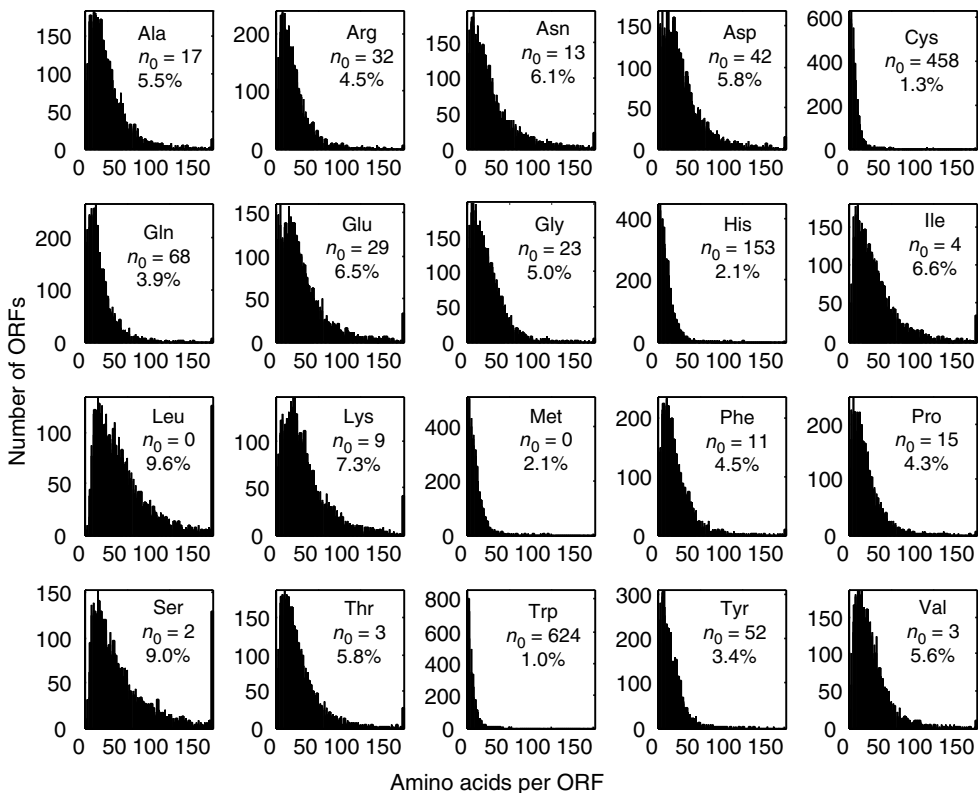

### 21.2.4.3 Proteins and Biogenic Amines

In chemical cytometry of protein and biogenic amines, cells are lysed and their constituents are labeled with a fluorescent or fluorogenic reagent before separation by CE and detection by laser-induced fluorescence. The use of fluorescent reagents to label proteins will target the most highly abundant proteins in the cell. The best data on the protein expression in a cellular homogenate were generated by Ghaemmaghami and coworkers,<sup>20</sup> who created a tick anticoagulant peptide (TAP) fusion of each open reading frame (ORF) in yeast; these cells were homogenized and assayed by Western blotting. Figure 21.2 presents a cumulative sum of protein abundance, starting from the most abundant protein. A few proteins are present at very high levels, and dominate the total population, while a large fraction (25%) of ORFs generated no detectable signal. The most abundant protein accounts for 3.4% of the total, and over 50% of the total protein content is due to the 100 most abundant proteins in a yeast cell. Chemical cytometry methods that target all proteins in a cell will be dominated by a relatively small number of highly abundant proteins.

We have also downloaded the ORF data for yeast;<sup>21</sup> this database includes the predicted sequence of 6057 ORFs that are 100 residues or longer. Note that these data are for the full-length ORF. As a result, all ORFs contain a methionine residue, which corresponds to the start codon. Post-translational proteolysis will remove the leader sequence from the N-terminus of the mature protein. Figure 21.3 presents a histogram of the abundances of each amino acid in those ORFs. The figure also reports the number of ORFs that do not contain that amino acid ( $n_0$ ) and the percentage of all amino acids. For example, only 9 out of 6057 ORFs contain no lysine residues. The three most abundant amino acids in yeast are leucine, serine, and lysine, which account for 9.6%, 9.0%, and 7.3% of all amino acids, whereas the three least abundant amino acids are tryptophan, cysteine, and methionine, which account for 1.0%, 1.3%, and 2.1% of all amino acids; the methionine abundance in mature proteins

**FIGURE 21.2** Cumulative abundance of proteins in yeast, starting from the most abundant protein. The 100 most abundant proteins represent 50% of the total protein content in this organism. Data obtained from Reference 27.

**FIGURE 21.3** Amino acid distribution in yeast ORFs. A total of 6057 ORFs coding for 100 or more amino acids were analyzed. The histogram of amino acid abundance in each ORF is plotted. The number of ORFs lacking that amino acid ( $n_0$ ) is listed. Finally, the percentage of each amino acid in the yeast ORFs is listed as the bottom line.

will be lower than predicted from these data because of the loss of the start codon during cleavage of the signal sequence from the precursor.

Most labeling chemistry targets primary amines, which are the  $\epsilon$ -amine of lysine residues and unblocked N-termini. Primary amines are also found on amino acids, aminolipids, aminosugars, neurotransmitters, and other biogenic amines, and understanding their role is of interest in physiology, molecular biology, and cell biology. These compounds make up 5–10% of the content of a cell, and are important mediators of a wide range of cellular processes. Their study is extremely difficult by classic cytometry methods, such as flow cytometry, because of the lack of specific affinity reagents.

#### 21.2.4.4 Fluorescence Labeling

While it is possible to detect proteins based on the native fluorescence of tryptophan, that amino acid is the least abundant in yeast, representing 1.0% of the total amino acid content of yeast. Excitation of tryptophan requires expensive and temperamental UV lasers. Instead, it is usually more convenient to label the protein with a fluorophore that is excited by inexpensive and reliable lasers that operate in the visible portion of the spectrum.

##### 21.2.4.4.1 Chemical Derivatization

As noted above, lysine is one of the most abundant amino acids, and most chemical cytometry experiments rely on reagents that target the primary amine found on lysine residues and the N-terminus. Classic fluorescent reagents, such as fluorescein, rhodamines, Cy-dyes, and bodipy, are not useful in chemical cytometry. While they create highly fluorescent products, unreacted reagent and trace levels of fluorescent impurities create a sea of background signals that can swamp the fluorescence signal from analyte. For example, if 1 nL of a  $10^{-4}$  M labeling reagent is used in an experiment, then there will be 100 amol of impurities present at the 0.1% level, and impurities present at the part-per-million level will contribute 100 zmol, which corresponds to the average protein level in a cell. These trace impurities are inevitably present, many are highly fluorescent, and they create a sea of background peaks that obscures target compounds.

We instead employ fluorogenic reagents, such as 3-(2-furoyl) quinoline-2-carboxaldehyde (FQ), in our experiments. These compounds are nonfluorescent until they react with a primary amine in the presence of a nucleophile. Fluorogenic reagents have very few fluorescent impurities and generate a very low background signal that does not interfere in the chemical cytometry experiment.

There is another subtle issue in fluorescent labeling of proteins. Heroic efforts are required to completely label all lysine residues in a protein, and these efforts are impractical in single-cell analysis.<sup>22</sup> Instead, the reaction targets the most labile residues, and usually creates a complex mixture of products; there are  $2^N - 1$  fluorescent products generated from a protein with  $N$  primary amines.<sup>23</sup> For example, ovalbumin has 20 lysine residues. Incomplete labeling can result in the production of  $2^{20} - 1 = 1048575$  different fluorescent products and each product will have a different mobility during electrophoresis, creating a complex electropherogram.<sup>23–25</sup> Both this group and Whitesides and coworkers<sup>26–28</sup> have noted that addition of an anionic surfactant, such as sodium dodecyl sulfate (SDS), causes the complex set of peaks to collapse into a single peak, which can have extraordinarily high separation efficiency that exceeds  $10^5$  plates. However, this phenomenon only appears to occur when acylation produces a neutral product and when an anionic surfactant is present.

An alternative strategy is to use very mild reaction conditions, so that few proteins have more than one fluorescent label. However, these conditions lead, by necessity, to inefficient labeling.

##### 21.2.4.4.2 Labeling by Genetic Engineering

Chemical labeling is best used to characterize the most abundant proteins in a cell. Low abundance proteins tend to be buried under the signal generated by high abundance components. Fluorescently labeled antibodies are commonly used to label specific components in flow cytometry, but

cellular autofluorescence limits their use to characterize the lowest abundance proteins. In addition, immunoassay seldom provides information on post-translational modifications on the target protein.

Genetic engineering can be used to introduce a label with high specificity. In this case, the label is a fluorescent protein, such as green fluorescent protein (GFP). Labeling is performed by fusing the gene for GFP with the gene of the target protein. Transcription and translation of the target gene leads to the production of a fusion protein that is labeled with GFP.

GFP is a relatively highly fluorescent protein that can be detected with high sensitivity.<sup>29</sup> The study of fusion proteins by microscopy and flow cytometry is common. However, there are three issues associated with study of GFP. First, autofluorescence from endogenous components provides a background fluorescence signal that limits the detection of trace level proteins. Second, GFP fluorescence reflects the structure of GFP itself, and provides no information on post-translational modifications to the target protein, such as phosphorylation or glycosylation. Third, GFP is a relatively proteolysis-resistant protein. As a result, the target protein may have undergone proteolytic destruction while GFP remains intact. Detection of fluorescence from GFP does not necessarily mean that the target protein is present; it simply means that the target protein had been expressed.

The use of chemical cytometry for the study of GFP fusion proteins deals with these issues.<sup>29</sup> Electrophoretic conditions can be manipulated to minimize overlap of GFP and autofluorescent components, so that GFP can be detected on a very low background, which improves detection limits. The migration time of the fusion will reflect any post-translational modifications to the protein, including proteolysis of the target protein.

## 21.3 PRACTICAL APPLICATIONS

### 21.3.1 CHEMICAL CYTOMETRY OF BIOGENIC AMINES AND PROTEINS USING ONE-DIMENSIONAL CAPILLARY ELECTROPHORESIS

Figure 21.4 presents a one-dimensional capillary sieving electrophoresis (CSE) analysis of the proteins from a human primary T-cell. In this separation, the cell was injected into the capillary, lysed, and primary amines were labeled with FQ. Components were separated by CSE. The electropherogram consists of a set of ~25 peaks, some of which are extraordinarily sharp; for example, the component that migrates at 14.2 min generates a peak with 2.8 million theoretical plates (7.7 million plates/m), whereas most peaks generate a few hundred thousand theoretical plates.

**FIGURE 21.4** One-dimensional CSE analysis of a single human T-cell. The inset expands the fluorescent signal to highlight lower amplitude components.

**FIGURE 21.5** CSE analysis of five human T-cells. Curves are offset for clarity.

**FIGURE 21.6** Chemical cytometry of a single yeast cell expressing the GFP–Gal4 fusion protein. The autofluorescence signal is similar in amplitude to the signal due to the fluorescent protein; without electrophoresis, accurate quantification of fluorescence due to the fusion protein would be difficult.

Figure 21.5 presents the electropherograms generated from five cells. While some cells, such as cells 1 and 2, generate similar electropherograms, there is a fairly wide cell-to-cell heterogeneity in expression patterns. This pattern likely reflects the inherent heterogeneity in this complex primary cell type.

Krylov and coworkers and this group<sup>29,30</sup> have also employed chemical cytometry to characterize GFP in single cells (Figure 21.6). This electropherogram shows the analysis of a single yeast cell that has been engineered to express the Gal4–GFP fusion protein. Figure 21.7 presents the electropherogram generated from a single cell of *D. radiodurans* expressing GFP. This organism is a prokaryote, which is ~1000-fold smaller in mass than typical mammalian cells.

**FIGURE 21.7** Chemical cytometry of a single *D. radiodurans* cell expressing GFP. The set of peaks appears to be associated with proteolytic fragments of GFP.

### 21.3.2 CHEMICAL CYTOMETRY OF BIOGENIC AMINES AND PROTEINS USING TWO-DIMENSIONAL CAPILLARY ELECTROPHORESIS

We have developed two-dimensional CE systems for the characterization of proteins and biogenic amines.<sup>27,31,32</sup> The use of this technology for chemical cytometry is similar to the use of one-dimensional electrophoresis: a cell is aspirated into the column, lysed, and its components labeled with FQ. For two-dimensional electrophoresis, components are separated based on CSE in the first-dimension capillary. Fractions are then transferred across an interface to a second capillary, where they undergo additional separation based on micellar electrokinetic chromatography (MECC) before detection by fluorescence. The voltage drop across the first capillary is set to zero during the second dimension separation, holding components stationary. In a typical experiment,  $\sim 300$  fractions are transferred between capillaries under computer control.

Figure 21.8 presents the raw fluorescence signal generated from the two-dimensional electrophoresis analysis of a single RAW 264.7 macrophage cell. The fluorescence signal consists of a long time series that contains a large number of peaks, and these peaks tend to repeat with 17 s periods, which was the time between transfers of fractions from the first to the second capillary.

The data can be considered a spiral wrapped around a cylinder (Figure 21.9), where the axial distance corresponds to the first dimension separation, the angle corresponds to the second dimension separation, and the density of the image is related to the fluorescence intensity. To generate an image, the cylinder is slit and flattened, creating a gel image of the separation.

Figure 21.10 presents such an image that resembles a silver-stained two-dimensional gel. The image consists of a set of spots, distributed across the surface. The positions of these spots are highly reproducible from cell to cell, with typical precision in spot position being on the order of the size of the spot itself.

The gel image is convenient for comparing spot position. However, the image, particularly when overexposed, is less useful in comparing the amplitude of spots or characterizing the dynamic range of the experiment. Instead, the data can be plotted as a surface in the form of a landscape, where height is proportional to the fluorescence intensity (Figure 21.11).

These data have a very large dynamic range, approaching  $10^4$  in favorable cases. This dynamic range is suggested by expanding the image by a factor of 10 (Figure 21.12). These separations tend

**FIGURE 21.8** Raw data generated from a single macrophage cell. Each fraction transfer from the first to the second capillary generates a set of peaks as the first capillary's components are separated in the second capillary. The inset shows a close up of a typical region.

**FIGURE 21.9** The raw electrophoresis data of Figure 21.8 are wrapped as a spiral around a cylinder, where the optical density is now related to the fluorescence intensity.

to give excellent peak capacity in the CSE dimension, but poorer capacity in the MECC dimension. The overall spot capacity of this two-dimensional separation is typically between 250 and 500 spots. This form of chemical cytometry has the potential of providing a very rich data set with which to characterize a cellular population.

### 21.3.3 METABOLIC CYTOMETRY

This research group coined the terms chemical cytometry and metabolic cytometry in 1999.<sup>33</sup> Metabolic cytometry is a form of chemical cytometry that monitors biosynthetic and biodegradation enzymatic cascades in a single cell.

**FIGURE 21.10** The cylinder is slit and flattened, creating a gel image, where the optical density is related to fluorescence intensity. The image is overexposed to highlight low-amplitude components.

**FIGURE 21.11** Landscape view, where height is proportional to fluorescence intensity.

In metabolic cytometry, cells are incubated with a substrate that is tagged with a highly fluorescent dye; we prefer tetramethylrhodamine because of its excellent spectroscopic properties and its compatibility with the frequency-doubled neodymium YAG laser. This substrate is prepared at high concentration and undergoes chromatographic purification to eliminate fluorescent impurities.

As long as the dye is preserved during the transformations, any enzymatic transformation can be monitored with exquisite sensitivity. Figure 21.13 presents an illustrative cartoon, where a substrate, tagged with a fluorescent label (star), undergoes biosynthesis (left path) or biodegradation (right path).

In our first report, we measured DNA ploidy, the uptake of a fluorescent carbohydrate, and that of carbohydrate's biosynthetic and biodegradation products in a single HT29 colon adenocarcinoma cell.<sup>33</sup> We also monitored similar transformations in a single yeast cell.<sup>34</sup>

More recently, we have been studying glycosphingolipid metabolism in single AtT20 cells. Glycosphingolipids are among the most common molecules on neural cell surfaces. These

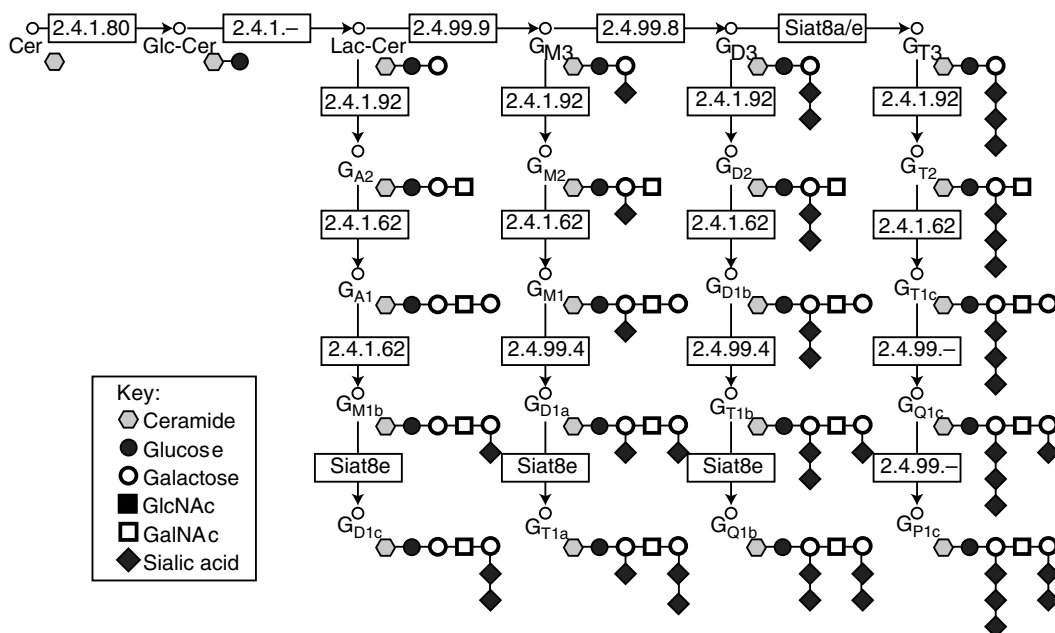

**FIGURE 21.12** The image of Figure 21.11 has been expanded by a factor of 10 to highlight low-amplitude components.

**FIGURE 21.13** Metabolic cytometry. A substrate (top) is fluorescently labeled (star). This substrate can undergo biosynthesis (left) or biodegradation (right). As long as the fluorescent tag remains intact, the metabolic products can be monitored by chemical cytometry.

compounds consist of several components. Ceramide is the nonpolar tail that consists of a long-chain amino alcohol linked to a long-chain fatty acid. A chain of saccharide groups attached to the ceramide form the constituent glycosphingolipids, and the presence of one to four sialic acids turns these glycosphingolipids into gangliosides. In the common naming of gangliosides, the subscript letter indicates the quantity of sialic acid groups: M for monosialo, D for disialo, and so forth; A refers to asialo that are glycosphingolipids without sialic acids. The number refers to the order of peak appearance in thin layer chromatography and thus the length of the sugar chain; the sequential removal of zero, one, and two terminal saccharides increases retention to give  $G_{M1}$ ,  $G_{M2}$ , and  $G_{M3}$ , respectively.

These glycolipids form a large fraction of neuronal cell membranes, and defects in their metabolism leads to a series of devastating diseases, the best known of which is Tay-Sachs. The compounds are synthesized from the lipid ceramide by successive addition of monosaccharides (Figure 21.14), where the numbers in boxes correspond to the E.C. number for the enzyme responsible

**FIGURE 21.14** Partial metabolic pathway associated with sphingolipids. The number in the boxes corresponds to the EC name for the biosynthetic enzyme responsible for the transformation.

**FIGURE 21.15** Structure of  $G_{M1}$ . A fluorescently labeled compound has been prepared where the ceramide group (box) is replaced with the TMR-label (bottom box).

for the addition of the corresponding sugar. Biodegradation is not shown; defect in the degradation of  $G_{M2}$  to  $G_{M3}$  leads to accumulation of the former, and is the underlying cause of Tay-Sachs disease.

We have synthesized the fluorescently labeled  $G_{M1}$  (Figure 21.15).<sup>35</sup> In the native compound, top, ceramide is shown in the box. In our labeled compound, the fatty acid has been replaced with tetramethylrhodamine.

We have also synthesized the biodegradation products for this compound, including the asialo  $G_{A1}$ , and  $G_{A2}$ , which are used as standards to tentatively identify metabolic cytometry products based on comigration.

**FIGURE 21.16** Metabolic cytometry analysis of three cells. AtT20 cells were incubated with the substrate of Figure 21.15, aspirated into a capillary, lysed, and analyzed by CE.

Figure 21.16 presents metabolic cytometry data generated from single AtT20 cells. In these experiments, a cell is incubated with the substrate. The substrate is taken up, which can be confirmed by fluorescence microscopy. Enzymatic transformations convert the substrate to products. To analyze the products, the cell is aspirated into a capillary, lysed, components are separated by CE, and products detected by laser-induced fluorescence.

These data show remarkable cell-to-cell variations in metabolism. The substrate,  $G_{M1}$ , is present in all cells, and all cells show a modest amount of  $G_{A1}$ , which requires complex transformation of the substrate. Some cells show very active biodegradation, completely removing the carbohydrates and leaving only the labeled ceramide. Other cells show much less biodegradation and no detectable ceramide.

## 21.4 METHOD DEVELOPMENT GUIDELINES

Instrumentation for chemical cytometry consists of three parts. The first is an injection module that facilitates aspiration of a cell into the capillary. The second is instrumentation to perform one- or two-dimensional CE. The third is a high sensitivity laser-induced fluorescence detector.

### 21.4.1 INJECTION BLOCK

Krylov et al.<sup>36</sup> designed and constructed an injection block that greatly facilitates single-cell analysis. This block consists of three Plexiglas pieces (Figure 21.17). The top piece holds both the capillary and the high-voltage electrode. The second piece contains a hole to connect to pure nitrogen, which is used to pressurize the chamber in order to flush buffer through the capillary. The bottom piece holds a microcentrifuge vial that contains the running buffer.

This injection block is attached to micromanipulators. In operation, the capillary is first flushed with buffer to prepare it for separation. The bottom piece is then removed, and micromanipulators are used to center the capillary over a cell of interest. The cell is aspirated into the capillary, the vial holder is replaced, and high voltage is applied to drive the separation.

**FIGURE 21.17** Injection block. A capillary and electrode are threaded through the top two blocks. The third block forms a gas-tight seal and is used to pressurize a reservoir that pumps reagents through the capillary. The bottom block is removed for injection of a cell.

Aspiration of a single cell typically requires a pulse of  $\sim 11$  kPa vacuum to the distal end of the capillary for 1 or 2 s. Control of such modest pressure is not trivial. Krylov<sup>36</sup> developed an elegant method for generating an extremely reproducible vacuum. The distal end of the capillary is connected to a sheath-flow cuvette, and the waste stream of the cuvette is connected to a three-way valve. In normal operation, the valve directs the waste to a receiving reservoir. To inject a sample, the valve directs flow to a solenoid valve, which is connected to a water-filled piece of tubing that terminates in a beaker placed 1 m below the level of the injection block. A timer circuit is used to open the solenoid valve for a precisely timed period, during which time the injection end of the capillary is connected to a water column of 1 m high, which applies vacuum necessary to aspirate the cell within the capillary.

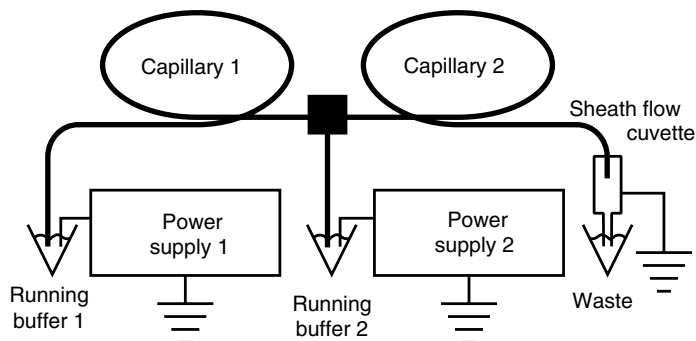

### 21.4.2 CAPILLARY ELECTROPHORESIS

Both one- and two-dimensional CE have been used for chemical cytometry. One-dimensional electrophoresis is similar to conventional experiments, albeit with the issues of sample loading, lysis, and on-column labeling.

Two-dimensional CE instrumentation is more complicated, with two power supplies, one for each capillary (Figure 21.18).<sup>37,38</sup> The sample undergoes separation by CSE. Fractions are transferred between capillaries by manipulation of the voltages applied across the two capillaries.

The interface is manufactured using standard macromachining technology. Two capillaries are aligned to be coaxial with a  $\sim 50$ - $\mu\text{m}$  gap in a buffer-filled chamber. Analyte is transferred between capillaries by creating a voltage drop across the interface. Figure 21.19 presents a micrograph of fluorescein being transferred between capillaries in an interface. The fluorescence is centered on the two capillaries. A stagnant zone appears to form an annulus about 10  $\mu\text{m}$  in radius about the inner lumen of the first dimension capillary. However, there is no evidence that analyte leaks from the interface or is lost during a transfer.

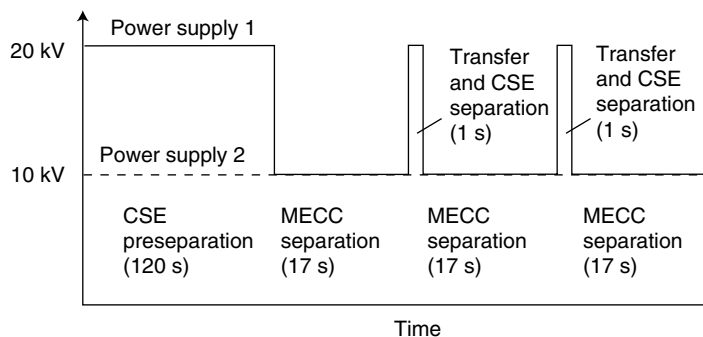

**FIGURE 21.18** Instrumentation for two-dimensional CE. Two capillaries are joined through an interface, that allows fractions to be transferred by manipulation of the voltage applied to the capillaries. In our system, the sheath-flow cuvette detector is held at ground potential.

**FIGURE 21.19** Transfer of fluorescein between capillaries in the interface used in two-dimensional CE.

This interface differs from Jorgenson and coworkers<sup>39</sup> flow-gated interface between a liquid chromatographic column and a CE column. In that design, analyte continually flows from the chromatographic column; cross-flow is used to flush analyte to waste except during fraction transfer. In contrast, analyte flow is easily stopped in two-dimensional CE by applying equal voltage at both ends of the capillary; as a result, there is no need for crossed flow with its accompanying sample loss.

A typical voltage program is shown in Figure 21.20. After lysis, a preliminary CSE separation is performed so that the fastest moving components approach the exit of the first capillary. Then, a series of fraction transfers and MECC separations is performed. There is a voltage drop across the first capillary during the transfer steps, which continues the CSE separation and which drives analyte to the second dimension capillary. There is also a voltage drop across the second dimension capillary during the transfer, so that separation also continues in that dimension during fraction transfer. There is no voltage drop across the first dimension capillary during the MECC separation step, and analyte does not migrate in that capillary.

**FIGURE 21.20** Typical timing diagram used in two-dimensional CE for chemical cytometry. The distal end of capillary 2 is held in the sheath-flow cuvette, which is at ground potential.

### 21.4.3 FLUORESCENCE DETECTION

High-sensitivity fluorescence detection is required for chemical cytometry. We use a postcolumn sheath-flow cuvette for detection. This device is based on a cuvette used in the venerable Ortho cytofluorograph, a flow cytometer developed in the late 1970s. A stream of flowing buffer ensheathes analyte flowing from the separation capillary. Fluorescence is detected in a flow chamber with high optical quality windows, which decreases light scatter and improves the detection limit compared to using the capillary itself as a detection cuvette.

### 21.4.4 DATA PROCESSING

There are a couple useful steps in data processing. First, a morphological opening procedure can be used to remove baseline drift. This process is available in the image processing toolbox in Matlab. Like many other filtering processes, baseline correction is subject to artifact. These artifacts are most obvious when performing the morphological opening procedure on too small an area; in this case, wide peaks and ridges in the data can disappear.

Second, filtering is useful. A number of filters are available for two-dimensional data. The most important is the median filter that effectively removes noise spikes caused by bubbles or particles passing through the laser beam. Next, it is often useful to smooth the data; convolution with a two-dimensional Gaussian filter is particularly useful if the shape of the Gaussian filter is matched to those of typical peaks.

## 21.5 CONCLUDING REMARKS AND FUTURE WORK

The field of chemical cytometry is in its infancy, and it is clear that there is much work to be done before the technology is widely used. First, instrumentation throughput must be increased. Flow cytometry today can process a 100,000 cells/s. While chemical cytometry will not produce similar throughput, it is reasonable to expect the technology to process 10,000 cells/day in one-dimensional electrophoresis and perhaps 1000 cells/day in two-dimensional electrophoresis. Such instrumentation will likely resemble the multiple-CE systems that have become ubiquitous in DNA sequencing.<sup>37,38,40</sup>

Second, separation efficiency must be improved. Current two-dimensional electrophoresis systems are generating a spot capacity of a few hundred components; an order of magnitude improvement is desirable. Spot capacity is given by the product of the peak capacity in each dimension, so that a threefold improvement in separation efficiency in each dimension will generate the desired improvement. MECC is not an ideal separation mode for proteins, and would be replaced with a technique

such as isoelectric focusing, which can provide exquisite resolution. A major hurdle deals with protein labeling. FQ, and presumably other dyes that produce an anionic or neutral reaction product, generate very complex isoelectric focusing electropherograms due to multiple labeling. Anionic surfactants are not compatible with IEF, and it will be necessary to employ a labeling reagent that produces a cationic product. The recently developed chameleon dyes are interesting examples of fluorogenic reagents that produce cationic products.<sup>41,42</sup>

Third, component identification must be improved. Current methods rely on comigration with standards. While practical for metabolic cytometry and biogenic amines, due to the relatively small number of possible compounds, spiking is extremely tedious for protein analysis. Ideally, an online mass spectrometer can be used to monitor compounds as they migrate from the capillary. Although the current generation of mass spectrometers does not have sufficient sensitivity to monitor the minute amounts of compounds present in a single cells, mass spectrometry could be used to study concentrated homogenates prepared from large numbers of cells. Based on excellent run-to-run reproducibility of the two-dimensional electrophoresis system, component identification should be practical in fluorescence-based detection of single cells. As a complication, it would be necessary to use fluorescently labeled proteins, which would need to be considered during interpretation of mass spectra.

## 22.1 INTRODUCTION

Under the action of enzymes globally called glycosyltransferases, proteins undergo cotranslational and post-translational modifications (PTMs) resulting in the covalent attachment of glycan chains to the polypeptide core. This fundamental process is called glycosylation and results in the formation of glycoproteins. Although many others exist, glycosylation is undoubtedly one of the most prevalent

PTM of eukaryotic proteins. For instance, in humans, glycoproteins account for more than 50% of all proteins. Despite this high frequency of occurrence, no generalized role can be attributed to glycosylation of proteins. In fact, the role of the glycan moiety can vary from one protein to another and have direct involvement in the biological properties of proteins such as transport, cell surface recognition, enzymatic processes, or the immune system. The large size of oligosaccharides may allow them to cover functionally important regions of proteins, to modulate the interactions of glycoconjugates with other molecules, and to affect the rate of the processes that involve conformational changes. Besides these important biological functions, glycosylation also confers physical properties to proteins such as solubility, hydrophilicity, stability, and assists in protein folding.

Just as for the rest of proteins, other PTM events and the existence of genetic variants contribute to the heterogeneity of glycoproteins. All of the heterogeneities are generically termed “forms” of a protein (e.g., deamidated forms), while forms arising from the glycosidic part of the protein are specifically called “glycoforms.” The term “sialoform” refers to the glycoforms that have the same number of sialic acid residues. In the field of capillary electrophoresis (CE), “isoform” indicates an electrophoretic peak or band, which can include one or more forms of a protein.

From an analytical point of view, there are several approaches to the study of glycoproteins. The protein can be submitted to partial or total hydrolysis/proteolysis resulting in the formation of glycopeptides, glycans, individual monosaccharides, peptides, or amino acids, which can then be analyzed separately. Alternatively, the different forms of the intact glycoprotein can be separated and studied using one of many suitable techniques providing high resolution of closely related proteins such as sodium dodecylsulfate–polyacrylamide gel electrophoresis (SDS–PAGE), isoelectric focusing (IEF), high-performance liquid chromatography (HPLC), mass spectrometry (MS), or CE. Traditionally, conventional gel electrophoresis methods have been employed to study the intact forms of glycoproteins and their hydrolysis/proteolysis products. However, these methods are laborious to carry out, cannot be automated, and do not consistently provide quantitative results. In contrast, CE analysis has been demonstrated to provide rapid, automated, and quantitative results. In addition, it is now often used as a complementary technique to the more established HPLC in several glycoprotein studies.

In this chapter, CE approaches to the study of intact forms of glycoproteins will be discussed with particular emphasis on factors such as separation conditions and modes of detection. In addition, an overview of practical applications of CE in different sectors of activities such as the pharmaceutical industry and clinical research will be presented. Although examples illustrating various aspects will be mentioned, the primary goal of this chapter is not to provide an extensive review of the literature reported on the subject or details about all of the glycoproteins that have been studied. For in-depth discussions several reviews covering this subject in part or in total, which are mentioned in Section 22.2 of this chapter, can be read.

The general principles related to the different modes of CE and of protein separation by CE have not been considered here as they are the subjects of other chapters in this book.

## 22.2 BACKGROUND

Glycoprotein formation is a complex process that involves multiple enzymatic reactions occurring in the endoplasmic reticulum and the Golgi apparatus.

A glycoprotein is usually present in an organism as a population of glycoforms, the heterogeneity of which is cell/tissue or organism-dependent, as well as a function of the pathophysiological status [1]. Changes in protein glycosylation occur in both congenital and acquired illnesses [2–4] and the study of these changes is generating considerable interest in the field of biomarkers. The production by recombinant DNA technology of glycoproteins for specific therapeutic uses is another field that has attracted considerable research efforts. In fact, many of the biopharmaceuticals currently produced are glycoproteins [5,6]. The glycosylation of these proteins is crucial in their role

**FIGURE 22.1** Representation of O- and N-linked glycosylation from the reaction of  $\alpha$ -N-acetylgalactosamine with serine/threonine and  $\beta$ -N-acetylglucosamine with asparagine, respectively.

as biopharmaceuticals since it will affect, for instance, their biological activities, solubility, and other properties [7,8]. In the case of recombinant glycoproteins, in addition to being cell-dependent, glycosylation is affected by culture media conditions and the purification process [1]. These considerations give an idea of the enormous variety of glycoforms that a glycoprotein can contain and, therefore, the difficult task that the in-depth analysis of all of these structures involves, particularly when the approach selected is the study of intact glycoprotein.

Glycans are attached to proteins through O- and N-linkages at specific amino acids (Figure 22.1). O-linked glycosylation occurs at the hydroxyl functional group of the side chain of serine (Ser) or threonine (Thr) residues and, to a lesser extent, as a secondary modification at hydroxylysine (Hyl) and hydroxyproline (Hyp) residues (e.g., in collagen). N-linked glycosylation takes place at the amide side chain of asparagine (Asn) residues. There are several monosaccharides involved in the glycosylation of proteins: mannose (Man), galactose (Gal), fucose (Fuc), N-acetylglucosamine (GlcNAc), N-acetylgalactosamine (GalNAc), and sialic acid. The latter is the generic term for several derivatives of neuraminic acid that includes N-acetylneuraminic acid (NeuAc), one of the most abundant sialic acids in mammals. All of these sugars are neutral at physiological pH except for sialic acid, which is negatively charged due to the presence of a carboxylic acid functional group.

N-glycans are usually classified into the following three types: complex, high-mannose, and hybrid [9]. Complex-type glycans have several antennae, with biantennary being the most abundant ones, although tri- and tetra-antennary ones are also common (Figure 22.2a) [10], each of which may feature high heterogeneity due to several possible permutations of the sugar residues. High-mannose-type glycans are common in cell-surface proteins and have, in most cases, between 5 and 9 mannose residues (Figure 22.2b). Hybrid glycans feature characteristics common to both high-mannose and complex glycans (Figure 22.2c).

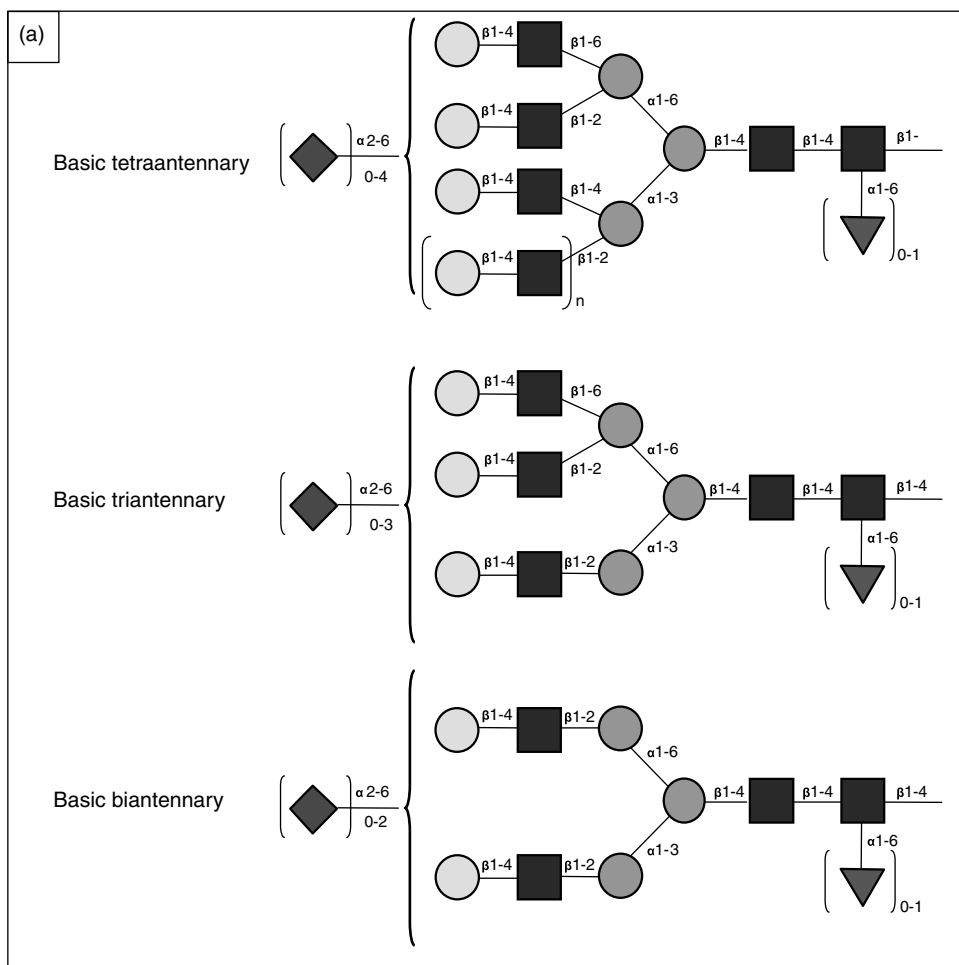

O-glycans are also composed of a variety of common monosaccharides that, in addition to those found in N-glycans, include xylose (Xyl), glucose (Glu), and arabinose (Ara) (Figure 22.2d). O-glycans are very common in mucines where long polypeptides with highly negatively charged zones are present due to the presence of sialic acids.

The complexity of glycoproteins and the fact that CE compares favorably with conventional electrophoretic techniques are among the reasons for which glycoprotein analysis has been a pre-eminent feature of CE from its very early days. A monograph dedicated to CE of proteins and peptides by Strege and Lagu [11] is available. Reviews covering the early development of analytical CE methods for proteins, including glycoproteins, for years up to 1997 have been cited by Prichett and Robey [12] in the previous edition of this handbook. Several recent reviews on the analysis of glycoproteins by CE have discussed various aspects [13–26].

## 22.3 THEORETICAL ASPECTS

Several CE modes that will be considered in detail in Section 22.4 of this chapter have been used in the separation of glycoproteins: capillary zone electrophoresis (CZE), capillary isoelectric focusing (CIEF), capillary electrophoresis in SDS (CE-SDS), micellar electrokinetic chromatography (MEKC), affinity capillary electrophoresis (ACE), and capillary isotachopheresis (CITP). It is out

**FIGURE 22.2** Typical structures of (a) complex-type N-glycans; (b) high-mannose N-glycans; (c) hybrid-type N-glycans; and (d) core structures of O-glycans. Representation according to Nomenclature Committee of the Consortium for Functional Glycomics (<http://www.glycomics.scripps.edu/CFGnomenclature.pdf>, accessed on November 2006).

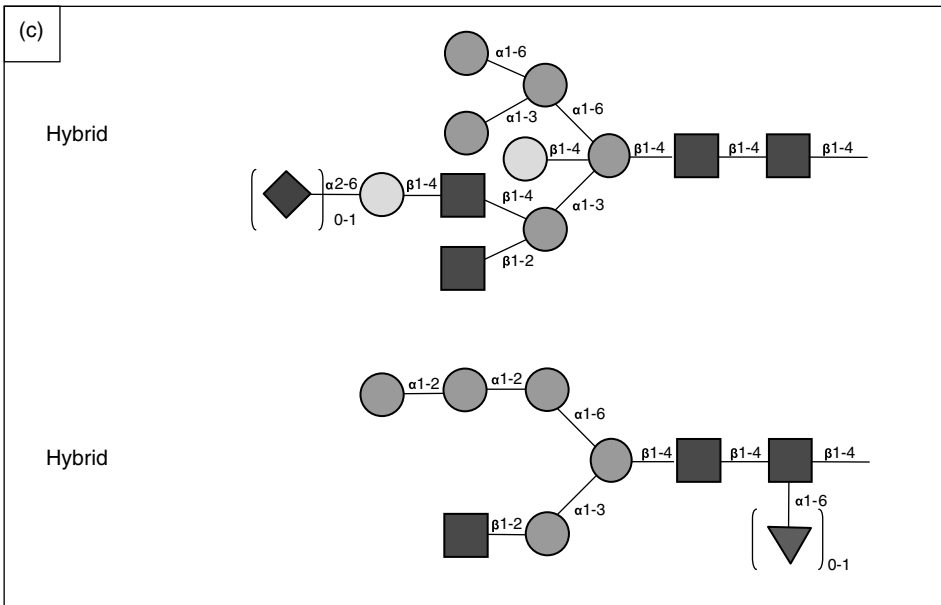

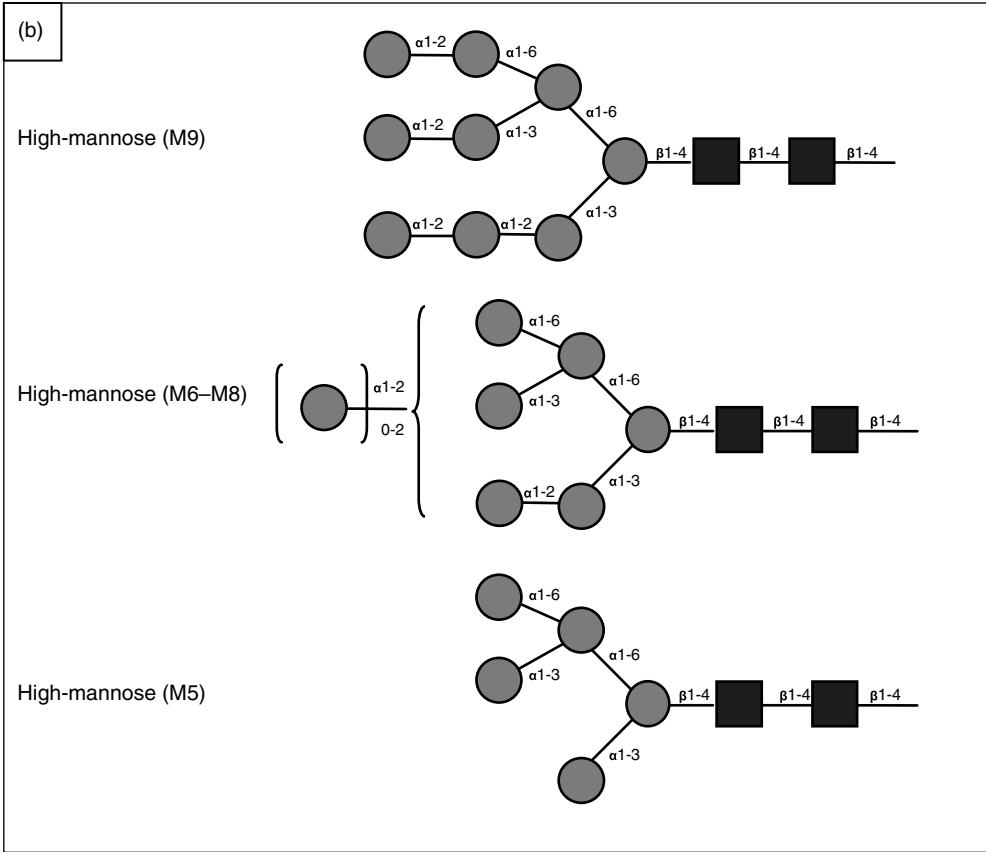

FIGURE 22.2 (Continued)

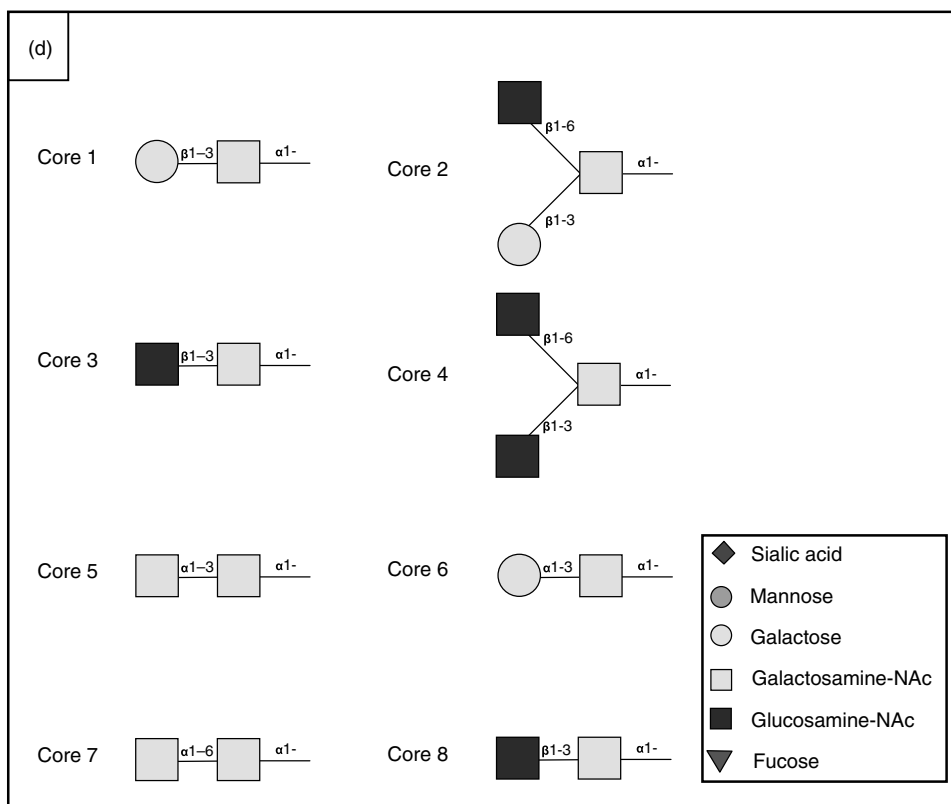

FIGURE 22.2 (Continued)

of the scope of this chapter to review the theoretical aspects of each of these techniques for glycoproteins. In this section, only a few considerations about the separation of proteins with a special emphasis on glycoforms separation by CZE will be presented.

In CZE, proteins can be considered from a theoretical point of view as charged particles. The mobility,  $\mu$ , can be described in a first approximation by [27]

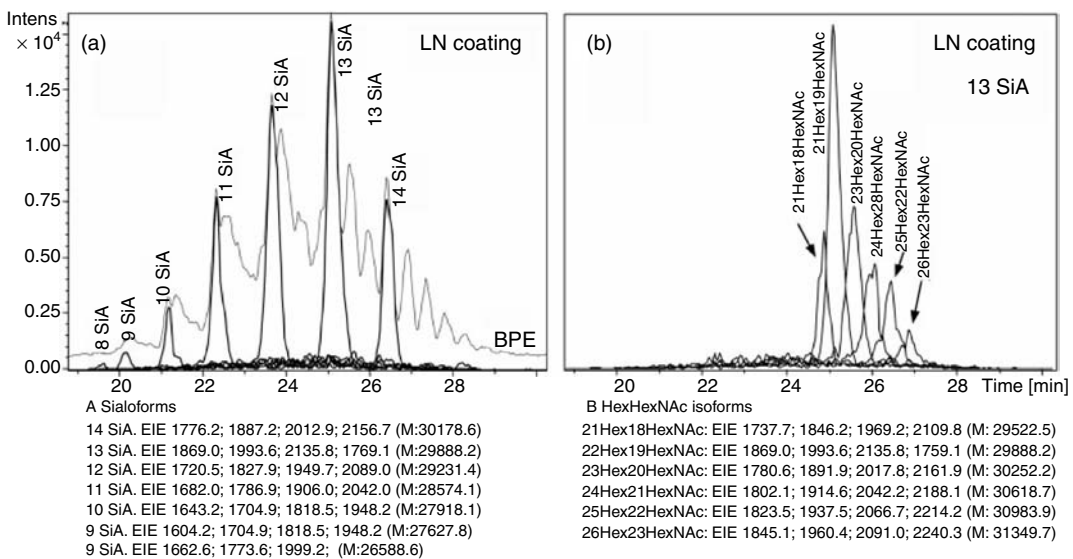

$$\mu = \frac{q}{f}, \quad (22.1)$$

where  $q$  is the charge of the particle and  $f$  is its friction coefficient in the separation buffer, which for small molecules is proportional to their respective mass. For proteins, the friction coefficient is also related to the shape of the particle. In fact, studies [12,28] have shown that the separation of proteins in CZE is better explained in terms of hydrodynamic radius, because this parameter describes both the mass and shape of the protein. In a similar way, studies have shown that the displacement of a protein in a given separation buffer is better described by the net charge of the protein and, consequently,  $q$  is better expressed as the net charge of the protein (for a review see Reference 29). The net charge includes contributions from all of the electrostatic elements of the protein, such as charged amino acids, metal ions, and cofactors bound to it. The net charge is screened to a certain degree by the microenvironment of the charged group, by the association of the protein with the counterions in solution, and by the characteristics of the protein that influence its attraction to counterions. In conclusion, electrophoretic mobility of proteins can be interpreted in terms of their hydrodynamic radius and net charge [12].

In CZE of glycoproteins the situation is more complicated than for nonglycosylated ones because of additional differences originating from the glycosidic part. For the sake of simplicity, the following will present only a limited discussion of the overall implications of the charge and composition of the glycans on the migration of glycoproteins.

The simplest cases are those in which glycoforms differ only in electric charge. These differences are very often due to the different content in sialic acid of the glycoforms (sialoforms). Sialic acid moieties occur in most cases in the outer part of the protein, in a relatively free position to move around the N- or O-linkage with the rest of the oligosaccharide. Therefore, differences in sialic acid content of these glycoforms produce important variations in the net charge of the proteins resulting in differences in their mobilities. One well-documented example of sialoforms separation by CZE is presented by Balaguer et al. [30]. Using neutral coated capillaries, the authors carried out the separation of recombinant human erythropoietin (rhEPO) isoforms (Figure 22.3). The main peaks were identified using electrospray ionization (ESI) time-of-flight mass spectrometry (ESI-TOF MS) coupled to CZE as several sialoforms (Figure 22.3a). Using the reconstructed extracted ion electropherograms together with the deconvoluted mass of the MS isoform peaks, they observed that, as predicted by the theory, only glycoforms differing in their sialic acid content migrated as separate peaks and that their mobilities were directly related to the number of sialic acids present in each sialoform.

More complex situations arise when different glycoforms have the same charge but the hydrodynamic radius increases with the size of the glycan chain. In the same study mentioned earlier [30], the authors obtained the extracted ion electropherogram of rhEPO glycoforms containing the same number of sialic acids but differing in the number of hexose and *N*-acetylhexosamine residues (Figure 22.3b). An increase in the effective hydrodynamic radius of the protein causing a mobility shift to lower migration times was observed.

**FIGURE 22.3** Electropherogram of rhEPO (BRP European Pharmacopeia, 2.5  $\mu\text{g}/\mu\text{L}$  in water). Separation performed in a capillary 80 cm  $\times$  50  $\mu\text{m}$  coated with a neutral polymer (UltraTrol Pre-Coated LN), separation buffer 2 M HAc, and separation voltage at +30 kV. (a) Clear trace represents the base-peak electropherogram (BPE) and darker trace represents the electropherogram reconstructed from the extracted ions together with the deconvoluted mass of the MS peaks of different sialic acid isoforms. (b) Extracted ion electropherogram obtained for glycoforms with different HexHexNAc content and identical sialic acid number. (From Balaguer, E. et al., *Electrophoresis*, 27, 2638, 2006. With permission.)

In some cases, however, a clear effect of either the charge or the size on the glycoform mobility cannot be discerned. This is illustrated in the work of Yim et al. [31] on the study of recombinant human bone morphogenic protein 2 (rhBMP-2). This basic protein ( $pI > 8.5$ ) is a dimer containing in each of the monomer an N-linked glycan of the high-mannose type. Using neutral hydrophilic capillaries and phosphate buffer at pH 2.5 as background electrolyte (BGE), the 15 possible rhBMP-2 glycoforms were separated into nine peaks. The use of the glycan and peptide maps, together with fast atom bombardment mass spectrum of the generated glycopeptides, enabled the authors to identify these peaks as the nine glycoforms of the structure  $(rhBP-2)_2-(GlcNAc)_4-(Man)_z$ , where  $z$  varies from 10 to 18. As all of the glycoforms have the same charge, the authors concluded that the size of a mannose residue was fundamental for the separation and that the increasing hydrodynamic radius of the protein could control the separation. However, in rhBMP-2, the mannose glycans appear to be large enough to cover part of the polypeptide backbone, a situation that would lead to the shielding of the most charged region of the protein and to a reduction of its effective charge. An estimation of the effect of the mass of a mannose on the mobility of rhBMP-2 in terms of differences in charge and frictional coefficient led to the conclusion that it was not possible to assess whether the effect of the mannose residue was from a reduction of the  $z$  potential, from an increase of the frictional coefficient, or from a combination of the two.

From the above discussion, it can be concluded that both the effective charge and the hydrodynamic radius play a major role in the control of the electrophoretic mobility in the separation of proteins by CZE. Since proteins are flexible molecules, the interplay of both factors has to be taken into consideration to explain their mobility in electrophoresis. For glycoproteins, a full understanding of the factors that control their separation in CZE is a complex task because the size and flexibility of the glycans constitute an additional cause of structural variability.

## 22.4 METHODS DEVELOPMENT GUIDELINES

### 22.4.1 SAMPLE PREPARATION

As in any other analytical procedure, sample preparation, in those cases where it is needed, is a key step in the separation of glycoforms by CE. The main goals of the sample preparation step are concentration and purification and, when designing the protocol, the peculiarities of each analyte and of the sample matrix must be taken into account. For protein separations by CE, in addition to aspects common to other types of analysis such as filtration, it is often necessary to eliminate compounds that may interfere either by causing a high electrical current, by adsorbing to the capillary walls, or by comigrating with the analytes.

Without sample preparation, the analysis of a dilute serum sample by CE with ultraviolet (UV) detection leads to the separation and detection of the major serum proteins,  $\gamma$ -globulin, transferrin (Tf),  $\beta$ -lipoproteins, haptoglobin,  $\alpha_2$ -macroglobulin,  $\alpha_1$ -antitrypsin (AAT),  $\alpha_1$ -lipoproteins, human serum albumin (HSA), pre-albumin, and complements [32], as shown in Figure 22.4. These proteins often mask other important analytes that are usually more clinically relevant than the major proteins. In fact, it has been widely mentioned that global approaches to proteome analysis detect less than 0.1% of the protein species present in a sample, which span a range of 10 orders of magnitude between the most abundant and the less abundant proteins [33].

The following discussion will focus on an example of a glycoprotein to which several sample preparation procedures have been reported, that is, erythropoietin (EPO) to which a lot of attention has been devoted for its analysis by CE.

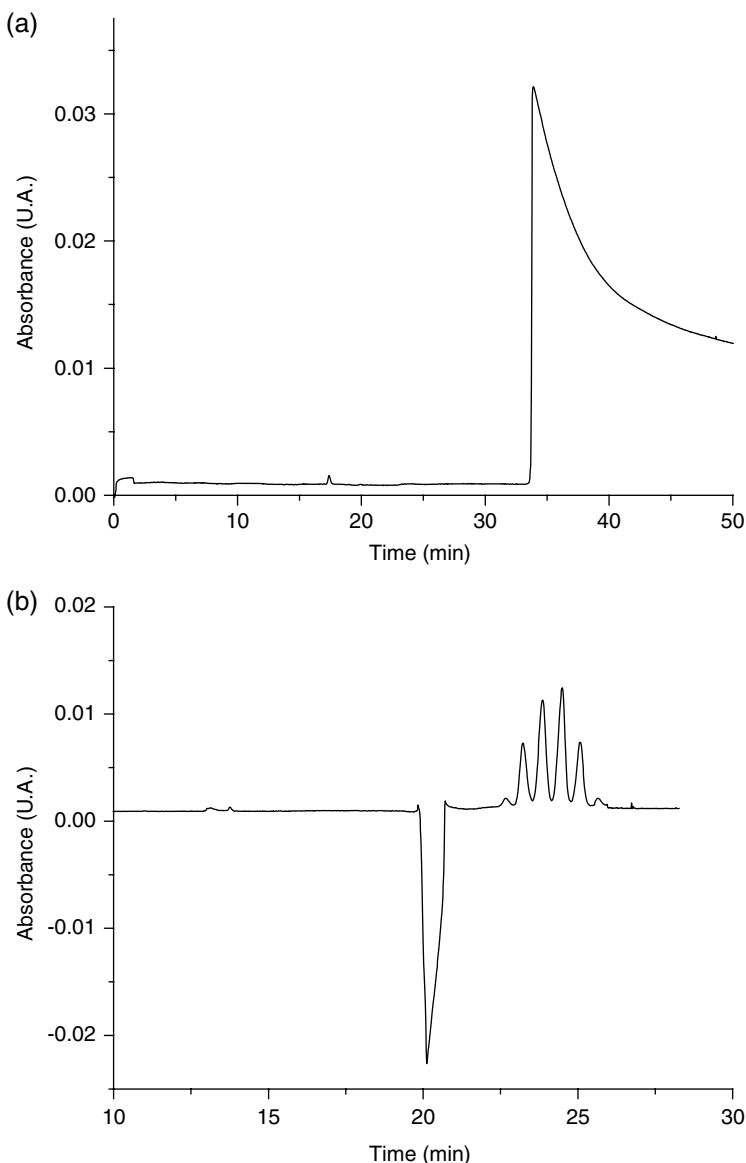

The elimination of low molecular weight (MW) compounds from a sample is widely carried out by using microcentrifugal devices provided with membranes of different MW cutoffs. Clean-up of the rhEPO Biological Reference Preparation (BRP) of the European Pharmacopoeia (EP) was carried out by passing an aqueous solution through a microconcentrator cartridge with a 10 kDa

**FIGURE 22.4** Electropherogram of a diluted normal control serum. Peaks: 1, neutral marker; 2,  $\gamma$ -globulin; 3, transferrin; 4,  $\beta$ -lipoproteins; 5, haptoglobin; 6,  $\alpha_2$ -macroglobulin; 7,  $\alpha_1$ -antitrypsin; 8,  $\alpha_1$ -lipoproteins; 9, albumin; 10, prealbumin; 2', complements. Analytical conditions: fused-silica capillary 25 cm  $\times$  25  $\mu$ m i.d.; buffer: Beckman proprietary buffer of pH 10.0; 10 kV; 22°C. (From Chen, F.-T.A., *J. Chromatogr.*, 559, 445, 1991. With permission.)

MW cutoff membrane and followed by two consecutive rinses with 0.2 mL water [34,35]. A more detailed procedure detailing the time and the centrifugal force to be applied as well as an increase in the number of washing steps was subsequently reported [36]. Ways to decrease the preparation time by increasing the centrifugal force [37,38], and to increase the recovery by repeatedly washing the membrane and inverting the filtering device were also described [38]. An intermediate procedure led to an enhanced resolution of rhEPO glycoforms when compared with the analysis performed under identical conditions but without sample pretreatment [30]. As it will be shown later, this type of sample preparation step that eliminates excipients of low MW is especially important when the separation mode is CIEF [36,39]. This same type of procedure for eliminating low MW excipients was also useful to remove mannitol from a standard of human urinary EPO (uEPO) to be analyzed by CZE [40].

When the sample matrix contains high MW components, such as in biological fluids or in pharmaceutical products formulated with protein excipients, strategies other than MW-based sample preparation are often required. Using again rhEPO as an example, glycoform analysis of products containing HSA under the same CZE conditions as those used for samples containing low MW components was unsuccessful. An approach at separation that did not require a sample preparation step was the development of a CZE method involving the selective binding of HSA. This was accomplished on a polyamine-coated capillary by adding nickel ions to the BGE. The metal ions selectively bonded HSA and decreased its mobility leading to separation of the otherwise comigrating rhEPO [41]. Polybrene (PB)-coated capillaries with a buffer containing acetic acid and methanol also allowed the separation of rhEPO from HSA [42]. A different approach relied on performing the immunochromatographic removal of HSA before separation. Figure 22.5 shows the electropherograms of the unresolved peak obtained for an HSA-formulated rhEPO sample before HSA removal and the separated rhEPO bands after the immunochromatographic HSA depletion [43]. Figure 22.6

shows the separation of a similar sample on polyamine-coated capillary and nickel ions added to the BGE [41]. Both methods provide separation of glycoforms and while the one performed on coated capillaries does not require a prior sample preparation step, the other method can be performed with bare fused-silica capillaries and provides better glycoform resolution.

Sample preparation steps used for other samples are mainly a function of the matrix, the most complicated ones being for the biological fluids. Specific methods used to prepare some of these samples are detailed in Section 22.5.2.

## 22.4.2 SEPARATION OF GLYCOFORMS

### 22.4.2.1 Solutions to Protein Adsorption Problems

Very high separation efficiency can be achieved when the interaction between a protein and the inner wall of the capillary can be eliminated [44]. This is especially important for glycoproteins where this type of unwanted interaction has to be prevented to achieve the high efficiency required for the separation of glycoforms. Two basic strategies can be utilized to overcome this problem. The first one consists in changing the buffer pH and the second one in modifying the inner capillary wall.

The first, and simplest, approach is to select a buffer pH at which interactions become small. At a pH below 3, the silanol groups on the silica surface are fully protonated and bear no electric charge, thus minimizing interactions since most proteins have pI values above 3. On the other hand, at pH 8 or higher, silanol groups are fully ionized and the silica surface becomes negatively charged. So, at pH 8, a protein having a pI smaller than 8 will have a net negative charge and will be repelled by the surface, while one having a pI higher than 8 (a basic protein) will be charged positively and may be adsorbed on the capillary walls. In such a case, a buffer with a pH higher than the pI of the

protein could be used for preventing their adsorption. Although these strategies have been proposed for the separation of proteins since the early days of CE [45,46], they limit the selection of buffer pH as a freely adjustable parameter for optimization. In addition, too large differences between the buffer pH and the protein pI can lead to structural changes resulting in band broadening and low recovery. These limitations have led to other approaches for preventing protein adsorption, which allow a wider selection of buffer pH.

Several methods employing capillary wall modifications have been developed and they can be grouped into several categories: dynamic coatings by the addition of a cationic modifier (usually an amine) to the BGE [47,48], permanent coatings by physical adsorption of a cationic modifier (usually a polymer) [47,48], and permanent coating by covalent bonding of a hydrophilic polymeric layer [49].

#### 22.4.2.1.1 Cationic Buffer Additives

The addition to the buffer of cationic substrates that interact with the silanol groups at the surface of the fused-silica capillary represents the simplest method to improve the separation efficiency in glycoprotein analysis. Several effects have been attributed to these additives, which include decreasing the interaction of the analyte with the inner capillary walls, controlling the electroosmotic flow (EOF), increasing the protein solubility, and enhancing the selectivity of the separation. Although additives of several types, including neutral and ionic substances, have been reported [47,48], amine modifiers have been more frequently used for the separation of protein glycoforms. There are two main groups of amines, one comprising diaminoalkanes and the other polyaminoalkanes.

In the first group, short alkyl chain diamines have been used at millimolar concentrations for the effective separation of glycoproteins such as ovalbumin (OVA) [50,51], rhEPO [52], recombinant factor VIIa [53], granulocyte colony-stimulating factor (rhGCSF) [54], Tf [55], and human chorionic gonadotropin (hCG) [56]. The diaminoalkanes play a role in the separation by affecting both the resolution and the migration time. The separation of hCG glycoforms in uncoated silica capillaries at different concentrations of 1,3 diaminopropane (DAP) in borate buffer (Figure 22.7) shows that an increase in the diamine concentration results in an increase in resolution with a concomitant increase in migration times [56].

Replacing the terminal diamino groups of diaminoalkanes by quaternary ammonium moieties gave rise to more efficient separations [57]. Although a similar resolution was achieved with both types of additives, lower concentrations of quaternary ammonium salts were necessary and shorter migration times were obtained, an indication of effectiveness of these bis-quaternary ammonium compounds. Quaternary ammonium salts such as hexamethonium chloride and bromide and decamethonium bromide (DcBr), having alkyl chains of 6 and 10 carbon atoms, respectively, have been used for the separation of the isoforms of OVA and hCG [57], and Tf [55]. For quaternary ammonium salts, the longer alkyl chains were shown to be more effective and chloride salts led to shorter analysis time than bromide ones.

Polyaminealkanes, such as spermine and spermidine, have been used for the separation of OVA glycoforms [51]. Interestingly, while the efficiency of a polyamine for preventing protein adsorption to the silica walls was shown to increase with the number of amino groups in the chain, this number needed to be higher than three for it to become an effective adsorption inhibitor [58].

#### 22.4.2.1.2 Capillary Coatings by Physical Adsorption

Physical adsorption of polymeric cationic coatings on the inner surface can be easily accomplished by equilibrating the capillary with a solution containing the polymeric additive. In some cases, the polymer remains so tightly bonded to the surface that this does not lose its coating even after performing rinses and, therefore, the polymer does not need to be included in the buffer.

Polybrene (PB) has been used to prepare physically adsorbed polymeric coatings [59,60]. PB is a polycationic polymer, composed of quaternary amines (*N,N,N',N'*-tetramethyl-1,3-propylenediamine), which strongly adsorbs to the inner surface of the capillary and reverses the

**FIGURE 22.7** Effect of various concentrations of diaminopropane on the electrophoretic migration and separation of hCG (4 mg/mL). Separation capillary: 100 cm  $\times$  50  $\mu$ m fused silica. Separation buffer: 25 mM borate (pH 8.8). Other separation conditions: 25 kV, 28°C. Detection: 200 nm. The diaminopropane concentrations used were: 0 (a), 1.0 (b), 2.5 (c), and 5.0 mM (d). (From, Morbeck, D.E. et al., *J. Chromatogr. A*, 680, 217, 1994. With permission.)

EOF in acidic buffers. In these buffers, most proteins are positively charged and are repelled from the surface. This strategy has been used for the separation of rhEPO glycoforms [37], however, with a lower resolution than that obtained with the diaminoalkane putrescine (1,4-diaminobutane, DAB). Its main advantage resides in that this coating allows the use of volatile buffers compatible with MS. Glycoforms of ribonuclease B (RNase B) and horseradish peroxidase (HRP) [61] have also been separated using this strategy. Other polymers prepared from 1,3-propylenediamine and having different charge density have also been reported [62].

PB has a limited stability and is degraded after a few separations. Better coating stability was shown for multiple ionic polymer layers. They are prepared from a first layer made up of a cationic PB coating that is then covered with another physically adsorbed layer from an anionic polymer such as dextran sulfate [63] or poly(vinylsulfonate) [64]. In these coatings the EOF is essentially constant at most pH values. However, because of the negative charge at the capillary surface, positively charged proteins could adsorb to the coating and as such cannot be separated in this type of capillaries. The use of a third layer composed of a cationic polymer, usually PB, has overcome this limitation and has improved the stability of the coating [63,65]. Several groups [66–69] have used commercial

reagents that produce a double ionic layer (e.g., CEofix-CDT kit; Analisis, Namur, Belgium) for the analysis of Tf isoforms in human serum as will be shown in detail in Section 22.5.2.

Recently, a new polyacrylamide (PAA) derivative that allows dynamic coating (UltraTrol LN-; Target Discovery, Palo Alto, CA) has been reported for the efficient separation of glycoforms of ATT [70]. A comparison of the ability of PB and UltraTrol LN for the separation of bovine alpha-1-acid glycoprotein (AGP), bovine serum fetuin (BSF), and rhEPO sialoforms and their application coupling with MS has been reported [30,71]. Better resolution of sialoforms was obtained with capillaries coated with UltraTrol-LN in acidic volatile buffers used for coupling CE to ESI-TOF MS.

#### 22.4.2.1.3 Capillary Coatings by Covalent Binding

The covalent binding of polymers to the inner capillary walls leads to permanent coatings with a thin layer of polymeric material. In a way similar to physically adsorbed polymeric coatings, they minimize protein adsorption by shielding the silanol groups at the surface. In addition, these types of coatings eliminate or fix the EOF over a wide range of buffer pH allowing for a better control on the separation. However, good permanent coatings are more difficult to prepare than dynamically prepared coatings. Typically, preparation is carried out in a two-step process. First, a bifunctional compound, usually a silane derivative, is reacted with the silanol groups at the capillary surface through one of its functional groups, giving rise to a first layer and leaving the second functional group available to be covalently bound to the second layer. The second layer is produced by reacting a monomeric unit and polymerizing it. In some cases, an out-of-column synthesized polymer is bonded directly to the first layer. Several hydrophilic polymers such as linear and cross-linked PAA [72,73], methylcellulose and dextran [74], and polyvinyl alcohol (PVA) [75] to cite only a few have been developed for the separation of proteins. Commercial hydrophilic-coated capillaries have also been used for the separation of recombinant human tissue plasminogen activator (rhtPA) glycoforms [76].

The importance of using coated capillaries for glycoform separations has been shown by Thorne et al. [77] who demonstrated that rhtPA does not migrate in uncoated capillaries, even when  $\epsilon$ -aminocaproic acid was added to the separation buffer. However, when the same buffer was used with capillaries having hydrophilic coatings, rhtPA could be separated into several isoforms. They also obtained better separations using PVA-coated capillaries than with PAA-coated ones.

The importance of additives to the separation buffer, even for coated capillaries, should be emphasized here. Both zwitterionic buffers and tensioactive additives have been shown to improve the separation and recovery of rhtPA with PVA-coated capillaries [77]. On DB1 capillaries, a dimethylpolysiloxane coating widely used in gas chromatography (GC), optimal separations of fetuin, rhEPO, and AGP isoforms were obtained with acidic acetate buffers containing 0.4–0.5% (w/v) hydroxypropylmethylcellulose (HPMC). In this case, the addition of a neutral polymer to the separation buffer makes the EOF almost negligible and protein interactions with the inner surface of the capillary were prevented [78].

The importance of the elimination of protein adsorption to the surface to obtain good glycoform resolution should also be emphasized. This is well illustrated in the separation of rhBMP-2 mentioned earlier, where the use of a commercial hydrophilic-coated capillary with a phosphate buffer without any additive led to efficiencies in excess of  $7 \times 10^5$  plates/meter and up to nine isoforms differing only in the number of mannose residues being separated (Figure 22.8) [31].

#### 22.4.2.2 Factors Affecting the Resolution of Glycoform Peaks

Owing to the importance of the capillary on resolution, the previous section was devoted to its coating. Besides preventing or diminishing interactions with the silanol groups on the silica surface, the capillary coating modifies the EOF. In this way, the apparent electrophoretic mobilities of the glycoform peaks are modified with respect to their effective mobilities, thus allowing for the modulation of the separation. In addition, some of the compounds used as dynamic coatings have been

**FIGURE 22.8** CZE separation of rhBMP-2 in a 50 cm  $\times$  50  $\mu$ m i.d. Bio-Rad coated capillary. Sample was electroinjected for 4–8 s at 6–12 kV in 0.1 M phosphoric buffer (pH 2.5). Detection: 200 nm. Separation temperature 20°C. (From, Yim, K. et al., *J. Chromatogr. A*, 716, 401, 1995. With permission.)

shown to play a role in the separation of glycoforms through interactions with glycoproteins or their complexes, and in this sense they will be considered in this section.

In principle, each CE mode should be adequate to perform the separation of intact glycoforms as long as they differ in molecular properties that are distinguished in the particular mode used. When taking into account that the change in mass between two glycoforms is often almost negligible compared with the total mass of the protein and that relative changes in charge, when occurring, are more noticeable, it is not surprising that most separations have been achieved by CZE and CIEF. However, the other modes, MEKC, CGE, ACE, and CITP have also proven to be useful in some instances. The respective advantages and drawbacks of different modes have been discussed for some glycoproteins [36,76,77,79,80]. The following discussion will focus on aspects of the effect of factors affecting glycoform resolution that can be helpful for methods development together with providing examples to illustrate them. Although this section is organized according to separation modes, it does not imply that in some instances more than one mechanism may be involved in the separation achieved. Details can also be found in Section 22.5.

#### 22.4.2.2.1 Capillary Zone Electrophoresis

CZE was used for the separations of forms of glycoproteins, namely iron-free Tf and RNase almost two decades ago [79,81]. Different factors are known to influence the CZE separation of glycoforms and, when possible, the influence of individual variables will be considered. However, as it will be mentioned, in several instances an interconnection between the effects of two or more factors exists.

The resolution between two peaks can be described [45] as

$$R_S = \frac{\Delta\mu_e}{4(\mu_{\text{EOF}} + \mu_e)} N^{1/4}, \quad (22.2)$$

where  $\Delta\mu_e$  is the difference in the electrophoretic mobility between two peaks,  $\mu_{\text{EOF}}$  is the electroosmotic mobility, and  $\mu_e$  is the mean electrophoretic mobility of the two peaks. Consequently, a decrease in the  $\mu_{\text{EOF}}$  should result in an increase in resolution for other factors remaining constant. An option to selectively modify  $\mu_{\text{EOF}}$  is through manipulation of the zeta potential of the capillary

and ways of achieving low values of  $\mu_{\text{EOF}}$  by using dynamically or covalently coated capillaries have been described in the previous section of this chapter. Other options to increase resolution would be to increase the capillary plate number, to decrease the mean electrophoretic mobility, to increase the difference in the electrophoretic mobility of the two peaks, or to match the electroosmotic and the mean electrophoretic mobilities of different signs so the vectorial result is close to zero. The following discussion will briefly present the influence of some factors on these parameters. Buffer additives, which can act as capillary coatings, will also be considered in this section with respect to their effects on resolution by a joint action with other additives.

**22.4.2.2.1.1 Buffer pH** A variable that is typically changed to optimize differences in effective mobilities between glycoforms is the buffer pH. This frequently used approach derives from the potential improvement in resolution when using a buffer at a pH close to the (pI) of the glycoprotein where both its charge and mobility are lower. In other words, the closer the pH and pI values the higher the chances of increasing charge differences between two glycoforms. An example of this effect was shown for rhtPA, a protein with pIs in the range 4.5–6.0, for which better resolution was obtained at pH 3.6 than at pH 2. [82]. The enhancement of resolution is frequently accompanied by an increase in the analysis time as a consequence of the decrease in apparent mobility. For example, enhanced resolution at the cost of doubling the migration time was obtained by decreasing the pH from 5.5 to 4.5 when analyzing the novel erythropoiesis-stimulating protein (NESP), a protein known to be more acidic than rhEPO [83]. The same effect was observed for AGP, a very acidic protein (pI 1.8–3.8), when the buffer pH was changed from 4.5 to 3.5. In this case, the increase in analysis time was compensated by using a shorter capillary, while maintaining baseline resolution (Figure 22.9) [84]. While the previous examples were carried out on bare fused-silica capillaries, a similar phenomenon has been observed on coated capillaries. Resolution of fetuin (pI 3.2–3.8) glycoforms on DB-1 coated capillaries gradually increased for the pH buffer going from 9.0 to 5.0 [78].

In some instances, the choice of the most appropriate buffer pH precludes the need for buffer additives. This is well illustrated in a study of rhGCSF that showed that although additives, mainly DAB, could be effective in enhancing the separation of glycoforms, the pH control in borate buffer

**FIGURE 22.9** CZE electropherograms of standard human AGP. Conditions: (a) uncoated capillary, 87 cm  $\times$  50  $\mu\text{m}$ ; separation buffer: 0.01 M Tricine, 0.01 M NaCl, 0.01 M sodium acetate, 7 M urea and 3.9 mM putrescine, pH 5.5; injection 30 s at 0.5 psi; 25 kV; 35°C; detection at 214 nm; pH of separation buffer 4.5, other conditions as in (a); (c) capillary length 77 cm, other conditions as in (b). (From Lacunza, I. et al., *Electrophoresis*, 27, 4205, 2006. With permission.)

was enough to obtain baseline resolution of the two glycosylated, the nonglycosylated, and the desialylated forms [54].

**22.4.2.2.1.2 Buffer Ionic Strength** The ionic strength of the separation buffer is another factor to be taken into account when trying to optimize glycoform resolution. Generally, an increase in ionic strength increases resolution by decreasing the EOF and the analyte apparent mobility. However, anomalous results have been observed. This is the case for formic acid used as the separation buffer in the CZE-MS analysis of RNase B on PB-coated capillaries. Increased resolution and decreased EOF were observed when the formic acid concentration was increased from 0.1 M to 2.0 M. Interestingly, at 0.5 M formic acid, resolution was worse than for any other concentration although the EOF was lower than at 0.1 M formic acid. This behavior was interpreted as resulting from conformational changes of the protein [61].

**22.4.2.2.1.3 Borate Buffer** In view of its ability to resolve peaks not solely based on charge differential borate has become a substance of major importance in the resolution of glycoforms. The formation of complexes between hydroxyl groups and borate ions is at the basis of the separation mechanism, making it possible to resolve peaks of glycoforms with the same charge. Borate complexation is usually favored with *cis* 1,2-diols over *trans* 1,2-diols, but some carbohydrates do not follow this rule [85]. For a constant amount of carbohydrate, the complex concentration increases with increasing borate concentration and pH as a result of higher alkaline borate ion concentration, which is known to be the species that complexes with diols [86]. Asialo fetuin analyzed in DB-1 coated capillaries with Tris-borate buffer at pH 8.5 and containing HPMC is an example. The addition of the cellulose polymer, which shields the capillary surface from interactions with the protein, was necessary to achieve resolution; however, excess HPMC hampered the separation, probably due to higher viscosity [78]. Depending on the polymer concentration a sieving effect could also be in play. A comparison of the separation buffers Tris-glycine, ammonium formate, and borate for the analysis of hCG glycoforms also showed an enhancement in resolution when using the borate buffer [56]. However, borate is not necessarily always the buffer of choice and depending on the glycoproteins and the specific separation conditions, other buffers provide better resolution [87].

**22.4.2.2.1.4 Borate Buffer and Diamino Additives** The combined action of borate and diamino additives in the separation buffer reported in 1992 by the groups of Taverna and Landers [50,82] has been widely used to achieve separation of glycoforms. In addition to those reported by the two groups, other types of bifunctional alkyl amines or bis-quarternary amines have been reported in separations involving borate-based buffers [56,57]. The necessity for the diamine to exist as a divalent cation was stated in these studies and a mechanism in which the borate-complexed protein interacts with the amino group of the capillary-bound additive was suggested. Such a partition mechanism that would involve CZE and electrochromatography components has been accepted by other authors [88].

**22.4.2.2.1.5 Other Components of the Separation Buffer** The use of zwitterions as buffer additives has the advantage of not affecting the conductivity of the separation buffer. These additives are thought to enhance glycoform resolution by suppressing protein-wall interactions, by forming ion pairs with the glycoproteins, and by preventing individual protein molecules from interacting with lysine residues on adjacent molecules resulting in precipitation. For example, EACA [76] and other similar  $\omega$ -amino acid buffers have proven effective in the separation of rhtPA forms [77]. In this instance, the addition of a nonionic detergent such as Tween 80 increased the protein recovery. Modified celluloses added to a borate buffer in DB-17 coated capillaries allowed the separation of Tf sialoforms. Although the separation mechanism is not clear, it is thought that both charge differences and gel sieving are contributing factors [89].

**22.4.2.2.1.6 CZE Separation of EPO Glycoforms** To illustrate the many factors that can be modified to optimize glycoforms resolution it is interesting to follow the different approaches reported

for the CZE separation of rhEPO, starting with the method reported by Watson and Yao [52]. On a bare fused-silica capillary, no separation was possible for a commercial rhEPO sample at pH values between 5 and 10 using buffers of different ionic strengths. However, at pH 6.2, the use of additives that decreased the EOF allowed some resolution, with the best results achieved with 2.5 mM DAB. Further improvement was achieved by adding 7 M urea to the buffer and the optimized conditions consisted of a separation buffer of 10 mM tricine, 10 mM NaCl, 2.5 mM DAB, 7 M urea, pH 6.2, in a 50 cm bare fused-silica capillary and applying 10 kV. Baseline resolution of six peaks was obtained in 35 min. A modified version of this method was developed and used for an international collaborative study to assess the BRP for rhEPO of the EP, which consisted in a mixture of alpha- and beta-epoetin. [34]. The modified method consisted in the addition of 10 mM sodium acetate to the separation buffer, adjusting the pH to 5.5 with 2 M acetic acid, and performing the separation at 30°C in a 107 cm capillary. In the initial study, large discrepancies in migration times were found among participants (between 32 and 120 min). These results were possibly attributable to differences of the capillary walls since capillaries from different manufacturers and even from different batches from the same manufacturer have been shown to have very different EOFs. This method was later implemented as an official method for the identification of rhEPO (see Section 22.5.1.1) [35]. A reduction of migration times from 70 to 36 min while keeping enough resolution between peaks and good repeatability has been achieved by decreasing the DAB concentration to 0.025 mM [36]. In contrast, the increased analysis time at higher DAB concentrations could be reduced by applying a higher voltage, from 15.4 to 30 kV [90]. In this instance, baseline resolution of glycoforms have been performed in less than 30 min, and this method could also be applied, although without baseline resolution, to the NESP [38,43].

The development of several CZE methods for the same glycoprotein, using buffers and capillaries other than those previously mentioned, clearly shows the versatility of CE. As another example, the early work by Tran et al. [91] on the influence of factors such as buffer pH and type, and the addition of organic modifiers showed the possibility of obtaining partial resolution of multiple rhEPO peaks with a 100 mM acetate–phosphate buffer at pH 4 in uncoated fused-silica capillaries. A marked effect on resolution was observed when the pre-equilibration time before using the capillary was increased from 4 to 10 h. The shorter pre-equilibration time and the same separation conditions have been used by others [92]. On the other hand, a different method for rhEPO analysis has been performed on C8-coated capillaries using a phosphate buffer [93]. A 300  $\mu\text{m}$  i.d. tube made up of fluorinated ethylene–propylene (FEP) copolymer was used in a hydrodynamically closed separation system, which allowed enhancing the loadability. A buffer consisting on *N*-(2-hydroxyethyl)piperazin-*N'*-2-(hydroxypropane sulfonic acid) (HEPPSO), 1,3-*bis*[*tris*(hydroxymethyl)-methylamino] propane (BTP), and methylhydroxyethylcellulose (MHEC) 30,000, at pH 7.25 allowed to obtain partial resolution of seven bands for rhEPO [94]. CZE under similar conditions with a borate buffer at pH 8.8 containing MHEC was used to monitor the fractionation of rhEPO by preparative CITP [95].

The coupling of the CZE step to detection systems other than UV has required the development of separation conditions compatible to the detection system used. For instance, the presence of primary amines, such as DAB, in buffers needed to be avoided for compatibility with laser-induced fluorescence (LIF) of compounds derivatized with fluorogenic substrates through their amino groups [90]. Baseline resolution of eight peaks in approximately the same time was achieved by substituting DAB by morpholine and tricine by boric acid (to avoid potential traces of primary amines in the tricine buffer) and by adjusting the concentration of other buffer components to compensate for the increase in electrical current. In the same work, modifications were also required to achieve compatibility with MS detection where nonvolatile salts, urea, and amines should be usually avoided. A physically adsorbed polyethylenimine-coated capillary was used to overcome protein adsorption to the capillary walls in the absence of cationic additives and the use of an acetate buffer at pH 5.05 allowed the partial resolution of at least five bands of rhEPO. Other types of coated capillaries have been used for the analysis of EPO by CE-MS as detailed in Section 22.4.3.3 [30,37,42,62,96].

#### 22.4.2.2.2 *Capillary Isoelectric Focusing*

Almost two decades ago, CIEF was described by Kilar and Hjerten [79,97] for the separation of Tf glycoforms and it has, in principle, some advantages over other CE modes, namely, (1) the large volume of sample introduced in the capillary would result in an increase in sensitivity compared with nanoliters amounts in other modes; (2) the measurement of an important molecular property, the isoelectric point (pI), is determined; and (3) a large number of experimental factors can be modified to improve resolution. With regard to the first two advantages, experimental considerations made it that their importance is not what it should be. With respect to the sensitivity issue, it should be stated that commercial ampholytes are generally not designed to work in a capillary format with UV detection and they show high absorbance at 214 nm. In fact, they are manufactured for classical IEF slab gels with detection at 280 nm, a wavelength at which the extinction coefficient of proteins is lower than at 214 nm. So, in practice, the sensitivity of CIEF has been shown in some instances to be similar to that obtained for the same glycoprotein by CZE [36]. With respect to the pI determination, the value obtained for a given analyte should be considered cautiously since, in many instances, urea or other additives that affect the pI of a protein are used in addition to the fact that the pH gradient is not always linear [98].

CIEF can be performed in two general ways: a one-step or a two-step process. In the one-step process, the capillary retains a residual EOF that allows protein bands to migrate through the detection window, while in the two-step process the absence of EOF is desirable for better focusing of the protein bands being mobilized to pass the detection point in the next step. However, even in the one-step mode a controlled EOF is necessary to achieve enough focusing before reaching the detector. Both modes have advantages and drawbacks as was shown for the effect of different factors in the separation of AGP [99].

In CIEF, the total time elapsed between sample introduction and detection depends on the focusing time and on the time for a band to reach the detection window during mobilization. These two effects can take place either simultaneously or consecutively depending on whether the process is a one-step or two-steps, respectively. So, the term “migration time” is not strictly correct in CIEF but it is used in this chapter for simplicity. It is important to note that the need for mobilization through the detector window can be eliminated in systems where whole-capillary imaging detection is used [100].

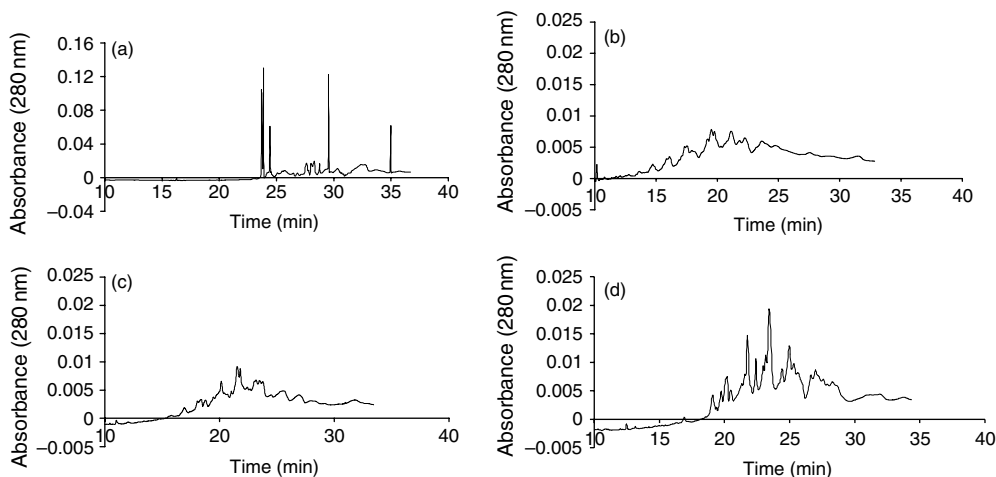

Samples are introduced in the capillary either separated or mixed from ampholytes, the latter being the most frequently used. In addition to the sample and ampholytes, additives can also be introduced in the capillary in the so-called sample mixture, as will be shown in later text.

The different types of capillary coatings providing reduced or no EOF have been described in a previous section. A comparison of different capillary coatings for the resolution of rhtPA glycoforms has been performed and, in some cases, capillaries with different degree of EOF reduction have shown similar resolution, a situation that was probably due to the presence of additives controlling the EOF [101]. While similar resolution has been achieved with different coatings, the stability of the coatings in terms of the number of runs performed was evaluated in the analysis of recombinant human antithrombin III (rhATIII) and the recombinant human immunodeficiency virus envelope glycoprotein rgp 160s. Higher stability was observed for dextran-coated [102] and PVA-coated [103] capillaries than for PAA-coated capillaries. Besides the capillary coating, other variables that can be controlled for improving resolution of glycoforms are described in the following text.

**22.4.2.2.2.1 *Additives for Reducing EOF*** Besides the use of coated capillaries for controlling the EOF, the addition of substances aimed toward reducing the EOF through an increase in the viscosity is frequently used. This is the case for poly(ethylene oxide) [36,39,77] and HPMC [101,103]. The latter has proven to be effective even when using bare fused-silica capillaries, where it acts as a dynamic coating [104].

**22.4.2.2.2.2 *Ampholytes*** This is one of the variables to which a lot of attention has been paid. Both the nature and pH of ampholytes as well as the combination of several pH ranges have been

**FIGURE 22.10** Effect of types of ampholytes on separation of AGP forms. Total ampholyte concentration in the sample mixture: 6.3% (v/v). Types of ampholytes, specified by their pH range (and ratios (v/v)): (a) range 3–10; (b) mixture of ranges 3–10 and 2.5–5 (1:1); (c) mixture of ranges 3–10, 2.5–5, and 2–4 (1:1:1), (d) mixture of ranges 3–10, 2.5–5, 2–4, and 3–5 (1:1:1:1). Other analytical conditions: PVA-coated capillary, 27 cm (effective length 20 cm). Sample mixture in CIEF gel: 1 mg/mL AGP, 5.6 M urea, 20 mM NaCl, and ampholytes. Catholyte: 20 mM NaOH titrated with  $\text{H}_3\text{PO}_4$  to pH 11.85. Anolyte: 91 mM  $\text{H}_3\text{PO}_4$  in CIEF gel. Focusing: 10 min at 20 kV. Mobilization step: 20 kV and 0.5 p.s.i.  $\text{N}_2$  pressure. Temperature: 20°C. Detection: 280 nm. (From Lacunza, I. et al., *Electrophoresis*, 28, 1204, 2007. With permission.)

considered. In general, better resolution is attained with mixtures of ampholytes. The influence of the commercial source of ampholytes on resolution has been shown, even when only a wide-range ampholyte solution is used [77]. Similarly, for a given total concentration of ampholytes mixed in constant proportions, the resolution was shown to depend on the nature of the ampholytes [105]. Besides providing different resolutions of rhtPA glycoforms, commercial ampholytes have different optical properties that have an impact on detection [106]. Ampholytes from different sources have been shown to be different in nature and in focusing properties [107,108]. As such, mixtures from different manufacturers are generally preferred, since the different nature of the compounds from the different sources may help to achieve better focused zones by reinforcing the pI range of interest. This effect was clearly seen for the separation of rhEPO [36] and AGP glycoforms [109] (see Figure 22.10).

Apart from the nature of ampholytes, their proportion and total concentration are other factors to be considered. Usually, higher proportions of an ampholyte or narrow-range ampholytes close to the pI of the glycoprotein provide better resolution [103]. For the amount of total ampholyte, a compromise is generally achieved since higher percentages not only provide better resolution but also lead to higher background absorption and, consequently, decreased sensitivity [39,103,109].

**22.4.2.2.3 Agents to Avoid Precipitation** Protein precipitation is favored during the focusing process where a protein is concentrated in a narrow zone close to its pI, and associated salts are separated from it. The addition of nonionic surfactants, organic modifiers, or chaotropes to the sample can be used to decrease chances of precipitation [110]. The presence of urea in the separation buffer has been shown to markedly improve the resolution of AGP and EPO glycoforms [36,100,109], being also used to obtain adequate separation of rhtPA glycoforms [77,104]. Triton X-100 was found to be unnecessary when urea was used to separate rhtPA glycoforms [101]. This detergent was used to avoid precipitation for the analysis of rhATIII [102]. However, it may be necessary to resort to a combination of agents. This was the case for recombinant human immunodeficiency virus envelope glycoprotein where several additives including a chaotrope (urea), a

**FIGURE 22.11** Effect of urea on CIEF separation of rhEPO. (a) Without urea in the sample mixture, and (b) with 7 M urea. Analytical conditions: polyacrylamide-coated capillary 27 cm (effective length 20 cm)  $\times$  50  $\mu$ m i.d. Focusing: 6 min at 25 kV. Sample mixed with CIEF gel and ampholytes. Ampholyte mixture (1:2, v/v) of pH 3–10 and 2.5–5 ranges. Detection: 280 nm. (From Cifuentes, A. et al., *J. Chromatogr. A*, 830, 453, 1999. With permission.)

zwitterion [3-(cyclohexylamino)-1-propanesulfonic acid, CAPS], and a sugar (saccharose) provided the best results [103].

**22.4.2.2.4 pH Extenders** In order to avoid the focusing of glycoforms past the detection window, a situation that would prevent their detection, it is necessary to add a substance with an appropriate pI to block that zone of the capillary. It is referred to as a pH extender and the most frequently used is *N,N,N',N'*-tetramethylethylenediamine (TEMED). It is usually added to the sample mixture at a concentration proportional to the length of capillary to be blocked. The larger the pH extender concentration is the farther away a glycoform will focus from the detection point and, consequently, the greater the migration time will be, as was observed for rhtPA without any marked

influence on resolution [105]. The same authors also reported that for TEMED concentrations about 10 times higher, in the range of 3.75–7.5% (v/v), the effect on migration time was not noticeable [101]. Caution should be taken when using TEMED as it has been shown to damage the capillary coating [99,103]. Depending on the pI of the glycoprotein, other less basic extenders, such as alanine, can be used [99].

*22.4.2.2.2.5 Focusing Time and Voltage* For the one-step CIEF separation of rhtPA glycoforms, an increase in voltage led, as expected, to a decrease in migration times without any influence on resolution [105]. For the two-step process, the two factors involved on the focusing step (i.e., voltage and time) have an impact on resolution. According to the theory [111], increasing voltages up to 25 kV provided slightly better resolution of rhEPO glycoforms; however, loss of resolution was observed at higher voltage, probably due to an excess of Joule heating [36].

It is usually considered that focusing is finished when the current decreases below 10% of its initial value and stabilizes. However, in practice, focusing times as short as 0.5 min and corresponding to 69% of the initial current have been shown to lead to the same resolution of EPO isoforms as for longer focusing times. This can be understood taking into account that during the pressure-mobilization step, the voltage is applied to avoid band broadening resulting in a continuation of focusing [36]. In contrast, focusing times longer than needed may have a detrimental effect not only on the analysis time but also on the quality of the separation. The total depletion of salts due to a long focusing time led to precipitation of monoclonal anti-alpha-1 antitrypsin [100]. In addition, focusing times that are too long may lead to greater anodic drift and can affect the isoform separation of highly acidic proteins such as AGP [109]. Incomplete focusing due to times shorter than needed, however, may lead to double peaks. These examples show that careful optimization of the focusing time is required.

*22.4.2.2.2.6 Presence of Salts in the Sample Mixture* The presence of salts in the sample mixture remains a controversial point. Some authors have claimed that the ionic strength of the sample should be as low as possible while others have found it to help improve resolution. For the analysis of anti-alpha-1 antitrypsin [100], AGP [109], or rhEPO [36,39], the presence of salt was necessary for the separation of isoforms. This effect is likely related to prevent protein precipitation and denaturation, although other effects such as improved focusing or masking of the silanols of the capillary walls cannot be excluded.

*22.4.2.2.2.7 Mobilization Step* In the two-step CIEF mode the mobilization step is performed after focusing. Hydrodynamic (more frequently performed by applying pressure rather than by vacuum) and chemical mobilization are the two general ways of driving the focused zones to the detection point.

As indicated earlier, when the mobilization is performed by pressure, a voltage is applied simultaneously, usually at the same strength as the voltage used during the focusing step. However, a higher voltage may be needed in some instances as shown for a monoclonal antibody (mAb) [112]. Chemical mobilization with a strong electrolyte has been shown to lead to better resolution than by using a weak one [97].

Performing hydrodynamic and chemical mobilizations together has been shown to be beneficial for the separation of rhEPO [39] and even necessary for the separation of glycoforms of acidic proteins such as AGP [109] (see Figure 22.12). The addition of phosphoric acid to the catholyte, which consists of sodium hydroxide, at the very beginning of the focusing step promotes chemical mobilization that continues when the pressure is applied at the hydrodynamic mobilization step.

### *22.4.2.2.3 Micellar Electrokinetic Chromatography*

There are many factors involved in the MEKC separation mode that contribute to the complexity of its mechanism. On the other hand, they provide a large number of variables that can be modulated to optimize the separation. MEKC has been used on a few occasions for the separation of glycoproteins,

**FIGURE 22.12** One-step CIEF of AGP. PAA coated-capillary 27 cm (effective length 7 cm)  $\times$  50  $\mu\text{m}$  i.d. Voltage:  $-20$  kV. Temperature:  $20^\circ\text{C}$ , Detection 280 nm. Sample mixture: 5.6 M urea, 1.7% (v/v) TEMED, 9.7% (v/v) ampholytes in the following distribution of pH ranges: 3–10, 2.5–5, 2–4, 3–5 (2:2:3:3) and 1 mg/mL AGP in CIEF gel. (a) anolyte: 91 mM  $\text{H}_3\text{PO}_4$  in CIEF gel, catholyte: 20 mM NaOH, (b) anolyte: 91 mM  $\text{H}_3\text{PO}_4$  in CIEF gel, catholyte: 20 mM NaOH titrated to pH 11.85 with  $\text{H}_3\text{PO}_4$ .

usually under conditions involving the use of borate or phosphate salts and SDS as the micellar agent. Factors, such as borate/phosphate and SDS concentrations, and the nature and pH of the buffer can be modified to optimize resolution. RNase B was separated into five peaks, each one of them corresponding to one of the Man5 to Man9 oligomannose structures, in a fused-silica capillary with a buffer consisting of sodium phosphate, SDS, and sodium tetraborate [113]. For recombinant human interferon- $\gamma$  (rhIFN- $\gamma$ ), over 30 species were resolved giving rise to three groups of peaks, PG1, PG2, and PG3, as shown in Figure 22.13 [114]. The increase in the concentrations of the borate buffer and SDS led to a concomitant increase in separation efficiency and migration times. The comparison between phosphate buffers at pH 6.5 and 7.5 and borate buffers at pH 8.5, at a constant SDS concentration and at buffer concentrations chosen to generate similar currents, showed that the best resolution was obtained with borate buffers. At a higher pH (9.5) and a lower borate concentration than that used at pH 8.5, higher current, slower separation, and lower efficiency were observed. The better resolution obtained with the borate buffer pH 8.5 was likely due to the effect of the complexation between borate anions and diols mentioned earlier. It has been hypothesized that the early migrating glycoforms would be those with the larger glycan structures and that this should be taken into account when designing a separation method or when assigning peaks to specific glycoforms. The reasoning behind this hypothesis is that at high borate concentrations, sugar residues would be extensively complexed and that the resulting negative charge, when added to that from sialic acid residues, would cause repulsion between SDS micelles and the borate-complexed glycoprotein. According to the authors, the repulsion intensity would depend on the glycan size. The same study reported the possibility of separating the glycoforms of RNase B and HRP, while the separation of BSF led to the separation of only one major peak and three minor, broad ones, and no separation at all of AGP glycoforms. According to the authors, the lack of separation for proteins glycosylated at multiple sites such as BSF and AGP could be due to the fact that the heterogeneity of individual oligosaccharides does not give rise to measurable differences in carbohydrate contents.

#### 22.4.2.2.4 Capillary Electrophoresis in SDS

In conventional polyacrylamide gel electrophoresis (PAGE) as well as in its capillary counterpart CE-SDS, proteins form stable complexes with SDS and are separated on the basis of their size. The separation of glycoproteins is known, however, to deviate from the linear relationship of migration versus MW observed with nonglycosylated proteins. This anomalous behavior arises from the fact that carbohydrate moieties bind with much lower amounts of SDS than expected for a corresponding

**FIGURE 22.13** Optimization of the separation of IFN- $\gamma$  glycoforms by MEKC. Borate/SDS buffer at the following concentrations: (a) 40 mM borate, 10 mM SDS; (b) 40 mM borate, 100 mM SDS; (c) 400 mM borate, 10 mM SDS; (d) 400 mM borate, 100 mM SDS. Fused-silica column 57 cm  $\times$  50  $\mu$ m i.d. Injection 5 s of 1 mg/mL protein in 50 mM borate, 50 mM SDS, pH 8.5. Voltage: 22 kV. In (d), the main groups are designated PG1, PG2, and PG3 in order of migration. (From James, D.C. et al., *Anal. Biochem.*, 222, 315, 1994. With permission.)

peptide of similar MW. Advantages were taken from this fact in order to differentiate glycosylated fetuin from the nonglycosylated protein produced by enzymatic hydrolysis [115]. The release of the carbohydrate moiety gives rise to a decrease in size that translates into an increase in the charge-to-mass ratio since the charge imparted by SDS to the carbohydrate moiety is low compared with that imparted by the interaction of the surfactant with the peptide core. The resulting differences in mobility make it possible to monitor the deglycosylation reaction. Similarly, rhATIII $\alpha$  was separated from rhATIII $\beta$  by CE-SDS due to the lack of glycosylation at Asp 135 in the latter [116].

**FIGURE 22.14** Changes in the migration times of OVA glycoforms with LCA concentration. Capillary: linear PAA-coated 58 cm  $\times$  50  $\mu$ m i.d; Buffer: 100 mM phosphate pH 6.8, (A) not containing LCA, (b–e) containing 0.4, 0.8, 1.4, and 2.0 mg/mL LCA, respectively. Voltage: 20 kV; Detection: 214 nm. (From Uegaki, K. et al., *Anal. Biochem.*, 309, 269, 2002. With permission.)

#### 22.4.2.2.5 Affinity Capillary Electrophoresis

Glycoform separations by ACE have been carried out by taking advantage of the known interactions between lectins and carbohydrates. The “partial filling technique” in which only a portion of the capillary is filled with an affinity ligand present in the separation buffer before injecting the sample was shown to be useful for separating AGP glycoforms. The separation of two peaks based on the dependence of the strength of the AGP-concanavalin A (Con A) interaction as a function of the content in biantennary glycans was achieved [117]. Differential interactions between lectins and glycans are useful not only to perform glycoform separations but also to estimate the values of the apparent association constant between the lectin and each of the separated glycoform. PB-coated and PAA-coated capillaries completely filled with a buffer containing the lectin *Lens culinaris* agglutinin (LCA) were shown to be suitable for separating glycoforms of RNase B and OVA, respectively, and for calculating the affinity constants without a prior separation of the glycoforms outside the capillary. Figure 22.14 shows the separation obtained for OVA glycoforms and the influence of the LCA concentration [118].

#### 22.4.2.2.6 Capillary Isotachopheresis

Few studies on the use of the CITEP electrophoretic mode have been reported for the separation of protein glycoforms. The separation of AGP isoforms by CIEF mentioned previously [109] can be considered to involve an isotachopheretic mechanism taking into account the concurrence of focusing and chemical mobilization [119]. Preparative CITEP has been used to fractionate rhEPO with a leading electrolyte containing chloride as anion and BTP as counter ion, and a terminating electrolyte containing glycine as anion and BTP as counter ion. Under these conditions, the fractions contained mixtures of glycoforms enriched in the predominant glycoform of each fraction. The process was monitored by CZE [95].

#### 22.4.2.3 Reproducibility Problems

With respect to the issue of reproducibility, the separation of protein glycoforms by CE is faced with the same kind of problems than for any other protein. However, the consequences of a lack of

adequate precision can have a detrimental impact due to the fact that differences in the charge/mass ratio or pI among isoforms are so small that the different peaks usually migrate very close to one another, making it sometimes impossible to compare samples. For example, peaks of rhBMP-2 separated by CZE on the basis of a single mannose residue between adjacent peaks differ in migration times by only 0.15–0.22 min or  $0.01 \times 10^{-4} \text{ cm}^2 \text{ V}^{-1} \text{ s}^{-1}$  in their respective mobility [31]. This can give rise to unreliable comparisons of samples since the difference in migration time between two consecutive peaks can be in the same range as the migration time dispersion for a given peak [38]. For instance, this problem made it impossible to correctly compare a reference hCG sample with a sample obtained from the urine of a patient with metastatic choriocarcinoma [56]. Solutions to this type of problems require a two-pronged approach. First, experimental factors affecting reproducibility must be carefully controlled. Once this is achieved, reliable migration parameters must be used for band assignment.

Some experimental factors such as buffer preparation are usually well controlled. However, there are other variables to which not enough attention is paid. One of these, which is of key importance for achieving good intra- and interday repeatability, is capillary conditioning. All of the steps performed for the conditioning of brand-new capillaries as well as the washing steps carried out between runs and before the storage of capillaries are decisive in achieving good precision. This may help in explaining the low reproducibility reported for some methods [17], while the same methods when applied to the same analytes showed highly reproducible results in other studies [36,38,90].

Another factor that has a large influence on migration time reproducibility, especially for coated capillaries, is capillary aging. Buffer components that can alter the coating need to be identified and avoided. However, even when using the appropriate buffers, capillaries gradually degrade and they should be discarded if the resolution achieved is no longer within easily verifiable limits or if peak assignments cannot be reliably performed.

Once experimental factors are controlled as much as possible there are several ways to minimize the problem of migration time reproducibility through the use of migration parameters. One of the more common approaches is the use of internal standards from which it is possible to calculate the migration time of each isoform relative to that of the internal standard. This approach has been used in the analysis of several glycoprotein isoforms [38,39,109,120]. For example, in the CIEF separation of rhEPO glycoforms, the intraday migration time reproducibility was improved from an RSD value of around 1.8–0.3% when using an internal standard [39]. In another approach and using the CZE analysis of rhEPO as a model, a statistical program was developed in order to choose, among others, the best migration parameter to correctly assign peaks and reliably compare different samples. The program estimated the probability of correct assignment for each migration parameter [38] and was used for the comparison of rhEPO from different samples [38,43] and for the comparison of electrophoretic profiles of AGP purified from healthy donors and cancer patients [84]. In the latter publication, it was shown that the electrophoretic mobility of each AGP peak and the migration time of each peak relative to the migration time of the EOF marker were more effective migration parameters than the migration time of each peak.

### 22.4.3 DETECTION AND IDENTIFICATION OF FORMS OF GLYCOPROTEINS

#### 22.4.3.1 UV Detection

The UV absorbance detector is one of the most widely used systems in CE. Detection takes place in the same separation capillary, avoiding band broadening of the separated compounds. Since the internal diameter of the capillary is very small (25–100  $\mu\text{m}$ ), the detection pathlength is very short and the concentration sensitivity is typically 10–20 times poorer than that obtained with the same type of detector in other separation techniques (e.g., HPLC).

Glycoproteins, similar to nonglycosylated ones, can be monitored at 280 nm at which wavelength the aromatic residues of the polypeptide chain, tryptophan, tyrosine, and, to a lesser extent, phenyl-

alanine give relatively good absorption. However, the detection limit at this wavelength remains in the low mg/mL range and instead, detection is usually accomplished at 200 nm where proteins present 50- to 100-fold greater absorptivity. At this wavelength, sensitivities in the  $\mu\text{g/mL}$  range can be obtained.

While this level of sensitivity may be enough for the quality control of glycoproteins, it is, in most cases, insufficient for the analysis of these proteins in clinical samples. Strategies based on sample concentration or protein derivatization can sometimes be used in these cases and some aspects have already been discussed in other parts of this chapter and will only be considered briefly in this section.

### 22.4.3.2 Laser-Induced Fluorescence Detection

For glycoproteins present at low sample concentrations (generally lower than  $10^{-6}$  M), such as in clinical samples, fluorescence detection will likely be one of the detection methods to be improved in the future for analysis of these proteins by CE. It should be recalled that, due to the small size of the detection volume in on-column monitoring (usually 5–10 nL), high optical power ( $> 1$  mW) from the light source should reach the detection window of the capillary for intense fluorescence excitation [121]. This is more efficiently achieved using a laser as a source of light than a ultraviolet-visible (UV-VIS) lamp and confirmed by practical experience of the fluorescence detection of proteins and glycoproteins by CE.

LIF detection of glycoproteins is not an easy task. Most analytes do not produce fluorescence at the wavelength of the emission of the most frequently used lasers (those with light emission in the 400–600 nm range) and, therefore, native fluorescence cannot be obtained with these light sources. Derivatization with a fluorescent reagent is a useful strategy for LIF detection when native fluorescence is unavailable. Although several fluorogenic compounds with good chemical and spectroscopic characteristics have been described in the literature [122], this approach suffers from several problems when the analyte is a glycoprotein, including the formation of multiple reaction products [123] and the difficulties associated with derivatization of proteins at low concentration (below  $10^{-8}$  M). In the following discussion, a few approaches reported in the literature to make LIF detection feasible for glycoproteins are presented.

Glycoproteins can be directly detected by native fluorescence owing to the fluorescence emission of the tryptophan and tyrosine residues; however, this requires the use of laser with emission in the UV region of the electromagnetic spectrum. This approach has been scarcely used [124] for glycoproteins, probably due to the high cost of such lasers and the expertise required for their maintenance. In the past few years, however, pulsed diode-pumped solid-state (DPSS) lasers with emission in the UV region (266 nm) have become affordable and this has opened the way to a more universal native LIF detection of glycoproteins.

The covalent derivatization of a glycoprotein with a fluorescent agent has been shown to be useful in some cases. As mentioned earlier, the main difficulty with this type of approach is the formation of multiple products due to the fact that each lysine residue in the peptide chain can react to a different extent with the derivatizing agent. As a result, protein molecules having a variable number of covalently bonded fluorescent tags are produced, resulting in a variable number of species with similar MW (the fluorescent moiety has a small MW in relation to that of the protein) but with different electric charges. In these cases, analysis by CZE or CIEF may give rise to broad or even multiple peaks for the same protein. On the other hand, when the separation mode is CE-SDS, narrow peaks with good efficiency are obtained and make LIF a more suitable technique for this separation mode.

Using this approach, a CE-SDS method with LIF detection has been developed and validated as a quality control procedure for the purity determination of a recombinant mAb [125]. 5-Carboxytetramethylrhodamine succinimidyl ester was used as fluorescent reagent and the optimal conditions for derivatization of the nonreduced and reduced (reacted with dithiothreitol) mAb and

their respective degradation products were determined. It is worth mentioning that for reduced samples, the proposed method was able to separate the fraction corresponding to the nonglycosylated fragment of the mAb from the glycosylated one. The commercial LIF instrumentation (argon ion laser,  $\lambda_{\text{exc}}$  488 nm,  $\lambda_{\text{em}}$  560 nm) provided excellent limits of detection (around 10 ng/mL) for the intact antibody and its degradation products.

One approach to overcome the formation of multiple derivatives and the difficulties associated with derivatization of proteins at low concentrations was proposed by the group of Dovichi [126,127]. They developed a derivatization procedure for proteins with the fluorogenic reagent, 5'-furoylquinoline-3-carboxaldehyde (FQ), that provided good sensitivity and minimized the band broadening caused by the variable labeling from the reaction of FQ with lysine residues. The derivatization could be carried out before the sample injection or inside the separation column. For the latter, two successive short plugs, one containing the sample and the other containing the reagent, were injected into the column; both plugs were mixed inside the capillary (due to their differences in electrophoretic mobility) and allowed to react. After derivatization, either inside or outside the capillary, the protein separation took place in a buffer containing *an*-alkylsulfate tensioactive (e.g., sodium dodecylsulfate or sodium pentylsulfate) at submicellar concentrations, which masked the charge differences introduced in the protein by the multiple labeling. The method provided good results in terms of sensitivity, with an assay detection limit of  $10^{-10}$  M for OVA (the authors define the assay detection limit as the minimum amount of protein that can be successively derivatized and detected), and band broadening (around 20,000 theoretical plates) (Figure 22.15). Limitations of the technique included variable protein sensitivity due to the different number of lysine residues and the possibility of masking differences in mobility of the protein glycoforms from the added tensioactive [128]. It should be noted that the reported sensitivity was achieved with postcolumn sheath-flow LIF detection; sensitivity using a commercial on-column LIF detector was about 100 times poorer.

**FIGURE 22.15** Comparison of ovalbumin analyzed under various conditions. Running buffer: (a–c) 25 mM tricine, pH 8.0; (d) 25 mM tricine +5 mM SDS. (a) FQ-labelled ovalbumin, 15 s reaction, LIF detection; (b) unlabelled ovalbumin, UV absorbance detection; (c) FQ-labelled ovalbumin, 10 min reaction. LIF detection. Note that electropherogram B is plotted versus top x-axis and right y-axis. (From Pinto, D.M. et al., *Anal. Chem.*, 69, 3015, 1997. With permission.)

Affinity binding is another good alternative for fluorescent detection of glycoproteins. This kind of binding involves several types of interactions between the glycoproteins and the fluorescent reagent (excluding the covalent one) and include electrostatic, van der Waals, hydrophobic, and hydrogen-bonding forces. A large choice of fluorescently labeled biomolecules can be used in this approach. The preparation of a homogeneously labeled biomolecule is in some cases a labor-intensive task involving chromatographic purification of the probe. Bornemann et al. [129] have used affinity derivatization with LIF monitoring to improve the selective detection of rhEPO. They first prepared a monomeric antigen-binding fragment (Fab) from the mAb 5F12 that bonded to a conformationally independent epitope of the N-terminal region of human EPO. This fragment was then labeled with the fluorescent dye, Alexa Fluor 488, yielding a mixture of labeled products (doubly and singly labeled and unlabeled) from which a homogeneous fraction was prepared by HPLC. This fraction was used as affinity reagent in CIEF with LIF detection (argon ion laser  $\lambda_{\text{exc}}$  488 nm,  $\lambda_{\text{em}}$  520 nm) for the detection of less than 100 pmol of rhEPO. Although this detection limit is far from the sensitivity necessary for the determination of this hormone in serum or urine, the authors believe that further refinement of the labeled Fab fragment and decrease of sample volume should permit the detection of smaller amounts of EPO.

Postcolumn derivatization with a fluorescent reagent is another alternative. However, this approach requires the selection of a fast derivatization reaction to achieve good sensitivity and a careful design of the postcolumn reactor that minimizes the loss in resolution achieved in the separation capillary. To this end, affinity interactions of some biomolecules, such as antibodies, with other glycoproteins are especially useful. That has been the case reported by Kelly and Lee [130] who have developed a CE method with online postcapillary affinity LIF detection for the monitoring and quantification of microheterogeneities of a mouse antihuman follicle-stimulating hormone mAb in samples containing culture medium without further purification. The fluorogenic reagent, consisting in fragment B (BF) of protein A conjugated with fluorescein, was mixed with the effluent of the CE column using a homemade postcolumn capillary reactor without causing large band broadening. Affinity binding between the antibody variants and the BF-fluorescein occurred in the reaction capillary and the complexes were monitored by the LIF detector (argon ion laser,  $\lambda_{\text{exc}}$  488 nm,  $\lambda_{\text{em}}$  515 nm) placed in the same capillary. By binding the BF-fluorescein fragment to the antibody, the emission of the fluorescein moiety was enhanced, so that the mAb peaks were detected with a low fluorescence background. The detection of up to five peaks was reported and the authors speculated that this could be due to the presence of different isoforms of the antibodies differing in the sialic acid content of their oligosaccharides.

### 22.4.3.3 Mass Spectrometry

Recent progress made in the development of MS ionization techniques has enabled its application to the analysis of intact glycoproteins. The most widely used ionization modes are ESI and matrix-assisted laser desorption ionization (MALDI). When considering the gains in sensitivity when compared with conventional UV detection, the structural information that can be derived from its use and the possibility of increasing the selectivity in the selected ion monitoring (SIM) mode, it is not surprising that MS has become a widely used detection system for coupling to CE. In this section, only those systems where the online coupling of CE to mass spectrometry (CE-MS), and for which MS is used as the detection (and information) system for the CE separation of glycoforms will be considered.

Owing to the high heterogeneity and structural complexity of glycoproteins, a prior separation step is generally necessary to obtain qualitatively and quantitatively useful results. Otherwise, only broad signals are obtained. Despite the compatibility of CE with ESI-MS and the relatively easy coupling of the two techniques, appropriate separation buffers, usually consisting of volatile substances,

must be employed. This is one of the more difficult issues to the coupling of CE to MS where buffer electrolytes compatibility with MS involves choosing buffers that do not inhibit ionization and that, at the same time, provide reasonable glycoform separation [30]. Formic acid was used as the separation buffer in a pioneering work aimed at the characterization of glycoforms [61]. Analysis required constructing a CE–MS interface that could be adapted to a commercial CE cartridge. Under these separation conditions, the CE-MS system provided analysis of intact RNase B and HRP, a more complex glycoprotein in which the microheterogeneity arises from glycosylation at two residues and variability in the carbohydrate composition at each site. Figure 22.16 shows the CE-UV and the CE-MS electropherograms obtained for RNase B.

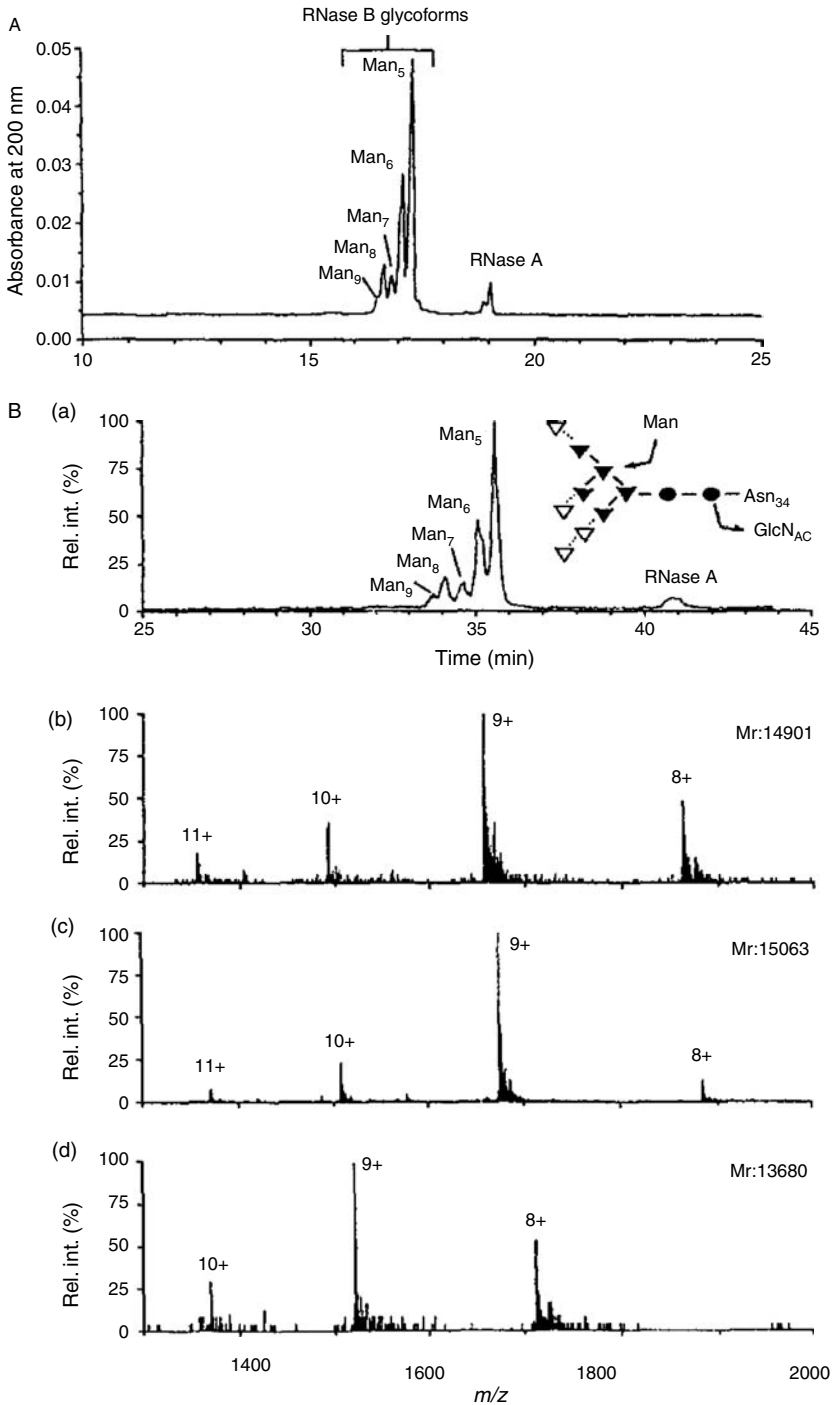

Although volatile buffers are usually employed, successful analyses of intact glycoproteins have also been achieved by using low concentrations of nonvolatile compounds in separation buffers with low ionic strength [131]. Using PAA-coated capillaries and a separation buffer consisting of 50 mM  $\beta$ -alanine adjusted to pH 3.5 with acetic acid, two high mannose-containing proteins, RNase B and rhBMP-2, were analyzed by CE-MS employing a home-built CE instrument. Reporter ions for carbohydrates generated by in-source fragmentation for the glycoforms separated by CE were used to provide information about the degree of glycosylation of the different isoforms.

The presence of urea in the separation buffer was found to be needed to accomplish the separation of antithrombin III (ATIII) glycoforms from a commercial sample purified from plasma [132]. In order to make the CZE separation step compatible with the ESI-MS ion trap, special precautions about the decoupling of the needle were needed to minimize the amount of urea introduced into the spray chamber. Although the resolution was lower than that obtained by CZE-UV, it was enough to allow deconvolution of the multiply charged peaks, even for minor isoforms. It was also possible to distinguish isoforms differing in fucosylation for which small differences in mass for species having similar pIs would not make it possible to be differentiated on the basis of electrophoretic mobilities. The precision of the molecular mass determination was better than 1%. Assignment of particular glycan structures to isoforms was aided by the known canonical structures of the main isoforms of alpha- and beta-ATIII.

Successful characterization of protein glycoforms has been reported using MS-friendly conditions on capillaries with dynamic coatings that generate low-EOF [70]. An acidic BGE containing an organic additive was used (1 M acetic acid/20% methanol at pH 2.4). Under these conditions, partial separation of glycoforms was attained for several glycoproteins including AGP and BSF [71].

By using ionene-coated capillaries and an acetate buffer at pH 4.8, baseline resolution of the three main isoforms of rhEPO and a comparison of rhEPO and uEPO were obtained by CE-ESI-MS [62].

The development of CZE-ESI-MS methods using an orthogonal accelerated time-of-flight (TOF) mass spectrometer has allowed distinguishing glycosylation differences between a reference preparation of rhEPO and a commercially available product sold for research purposes [42]. Membrane concentrators were used to obtain sample concentrations at the required level followed by separation on PB-coated capillaries (the amine coating effectively reverses the EOF). The concentration step provided the additional advantage of removing small MW excipients (e.g., salts, polysorbate), which are known to interfere in the ionization step. Despite the lack of complete resolution in the CE separation step, the MS dimension provided additional resolution and enabled the identification of intact glycoforms varying in the number of HexHexNAc residues, sialic acids, and even the identification of fucosylated, acetylated, and oxidized glycoforms. A total of about 135 isoforms were distinguished in the rhEPO BRP of the EP. A possible composition of the recombinant protein was speculated taking into account the information provided by the CE-MS system and that obtained by other methods. The same method allowed the characterization of the two pharmaceutical products, epoetin- $\alpha$  and epoetin- $\beta$  [96]. Ultimately, the two products could be distinguished on the basis of the presence of two additional basic (i.e., glycoforms containing less sialic acids) glycoforms in epoetin- $\beta$ .

(A) Fused-silica capillary 80 cm  $\times$  50  $\mu$ m i.d. coated with a solution of polybrene and ethylenglycol; Buffer containing 2M formic acid; injection of 6 pmol of RNase B; UV detection. (B) Fused-silica capillary 110 cm  $\times$  50  $\mu$ m i.d. coated with a solution of polybrene and ethylenglycol; Buffer containing 2 M formic acid; injection of 6 pmol of RNase B; ESMS detection. Sheath flow 5  $\mu$ L/min of an aqueous solution of 0.2% formic acid and methanol. (a) Total ion electropherogram for the full mass scan acquisition ( $m/z$  1300–2000). (b) Extracted mass spectra for peaks migrating at 35.2 min, (c) at 35.6 min, and (d) at 40.8 min. The calculated molecular mass is shown on the right corner of each spectrum. (From Kelly, J.F. et al., *J. Chromatogr. A*, 720, 409, 1996. With permission.)

A comparison of rhEPO by CZE-ESI-MS using capillaries that provided reversal of the EOF (PB coating) or suppressed EOF (UltraTrol Dynamic PreCoat LN) showed, as indicated in a previous section of this chapter, that increased resolution was obtained with the suppressed EOF capillaries (see Figure 22.3) [30]. The improved separation allowed detection of low-level glycoforms. The observed mass differences were attributed to differences in the content of sialic acids, hexoses, and *N*-acetylhexosamines. In addition, the high mass resolution of the system allowed the detection of comigrating substances differing by 42 and 16 Da corresponding to acetylated and oxidized variants, respectively. Similarly to the results obtained for rhEPO, better glycoform resolution was obtained for bovine fetuin and bovine alpha 1-acid glycoprotein standards on capillaries with suppressed EOF [71].

Despite a level of sensitivity about 100 times lower than that obtained by CE-UV, inductively coupled plasma mass spectrometry (ICP-MS) coupled to CZE has been shown to separate and distinguish between isoforms containing 3, 4, and 5 sialic acid residues in standard Tf samples [133].

For more complete details on the use of CE-MS for glycoproteins some recent reviews have also appeared [134–138].

#### 22.4.3.4 Other Detection Modes

Conductivity detection has been used in a CITP instrument for the fractionation of glycoforms of rhEPO mentioned previously in this chapter [95]. The preparative CITP instrument is composed of two columns made out of a fluorinated ethylene copolymer, one acting as a separation column and the other one as a trapping column. Both columns are provided with their respective conductivity detectors. That of the first one served, in addition to monitoring the CITP separation, as a proper timing in the switching of the columns. The other one in the second column provided the isotacopherograms used in the control of the fraction collector placed at the end of this second column, and equipped with a collection valve. Although the sensitivity of conductivity detectors was poor for the monitoring of proteins, in this case sensitivity was not an issue since 100  $\mu\text{g}$  of rhEPO were injected in each run.

## 22.5 PRACTICAL APPLICATIONS

### 22.5.1 CHARACTERIZATION AND QUALITY ASSESSMENT OF BIOLOGICALS AND BIOPHARMACEUTICALS

#### 22.5.1.1 General Considerations

The development of physicochemical methods of analysis based on high-resolution techniques such as CE has had a significant impact on fields of activities dealing with complex biomolecules such as glycoproteins. While undoubtedly variable in magnitude, this impact has been considerable in the development of foods, pharmaceuticals, vaccines, blood and blood products, diagnostics, and for regulatory authorities. In many of these areas, the establishment of more sensitive, precise, and selective methods of analysis has particular relevance since manufacturers are required to provide scientific evidence with regard to major tenets that guide the development of regulatory requirements in most jurisdictions: that products entering the market must be safe and of high quality. More specifically, the assessment of a product through the verification of its identity, the quantitative evaluation of its purity, its stability, or the consistency of its manufacturing is of prime importance. For example, considerations regarding the decision to market a pharmaceutical protein resides not only on the demonstration of its biological activity but also on the demonstration that the manufacturing process can provide a product consistently, at the same level of quality and purity as that used for clinical trials. While the application of these specifications does not affect all areas universally

(e.g., purity evaluation may not be a significant factor for a diagnostic product), they nevertheless are now generally well adhered to an industry and applied at various stages of the manufacturing process. Data generated are then incorporated in the preparation of documentation to be submitted to regulatory authorities for evaluation. In certain instances, harmonized guidelines relating to test procedures have been developed. This is the case for biotechnological and biological products where an international initiative, the International Conference on Harmonization (ICH), has enshrined these principles in a series of guidelines of test procedures for the quality evaluation (Q5A–Q5E) and specifications (Q6B) of these products [139].

Traditionally, complex biomolecules such as glycoproteins have been assessed using conventional gel electrophoresis methods. However, these methods are laborious to carry out, cannot be automated, and do not consistently provide quantitative results. In contrast, CE has been demonstrated to provide rapid, automated, and quantitative results. In addition, it is now often used as a complementary technique to the more established HPLC in several fields of activities. This progress has led to the recognition by pharmacopeial authorities in Japan, the United States, and Europe of CE for the generation of data relating to product identification, assay or tests for related protein impurities, and to its use by industry in various other aspects of the development process including drug substance and drug product characterization, in-process monitoring, and stability determination. It is also one of the recommended physicochemical techniques of the ICH Q6B guideline on specifications for biotechnological/biological products mentioned earlier. Underlying this recognition is the necessity to devise validated methods based on widely accepted analytical parameters. Typically, method validation involves the determination of one or more analytical parameters (e.g., accuracy, precision, linearity range, limit of detection, limit of quantitation, robustness, specificity) to demonstrate that the method performs according to its intended purpose. The degree with which a method requires validation varies according to the procedure being implemented as shown in Table 22.1 derived from the ICH guidelines Q2(R1). For example, while an identification test requires only that specificity be demonstrated, the quantitative evaluation of impurities necessitates that all characteristics be determined with the exception of the limit of detection.

The coming of age of CE as a recognized analytical method has been marked by its introduction into pharmacopeial monographs. Given its improved separation and quantification capabilities, a CZE method for rhEPO glycoform separation was found suitable to replace conventional IEF as an identification test and, as previously mentioned, has been incorporated into the EP monograph for rhEPO concentrated solution (i.e., the bulk substance solution before formulation) [35]. Using

conditions adapted from the method of Watson and Yao [52], rhEPO glycoforms are separated on a bare fused silica with a BGE consisting of 0.01 M tricine, 0.01 M sodium chloride, 0.01 M sodium acetate, 7 M urea, and 2.5 mM putrescine at pH 5.55. The method system suitability specifies several required criteria including the separation of the BRP into a number of well-resolved peaks [34] as shown in Figure 22.17. For this particular preparation, the rhEPO BRP batch 1, eight glycoforms are separated with nearly baseline resolution and the order of migration follows the increasing total number of terminal sialic acid residues present on the carbohydrate chains. In other words, glycoforms with the lowest total number of sialic acids migrate first and those with the highest number migrate last. It should be noted here that the BRP was a mixture prepared from known quantities of two commercialized rhEPO forms, rhEPO- $\alpha$  and rhEPO- $\beta$ . Characterization of these two products had shown that they had different glycoform profiles and distribution, with rhEPO- $\beta$  containing higher amounts of the more basic glycoforms (i.e., those with lower total amounts of sialic acid residues). The use of a mixture of products for the BRP allowed the preparation of a unified monograph appropriate to analyze both forms of rhEPO that have essentially identical biological activities. Specifications on the distribution of glycoforms as a percentage of the total content in the test solution are provided and constitute an integral part of the identity test (Table 22.2). (At present, a new standard, rhEPO BRP batch 2, has been established with a slightly different electropherogram to that shown in Figure 22.17).

Somatropin, the recombinant version of the 22 kDa form of human growth hormone, is another important biopharmaceutical for which a CZE method has recently been adopted for inclusion into the EP somatropin monographs. Although not a glycoprotein, it is mentioned here to exemplify the increased use of CE for the specifications of proteins. In this case, the test is for the quantitative assessment of charged variants [140]. It is expected that CE will become a regularly used technique in pharmacopeial monographs of biopharmaceuticals in view of its usefulness for the characterization of these structurally complex molecules. In addition, the patent expiration date for several biopharmaceuticals has either passed or is fast approaching and this will undoubtedly lead to several manufacturers wishing to enter this growing market to produce similar products.

---

From a strategic perspective, product characterization is paramount to the development of identity, purity, or assay procedures since it involves the determination of many of the structural and physicochemical properties of the product under study. Consequently, product characterization is, by necessity, first in the series of test procedures to be developed. For glycoproteins, in addition to the more basic structural properties inherent to proteins such as amino acid sequence and higher-order structural elements (i.e., secondary, tertiary, and quaternary structures), in-depth characterization of carbohydrate-mediated properties are required.

In the following sections, an overview of the applications of CE with respect to the guiding principles and analytical parameters described earlier will be presented. For more in-depth discussions on specific aspects or individual glycoproteins, excellent reviews cited in the Section 22.2 can be read.

### 22.5.1.2 Product Characterization and Identity Testing

As previously mentioned, glycoproteins exist as mixtures of closely related species that differ in their glycosylation patterns. These differences are often the result of both compositional and sequence variations of the glycan chains. Moreover, the biological activity of glycoproteins is frequently linked to the presence of these carbohydrates and, consequently, the characterization of glycoprotein microheterogeneity represents one of the more challenging tasks for the characterization and identity testing. In both cases, high specificity is required since it is expected that the method will differentiate between the active ingredient, variants, impurities, and contaminants. Identity tests typically involve the determination of one or more intrinsic properties of a molecule, whether physicochemical, biological, and/or immunological and are often carried out by comparison with a reference standard. Apart from performing a simple identity test through coanalysis of the substrate and the reference standard, qualitative and quantitative information derived from CE experiments with respect to specific structural characteristics such as carbohydrate-mediated glycoform profiles, pI, or MW determination can be useful for product characterization and identity testing.

### 22.5.1.2.1 Recombinant Sialoglycoproteins

Several important biopharmaceuticals that received market authorization around the world in the past decades are recombinant glycoproteins that include such successful products as EPOs (rhEPO- $\alpha$  and - $\beta$ ), darbepoetin- $\alpha$  (also called NESP), rhtPA, interferons (rhIFN- $\beta$ 1, - $\gamma$ ), and colony-stimulating factors (rhGCSF, recombinant human granulocyte macrophage colony-stimulating factor, rhGM-CSF). They are used for the management of diseases not otherwise well treated with small molecule pharmaceuticals. Unequivocally, it is advances in molecular biology and recombinant DNA technology that are largely responsible for the availability of these molecules in large quantities, thus allowing biopharmaceutical companies to introduce them in the markets. Despite these advances, protein glycosylation remains a crucial factor that requires a thorough assessment especially when considering that the glycosylation of recombinant proteins is inherently heterogeneous and rarely identical to that found in humans, a situation that has the potential to result in problems linked to immunogenicity.

The ubiquitous occurrence of sialic acid residues on glycan chains of recombinant glycoproteins has provided an ideal tool for analysis by CE by taking advantage of the presence of the ionizable carboxylic acid group. As indicated in previous sections, both CZE and CIEF have been shown to be particularly sensitive to differences in net charge and, as such, have been widely applicable to characterize sialic acid-mediated glycoprotein profiles. However, as it will become evident in the remainder of this section, the biggest limitation to the application of CE methods is undoubtedly the complex nature of sialoglycoproteins, especially when more than one glycosylation site is present in the molecule. In such cases, the number of possible combinations and permutations of individual carbohydrate residues make it difficult to even anticipate separating all glycoforms.

Studies of relatively simple sialoglycoproteins, that is, containing a single glycosylation site, were among the first examples of the use of CE for characterization of intact glycoproteins. RhGCSF stimulates progenitor cell proliferation, differentiation, and activation of neutrophils and features a single glycosylation site at Thr-133. It was separated into two glycoforms under basic (pH 7–9) [54] or acidic (pH 2.5) conditions [141]. In the latter case, rhGCSF was analyzed in a preparation containing HSA and the addition of HPMC prevented adsorption to the capillary walls and facilitated detection at low pH. In both cases, the order of migration occurred in a predictable fashion according to increasing number of sialic acid residues. Both methods could distinguish between the nonglycosylated and glycosylated products.

A highly efficient CZE method capable of resolving in excess of 30 glycoforms of a simple sialoglycoprotein, a recombinant 24 kDa glycoprotein containing a single glycosylation site, has been reported by Berkowitz et al. [142]. Using a bare fused-silica capillary with triethanolamine/phosphoric acid, pH 2.5 as BGE, the 30 glycoforms were separated on a 27 cm capillary in less than 15 min (Figure 22.18). Lengthening the capillary to 77 cm resolved over 60 peaks in less than 30 min. Partial validation of the method was carried out by examining day-to-day reproducibility and sample matrix effect. For the latter, it became apparent that increased resolution was obtained for samples dissolved in low ionic buffer and low pH. While the effect of low sample ionic strength compared with the BGE is well known and is due to stacking effects, the low sample pH effect was explained in terms of the initial movement of the protein, which if injected from a sample at high pH was toward the anode and, consequently, against the stacking effect since the protein has a relatively high pI ( $6.5 < \text{pI} < 8.0$ ). Using a kinetic study of the enzymatic removal of terminal sialic acids in conjunction with fractionation of the glycoprotein by anion exchange, they were able to identify several glycoforms according to their antennarity and sialic acid content as shown by the shaded areas in Figure 22.18. Although not all of the peaks were identified, this approach allowed to demonstrate that parts of the observed microheterogeneity were due to the presence of large amounts of deamidated variants (i.e., >30%). In addition to the qualitative assessment of the product, the results when taken collectively allowed to derive quantitative expressions for determination of the content in deamidated forms, nonglycosylated forms and monoglycosylated forms, biantennary forms, and

**FIGURE 22.18** CZE separation of 24 kDa sialoglycoproteins with peak region assignments (shaded areas). In (a): BiNA0, biantennary oligosaccharides with no terminal sialic acid residues; BiNA1, biantennary oligosaccharides with one sialic acid terminal residue; and BiNA2, biantennary oligosaccharides with two terminal sialic acid residues. In (b): nonglycosylated protein and monosialylated glycoforms (area #4). Separation conditions: fused-silica capillary, 50  $\mu\text{m} \times 27$  cm capillary, 100 mM triethanolamine–phosphoric acid, pH 2.5, 10 kV, 25  $^{\circ}\text{C}$  and UV detection at 214 nm. (From Berkowitz, S.A. et al., *J. Chromatogr. A*, 1079, 254, 2005. With permission.)

finally, sialylation level of biantennary forms. The method was also adequate to monitor the effects of changes in culture conditions such as host strains or growth conditions.

The analysis of complex sialoglycoproteins, that is, containing multiple glycosylation sites has been the subject of many reports. One such example is rhtPA, an important biopharmaceutical used in the treatment of myocardial infarction, which contains three N-glycosylated sites. Among several articles published on CE separation conditions, Thorne et al. [77] reported the separation of rhtPA into no less than eight glycoforms by CIEF. The method showed high reproducibility and precision for migration times and good total recovery of rhtPA from the capillary was demonstrated. CZE conditions using amines as additives to the BGE were also used to separate numerous major and minor glycoforms. In addition, they demonstrated the use of CE-SDS as a potential purity test for rhtPA Type I and Type II, which differ in the level of glycosylation site-occupancy.

RhEPO is another complex sialoglycoprotein, with three N-linked and one O-linked glycosylation sites, that has been extensively characterized by CZE and cIEF as described in previous sections. The comparison of rhEPO and uEPO has been reported on uncoated capillaries [40] and on capillaries dynamically coated with ionene [62]. Although increases in resolution and sensitivity are desirable, and the samples of uEPO corresponded to purified standards, these works showed the potential of discriminating between exogenous and endogenous EPO.

CE was also used to fractionate rhEPO glycoforms as briefly discussed previously. Madajova et al. [95] developed a preparative CITP method, operating in a discontinuous mode, which enabled the separation of 100  $\mu\text{g}$  of rhEPO into six fractions in 30 min. The number of collected fractions corresponded approximately to the number of glycoforms detected in the original product by CZE. Subsequent analysis of the collected fractions by CZE showed that several glycoforms had been substantially enriched by 10- to 100-fold in some cases. Such an approach may provide a desirable way to access specific glycoform levels in relation to their biological activity or for the evaluation of low glycoprotein levels in biological matrices.

Recombinant human deoxyribonuclease (rhDNase) is a complex sialoglycoprotein whose heterogeneity is due in part to the presence of phosphorylated mannose residues. CE studies of this acidic ( $3.5 < pI < 4.5$ ) phosphosialoglycoprotein that contains two glycosylation sites have been reported [143,144]. CZE methods were developed under both acidic (pH 4.8) and basic (pH 8.0) conditions. The addition of calcium ions significantly improved resolution at both pH as a consequence of interactions with calcium-binding sites that stabilize the protein and make it more resistant to proteases. The pH-dependent calcium binding provided a means to distinguish between acidic and neutral glycoforms that were identified by a two-dimensional (2D) investigation of neuraminidase and alkaline phosphatase–protein digestions. The acidic pH resolved acidic charge heterogeneity and the basic pH discriminated neutral heterogeneity.

#### 22.5.1.2.2 *Naturally Occurring Sialoglycoproteins*

The need for characterization and identity determination of naturally occurring glycoproteins has been one of the driving forces behind the development of CE methods. Naturally occurring glycoproteins are highly heterogeneous and sometimes present a formidable challenge. Only a few examples of approaches to their characterization will be discussed in this section.

ATIII is a glycoprotein that plays a key role in the inhibition of blood coagulation. Despite the availability of a recombinant version, plasma-derived ATIII has continued to be the subject of recent characterization studies by CE. Two isoform groups isolated from plasma-derived ATIII that differ in the number of glycosylation sites, ATIII- $\alpha$  (glycosylated at four asparagines) and ATIII- $\beta$  (glycosylated at three asparagines), were studied by a combination of techniques that included gel IEF, 2D-gel electrophoresis, CIEF, and CZE [145]. The two isoform groups were separated by CZE as shown in Figure 22.19. With a lower glycosylation site-occupancy and, consequently less sialic acid residues, the major component of ATIII- $\beta$  (peak A in Figure 22.19a and d) predictably migrated before the ATIII- $\alpha$  components. The quantitative analysis indicated a content of about 70% ATIII- $\alpha$  main isoform and about 6.6% of ATIII- $\beta$  in good agreement with published data. The pI values of ATIII determined by CIEF using an internal calibration were in fair agreement with values of the main isoforms measured by 2D-gel electrophoresis. The CZE method provided a definite advantage in terms of quantification and accuracy. In another report, the same group further characterized the separated isoforms by online coupling with MS [132].

The commercially available glycoprotein, OVA, has been extensively used as a model protein for approaches to glycoform separations by CE since the very early years of the technique. Recent studies on OVA have focused on novel separation conditions that included the effect of new additives to the BGE and new dynamic coatings [87,146,147] as well as conditions suitable for online coupling to MS [148]. As indicated in a previous section, an innovative separation approach based on the free-resolution (i.e., without immobilization) selective affinity of OVA glycoforms to a common protein, LCA, has been reported [118]. The separation mechanism was explained in terms of the increased affinity of glycoforms having high-mannose type N-glycans for LCA and, consequently, these species were more strongly retarded than other glycoforms. A similar type of approach was recently used to separate AGP glycoforms without biantennary glycans from those having one or more biantennary glycans [117]. Once again, the separation mechanism appeared to involve greater affinity of the ligand for high-mannose species.

#### 22.5.1.2.3 *Glycoproteins without Sialic Acids*

CE separation of glycoforms of proteins where no sialic acid residues are present has been reported. RhBMP-2 is a protein with high-mannose glycan chains that has been unexpectedly separated under CZE conditions [31,131]. Glycoforms were separated on the basis of the number of mannoses a given rhBMP-2 molecule possesses (see Figure 22.8). This type of approach may prove useful for the qualitative and quantitative monitoring of fermentation processes for glycoproteins without substantial charge differences.

**FIGURE 22.19** CZE of (a) ATIII, (b) ATIII- $\alpha$ , (c) ATIII- $\beta$ , and (d) ATIII-( $\alpha + \beta$ ). Separation conditions: PVA-coated capillary 50  $\mu\text{m}$  i.d.  $\times$  64.5 cm (56 cm effective length), 1 M acetic acid containing 4 M urea, 0.1 M sodium chloride added to the aqueous sample solution, 120 kV, UV at 214 nm. (From Kremser, L., et al., *Electrophoresis*, 24, 4282, 2003. With permission.)

Cellobiohydrolase I (CBH-I) is a phosphoglycoprotein that contains a catalytic domain with four N-glycosylation sites and where phosphate groups form phosphodiester links between the anomeric carbon and the C6 of two consecutive Man residues (i.e., Man1-P-6Man). CIEF was used to separate the phospho-isoforms of the catalytic domain of CBH-I into four glycoform species according to the number of phosphate groups, that is, 0, 1, 2, and 3 groups [149]. Since glycosylation of CBH-I is dependent on the strain and growth medium, the method may be useful for the analysis of cellulase glycosylation from different strains, different organisms, mutated organisms, or cellulases expressed in other organisms.

#### 22.5.1.2.4 Monoclonal Antibodies

A number of therapeutic mAbs produced by recombinant DNA technology have been marketed in recent years. Most mAbs exhibit some heterogeneity due to PTM and degradation occurring during the manufacturing process and shelf life of the product. As such, they have been the subject of several studies using CE-based methods and reviewed [150]. Charge heterogeneity is a parameter commonly monitored for mAbs. Common sources of charge heterogeneity include sialylation, deamidation, and C-terminal lysine cleavage. Sialylation can vary widely between mAbs, from being insignificant in some cases to being the major source of charge heterogeneity in other cases. It follows that the sialic acid-mediated heterogeneity is commonly determined from the characterization of the charge heterogeneity before and after enzymatic treatment with sialidase.

Both CIEF and CZE-based methods have been used to study mAbs. A combination of cation exchange chromatography and CIEF was used to study human tumor necrosis factor (hTNF) mAb [151]. Of the four peaks separated by cIEF, three corresponded to C-terminal lysine variants and the remaining peak to sialic acid-mediated charge differences. Similarly, CIEF was used to determine the sialic acid-mediated heterogeneity of a IgG<sub>1</sub> mAb that contained N-linked glycosylation in the Fab region at Asn56, with approximately half of the biantennary glycans being sialylated [152]. Using an approach based on the well-known formation of complexes between borate and diols, the carbohydrate heterogeneity of a mAb was demonstrated by CZE [153]. Three partially resolved peaks were observed after optimization of the conditions to 150 mM borate, pH 9.4, on a fused-silica capillary. The method was further used to monitor batch-to-batch consistency and for stability testing.

In addition to providing molecular mass information, CE-SDS has been used for the detection and quantification of low levels of unglycosylated heavy chain (HC) in mAbs. The optimization and validation of generic and quantitative CE-SDS procedures with LIF detection was reported [125,154]. An alkylation step was incorporated to decrease thermally induced fragmentation of nonreduced, labeled mAb samples. The unglycosylated variant was detected under reducing conditions where light chain (LC) and HC are separated (Figure 22.20). A collaborative study report involving multiple laboratories in different organizations has demonstrated the robustness of CE-SDS without labeling and using UV detection for assessing mAbs and the unglycosylated variant [155].

**FIGURE 22.20** CE-SDS separations of reduced labeled mAb samples in the presence of different alkylating agents: NGHC, nonglycosylated heavy chain; LC, light chain; HC, heavy chain; IAA, iodoacetic acid; IAM, iodoacetamide. Separation conditions: uncoated fused-silica capillary 50  $\mu\text{m}$  i.d.  $\times$  30 cm (effective length 19.4 cm), both anode and cathode buffers were the Bio-Rad SDS running buffer, samples were injected at a constant electric field of 417 V/cm for 15 s and electrophoresed at 625 V/cm (21.2  $\mu\text{A}$ ) at 20°C, detection was performed with LIF using a 3.5-mW argon ion laser, 488 nm excitation, 560  $\pm$  20 nm emission. ### 22.5.1.3 In-Process Monitoring and Product Consistency

Studies of recombinant DNA technology processes have clearly demonstrated that PTM such as glycosylation are not constant throughout culture and that many factors must be examined to obtain and maintain the required glycosylation. They include choice of host cell, genetic engineering of glycan processing, or control of bioprocess parameters such as culture environment, method of cell culture, and culture time [156]. Furthermore, even after a process has been well established, changes may be required from time to time, a situation that may also have an impact on PTM. Examination of pre- and postchange products is then required to ascertain the absence of unwanted changes to the product quality [157]. It follows that monitoring of glycosylation at all stages of a bioprocess has become a necessity to ensure product quality and batch-to-batch product consistency. Practical considerations to the application of an analytical technique for in-process monitoring and product consistency assessment range from the necessity of the method to have high accuracy and sensitivity, to provide high reproducibility and be relatively simple in its application, to be robust enough to sustain minor changes in sample matrix, to be specific and quantitative, and to permit fast development and analysis time. CE has become widely applicable at various stages of the manufacturing process due to its already mentioned advantages regarding the flexibility provided by the various separation modes that can be applied, the low sample volume required, and its capability for automation and fast analysis.

#### 22.5.1.3.1 In-Process Monitoring

RhIFN- $\gamma$  is, as mentioned in a previous section of this chapter, a sialoglycoprotein with two N-linked glycosylation sites at Asn25 and Asn97, which has been shown to be heterogeneous in the number of species resulting from variable glycosylation site-occupancy (nonglycosylated: 0N; monoglycosylated at Asn25: 1N; and diglycosylated at Asn25 and Asn97: 2N) as well as from variability in the number of terminal sialic acids [114,134,158]. In combination with CIEF, a method based on MEKC conditions discussed previously (see Section 4.2.2.3 and Figure 22.13) was used to monitor rhIFN- $\gamma$  glycosylation during perfused fluidized-bed production [159]. Glycosylation site-occupancy was monitored by MEKC. A plot of the relative amounts of each of 0N, 1N, and 2N provided evidence of constant levels of glycosylation site-occupancy over the course of the process. In addition, the sialic acid mediated isoform content was monitored by CIEF using a commercial kit over a pI range of 3–10. No less than 11 major variants were detected between pI values of 3.4 and 6.4 (Figure 22.21b). After enzymatic desialylation of this mixture, a decrease in the number of variants and, as expected, a major shift to higher pI values was obtained (Figure 22.21a), indicating that most of the observed heterogeneity resulted from sialic acid variability. The remaining heterogeneity was ascribed to C-terminal truncated variants. The quantitative analysis of sialylated variants indicated a sharp decrease in the mean pI after 200 h of perfusion culture (Figure 22.21c). This suggested that sialylation is increased during the perfusion process to reach a constant level afterward. On the other hand, examination by MEKC of glycosylation site-occupancy for a stirred-tank batch culture showed that the process did not provide constant levels, but gradually declined throughout the fermentation process. They also demonstrated that this decline was at the expense of the 2N variant and that there were generally higher proportions of the doubly glycosylated (2N) rhIFN- $\gamma$  glycoform and lower proportions of the nonglycosylated (0N) variant in the perfused fluidized-bed process compared with stirred-tank culture, that is, the rhIFN- $\gamma$  protein was more heavily glycosylated during perfusion culture.

Similar MEKC conditions were used to monitor rhEPO glycosylation during continuous culture of Chinese hamster ovary (CHO) cells in a fluidized-bed bioreactor [160]. While individual glycoforms were not separated under these conditions, clear differences in both peak shapes and migration times were observed when compared with unglycosylated EPO, suggesting that adequate glycosylation was obtained. Analysis of the product by 2D-electrophoresis provided further evidence that the required isoforms had been obtained.

**FIGURE 22.21** Monitoring of rh IFN- $\gamma$  microheterogeneity by capillary isoelectric focusing. (a) rhIFN- $\gamma$  desialylated with neuraminidase from *A. ureafaciens*. (b) Typical electropherogram of immunoaffinity-purified rhIFN- $\gamma$  from perfusion culture of CHO cells. (c) The weighted mean pI of rhIFN- $\gamma$  variants secreted by CHO cells during perfusion culture. (From Goldman, M. H. et al., *Biotech. Bioeng.* 60, 596, 1998. With permission.)

The influence of changing conditions for the fermentation process of rhATIII using a combination of liquid chromatography and CZE has been reported [161]. While the CZE method only partially resolved glycoforms, it provided quantification within 2 min. The use of a 2D-HPLC/CZE design provided additional sensitivity and resolution and quantitative results in 5 min.

Although not developed specifically for glycoproteins, a rapid CE-SDS method for the in-process monitoring of fermentation, hybridoma cell cultivation, and purification has been reported [162]. It was carried out in a total analysis time of less than 5 min.

#### 22.5.1.3.2 Product Consistency

The ability to detect differences of product quality is a key component of the assessment of any manufacturing process. As seen in the preceding section, biological processes are complex and many factors influence the quality of the resulting product. In addition, manufacturing processes are rarely static and more often than not involve continual refinement to improve yields, to obtain higher quality products, or to implement new technologies. In these cases, manufacturing changes are implemented and the significance of these changes on the product consistency needs to be assessed.

In addition to examples already described in previous sections, a CIEF method was used to compare the isoform profiles of IgG<sub>2a</sub> obtained under different conditions of osmolality and CO<sub>2</sub> partial pressure (pCO<sub>2</sub>) in growth media [163]. Significant increases in the pIs of the major peaks as well as in the number of peaks were observed with increases in osmolality and pCO<sub>2</sub> (Figure 22.22). The change in pI was not a consequence of differences in sialic acid content (this particular mAb

**FIGURE 22.22** Representative CIEF separations showing the effect of osmolality on the pI distribution of IgG<sub>2a</sub> produced in serum-containing medium. The pI standard curve is shown at the bottom of the figure for comparison. A shift in the main pI peaks toward higher pI values with increasing osmolality, as well as an increase in the number of peaks, especially at higher pI values are observed. (From Schmelzer, A. E. and Miller, W.M., *Biotechnol. Prog.*, 18, 346, 2002. With permission.)

was not sialylated) and was due to an increase in the level of galactose incorporation, a situation that indicated that hyperglycosylation was occurring, possibly arising from galactosylation at another Asn site.

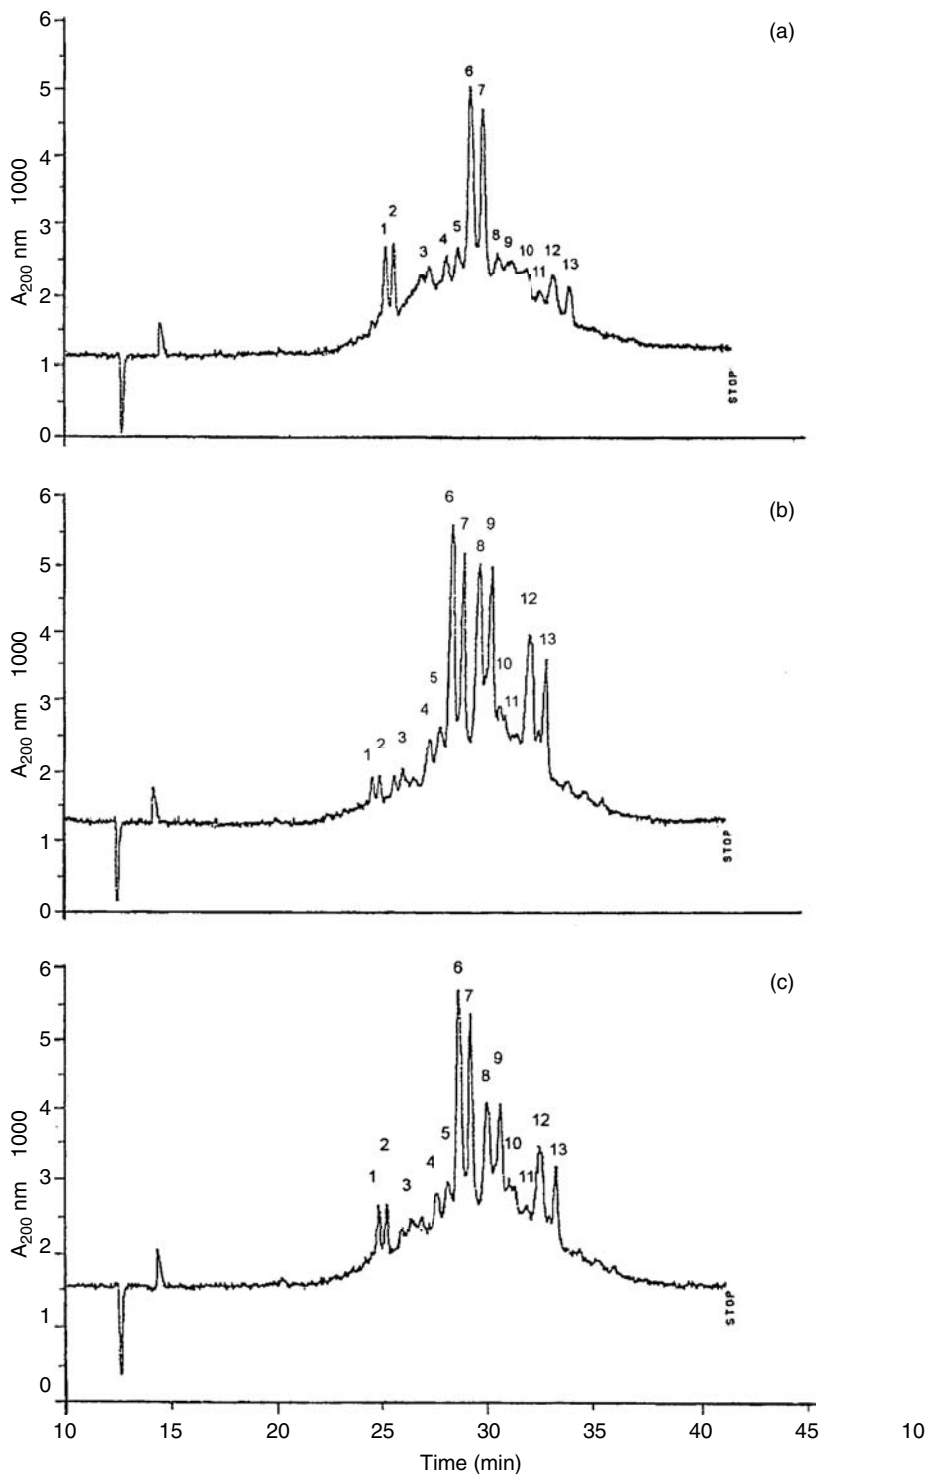

#### 22.5.1.4 Product Comparability and Analysis of Finished Products

The ability to compare products derived from different manufacturing processes or sources is an important aspect of the regulatory process, for the setting of standards, the evaluation of potential problems related to one specific product or the assessment of differences linked to product characteristics such as biological activity. For example, currently throughout the world, there are biopharmaceuticals for which more than one manufacturer have received marketing authorization and this situation is likely to expand as the expiration dates of patents for several products are fast approaching. In addition, some biopharmaceuticals are being used in situations other than those for which they were marketed, such as their use as performance-enhancing substances by athletes. In many instances, products can be obtained through a number of sources other than conventional pharmacies and may, in some instances, be produced by unauthorized manufacturers. In this context, it has become essential to develop generic methods for the evaluation of multisource products.

##### 22.5.1.4.1 Product Comparability

There are several sources of commercially available OVA, and CZE can be used to distinguish their glycoform profiles [146]. Two batches of turkey egg ovalbumin (tOVA) showed qualitatively similar glycoform profiles with some differences in the levels of a number of glycoforms (Figure 22.23a and b). On the other hand, the glycoform profile of chicken egg ovalbumin (cOVA) (Figure 22.23c)

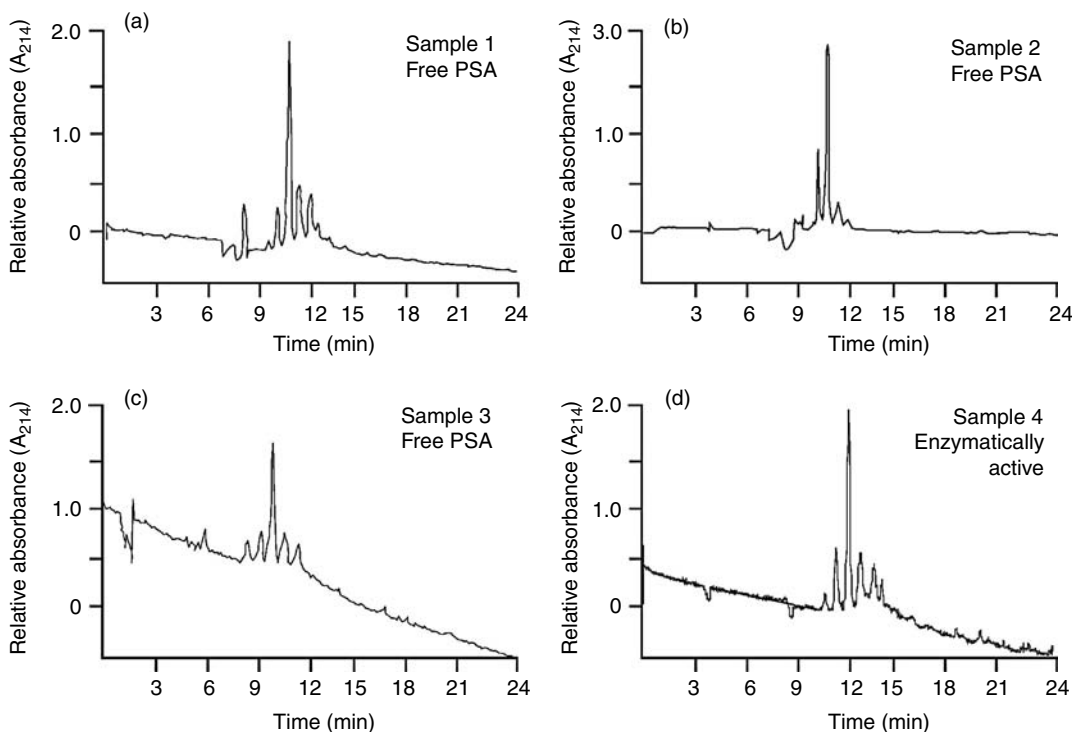

**FIGURE 22.23** Electropherograms of (a) and (b): two batches of turkey ovalbumin and (c): chicken ovalbumin. Separation conditions: fused-silica capillary 72 cm (50 cm effective length), 100 mM  $\text{H}_3\text{BO}_3/\text{NaOH}$  and 1.8 mM putrescine, pH 8.6, 20 kV, detection at 200 nm, temperature controlled at 30 °C. (From Che, F.Y. et al., *J. Chromatogr. A*, 849, 599, 1999. With permission.)

revealed marked qualitative differences when compared with tOVA with respect to migration times. These differences were a result of both polypeptide and glycan chains structural variations.

Caseinoglycomacropeptide (CGMP) is a small glycoprotein (MW of approx. 7000 Da) derived from bovine  $\kappa$ -casein that has been shown to have a variety of biological activities such as inhibition of gastric secretion, depression of platelet aggregation, growth promoting effect on bifidobacteria, inhibition of oral *Actinomyces* adhesion to red blood cell membranes, inhibition of adhesion of oral *Streptococci* to saliva-coated hydroxyapatite beads, inhibition of adhesion of *Streptococcus sanguis* to human buccal epithelial cells, and inhibition of cholera toxin binding to its receptor. A CZE method that had been previously reported for the separation of CGMP glycoforms [164] and for stability monitoring in cosmetic lotions [165] was also used for the assessment of sialylation levels of commercial batches of CGMP [166]. Results indicated that the quantitative assessment using CZE were in good agreement with those obtained by enzymatic release of sialic acids or colorimetric methods. The CZE method was fully validated for the usual analytical criteria (e.g., linearity, precision, accuracy, LOD, and LOQ). This approach provided a fast, reliable, precise, and cost-effective way to compare products.

Another example of product comparability was reported for prostate-specific antigen (PSA), a single-chain glycoprotein that is used as a biomarker for prostate-related diseases [167]. PSA has one known PTM, a sialylated biantennary N-linked glycan chain attached to Asn45. It is commercially available from different sources. The glycoform profiles of seven free PSA (fPSA) samples from several manufacturers, of which two were specialized, enzymatically active PSA (EA-PSA) and noncomplexing PSA (NC-PSA), were assessed by CZE. Results indicated that PSA samples could be classified into three distinct groups according to glycoform profiles. Figure 22.24 shows

**FIGURE 22.24** Electropherograms of protein specific antigen (PSA) group I. (a) Sample 1 (fPSA); (b) Sample 2 (fPSA); (c) Sample 3 (fPSA); (d) Sample 4 (EA-PSA). Separation conditions: 50  $\mu$ m i.d.  $\times$  60 cm fused-silica capillary, 20 mM sodium borate (pH 8.0)/5 mM diaminopropane or 20 mM sodium phosphate (pH 7.0 or 8.0), 25 kV, detection at 214 nm. (From Donohue, M.J. et al., *Anal. Biochem.*, 339, 318, 2005. With permission.)

electropherograms of products from group I that contained 4–7 peaks with one peak dominating and representing 51–70% of the total fPSA in the sample. This study demonstrated that proprietary purification procedures have a major influence on the composition and yield of the number of structural forms observed in a PSA sample.

#### 22.5.1.4.2 Glycoprotein Drug Products

Methods capable of analyzing the active ingredient in a formulated (i.e., finished) drug product are useful to measure product integrity and/or its stability as well as for comparison to other products. However, the approach to their analysis entails careful consideration of a number of specific issues to drug products such as the low amounts of active ingredient, the presence of large amounts of excipients, or the potential of modifying the product through manipulation.

(Glyco)protein drug products generally contain low amounts of the active ingredient since the therapeutic effect can usually be achieved at low concentrations. For example, it is not unusual to find active ingredient at low microgram quantities in a dosage form. In turn, formulations at low protein content usually require the addition of large amounts of excipients to enhance product stability and prevent nonspecific adsorption to the container. Commonly used excipients vary widely in terms of their chemical nature and include inorganic salts, amino acids, sugars, and surfactants such as polysorbate or other proteins such as HSA. Typically, isotonic salt preparations are produced as most of these products are injectables and, consequently, high salt concentrations are present. Furthermore, many of these excipients may be present simultaneously, leading to complex mixtures. They have also been shown in some cases to interfere with traditional assay methodologies such as UV or high-pressure liquid chromatography (HPLC). The choice of CE as a separation technique to be applied to the analysis of protein drug products resides in its ability to provide sufficient selectivity to separate the active ingredient from interfering species.

Studies aiming the direct analysis of finished products with no or minimal prefractionation or manipulations in order to minimize potential loss of product or the generation of product artifacts have been reported. As mentioned previously, a CZE method using an amine-coated capillary to separate rhEPO glycoforms in drug products containing large amounts of HSA and inorganic salts has been reported [41]. The addition of nickel ions to the high ionic strength BGE (200 mM phosphate, pH 4.0) selectively altered the mobility of HSA and allowed the separation of the otherwise comigrating proteins (Figure 22.6). Dosage forms containing HSA/rhEPO at a ratio of 250:1 w/w could be analyzed under these conditions. The method was validated and provided satisfactory results for active ingredient assay, quantification of glycoforms, and comparison of products from different manufacturers. The usefulness of the method was further extended to assess manufacturing changes and to compare rhEPO products formulated with different excipients as shown in Figure 22.25 for different rhEPO- $\alpha$  and rhEPO- $\beta$  products formulated with HSA or polysorbate [168]. As described in a previous section, a similar comparison of finished rhEPO products was carried out following the immunochromatographic removal of HSA from formulations (see Section 4.1) and enabled the comparison of glycoform profiles of products from different manufacturers and from the BRP of the EP formulated with excipients of low-MW and with HSA [43].

The biophysical properties of two commercially available rhEPO- $\alpha$  products, Epopgen and Eprex, both of which are produced under similar conditions by different manufacturers, were studied [169]. Among many techniques used in this study, the analysis by CZE showed that the products had similar glycoform profiles in terms of isoform type and distribution, an indication that the products had similar sialic acid contents.

CZE was also used for the analysis of two preparations of rhGCSF, Granocyte, a glycosylated product formulated with large amounts of HSA, and Gran300, a nonglycosylated product [170]. The two products were compared with a bulk rhGCSF preparation that had been obtained from *Escherichia coli* (nonglycosylated). Analysis with 50 mM Tricine, 20 mM NaCl, 2.5 mM DAB, pH 8.0, as BGE showed the separation of two glycoforms in Granocyte that corresponded to monosialylated and disialylated glycoforms. As expected, the nonglycosylated product, Gran300, showed

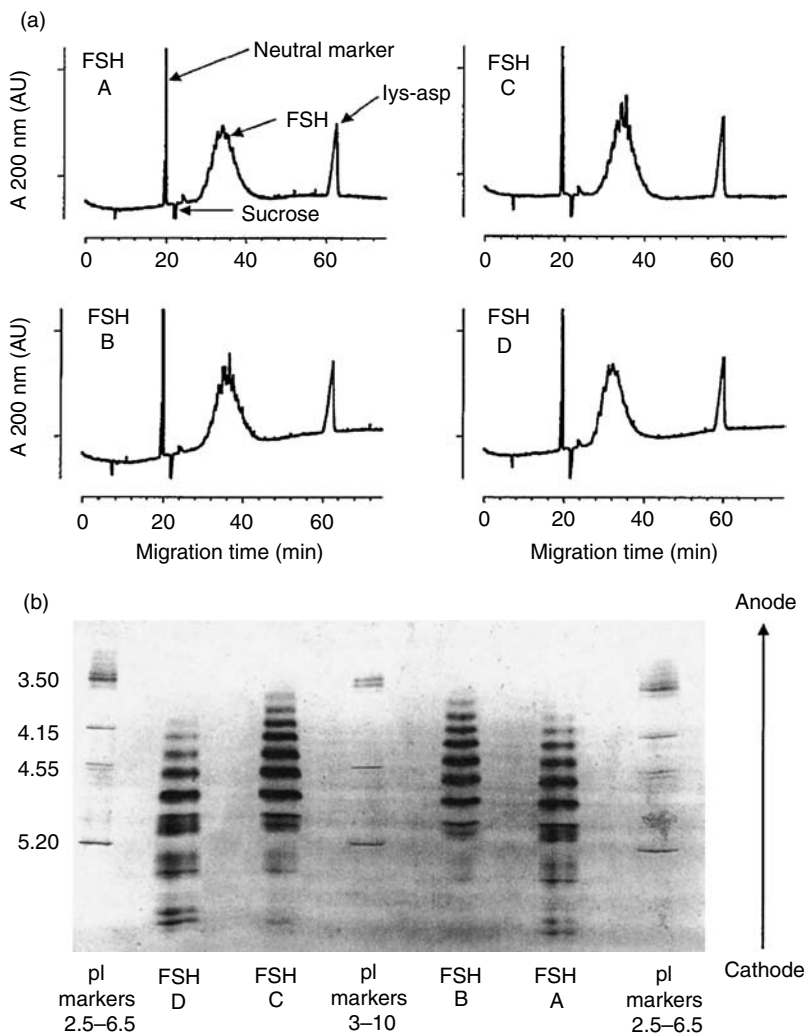

**FIGURE 22.25** Typical electropherograms of rhEPO drug products (from top to bottom): rhEPO- $\alpha$  formulated with HSA (product I), rhEPO- $\alpha$  formulated with polysorbate 80 (product II), rhEPO- $\alpha$  formulated with HSA (product III), and rhEPO- $\beta$  formulated with polysorbate 20 (product IV). Separation conditions: Beckman eCAP amine capillary, 200 mM sodium phosphate/1 mM nickel chloride pH 4.0, -15 kV (75  $\mu$ A), UV detection at 200 nm. (From Girard, M. et al., Presented at the 7th International symposium on capillary electrophoresis in the biotechnology and pharmaceutical industries, Montreal, August 2005.)

a single peak with a shorter migration time than that of the two glycosylated counterparts and that corresponded to that of the bulk rhGCSF from *E. coli*.

### 22.5.1.5 Determination of Biological Activity/Potency

The determination of the biological activity of biopharmaceuticals by physicochemical methods has long been a desirable goal of manufacturers, regulatory authorities, and policy makers alike, driven in part by the ability to replace costly and often imprecise biological assay testing using animals. There are currently a few examples of biopharmaceuticals for which this has occurred. Recombinant insulin and recombinant somatropin (human growth hormone) are two such products, both of which can be described as relatively simple, well-characterized proteins. For both of these two nonglycosylated proteins, physicochemical tests have replaced animal-based bioassays for batch release of bulk products (for somatropin see [140]). In-depth physicochemical characterizations as well as the establishment of a direct correlation with the *in vivo* bioassay were carried out.

For more complex products such as glycoproteins, difficulties in obtaining in-depth characterization of the glycosylation-mediated microheterogeneity have limited the development of this type of approach. However, in a few cases, reports have shown that there exists a correlation between glycoform profiles and biological activity. This is the case for recombinant follicle stimulating hormone (rhFSH) where the CZE-derived glycoform profile has been shown to correlate with the *in vivo* bioassay in a study directed at predicting the biological potency of several preparations [171]. Using CZE conditions consisting of a fused-silica capillary and 100 mM borate, 5 mM DAP at pH 8.9 [172], where rhFSH isoforms migrated as a broad peak between two internal standards, sucrose and the dipeptide Lys-Asp, four highly purified rhFSH preparations differing in their isoform composition and biological potencies were analyzed (Figure 22.26a). The inclusion of internal standards enabled the accurate determination of the median migration time ( $t_m$ ) of the rhFSH peak in each of the four

**FIGURE 22.26** (a) Electropherograms of rhFSH preparations A–D with different isoform compositions and biological potencies. Separation conditions: fused-silica capillary i.d.: 20  $\mu\text{m}$   $\times$  77 cm (effective length 70.6 cm), 100 mM borate, 5 mM diaminopropane (DAP) at pH 8.9, 20 kV (approx. 3.5  $\mu\text{A}$ ), 28  $^{\circ}\text{C}$ , detection at 200 nm. (b) Isoelectric focusing electropherograms of preparations A–D. (From Storrington, P.L. et al., *Biologicals*, 30, 217, 2002. With permission.)

preparations; tm correlated directly with the biological potency on the basis that an increase in the content of highly sialylated (the more acidic) isoforms led to a corresponding increase in biological activity. The same four preparations were also analyzed by gel IEF (Figure 22.26b) and the predicted biological potencies were derived and compared with those obtained by CZE. In both cases it was found that the methods were sufficiently accurate, precise, and robust to predict the bioactivity of batches of rhFSH when used in conjunction with a standard preparation.

### 22.5.2 CE OF ISOFORMS OF INTACT GLYCOPROTEINS IN THE CLINICAL FIELD

As mentioned in the introduction to this chapter, changes in the glycosylation of proteins have been widely related to pathophysiological changes in an individual [1–4]. For instance, a common

phenotypic alteration in malignant cells is the transformation of their glycosylation [173]. CE is an attractive technique for the study of glycoproteins with a clinical interest, due to its well-known quantitative results and speed of analysis [21]. However, not many works dealing with this subject have been published. There are many challenges in the application of CE to glycoproteins of clinical interest. One of the problems is that, as for many other important molecules, these glycoproteins often exist at low concentrations in biological matrices where other proteins are usually present in large amounts and interfere in the analysis. Thus, a sample preparation step, sometimes including concentration, is required. Moreover, increasing the detection sensitivity of CE for the analysis of glycoproteins is one of the challenges reviewed in this chapter. Another pitfall of the technique is that it is not easy to develop a single method for the analysis of most of the proteins as it is the case for other analytical techniques such as SDS-PAGE. On the other hand, CE presents the advantage of its high resolving power that enables the study of slight modifications in protein composition such as for glycoproteins. In addition, its small sample volume requirements make it appropriate for the analysis of clinical samples. This section is devoted to a discussion of CE reports on the separation of isoforms of glycoproteins with a clinical interest.

### 22.5.2.1 Transferrin

The isoforms of Tf, one of the major proteins in serum, have been widely analyzed by CE as alcohol abuse markers. Tf is a glycoprotein synthesized mainly in the liver, which consists, in a single polypeptide chain, of 679 amino acid residues and two N-linked complex-type oligosaccharide chains. It has an important role in iron metabolism and it also acts as a growth factor [174,175]. Human Tf presents several heterogeneities due to its iron content, its genetic polymorphism, and its carbohydrate moieties. With respect to iron content, a Tf molecule can be apotransferrin, monoferric transferrin, or diferric transferrin [174,175]. The influence of this heterogeneity on CE separations of glycoforms can be easily overcome by iron saturation of the sample. On the other hand, more than 38 genetic Tf variants, attributable to substitutions at one or more amino acids, have been described, although only four of them show a prevalence of  $\geq 1\%$  [176]. The common type of Tf is called C-type and most Caucasian individuals express this allele [177]. With respect to carbohydrate heterogeneity, each carbohydrate chain can be bi-, tri-, or tetra-antennary and each antenna possesses a terminal sialic acid residue. Therefore, nine sialoforms (from zero to eight sialic acid residues per molecule) may be present in serum, resulting in pI variations of 0.1 pH unit/residue. The most abundant Tf-form in normal sera is tetrasialo-Tf and it has a pI of 5.4. The other forms have higher and lower pI values [178].

Variations in the heterogeneity of Tf are induced by several pathological and physiological conditions, such as rheumatoid arthritis (RA), congenital disorders of glycosylation (CDG), or pregnancy [175,179], even though variations in the Tf pattern due to alcohol abuse has attracted the highest interest [176,178,180]. The first to report abnormal Tf heterogeneity in cerebrospinal fluid (CSF) associated with alcoholic cerebellar degeneration were Stibler and Kjellin [181] and further studies determined the Tf abnormality in serum of alcohol abusers [182,183]. The variation in Tf heterogeneity in sera from alcohol abusers corresponds to increased amounts of asialo-, monosialo-, and disialotransferrin (generically called carbohydrate-deficient transferrin or CDT). At first, the increased CDT was only attributed to changes in the number of sialic acid residues. However, it was later learnt that the difference was more complex and included changes in some of the neutral carbohydrates [178]. CDT has become the most specific marker for chronic alcohol abuse [66,177,178,184].

The first studies dealing with the quantitative determination of CDT in sera from alcohol abusers were performed by conventional IEF with immunological detection. This method can easily detect genetic variants and has the power to resolve individual isoforms. However, it is laborious and time consuming [178,184]. Since then, a number of CDT methods of analysis, such as anion-exchange chromatography, chromatofocusing, HPLC, and CZE have been developed [176,184].

At the present time, there are several commercial kits for the quantification of CDT based on the fractionation of CDT and non-CDT serum variants by anion-exchange chromatography with immunochemical detection [176]. The main characteristic of almost all of these micro columns is that they do not separate CDT sialoforms and they are quantified as a whole. Therefore, the CDT forms may contain an undetermined amount of trisialo-Tf, which is under debate as to whether it should be considered a CDT form, and that introduces an error in the determination [185,186]. Another drawback of the anion-exchange chromatographic methods is that they fail to detect genetic variants, which may give rise to incorrect determination of CDT or even false-positive results when sera from individuals with genetic Tf variants are analyzed [177,186]. Some authors have claimed that the separation of individual Tf sialoforms is a more accurate procedure than CDT quantification as a whole [68,69,185,186]. One of these commercial tests was compared with HPLC and CZE methods to conclude that the data obtained needed to be systematically confirmed by HPLC or CZE [187]. In spite of these drawbacks, these kits are still convenient for routine analysis due to their speed.

HPLC and CZE methods have been developed to resolve all of the Tf sialoforms present in serum. An HPLC method based on anion-exchange chromatography with direct detection at 420 nm was developed by Jeppsson et al. [188] to individually separate Tf sialoforms in about 16 min. The serum required to be saturated with iron and lipoproteins to be precipitated. Several authors followed the method with minor changes and improvements [186,189,190].

#### 22.5.2.1.1 CZE of Carbohydrate-Deficient Transferrin (CDT)

In general, the CZE identification of Tf sialoforms in the electropherograms has been performed in three ways: first, using anti-Tf to perform immunosubtraction and then comparing the electropherograms of the Tf sample before and after being immunosubtracted; second, the amounts of the different sialoforms can be monitored by CZE analysis after progressive desialylation of Tf with neuraminidase treatment of the sample; and third, by identification from the migration times of each sialoform. With very few exceptions, Tf is iron-saturated before performing CE to eliminate the iron-binding-mediated heterogeneity.

*22.5.2.1.1.1 Sample Preparation* Commercially available Tf standards were first separated by CIEF and CZE by Kilar and Hjerten [79,97] and Oda and Landers [55]. Iourin et al. [120] purified Tf from sera of one donor and of two CDG type I syndrome by consecutive precipitation of sera with rivanol and ammonium sulfate for their analysis by CZE. On the other hand, immunopurification of Tf from sera was used as sample preparation before CE analysis [89,191]. While these were pioneering attempts at the use of CZE to study CDT as a disease marker, the laborious and time-consuming sample preparation steps required were not conducive to their use in routine settings. Sample preparation of Tf from serum became easier after the development of a procedure that involved only iron saturation and dilution of the serum [192]. This sample preparation method has since then been adopted by most authors with only slight modifications [66–68,177,185,193–201]. In another approach, interfering proteins, such as immunoglobulins, can be eliminated from serum with protein A to enhance CDT detection [202]. Another interesting approach to sample preparation is the direct injection of serum into the capillary, carrying out complexation of Tf with iron during the electrophoretic separation [203].

*22.5.2.1.1.2 CZE Separation* With respect to CZE performance, many approaches have been published for the separation of Tf sialoforms. Two groups of methods can be distinguished. In the first one, studies were conducted with a commercial buffer system (CEofix-CDT kit; Analisis, Namur, Belgium), as already mentioned in a previous section, widely accepted and used, sometimes with slight modifications to the protocol proposed by the manufacturer [66–69,177,185,195,197–199,203]. This commercial reagent kit offers the advantage of interlaboratory standardization. In the second group of studies, methods developed in-house were used

[55,79,89,97,120,185,191,192,196,200–202]. To the best of our knowledge, all of the reported methods were carried out at basic pH (around 8.5) so that Tf is negatively charged to prevent protein adsorption to the capillary wall.

The commercial buffer system is based on the dynamic double coating of an uncoated, bare fused-silica capillary. A first buffer (the so-called initiator) is used to coat the capillary wall with a polycation and a second buffer containing a polyanion adds the second layer. The separation buffer is usually borate-based. Between injections, the capillary is rinsed with NaOH so that the coating layers are eliminated after each analysis. This procedure ensures a constant EOF and increases the negative charges on the capillary wall for preventing protein adsorption and increasing the speed of analysis (usually between 6 and 13 min, depending on the modifications of the method) [185,203]. Although in one of the first studies with this commercial system, disialo- and trisialo-Tf could not be resolved [203], modifications of the initial method, which included among others offline iron-saturation and dilution of serum, increased capillary length, and injection of an SDS solution before the injection of the sample, led to baseline resolution of tri, tetra, penta, and hexasialo-Tf in nonalcoholic donors and asialo, di, tri, tetra, penta, and hexasialo-Tf in alcoholic patients [177]. It appears that the SDS plug before sample injection is performed to keep  $\beta$ -lipoprotein peaks out of the area of the electropherogram of interest. SDS is now incorporated in the  $\text{FeCl}_3$  solution used for iron saturation of the commercial reagent set, so it is not necessary to add it separately if the complete reagent kit is used [69].

In the second group of CZE separations, many different approaches have been published. The main goal has been to avoid Tf adsorption to the capillary walls. This problem has been overcome by working with covalently coated capillaries, in some cases with hydroxyethylcellulose in the running buffer [79,89,191,202], or silica capillaries dynamically coated with DAB [185,196,200,202], spermine [185], DcBr [55], or diethylenetriamine (DETA) [201]. In general, the methods performed in uncoated capillaries with dynamic coatings are slower than the ones performed with the commercial buffers. On the other hand, the methods using covalently coated capillaries are as fast (usually in less than 10 min of analysis time) as the methods developed with the commercial buffers.

Lanz et al. [185] compared two different methods in fused-silica capillaries with alkaline borate buffers and different dynamic coatings (DAB and spermine, respectively) and with the double-coating method based on commercially available buffers. The latter method provided faster and more reproducible results. In addition, Tf isoforms peaks were more intense when analyzed with the latter method.

The same group [66] studied the precision of a method based on the double-coating buffer kit over a 20-day period. They found out that the method is highly reproducible both in migration times and peak areas of Tf isoforms. Martello et al. [198] ran an interlaboratory comparison of a method based on the dynamic double coating of the capillary wall performed with commercially available reagents. Results from both laboratories showed high correlation.

#### 22.5.2.1.2 Clinical Applications

In general, the study by CZE of CDT as an illness marker is performed by qualitative or quantitative comparison of CDT between two different groups of participants. To the best of our knowledge, CDT reference limits for direct classification of samples are not yet routinely used, although some attempts have been performed. In that sense, not even a common CDT calculation is performed. For example, area of disialo-Tf as a percentage of tetrasialo-Tf [185,192,201,204], area % of disialo-Tf in relation to the sum of all Tf-isoforms [191,202], and CDT isoforms (asialo-, monosialo-, and disialo-Tf) as area % of total Tf isoforms [177,194,203] have been used as CDT measurements. Lanz and Thormann [205] worked on the establishment of normal CDT reference limits using a CZE method based on a dynamic double coating of the capillary with commercially available reagent kits. They found that the reference CDT intervals (in the case of CDT, only the upper reference limit is important) for a group of 54 individuals with no or moderate alcohol consumption was dependent on the complete or incomplete separation of disialo- and trisialo-Tf, on the integration approach

and on the applied voltage. The upper reference limit obtained by Lanz et al. [197] was used in a subsequent study where more than 600 samples were analyzed with a CZE method established as a routine method. Later on, the reference intervals found by those authors [205] were revised for a modified version of the commercially available reagent kits [67]. The same samples from the 54 individuals were re-analyzed with the new reagents and the CDT reference limits were found to be comparable, although slightly smaller, to the old ones so that the same upper reference limit was valid for the study. The establishment of reliable reference CDT intervals is critical in the sensitivity (number of false negatives) and specificity (number of false positives) of the method.

*22.5.2.1.2.1 Alcohol Abuse* Alcohol abuse is an important public health problem, and self-reporting of alcoholism or alcohol abuse is not reliable. Furthermore, diagnosis on the basis of clinical symptoms is not easy [197]. Therefore, reliable alcohol markers are required for the diagnosis of alcoholism and CDT is one of the better markers of alcohol abuse.

Prasad et al. [191] based their CDT calculation of Tf separated by CZE on the ratio of the area of disialo-Tf (they did not detect asialo-Tf) to the area of total Tf in the sample. On the basis of this index and with a control population of social drinkers, they established a CDT cutoff value. This cutoff value was exceeded by the majority of alcohol abusers studied. This CDT measurement was compared with other alcohol abuse markers (e.g., aspartate amino transferase, alanine amino transferase, and others) and it was found to be the most specific one.

In another study, Tagliaro et al. [192] found that by comparing the Tf profile of a control group of 30 participants against a group of 13 alcoholics, the latter showed a significant increase in disialo- and trisialo-Tf (expressed as percentages of the tetrasialo-Tf peak). They did not detect asialo-Tf in alcoholic samples. These results are controversial since several studies have claimed that not only trisialo-Tf is not an alcohol abuse marker [68,195] but also that it interferes with the correct CDT quantification [204]. On the other hand, there are also favorable opinions to include trisialo-Tf in the calculation of CDT or, at least, to establish a debate [177,206,207]. Crivellente et al. [193] improved on their published method [192] and tested it with real samples. Although the presence of asialo-Tf was suspected to be present in the sera of alcoholic individuals, no confirmation was performed. An increase in disialo- and trisialo-Tf (expressed as percentage of the tetrasialo-Tf peak) compared with healthy participants happened in alcoholic individuals.

Another study using CZE for the analysis of CDT as a marker of alcohol abuse was carried out by Giordano et al. [202]. They did not detect asialo-Tf in sera from alcoholic people, but they detected a significant increase in the disialo-Tf (related to total Tf) in those samples in comparison with control (nonalcoholic subjects) samples. In the same direction, and by establishing the Tf index as % area of disialo-Tf in relation to tetrasialo-Tf, Lanz et al. [185] found that a good classification of sera could be performed on the basis of this index increasing in sera of alcoholic individuals.

Interesting CZE studies on CDT isoforms were reported by Legros et al. [68,69]. They found that asialo-Tf was missing in teetotalers and was present in 92% of alcohol abusers, and that disialo-Tf was increased in alcohol abusers. Figure 22.27 shows the comparison of the Tf profiles of an alcoholic and a teetotaler. Under these conditions, C-reactive protein (CRP) comigrated with monosialo-Tf in the alcoholics electropherogram. Samples before and after Tf immunosubtraction are also compared in the figure. They proposed to use the presence of asialo-Tf as alcohol intake marker because it showed the highest sensitivity and specificity when compared with other CDT isoforms or combination of CDT isoforms. The study focused on clearly different groups (teetotalers and alcohol abusers). In their subsequent work [69], they included moderate drinkers in another group. They found that asialo-Tf was able to discriminate between moderate drinkers and alcohol abusers better than other CDT measurements tested.

*22.5.2.1.2.2 Congenital Disorders of Glycosylation* Congenital disorders of glycosylation (CDG) (previously known as carbohydrate-deficient glycoprotein syndromes) are inherited

**FIGURE 22.27** Comparison between CZE Tf electropherograms of an alcohol abuser (AA) and a teetotaler (TT). In both cases, anti-Tf antibody was added after the first electrophoretic run. P0: asialo-Tf; 1/CRP: comigration of monosialo-Tf and CRP; P2: disialo-Tf; P3: trisialo-Tf; P4: tetrasialo-Tf; P5: pentasialo-Tf; P6: hexasialo-Tf. Analytical conditions: fused-silica capillary 57 cm  $\times$  50  $\mu$ m i.d.; buffer: reagents from the CEofix CDT kit. Capillary was first rinsed with a solution of polycation dissolved in malic acid, pH 4.8; then rinsed again with a polyanion dissolved in Tris-borate, pH 8.5. Capillary was rinsed with the same buffer for 0.5 min under low pressure. After 3 s low-pressure injection of SDS, the iron-saturated sample was injected by low pressure for 2 s; Voltage: 28 kV; Temperature: 40°C; Detection: 214 nm. (From Legros, F.J. et al., *Clin. Chem.*, 48, 2177, 2002. With permission.)

conditions that are usually recognized from glycosylation changes of serum proteins [2]. The hypoglycosylation of different proteins and sometimes of other glycoconjugates leads to several symptoms, such as mental retardation. IEF measurement of Tf is the main diagnostic test used for the detection of CDG because these disorders appear to have an influence on its sialylation (and consequently on its pI) [199,208]. There are several studies that have been reported in which the CZE of Tf has been used to study CDG. An increase in disialo- and asialo-Tf in CDG patients has been reported by several authors [89,120,196,203]. Carchon et al. [199] demonstrated that patients with abnormal IEF results and with confirmed CDG could be identified by CZE. However, they warned about the possibility of finding compounds migrating in the Tf-region and when this is suspected in a sample, CZE analysis with immunosubtraction should be performed.

*22.5.2.1.2.3 Genetic Variants* In addition to the common C-type Tf, other variants such as B and D have been reported. As stated earlier, genetic polymorphism is limited to Caucasians. Most individuals present CC phenotypes (homozygous for Tf with the C gene variant) and, rarely, CB phenotypes. West African, African American, and indigenous American populations, for example, present higher frequency of the D allele [177]. Certain genetic variants are not detected by anion-exchange chromatography-based methods and may result in false positives for alcohol abuse [177,178]. In that sense, CZE is a promising tool for the determination of genetic variants due to its high resolving power. Several workers have published Tf CZE patterns of different genetic variants [66,67,177,197,203]. In general, these patterns are characterized by having two major peaks instead of one (corresponding to the tetrasialo-Tf of both genetic variants). Wuyts et al. [177] found that their CZE method was able to separate (in an alcoholic carrying a CD phenotype) D-asialo-, D-disialo-, D-trisialo-, D-tetrasialo-, and D-pentasialo-Tf in addition to C-tetrasialo-, C-pentasialo-, and C-hexasialo-Tf. In spite of this high resolution power, some of the D-Tf peaks comigrated with C-CDT forms. To solve this problem for the CDT calculation for alcohol consumption diagnostic purposes, the authors proposed a CDT calculation adjusted to CD-phenotypes in order to avoid false positives. Figure 22.28 shows the comparison of Tf patterns from a nonalcohol consumer homozygous (CC), an alcoholic homozygous (CC), a non-alcohol consumer heterozygous (CD), and an alcoholic heterozygous (CD). On the other hand, Lanz et al. [67] analyzed a CD-phenotype alcoholic individual. They detected two peaks for asialo-Tf and two peaks for disialo-Tf. Since C-disialo-Tf was not baseline resolved, the CDT calculation was done by taking twice the area of D-disialo-Tf because both peaks had the same height. The CDT value clearly exceeded the upper CDT reference limit established for normal nonalcoholic-CC phenotypes.

*22.5.2.1.2.4 Transferrin and Cancer* A study has been recently performed in which the Tf CZE profile of a group of cancer patients who consumed alcohol moderately and a group of cancer patients who were alcoholics has been studied [195]. Their profiles were compared with a group of participants without cancer and that were teetotalers, moderate drinkers, and alcohol abusers. While asialo-Tf was present in 95% of alcohol abusers (with and without cancer), trisialo-Tf was higher in cancer patients. The CZE peak corresponding to this trisialo-Tf was not completely eliminated by Tf immunosubtraction. Some tests on the remaining peak suggested that it might be a polysaccharide.

*22.5.2.1.2.5 Interferences in CDT Determination* Usually, Tf analysis by CZE is performed after the injection of diluted, iron-saturated serum, which is an extremely complex media. Therefore, possible interferences in the determination of Tf should be taken into account. Generally, interferences are found after Tf immunosubtraction of the sample and re-analysis. Sometimes, immunosubtraction of the interference is also performed. Legros et al. [68] detected comigration of CRP with monosialo-Tf, so this peak was not taken into account in the CDT calculations. CRP was also identified and migrated before disialo-Tf in some samples analyzed by Lanz et al. [66,197]. In some patients with hepatic disorders, a broad interference, assumed to be due to high levels of immunoglobulin A, was found under the Tf peaks [197]. Wuyts et al. [203] added antihemoglobin and anti-C3c (degradation products of complement-C) antibodies to the running buffer to avoid interferences from these compounds. As described before, SDS was injected into the capillary before the sample for methods performed with commercial reagent buffers to avoid  $\beta$ -lipoprotein peaks comigrating with Tf [68,69,177,195]. This modification was later adopted by the manufacturer [69]. Moreover, a compound comigrating with trisialo-Tf (probably, a polysaccharide) in cancer patients was described [195]. Recently, the commercial reagents for the double-coating CZE method have been reformulated to avoid undesired interferences, and CRP comigration is no longer interfering, neither are some paraproteins that interfered in some samples [67].

**FIGURE 22.28** Comparison between CZE Tf electropherograms of a healthy nonconsuming (CC nonalcoholic) and an alcohol-consuming (CC alcoholic) carrier of the homozygote CC-Tf, and a nonconsuming (CD nonalcoholic) and an alcohol-consuming (CD alcoholic) carrier of the heterozygote CD-Tf. C<sub>0</sub>: asialo-C, C<sub>2</sub>: disialo-C, C<sub>3</sub>: trisialo-C, C<sub>4</sub>: tetrasialo-C, C<sub>5</sub>: pentasialo-C, C<sub>6</sub>: hexasialo-C-Tf. D<sub>2</sub>: disialo-D, D<sub>3</sub>: trisialo-D, D<sub>4</sub>: tetrasialo-D, D<sub>5</sub>: pentasialo-D-Tf. Analytical conditions: fused-silica capillary 67 cm × 50 μm i.d.; buffer: reagents from the CEofix CDT kit. Capillary was first rinsed with the initiator solution, then rinsed again with the buffer solution containing a polyanion. A plug of SDS was injected during 5 s before the sample. The iron-saturated sample was injected for 1 s. Voltage: 28 kV; detection: 214 nm. (From Wutys, B. et al., *Clin. Chem. Lab. Med.*, 39, 937, 2001. With permission.)

### 22.5.2.1.3 Concluding Remarks

The CZE analysis of Tf seems to be an alternative to CDT measurements kits, which are prone to inaccurate diagnostics. Normal CDT ranges are method-dependent and, consequently, results must be interpreted by taking into account method-specific cutoff values [176,184]. In any case, several authors support the application of CZE for CDT determination in the clinical laboratory [191] and claim that it represents an alternative to HPLC and that it should be taken into account as a reference method for CDT [67]. In comparison to HPLC, CZE methods have the advantages of easier sample preparation, faster analysis times, higher isoforms resolution, and faster column reconditioning [197].

### 22.5.2.2 Alpha-1-Acid Glycoprotein

AGP or orosomucoid is synthesized mainly in the liver. It is an acute-phase protein with an unclear function, although it is usually accepted as a natural immunomodulatory and anti-inflammatory agent. It is a 41–43 kDa protein with a pI of 2.8–3.8 with 5 N-complex type glycans. Terminal sialic acid residues are usually present and contribute to the acidity of the protein [209]. Since it is expressed by various alleles at two *loci*, it exhibits genetic polymorphism [210].

Changes in the glycosylation of AGP, as well as in the distribution of genetic AGP forms, have been related to several pathophysiological states, such as cancer [210–213], RA [214,215], and other types of inflammation [216–218].

There are several studies that have described the separation of AGP forms by CE [78,84,87,100,109,117,219,220]. However, only a few authors have carried out CE analysis of AGP samples from patients in order to study if the technique is suitable for distinguishing the changes described earlier.

Kinoshita et al. [78] analyzed AGP purified from rat sera from normal and inflammation states. They separated electrokinetically injected AGP into several nonbaseline resolved peaks in a DB-1 capillary with an acetate buffer (pH 4.1) containing HPMC. They found qualitative differences between the two samples. The sample from rat sera in the inflammation state had more AGP bands moving slower than the AGP sample from sera in normal state. The authors speculated about those bands having decreased sialic acid content. Later on, Kakehi et al. [219] proposed an interesting approach to the analysis of AGP by CZE. They performed electrokinetic injection of desalted serum in a DB-1 coated capillary with a running buffer at pH 4.5. They assumed that almost all serum proteins have pIs above that pH except for AGP, which is negatively charged at that pH. Therefore, a selective electro-injection of AGP was performed. They obtained nonbaseline resolution of 10 AGP forms. They analyzed two serum samples from patients who had acquired methicillin-resistant *Staphylococcus aureus* during hospitalization and one serum sample from a healthy volunteer. However, they did not find a relationship between the abundance of each glycoform and the clinical data of patients.

A completely different approach, based on lectin-affinity CE was used by Bergstrom et al. [117] to separate AGP fractions. As mentioned in a previous section, using Con A as affinity ligand, they separated AGP into two peaks according to the biantennary content of the glycoforms. They applied this methodology to two AGP samples from patients with severe RA and one sample from a healthy donor. They found that the RA samples showed a decrease in the relative peak area of the biantennary peak compared with normal AGP.

In another study, a CZE method capable of baseline separation of up to 11 AGP bands was developed [84]. This method, together with a statistical program that allowed to correctly compare AGP bands from different samples, was used to compare three AGP samples from one healthy donor and two pools of sera from cancer patients. Results showed that samples from cancer patients had one extra AGP band with a higher charge to mass ratio, while the AGP profile from the healthy donor presented one extra band with lower charge to mass ratio. A quantitative study of the samples demonstrated that there were peak area differences for the AGP forms. The cancer patient samples

presented higher proportion of forms with higher charge to mass ratio and lower proportion of forms with lower charge to mass ratio when compared with AGP from the healthy donor (Figure 22.29). The same authors also developed a CIEF method to separate AGP isoforms and applied it to the analysis of AGP from sera from ovary cancer patients [109].

The studies discussed earlier represent the beginning of research efforts directed toward the utility of CE analysis of AGP for clinical uses. In all cases, AGP samples from people and animals with different pathophysiological conditions were analyzed as a proof of concept for the methods developed. Studies of large populations are needed to make clinical conclusions.

### 22.5.2.3 Other Glycoproteins

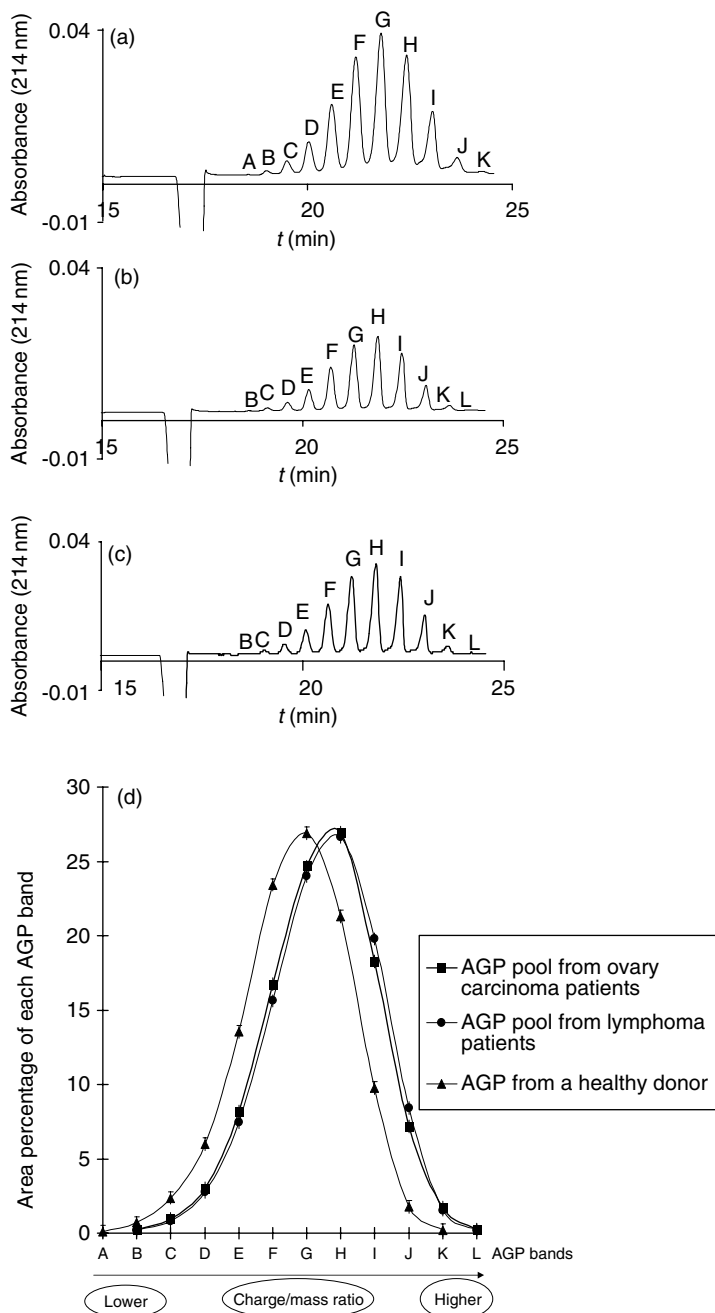

hCG is a glycohemone of 38,000 Da that consists of two noncovalently bound subunits. Both subunits ( $\alpha$  and  $\beta$ , respectively) contain two N-glycans and the  $\beta$ -subunit also contains four O-glycosylated chains. Its role is to avoid the disintegration of the corpus luteum in the ovary. The more acidic hCG glycoforms have increased biological activity. In addition, the glycosylation pattern of this hormone seems to change in patients with trophoblastic disease [56]. As indicated previously, this glycoprotein (in its native heterodimer form) was separated into eight peaks in an uncoated capillary with a borate buffer containing DAP [56]. The method was used to analyze a reference hCG, two samples purified from crude urinary hCG, and one hCG sample from the urine of a patient with metastatic choriocarcinoma. The four hCG electropherograms had the same number of forms, but the relative concentration of each one appeared to vary. However, the hCG sample coming from the cancer patient migrated in a way that did not allow an accurate comparison with the other samples. Those peaks could be aligned with either the previous or subsequent peak, resulting in a different quantitative result.

Hiroaka et al. [221] developed a one-step CIEF method for the analysis of CSF proteins with molecular masses between 10,000 and 50,000 Da. They found differences in the distribution of lipocalin-type prostaglandin D synthase isoforms (a sialic acid-containing glycoprotein) in the CSF of patients with certain neurological disorders. It was speculated that the four different peaks attributable to this protein were due to different numbers of sialic acid residues.

PSA is a glycoprotein that is used as a biomarker for prostate cancer. Its release into blood is increased during the development of prostate cancer. It has a MW of 28,430 Da and contains one N-glycosylation site. A fraction of circulating PSA is bound to plasma proteins. The measurement of unbound PSA increases the diagnosis specificity of total blood PSA [222]. However, these measurements do not take into account the glycosylation pattern of PSA. It was recently stated that when comparing PSA oligosaccharides from healthy donors with that from a prostate tumor cell line, the PSA glycosylation pattern may be different [223]. In that case, the use of CZE for the comparative analysis of PSA glycosylation patterns in samples from healthy persons and prostate cancer patients would contribute to the study of PSA glycosylation as prostate marker. Donohue et al. [167] obtained a separation of PSA forms from several manufacturers in 12 min in an uncoated capillary with a borate buffer containing DAP using UV detection. The commercial PSA samples had been purified from human seminal fluid. As mentioned earlier in this chapter, an interesting finding of this work was that the purification procedure influences the PSA pattern.

## 22.6 CONCLUDING REMARKS AND FUTURE PROSPECTS

As demonstrated in this chapter, CE has clearly become a widely applicable tool for the analysis of glycoforms of glycoproteins, without which the determination of some significant qualitative and quantitative information would not have been possible. This is aptly exemplified from some of the earliest work in the field on Tf, work which has culminated in the use of CE in clinical settings, to a more recent application of CE-MS from which over 130 glycoforms of rhEPO were

**FIGURE 22.29** (a, b, and c): Electropherograms of AGP purified from serum of a healthy donor, a pool of sera from ovary cancer patients, and a pool of sera from lymphoma patients, respectively. A statistical program was used to compare the three electropherograms, showing the different AGP profile between the healthy donor and the cancer patients. Analytical conditions: fused-silica capillary 77 cm  $\times$  50  $\mu$ m i.d.; buffer: 0.01 M Tricine, 0.01 M NaCl, 0.01 M sodium acetate, 7 M urea and 3.9 mM putrescine, pH 4.5; voltage: 25 kV, 35°C. (d) Mean percentage areas and standard deviation (indicated as "I" and calculated with standard AGP,  $n = 6$ ) of AGP peaks in real samples (2 injections each). Names of the AGP peaks according to electropherograms (a), (b), and (c). Discontinuous lines are used to link the real values for the sake of clarity of the representation. (Adapted from Lacunza, I. et al., *Electrophoresis*, 27, 4205, 2006. With permission.)

identified. Undoubtedly, efforts at understanding the separation mechanism of glycoforms have made it possible. The applicability of CE at most stages of biopharmaceutical manufacturing processes as well as its usefulness for comparing products from different sources, whether of recombinant or natural origins, has led most manufacturers to endorse this technique. CE methods have also appeared in pharmacopeial monographs to replace the more laborious, conventional gel methods. A list of several proteins for which glycoforms have been separated and the CE method employed in each case can be seen in Table 22.3.

One particular aspect of CE analysis that requires improvement to make its practical application wider is sample preparation. There is little sense in developing simple and fast CE methods if

they first require time-consuming and labor-intensive steps for obtaining adequate samples. Additional efforts along the lines of work described in this chapter for developing CE methods that do not require a prior purification step, or developing fast and simple purification methods will be required. In combination to more general purification methods, specific ones could be included

to reach this goal. The use of affinity-based systems using lectins, antibodies, or aptamers may provide elegant solutions in this regard. The online combination of an affinity purification step with the CE separation has been demonstrated recently and appears promising even in cases where high throughput is achieved by using multicapillary systems, such as the one described for other analytes [224].

One of the major challenges to be faced in future years will be that of subsequent entry biologics (Canada)/follow-on biologics (USA)/biosimilar medicines (EU), and the ability to establish parameters that will allow the comparison of complex glycoproteins whether it is at the glycoform or isoform levels. Work in this area has been reported in recent years but it is anticipated that with the expiration of patents for several biopharmaceuticals currently on the market, many of them will be produced under a wide variety of manufacturing conditions. This will be even more challenging as it has been shown in this chapter that many parameters can affect the glycosylation profiles. Consequently, the refinement of CE methods will be required in order to improve peak resolution as well as to detect minor glycoforms.

The development of multidimensional, multimodal CE, that is, the online coupling of two or more CE separation modes has been reported several years ago. However, despite its potential for the analysis of complex mixtures such as glycoproteins, its application to practical problems has been limited and it is expected that more applications will be reported.

The field of microchip CE (MCE) has progressed tremendously over the past few years and its application to the analysis of glycoproteins has only been recently reported [225] and will undoubtedly continue to find applications in the coming years.

The majority of the work on CE of glycoforms carried out up to now is related to methods development and the successful demonstration of proof of concept for specific applications. This should lead as a logical next step to its application to a larger number of practical situations, especially in the clinical and diagnostic fields. This will require the methods to be applied to large, well-controlled populations to achieve well-defined conclusions about their validity. However, the application of CE techniques (including MCE) to the clinical field for specific applications such as the analysis of glycoforms as disease markers may be somewhat restrained (if not completely prevented) if more sensitive detection methods are not available. In this sense, newer detection schemes, perhaps involving the development of new fluorescent labeling agents for LIF detection of glycoproteins are required.

## ACKNOWLEDGMENTS

Financial support from Spanish Ministry of Education and Science (Projects TIC2003-01906, HH04-33, CTQ2006-05214, DEP2006-56207-CO3-01), Fundacion Ramon Areces (Project Biosensors), Fundacion Domingo Martinez (project Microorganisms), and Comunidad de Madrid (Project S2006/GEN-0247) is acknowledged.

## ABBREVIATIONS

ACE	Affinity capillary electrophoresis
AGP	Alpha-1-acid glycoprotein, orosomucoid
Ara	Arabinose
Asn	Asparagine
AAT	Alpha-1-antitrypsin
ATIII	Antithrombin III
BGE	Background electrolyte

BRP	Biological Reference Preparation
BSF	Bovine serum fetuin
BTP	1,3-Bis[tris(hydroxymethyl)-methylamino] propane
CAPS	3-(Cyclohexylamino)-1-propanesulfonic acid
CBH-I	Cellobiohydrolase I
CDG	Congenital disorders of glycosylation
CDT	Carbohydrate-deficient transferrin
CE	Capillary electrophoresis
CE-MS	Online coupling of CE to mass spectrometry
CE-SDS	Capillary electrophoresis in sodium dodecylsulfate
CGMP	Caseinoglycomacropeptide
CHO	Chinese hamster ovary
CIEF	Capillary isoelectric focusing
CITP	Capillary isotacophoresis
Con A	Concanavalin A
CRP	C-reactive protein
CSF	Cerebrospinal fluid
CZE	Capillary zone electrophoresis
DAB	1,4-Diaminobutane, putrescine
DAP	1,3-Diaminopropane
DcBr	Decamethonium bromide
EACA	$\epsilon$ -Aminocaproic acid
EOF	Electroosmotic flow
EP	European Pharmacopoeia
EPO	Erythropoietin
ESI	Electrospray ionization
ESI-TOF MS	Electrospray ionization time of flight mass spectrometry
Fuc	Fucose
Gal	Galactose
GalNAc	<i>N</i> -Acetylgalactosamine
GlcNAc	<i>N</i> -Acetylglucosamine
Glu	Glucose
HC	Heavy chain
hCG	Human chorionic gonadotropin
HEPPSO	<i>N</i> -(2-hydroxyethyl)piperazin- <i>N'</i> -2-(hydroxypropane sulfonic acid)
HPLC	High performance liquid chromatography
HPMC	Hydroxypropylmethylcellulose
HRP	Horseradish peroxidase
HSA	Human serum albumin
hTNF	Human tumour necrosis factor
Hyl	Hydroxylysine
Hyp	Hydroxyproline
IEF	Isoelectric focusing
LC	Light chain
LCA	<i>Lens culinaris</i> agglutinin
LIF	Laser-induced fluorescence
mAb	Monoclonal antibody
MALDI	Matrix-assisted laser desorption ionization
Man	Mannose

MEKC	Micellar electrokinetic chromatography
MHEC	Methylhydroxyethylcellulose
MS	Mass spectrometry
NESP	Novel erythropoiesis-stimulating protein
NeuAc	<i>N</i> -Acetylneuraminic acid
OVA	Ovalbumin
PAA	Polyacrylamide
PAGE	Polyacrylamide gel electrophoresis
PB	Polybrene
pI	Isoelectric point
PSA	Prostate specific antigen
PTM	Postranslational modification
PVA	Polyvinyl alcohol
RA	Rheumatoid arthritis
rhATIII	Recombinant human anti-thrombin III
rhBMP-2	Recombinant human bone morphogenic protein 2
rhDNase	Recombinant human deoxyribonuclease
rhEPO	Recombinant human erythropoietin
rhFSH	Recombinant human follicle-stimulating hormone
rhGCSF	Recombinant human granulocyte colony-stimulating factor
rhGMCSF	Recombinant human granulocyte macrophage colony-stimulating factor
rhIFN- $\gamma$	Recombinant human interferon- $\gamma$
rhtPA	Recombinant human tissue plasminogen activator
RNase	Ribonuclease
SDS	Sodium dodecylsulfate
SDS-PAGE	Sodium dodecylsulfate polyacrylamide gel electrophoresis
Ser	Serine
SIM	Selected ion monitoring
TEMED	<i>N,N,N',N'</i> -Tetramethylene diamine
Tf	Transferrin
Thr	Threonine
TOF	Time-of-flight
uEPO	Human urinary EPO
UV	Ultraviolet
Xyl	Xylose

## 23.1 INTRODUCTION

A large number of chemical modifications can occur in individual amino acids that can fundamentally affect their physicochemical and functional properties. Over 200 distinct covalent modifications have been reported, with phosphorylation, glycosylation, acetylation, methylation, and ADP-ribosylation being the most common. Some amino acids can be converted into other amino acids, for example, asparagine in aspartic acid or glutamine in glutamic acid by deamidation. Knowledge of these modifications is extremely important because they may alter physical and chemical properties, folding, conformation distribution, stability, activity, and consequently, function of the proteins.

Phosphorylation, principally on serine, threonine, or tyrosine residues, is one of the most important and abundant post-translational modifications (PTMs), with more than 30% of proteins being modified by the covalent attachment of one or more phosphate groups. It plays a critical role in the regulation of various cellular processes including cell cycle, growth, apoptosis, and transmitting extracellular signals to the nucleus. In fact, protein phosphorylation is

probably the single most common intracellular signal transduction event. Owing to its biochemical importance, various analytical techniques for the detection and analysis of protein phosphorylation have been described.<sup>1</sup> A widely used approach for the detection of phosphorylation involves metabolic labeling with [<sup>32</sup>P]orthophosphate followed by one- or two-dimensional polyacrylamide gel electrophoresis. Detection of phosphorylation sites is based on radiography combined with enzymatic digestions of the separated proteins and two-dimensional phosphopeptide mapping. High-performance capillary electrophoresis (HPCE) offers substantial method inherent advantages over such protocols, for example, a more rapid and accurate analysis with less sample consumption, while avoiding hazardous radioactive labeling.

*In vivo* methylation of the side chains of specific arginines, histidines, and lysines in proteins is a common phenomenon in nature involving numerous classes of proteins in both prokaryotic and eukaryotic cells.<sup>2,3</sup> Methylation has been most well studied in histones, with distinct lysine residues mono-, di-, or tri-methylated playing a major role in the regulation of gene expression, DNA replication, and repair. Methylated amino acids have often been determined in protein and tissue hydrolysates using amino acids analyzers and through cells radiolabeled with [methyl-<sup>3</sup>H]methionine.

Acetylation of proteins occurs in two different ways. The N-terminal acetylation is one of the most common protein modification reactions in eukaryotes and it is estimated that up to about 85% of all mammalian proteins are affected. It is an irreversible process occurring cotranslationally, unlike the reversible side chain acetylation of internal lysine residues, most famously for histones and transcription factors that affect selective gene transcription and chromatin structure. Despite many hypotheses about the role of N-terminal acetylation, its biological significance is still unclear.

Protein glycosylation is a PTM of eukaryotic proteins and does not occur in prokaryotes. The carbohydrate groups are highly variable with significant effects on protein folding, stability, and activity. The importance of HPCE for the analysis of glycosylated proteins is described in Chapter 22.

Nonenzymatic deamidation of peptides or proteins represents an important degradation reaction occurring *in vitro* in the course of isolation or storage and *in vivo* during development and/or aging of cells.<sup>4,5</sup> Deamidation is a hydrolytic reaction resulting not only in the introduction of negative charges but also in a change in the primary structure of proteins or peptides. Deamidation is a common PTM resulting in the conversion of an asparagine residue to a mixture of isoaspartate and aspartate. Deamidation of glutamine residues can occur but does so at a much lower rate. Detecting and separating deamidated forms from the parent molecules are still problematic aspects of protein analysis.

HPCE continues to become more widely used for the detection, separation, and quantification of peptides and proteins, since the use of capillaries greatly reduces sample volume and analysis time compared to conventional gel electrophoresis. This offers perfect qualification for the analysis of PTMs, but surprisingly only a small number of HPCE applications have been developed during the past years. Since these modifications represent phenomena that occur *in vivo* often in very small amounts, they can be easily missed. This may explain why in certain cases recombinantly expressed proteins have an altered or absent activity compared with the naturally expressed proteins.

Taking this into account, more sensitive methods of sample detection have been developed, for example, special detection cell constructions for ultraviolet (UV) adsorption and laser-induced fluorescence (LIF), and particularly the introduction of mass spectrometry (MS) brought tremendous progress in online and offline characterization not only of modified peptides but also of modified proteins. In this chapter, we try to provide information about capillary electrophoresis (CE) methods developed for the separation of proteins and peptides with various PTMs.

## 23.2 THEORETICAL ASPECTS

More or less all modification reactions occurring on proteins may alter their overall charge either by introducing or eliminating charges, thereby changing to some extent the  $m/z$  ratio and the pI of

the parent proteins. For this reason, capillary zone electrophoresis (CZE) and isoelectric focusing (IEF) are CE modes that are especially well suited to separate post-translationally modified forms. However, the ease of use makes CZE the preferentially used method in the laboratory and only very few applications employing other CE modes can be found in the literature.

Depending on the pI of the proteins and the pH of the buffers used for the separation in CZE proteins are either positively or negatively charged (except when  $pI = pH$ , where the overall charge of the proteins is zero). In the course of phosphorylation, for example, negatively charged phosphate groups are bound to uncharged amino acids such as Ser, Thr, or Tyr. Also, glycosylation has an impact on protein charge if one or more charged sialic acid molecules are attached (detailed in Chapter 22). In both cases, modification causes either a decrease in the overall positive charge or at appropriate buffer pH conditions an increase in the negative charge of the modified forms.

Acetylation can take place either on the N-terminal amino group of the first amino acid of a protein or at the  $\epsilon$ -amino group of lysines. As basic amino groups, forming cationic ammonium ions under usual buffer conditions, become neutral due to amide formation one positive charge for each acetyl group bound will be removed in course of this modification reaction. This charge difference enables the separation of distinctly acetylated proteins from each other and from their unacetylated form.

Another modification of lysine, its mono-, di-, and tri-methylation, has been the focus of great attention in histones due to its biological importance in gene regulation. As expected, the impact of methylation on charge is not as pronounced as of acetylation; however, electron donor effects of the alkyl group slightly increase the charge density of the nitrogen of the amino group. These differences can be sufficiently high for a CE separation provided the molecular mass of the protein is low.

An essential and in terms of its biological importance as well as of its frequency often underestimated modification reaction of proteins and peptides occurring under both physiological and laboratory conditions involves the nonenzymatic spontaneous deamidation of asparagine and glutamine residues to aspartate and glutamate, respectively. The deamidation of Asn, which takes place much more frequently than that of Gln, follows a rather complex mechanism via a cyclic imide intermediate. End products of its hydrolytic cleavage are the formation of isoaspartic acid as main reaction product and aspartic acid. In certain cases also truncation of the protein backbone can occur.<sup>4</sup> Under buffer conditions where proteins are cations ( $pH < pI$ ) the presence of both isoaspartic and aspartic acid reduces the overall positive charge of the proteins compared to the Asn containing protein. Moreover, due to minor differences in the  $pK_a$  values of iso-Asp and Asp ( $pK_a$  isoAsp  $<$   $pK_a$  Asp) a separation of these two isomeric protein forms can be achieved if pH of the separation buffer is adjusted thoroughly.

Certain protein classes are known to be multiply modified. Histone proteins are most probably the best investigated representatives in this respect. Under certain biological conditions, they are known to be acetylated, phosphorylated, and methylated, for example, in a definite manner at the same time. Several examples of successful CE separations of even multiply modified proteins are reported in the literature.<sup>6,7</sup>

Problems in CE occurring with the analysis of PTMs are usually not related to the presence of the modifying residues. They are much more associated with problems generally occurring when proteins are analyzed by capillary electrophoresis. Proteins stick to many different surfaces including metals, plastics, and also glass, which are the most commonly used materials for capillaries in CE. Depending on the extent of interaction between proteins and the glass surface of the capillary peak tailing, loss of resolution, reduced sensitivity, or even total adsorption can occur. The primary causes for these detrimental effects are ionic interactions between cationic protein regions and the negatively charged silanol groups of the capillary surface. Moreover, also hydrophobic interactions may contribute to these adsorption phenomena.

A variety of strategies were developed in the past to overcome these troublesome effects. Among these, a few are very simple to accomplish, for example, avoiding very low buffer concentrations. Increasing the buffer concentration decreases protein–wall interactions by reducing the effective

**FIGURE 23.1** CZE separation of phosphorylated histone H1.5 from human tumor cells (CCRF-CEM) in a 100 mM phosphate buffer (pH 2.0). Other conditions: voltage 12 kV, temperature 25°C, injection 2 s, detection 200 nm, untreated capillary (50 cm  $\times$  75  $\mu$ m i.d.).

surface charge and, depending on buffer type also ion-pairing effects come into play. Another approach to limit adsorption is simply by working at pH extremes: At low pH ( $\sim$ 2) silanol groups are protonated, their dissociation is significantly reduced and in this way the interaction of the under these conditions cationic proteins with the now more or less uncharged surface minimized. Conversely, at high pH ( $\sim$ 10) both the silica surface and the proteins will be deprotonated and negatively charged. In this case, adsorption is remarkably reduced as a result of a charge repulsion effect. However, while these approaches may be very successful strategies for the separation of modified forms of peptides and some small proteins ( $<$ 5 kDa), their application is very limited to the separation of “normal sized” proteins as in this case undesired wall interactions cannot sufficiently enough be suppressed. A striking example is illustrated in Figure 23.1. It shows the separation of a mixture of distinctly phosphorylated and nonphosphorylated human linker histone H1.5 using an uncoated capillary and a sodium phosphate buffer with pH 2.0. Owing to their remarkably basic ( $pI > 10$ ) and also hydrophobic properties, histone proteins particularly strongly interfere with the inner surface of the silica wall. From Figure 23.1, it is evident that even at this low pH essential electrostatic protein–wall interactions still occur, which are responsible for the poor resolution, broad peaks, and low sensitivity.

In contrast to separations performed at low pH, working at high pH is not always feasible for the following reasons:

1. Artificial protein modification reactions can be induced, for example, deamidation of proteins.
2. At very high pH ( $>$ 11) dissolution of the silica becomes an issue.

For this reason, distinct coating procedures, often combined with low pH buffers, have been found to be a prerequisite for the successful separation of proteins as well as of their PTMs.

Two basic strategies have been applied in CE to limit protein adsorption.

1. Permanent modification by covalently bonded or physically adhered phases. Basically, hydrophilic polymers, polar functional groups, or even positively charged residues, for

example, amino groups are bound to the silica surface.<sup>8</sup> In general, life time of the permanent coating and batch to batch reproducibility may still be a problem. Therefore, it is not so surprising that most applications for the separation of protein modifications, which can be found in the literature, are based on an alternative approach to suppress undesired protein–surface interactions.

2. It is the concept of dynamically coating the inner wall of the capillary by the addition of suitable additives to the running buffer. These additives themselves show high affinity to the silica surface and act like a shield to prevent positively charged proteins from coming into close contact with the capillary wall. Various compounds have been used for this purpose; for instance, neutral and cationic hydrophilic polymers, cationic hydrophobic polymers, diamines, and so on.<sup>8</sup> Outstanding advantages of this approach are stability of the coating and simplicity of handling. Since the coating agent is in the buffer, the coating layer of the capillary surface is continuously regenerated and no permanent stability is required. Moreover, cleaning of the capillary can be performed easily by rinsing with 0.1 M sodium hydroxide and water. However, potential disadvantages of the dynamic coating approach are effects of the surfactants, for example, influencing protein structure, incompatibility with MS analysis, range of pH applicable can be limited, time for equilibrium needed to obtain reproducible surface coating, surface properties may influence quality and reproducibility of the coating.

As a consequence, both methods have advantages and shortcomings and no method is clearly superior. For this reason, depending on protein primary structure and type of modification method development is still an issue; however, many promising recipes for their successful separation are available in the meantime.

### 23.3 APPLICATIONS

Many proteins such as histones, ribonucleic acid (RNA) polymerase II, tubulin, myelin basic protein, p53, and tyrosine kinases are post-translationally modified at multiple sites. Among them histones are the most extensively studied group as their hydrophilic N- and C-terminal tail domains are subjected to a great variety of PTMs including phosphorylation, acetylation, methylation, deamidation, ubiquitination, and ADP-ribosylation. Distinct combinations of covalent histone modifications including lysine acetylation, lysine and arginine methylation, and serine phosphorylation form the basis of the histone code hypothesis.<sup>9–11</sup> This hypothesis proposes that a pre-existing modification affects subsequent modifications on histone tails and that these modifications generate unique surfaces for the binding of various proteins or protein complexes responsible for higher-order chromatin organization and gene activation and inactivation. Owing to their biological importance, it is not surprising that a variety of methods were developed particularly for the CE separation of histone modifications, more than for any other protein family.

This chapter summarizes practical applications of HPCE on the analysis of various modified histones, other proteins and, moreover, also some modified peptide separations are described.

#### 23.3.1 PROTEINS

##### 23.3.1.1 Phosphorylation

A set of different microscale techniques of CE exists for analyzing phosphorylated proteins and peptides. The effectiveness of a buffer system containing hydroxypropylmethyl cellulose (HPMC) as dynamic coating agent in combination with low pH preventing undesired interactions of positively charged histone proteins with the silica surface could be first demonstrated by Lindner et al.<sup>12–14</sup> A complex mixture of rat testis H1 histones consisting of eight microsequence variants and, in addition,

**FIGURE 23.2** CE separation of phosphorylated histone H1.5 from human tumor cells (CCRF-CEM) in a 100 mM phosphate buffer (pH 2.0) and in the presence of 0.02% HPMC. Other conditions: voltage 12 kV, temperature 25°C, injection 2 s, detection 200 nm, untreated capillary (50 cm  $\times$  75  $\mu$ m i.d.). Designations p0–p5 = non-, mono-, di-, tri-, tetra-, and pentaphosphorylated histone H1.5.

various phosphorylated forms, was separated using an uncoated capillary and a sodium phosphate buffer (pH 2.0) and 0.03% HPMC. A striking example for the resolving power of this separation buffer system is depicted in Figure 23.2, illustrating the CE separation of the same multiphosphorylated histone H1.5 sample already shown in Figure 23.1. Applying the same CE conditions as described in Figure 23.1, except that 0.02% HPMC was added to the phosphate buffer, all five phosphorylated forms are now clearly separated from each other and from the unphosphorylated parent protein. The nonphosphorylated protein migrates fastest, followed by the distinctly phosphorylated forms, because binding of the negatively charged phosphate groups decrease the overall positive charge of the histone molecule thus diminishing the electrophoretic mobility of the phosphorylated protein species.

Recently, Yoon et al.<sup>15</sup> developed a CE-LIF method to determine phosphorylation levels and to follow the translocation of the green fluorescent protein-extracellular signal regulated protein kinase 2 (GFP-ERK2) from the cytoplasm to the nucleus. CE conditions applied were an untreated capillary and a 100 mM CAPS buffer (pH 11.0) containing 2 M betaine. LIF detection was performed with a 5 mW air-cooled argon ion laser (excitation, 488 nm/emission, 520 nm). Phosphorylated and non-phosphorylated GFP-ERK2 were not separated simultaneously, but in consecutive runs. Significant differences in migration time allowed a clear assignment of the modified and unmodified protein. Owing to separation conditions employed (high pH, high salt buffer), the GFP-ERK2 proteins are negatively charged and, therefore, no dynamic coating agent was added. Phosphorylation causes a further increase in the negative charge; thereby, phosphorylated GFP-ERK2 migrates slower. Compared to conventional Western blotting, the CE method allows the analysis of sample volumes as low as a few nanoliters and does not require a separate sample purification step and radiolabeling.

On the basis of their differences in isoelectric point (pI), phosphorylated proteins can be separated in capillary isoelectric focusing (CIEF). Wei et al.<sup>16</sup> employed a CIEF method using a capillary covalently coated with linear polyacrylamide and a pH gradient from 4 to 6.5 for the resolution of mono- and diphosphorylated ovalbumins. Proteins were detected by their UV absorbance at 280 nm. Additional ovalbumin variants within each of the mono- and diphospho-ovalbumins, differing in their amount of glycosylation, were further analyzed by online CIEF-electrospray ionization (ESI)-MS.

In a similar manner, non-, mono-, and diphosphorylated myosin light chain using CIEF, either with UV or LIF detection, was separated by Shiraishi et al.<sup>17</sup> Neutral coated capillaries (eCAP; Beckman Coulter) and HPMC in the ampholyte solution reduced electroosmotic flow (EOF) and protein adsorption. A detection limit of  $\sim 1$  pg fluorescently labeled myosin light chain/capillary was achieved.

### 23.3.1.2 Acetylation

Histone H4 with a calculated pI of 11.9 is one of the most basic proteins known. Under certain biological conditions, it can be reversibly acetylated in its N-terminal region at four lysine residues. CE separation of these different acetylated forms was not possible applying chemically coated capillaries. However, when HPMC was used as a dynamic coating agent, the histone H4 sample isolated from whole histones by reversed phase chromatography (RPC) was clearly resolved into the non-, mono-, di-, tri-, and tetra-acetylated forms within about 22 min.<sup>18</sup> Applying a special buffer system consisting of 500 mM formic acid/LiOH/10 mM urea (pH 2.0) with 0.02% HPMC, an ultrafast CE separation (4 min) of the distinctly acetylated H4 proteins could be achieved (shown in Figure 23.3). As acetylation of lysines decreases the positive charge of histone H4, the unacetylated protein migrates fastest.

Using HPMC as buffer additive another core histone, subfraction H2A, which is a single peak in RPC, could be further separated by CE into five peaks consisting of non-and monoacetylated H2A.2a and H2A.2b, respectively, and even a third subtype H2A.3 was resolved.<sup>19</sup>

Wiktorowicz and Colburn<sup>20</sup> separated core histone H4 into its different acetylated forms using a commercially available cationic surfactant (MicroCoat, ABI). Coating of the silica surface was performed by rinsing the capillary with the reagent followed by a wash with running buffer. Like other cationic surfactants such as cetyl trimethylammonium bromide (CTAB), the coating reagent is primarily bound to the silica surface by ionic interaction. In a second step, the surface-bound neutralized surfactant binds additional reagent cations by virtue of hydrophobic interactions between alkyl side groups. In this way, a remarkably stable bilayer is formed and the charge of the capillary wall is reversed from negative to positive. Consequently, the positively charged histone molecules

**FIGURE 23.3** Electropherogram of multiacetylated histone H4 from mouse tumor cells (NIH) in 500 mM formic acid/LiOH/10 mM urea buffer (pH 2.0) containing 0.02% HPMC. Conditions: voltage 30 kV, injection 1 s. Other conditions are as in Figure 23.2. Designations ac0–ac4 = non-, mono-, di-, tri-, and tetra-acetylated histone H4.

are repelled from the capillary surface and under the influence of an electric field, a reversal of the EOF takes place. It should be mentioned, however, that strictly speaking this particular approach of charge reversal is a special case of the dynamic coating concept, as no coating reagent is included in the running buffer. For this reason, periodic replenishment of the coating by flushing the capillary with the surfactant solution is required.

Besides histones, very little is described about the CE analysis of other acetylated proteins. Some articles report on the separation of N-terminally acetylated and unacetylated forms of metallothioneins (MTs). MTs are structurally unusual proteins due to their small size (6–7 kDa), high cysteine and metal content, and remarkable kinetic lability. Purified rat MT-2 protein was separated by MEKC using an electrolyte of 100 mM sodium borate buffer containing 75 mM SDS at pH 8.4 and showed two peaks.<sup>21</sup> Identification of both peaks was performed with online CE-MS using 100 mM formic acid and 2% methanol. The two peaks differed by a mass equivalent to that of a single acetyl group. Another group established a CE-ESI-time of flight (TOF)-MS method to characterize rabbit liver MT isoforms and was successful in separating several N-acetylated and non-N-acetylated forms using 100 mM acetic acid:100 mM formic acid (pH 2.3).<sup>22</sup>

CIEF has been applied to the separation and quantification of the three main hemoglobin components of umbilical cord blood (fetal, acetylated fetal, and adult hemoglobins).<sup>23</sup> CIEF was performed with a poly (acryloylaminoethoxy-ethonal) [poly(AAEE)] coated capillary and a carrier ampholyte consisting of 5% Ampholine pH 6–8, supplemented with 0.5% TEMED.

An interesting CE application has been the use of so-called charge ladders of proteins for measuring the role of charge in protein stability, protein–ligand binding, and ultrafiltration.<sup>24–26</sup> A protein charge ladder is a collection of derivatives of a protein by converting its charged groups into electrically neutral ones. Charge ladders can be easily generated *in vitro* by the treatment of a variety of model proteins with acetic anhydride. CE has been shown to be an effective tool in the analysis of such charge ladders, as it is used to separate the proteins that constitute the charge ladder into individual “rungs,” each rung contains derivatives with the same number of modified groups.

Cordova et al.<sup>27</sup> explored the CE behavior of protein charge ladders obtained by acetylation of lysozyme and carbonic anhydrase II using noncovalent polycationic coated capillaries. Two of them, polyethylenimine and Polybrene, were very effective in preventing the adsorption of positively charged proteins. Conditions used were fused-silica capillary (50  $\mu\text{m}$  i.d.  $\times$  38 cm) coated with the polymer by flushing the capillary with a 7.5% (w/v) polymer solution, prepared in 25 mM Tris–192 mM Gly buffer (pH 8.3), for 15 min. The running buffer was 25 mM Tris–192 mM Gly buffer (pH 8.3) in the absence of polymer. Separations were obtained within 5 min.

Carbeck et al.<sup>28</sup> showed CE-ESI MS to be a useful tool for the study of charge ladders of lysozyme, carbonic anhydrase II, and bovine pancreatic trypsin inhibitor and for the examination of the relationship between the properties of proteins in the solution phase and in the gas phase.

An example for a CE separation of such a charge ladder is shown in Figure 23.6 (Section 23.4.3).

Separation of multiply modified proteins place high demands on the method applied. An example for a successful separation of a protein containing differently phosphorylated and acetylated forms in a single run using the HPMC-based CZE method is shown in Figure 23.4.

### 23.3.1.3 Deamidation

The analysis of recombinant human growth factor (rhGH), one of the first biotechnologically produced proteins in *Escherichia coli*, by CE with UV absorbance and MS detection using bilayer-coated capillaries was demonstrated very recently.<sup>29</sup> The authors present an improved CE method using capillaries noncovalently coated with polybrene and poly(vinyl sulfonic acid) and a background electrolyte of 400 mM Tris phosphate (pH 8.5) to achieve efficient separations of intact rhGH and degradation products like deamidated and oxidated forms.

**FIGURE 23.4** Electropherogram of histone H5 from chicken erythrocytes. Conditions were the same as in Figure 23.2. Designations ac0p0 = nonacetylated nonphosphorylated H5; ac0p1 and ac0p2 = nonacetylated mono- and diphosphorylated H5; ac1p0 and ac1p1 = monoacetylated non- and monophosphorylated histone H5.

A novel method for the determination of glutamine deamidation in a long repetitive protein polymer via bioconjugate capillary electrophoresis was published recently by Won et al.<sup>30</sup> By conjugating a monodisperse, fluorescently labeled DNA oligomer to long polydisperse nearly electrostatically neutral protein polymers, protein polymers differing in degree of deamidation were successfully separated. For protein polymers with increasing extents of deamidation, the electromotive force of DNA + polypeptide conjugate molecules increases due to the introduced negative charge of deamidated glutamic acid residues. CE analysis reveals increasing differences in the electrophoretic mobilities of conjugate molecules, which qualitatively shows the degree of deamidation. CE of protein–DNA conjugates was performed using a capillary coated with POP-5 polymer and a 50 mM Tris, 50 mM TAPS, 2 mM EDTA buffer containing 7 M urea (pH 8.4) added with 3% POP-5 solution.

Histone H1<sup>0</sup> is known to be deamidated in the course of aging.<sup>5</sup> Intact H1<sup>0</sup> contains asparagine in position 3, while depending on the age of the organ deamidated forms of H1<sup>0</sup> containing either aspartic acid or isoaspartic acid accumulate. The buffer system containing HPMC enables the separation of intact histone H1<sup>0</sup> fragment (residues 1–52) as well as its deamidated forms (Figure 23.5).

#### 23.3.1.4 Methylation

Unlike protein modification by acetylation or phosphorylation, methylation does not greatly influence the charge of individual amino acids, thus making the electrophoretic separation of distinct methylated proteins from each other and from the unmethylated parent protein a problematic part. Separation of acetylated histone H4 has already been described by Lindner et al.<sup>18</sup> using CZE with HPMC as dynamic coating reagent. The same method enables the simultaneous separation of mono-, di-, and trimethylated H4, including their distinct acetylated forms.<sup>6</sup> Changes in the modification pattern of H4 from normal tissues, cancer cell lines, and primary tumors were found suggesting that a global loss of monoacetylation and trimethylation of histone H4 is a common hallmark of human cancer.

**FIGURE 23.5** CE separation of deamidated proteins. Histone H1<sup>0</sup> from rat liver was digested with chymotrypsin and the N-terminal fragment obtained by RPC analyzed by CE. Conditions were the same as in Figure 23.2. Designation Asn, Asp, isoAsp = asparagine, aspartic acid, and isoaspartic acid containing fragments.

## 23.3.2 PEPTIDES

### 23.3.2.1 Phosphorylation

A CZE procedure for detection and assay of protein kinase and phosphatase activities in complex biological mixtures has been developed by Dawson et al.<sup>31</sup> The phosphorylated and dephosphorylated forms of several peptides were resolved using an uncoated capillary and a 150 mM phosphoric acid buffer at pH 2.0 or pH 5.0. Furthermore, the CZE-based assay was capable of resolving a peptide phosphorylated on different sites and permitted the quantification of each peptide. Since this application, much research has been done on protein kinase assays based on CE.

For the same purpose, Gamble et al.<sup>32</sup> tested both neutral and cationic coated and uncoated capillaries and found that the best conditions for the separation of phosphopeptide isomers is formic acid or phosphate buffer with pH ranging between 5.5 and 6.5 and a PVA-coated capillary. Synthetic peptides were incubated with various protein kinases and phosphatases and the phosphorylation and dephosphorylation was monitored using CZE. These methods enabled the assay of several protein kinases and phosphatases and the determination of the sites of phosphorylation.

Improved CE-based methods to measure kinase activation in single cells have been described recently.<sup>33</sup> Phosphorylated and nonphosphorylated forms of peptide substrates for protein kinase C and calcium-calmodulin activated kinase were separated by CZE using a polydimethylacrylamide (PDMA) coated capillary and buffers containing different concentrations of betaine (0–1 M). The separation system is compatible with a living cell and, therefore, adaptable to the laser micropipet system, a strategy to measure the activation of enzymes in single mammalian cells.

Synthetic peptides containing phosphorylated tyrosine have been shown to be easily separated by a CZE method using a linear polyacrylamide-coated capillary and a 300 mM borate buffer (pH 8.5).<sup>34</sup>

Another separation mode of HPCE, namely MEKC, has been used to separate a mixture of phosphopeptide isomers of the insulin receptor peptide.<sup>35</sup> The resolution in coated and uncoated capillaries was compared using a 50 mM phosphate buffer with 25 mM SDS (pH 6.1). An efficient separation of diphosphorylated isomers could be obtained by using polyacrylamide-coated capillaries.

Mass spectrometry of phosphopeptides has become a powerful tool for phosphorylation site identification. However, proteolytic digests examined by MS are often likely to fail to detect phosphopeptides because the ionization of phosphorylated peptides in positive ion mode MS is generally less efficient compared with the ionization of their nonphosphorylated counterparts resulting in ion suppression effects. A further problem is that phosphopeptides may not be retained by RP chromatography because they are too small and/or hydrophilic to bind to the C18 stationary phase. Therefore, capillary electrophoresis coupled to MS is a powerful method to enhance the detection of phosphoproteins and phosphopeptides due to their efficient separation by CE.

Sandra et al.<sup>36</sup> developed a CE-MS technique to the characterization of the N-glycans from the glycoprotein cellobiohydrolase I (CBH I) with special interest for the phosphorylated species. CBH I shows phosphorylated glycans that are only present when the organism is grown under minimal conditions and could be related to stress response. The glycans were labeled with the negatively charged tag 8-aminopyrene-1,3,6-trisulfonate (APTS) by reductive amination and separated using an untreated capillary and a 25 mM ammonium acetate buffer (pH 4.55), allowing the simultaneous analysis of uncharged and charged glycans and, moreover, the differentiation of phosphorylated isomers.

Detection of phosphorylated proteins and peptides can be enhanced by selectively isolating these species. Online immobilized metal affinity chromatography (IMAC)-CE-ESI-MS is such a powerful analytical tool. The IMAC resin retains and preconcentrates phosphorylated proteins and peptides, CE separates the phosphorylated species and MS/MS identifies the components and their phosphorylation sites. Cao and Stults<sup>37,38</sup> applied this method to the analysis of phosphorylated angiotensin II and tryptic digests of  $\alpha$ - and  $\beta$ -casein (CE conditions: buffer, 0.1% acetic acid/10% methanol; uncoated capillary). Beta-casein is a well-characterized protein with five phosphorylation sites and is widely used as a standard for protein phosphorylation studies.

### 23.3.2.2 Deamidation

The effectiveness of CZE for the separation of deamidated peptides was shown by Ganzler et al.<sup>39</sup> Excellent resolution of peptides containing all three forms, Asn, Asp, and isoAsp, could be achieved by using a 20 mM sodium citrate buffer (pH 2.5).

### 23.3.2.3 Farnesylation

Protein farnesylation, catalyzed by protein farnesyltransferase, plays important roles in the membrane association and protein-protein interaction of a number of eukaryotic proteins. The enzyme transfers a 15-carbon farnesyl moiety from farnesyl diphosphate (FPP) to the sulfhydryl group of cysteine. The activity of the enzyme was measured by CE with LIF detection, which is a powerful alternative to classical methods involving radiolabeled FPP.<sup>40</sup> LIF detection was performed with an argon ion laser (excitation, 488 nm/emission, 520 nm). A fluorescently labeled pentapeptide that was used as substrate was clearly separated from its farnesylated form under the four CE buffer conditions investigated (e.g., 25 mM borax, 25 mM SDS, pH 9.3, uncoated capillary). The method will be of great value in studies of inhibitors of protein farnesyltransferase *in vitro*.

## 23.4 METHOD DEVELOPMENT GUIDELINES

Many factors may influence the quality of CE separations and contribute to the resolution of protein modifications. Generally, optimization strategies, precautions, and CE conditions applied to peptides are also applicable to the separation of modified proteins. However, optimum parameters for protein separations must still be determined empirically to some extent. In addition to well-known factors influencing resolution in CE like capillary surface and coating, buffer pH, also effects of different

buffer cations and anions, buffer concentration, additives, and chaotropic agents can be utilized to enhance resolution of protein mixtures.

### 23.4.1 BUFFERS

The running buffer selection is substantial to the success of any CE separation. Factors being most important are the UV absorbance at low wavelengths, good pH stability, and conductivity. The highest sensitivity detection is achieved at low UV wavelengths (190–220 nm) where peptide bonds have an absorbance maximum. Good sensitivity at these wavelengths requires buffer systems with high-UV transparency. The most frequently used buffers are sodium phosphate, sodium citrate, Tris, and sodium borate. Sodium formate shows optimal compatibility to mass spectrometric analysis and is therefore often used in CE coupled online to MS.

The buffer pH should be stable during a series of analyses. For reproducible analysis times the buffer should be exchanged or remixed every 5–10 runs. Cellulose-based buffers should be freshly prepared at least once a week, depending on the number of runs, and should not(!) be stored in the refrigerator. The quality and purity of all buffer components should be of the highest grade and the buffers should be filtered through 0.45  $\mu\text{m}$  pore size filters before use. A starting buffer, which gives superior results in many cases, is a 100 mM sodium phosphate buffer (pH 2.5) with the addition of 0.02% HPMC. Owing to the excellent UV transparency of the separation buffer, proteins can be detected very sensitively at 200 nm. In case this system does not provide satisfying results, more complex separation conditions must be taken into account according to specific properties of the proteins (e.g., pI, hydrophobicity, etc.).

### 23.4.2 CAPILLARY TREATMENT

Using an untreated capillary every 10–15 injections the capillary should be rinsed with water, 0.1 M NaOH, water, 0.5 M  $\text{H}_2\text{SO}_4$ , and finally with the running buffer. Washing should be done for 2 min with each solvent. The same wash, but without running buffer, should be applied at the end of sample analyses. After flushing the capillary with air, it can be stored.

There are many different static wall coatings described in the literature, recently reviewed by Horvath and Dolnik.<sup>8</sup> Static coated capillaries should be treated according to the manufacturer's guidelines. Solvents such as NaOH and  $\text{H}_2\text{SO}_4$  must not be used.

### 23.4.3 METHOD EVALUATION

The evaluation of the applicability of a certain CE method for the separation of modified proteins can easily be performed by analyzing acetylated lysozyme generated by the treatment of the protein with acetic anhydride (described in Section 23.3.1.2). An aqueous solution of lysozyme (0.1 mM, 0.5 mL) adjusted to pH 10 by using 0.1 M NaOH is incubated with 4.5  $\mu\text{L}$  acetic anhydride (100 mM in dioxane) for 5 min at room temperature according to Cordova et al.<sup>27</sup> An example using the suggested phosphate buffer with HPMC is shown in Figure 23.6.

## 23.5 CONCLUDING REMARKS

The analysis of post-translationally modified proteins is due to their biological significance a field of ever increasing importance. For many years, different kinds of PAGE have been the most commonly used tool for studying modified proteins with all the shortcomings of this technique generally known. The advent of capillary electrophoresis provided a promising new tool for their separation. HPCE has made significant advances in recent years and is establishing itself as a rapid, reproducible, sensitive, and highly resolving method. Hyphenated techniques, for example, the combination with MS, will

**FIGURE 23.6** CE analysis of the lysozyme charge ladder. (a) Untreated lysozyme and (b) charge ladder from acetylation of lysozyme. Conditions were the same as in Figure 23.2.

be able to provide detailed structural information like modification status and sites and will further increase the range of potential CE applications in this field.

## 24.1 INTRODUCTION

The majority of difficult separations can be divided into two main classes: complex mixtures and challenging pairs (Figure 24.1). Complex mixtures, such as proteins and protein digests, demonstrate “random” or broad spectrum behavior with respect to their properties, whereas “well-behaved” analytes such as nucleic acids display predictable behavior determined mainly by the size of the molecule. The analysis of these complex samples requires a separation system with high peak capacity and the ability to cover a broad spectrum of physical properties.

Challenging pairs, such as enantiomers and isotopomers, display properties that are so similar in nature that a separation technique must have extremely high efficiency in order to resolve the analytes. The high efficiency can come at the expense of the ability to analyze a broad spectrum of different analyte properties because the species of interest are confined to closely migrating bands.

Conventional approaches to increasing the resolution for difficult separations in capillary electrophoresis (CE) usually require extensive development of buffers and/or capillary coatings particular to an individual separation. The improvement in resolution is usually the result of exploiting a specific intrinsic property of the analytes. A universal approach to achieving broad spectrum high resolution separations can be achieved using CE with an extremely high applied potential. Separation efficiency increases linearly with applied voltage, and resolution improves with the square root of applied voltage. Ultrahigh voltage CE (UHVCE) uses existing buffer systems and separation conditions but gives the analytes more time to separate at a given electric field strength.

The separation of challenging pairs that are not resolved using traditional methods is often achieved by developing novel pseudo-stationary phases for enantiomers or by utilizing mass spectrometry for analyzing isotopomers. Resolution of these tough pairs can also be achieved using

**FIGURE 24.1** Dividing difficult separations into several categories can help in the development of separation strategies.

extended separation times under high electric field strength. Because the difficult pairs exist as closely migrating analyte bands, techniques such as flow counterbalanced CE (FCCE) and synchronous cyclic CE (SCCE) can be used. These methods use conventional separation voltages in relatively short capillaries but use procedures to increase the duration in a high electric field.

## 24.2 ULTRAHIGH VOLTAGE CAPILLARY ELECTROPHORESIS

### 24.2.1 BACKGROUND AND THEORY

Early work with CE demonstrated how higher applied voltages offered vast improvements for electrophoretic separations.<sup>1–5</sup> Separation efficiency shows a linear dependence on applied voltage when analytes are detected very close to the end of the capillary:

$$N \cong \frac{(\mu_e + \mu_{\text{EOF}}) V}{2D}, \quad (24.1)$$

where  $N$  is the efficiency in theoretical plates,  $\mu_e$  is the electrophoretic mobility of the analyte,  $\mu_{\text{EOF}}$  is the mobility of the electroosmotic flow (EOF),  $V$  is the applied voltage, and  $D$  is the diffusion coefficient of the analyte.<sup>6</sup> Resolution between analytes with electrophoretic mobilities  $\mu_1$  and  $\mu_2$  show a dependence on the square root of the applied voltage:<sup>7</sup>

$$R_s = 0.177(\mu_1 - \mu_2) \left( \frac{V}{D(\mu_e + \mu_{\text{EOF}})} \right)^{1/2}. \quad (24.2)$$

In addition, the speed of a separation can be greatly increased with higher applied voltages. Migration time for an analyte ( $t_m$ ) displays an inverse linear relationship with applied voltage for the same length capillary ( $L$ ) and separation distance ( $l$ ):

$$t_m = \frac{lL}{V(\mu_e + \mu_{\text{EOF}})}. \quad (24.3)$$

The flat electrokinetic flow profile suggests that as long as Joule heating can be prevented, there is no theoretical limit to the improvements to be gained by increasing the applied voltage. In practice, several factors combined to limit the applied voltage used in early instrumentation to approximately 30 kV.

High electric field strengths can lead to resistive or Joule heating of the buffer solution within the capillary. A detailed discussion of the effects of Joule heating with voltages up to 60 kV has been described by Palonen et al.<sup>8</sup> In the simplest of terms, the power ( $P$ ) running through the capillary is given by

$$P = iV = \frac{V^2}{R}, \quad (24.4)$$

where  $R$  is the resistance of the capillary. Since it is desirable to have the greatest possible voltage, the resistance of the capillary must be large enough to keep the power below about 1 W per meter of capillary length.

Initial experiments conducted at voltages in excess of 30 kV resulted in broken capillaries. A quick calculation of the radial electric field at the silica/buffer interface (Figure 24.2) using the following equation explains why this occurs:<sup>9</sup>

$$E_{\text{radial}} = \frac{V_i - V_o}{\ln(b/r_c)K r_c}, \quad (24.5)$$

**FIGURE 24.2** Longitudinal electric fields are used to separate analytes in CE. Radial fields also exist through the capillary wall, and at high voltages, they can destroy the capillary via dielectric breakdown.

where  $V_i$  is the voltage inside the capillary,  $V_o$  is the voltage of a nearby conductor distance  $b$  from the center of the capillary,  $r_c$  is the length of the inner radius of the capillary, and  $K$  is the dielectric constant of the capillary wall ( $\sim 3.9$  for fused silica). For a capillary  $50 \mu\text{m}$  in diameter, 1 m from the nearest grounded conductor, with 100 kV applied, the radial electric field strength is about 100 million V/m. Radial electric fields greater than the dielectric strength of fused silica ( $\sim 15$  million V/m) damage the fused silica wall and cause defects in the structure leading to fragmentation.

Early efforts using a van de Graff generator<sup>10</sup> at  $\sim 200$  kV and a thick dielectric coating such as a sleeve of Teflon<sup>®</sup> tubing around the capillary were unsuccessful. In another attempt, a plastic tube surrounding the capillary was filled with isopropyl alcohol.<sup>11</sup> In theory, both the capillary and the tube filled with alcohol can be treated as long resistors, and therefore the potential will drop linearly down the length of the capillary. The potential drop in the outer tube should match the potential drop in the capillary and therefore reduce the radial field through the capillary wall. Unfortunately, the capillaries still degraded in a very short time.

The first capillary shielding system that could prevent dielectric breakdown of the fused-silica capillary was demonstrated by Hutterer and Jorgenson.<sup>12–15</sup> The capillary was placed inside a series of metal rings charged to potentials closely matching those inside the capillary (Figure 24.3). The electric potential from the rings counteracts the radial field from the capillary and shields the capillary from damage. The high voltage direct current (HVDC) was generated using a 26-stage Cockcroft–Walton voltage multiplier<sup>16</sup> with 2.4 nF HV capacitors. The voltages needed to charge the rings were supplied by different stages of the multiplier. The entire instrument was submerged in a tank containing transformer oil to provide electrical insulation.

This instrument showed the expected improvements in efficiency and resolution for samples of peptides via CE,<sup>7,12</sup> hyaluronic acid via capillary gel electrophoresis (CGE),<sup>12,14</sup> and oligosaccharide mixtures via micellar electrokinetic capillary chromatography.<sup>12,15</sup> Application of up to 120 kV was possible, and no degradation of the capillary was observed. Figure 24.4 shows electropherograms of a cytochrome *c* digest separated on the same capillary using 28 kV and 120 kV.<sup>12</sup> It is easy to see the improvements in resolution and the decrease in separation time when higher voltages are applied.

The current state-of-the-art instrumentation uses larger capacitors (10 nF) to create a 100-fold Cockcroft–Walton voltage multiplier capable of reaching potentials as high as 410 kV.<sup>6</sup> A total of 25 shielding rings keep the potential difference between the capillary and shielding system at less than 20 kV. The benchtop instrument runs in air, using plastic dielectric material instead of the tank of transformer oil. The HV polarity can easily be reversed, allowing both positive and negative HV separations. The temperature of the instrument can be controlled to within a few degrees over a range of ambient temperature up to  $60^\circ\text{C}$ . It can be easily moved and coupled to different detection systems including laser-induced fluorescence (LIF) detection, UV absorbance detection, and electrospray ionization-mass spectrometry (ESI-MS). Separations of peptides, proteins, and nucleic acids using the instrument with these detectors are described in Sections 24.2.2.4, 24.3.3.3, and 24.4.3.3.

**FIGURE 24.3** Charged metal shielding rings can be used to reduce the radial electric field strength. Closely matching the potential charge on the ring to that within the capillary prevents dielectric breakdown and allows operation at very high voltages. (Reprinted from Henley, W. H., PhD Dissertation, University of North Carolina, Chapel Hill, 2005. Copyright 2005. With permission.)

## 24.2.2 PRACTICAL IMPLEMENTATION

### 24.2.2.1 High Voltage Capillary Shielding System

The first step in implementing UHVCE is to devise a capillary shielding system adequate for the desired separation voltage. The radial field that causes dielectric breakdown of the capillary must be dealt with in some manner. The dielectric breakdown strength of silica is approximately 15 MV/m. Equation 24.4 can be used to show that small diameter capillaries have a large radial electric field at relatively modest voltages. One approach is to simply use a large i.d. capillary with a thick wall. This may work for relatively low voltages, but not without band broadening and heat dissipation problems inherent to large bore capillaries. Another approach uses a conductive, but high resistance, material to surround the capillary in a uniform coating. High voltage is applied to the capillary and to the surrounding material. If the resistance of the material is equal along its length, the potential drop should mirror that of the capillary and thus neutralize the radial electric field through the wall of the capillary. Attempts using isopropyl alcohol in a tube surrounding the capillary resulted in failure after a relatively short time.<sup>11</sup> Nevertheless, such a system should be possible.

The most suitable method found so far is the use of charged metal rings to surround the capillary and neutralize the radial field (Figure 24.3). Briefly, the capillary is surrounded by a series of metal rings charged to a potential that roughly matches those inside the capillary. Long lengths of capillary can be equally spaced within the rings by winding them onto a suitable spool. This method has been successfully used without any noticeable degradation of the capillary.

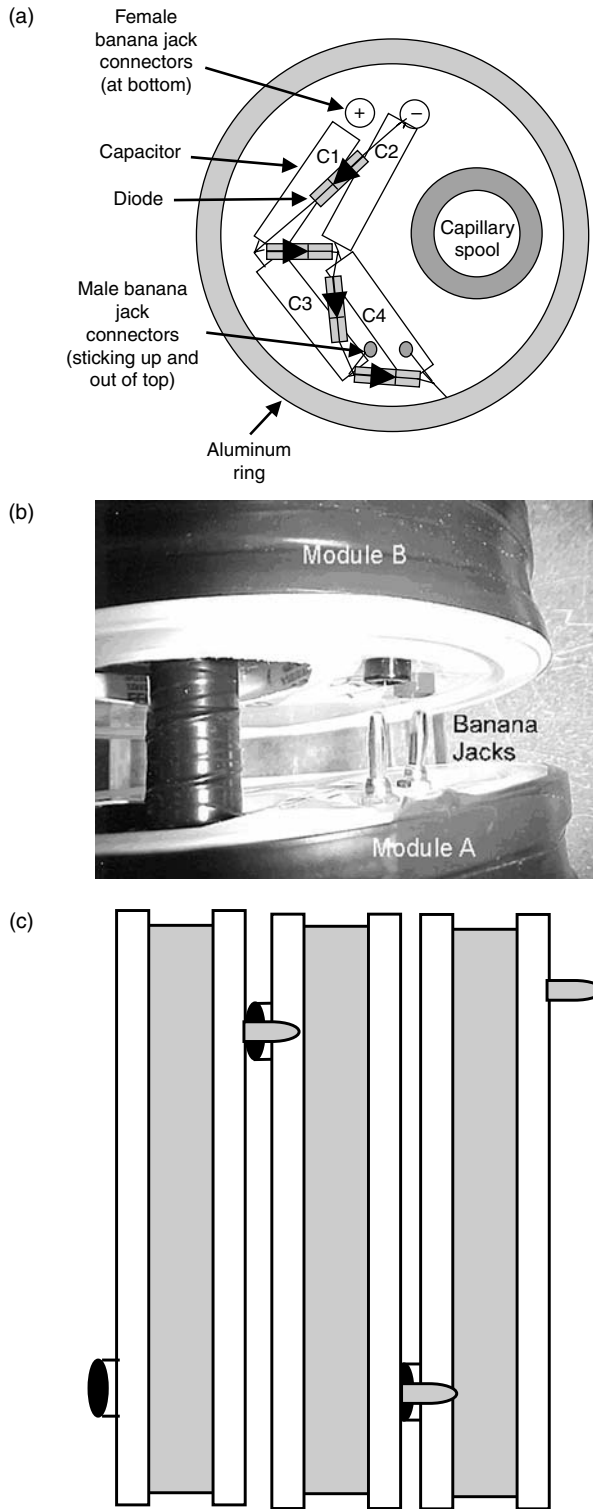

### 24.2.2.2 Power Supply and Development

The development of the power supply for UHVCE requires several considerations. Voltages of the magnitude used for UHVCE can easily arc through the air and “crawl” along insulating surfaces for several feet. Safety is paramount, and a grounded metal shell or Faraday cage should be used to protect the operator from electrocution and to protect sensitive nearby equipment from electromagnetic pulses caused by stray electric arcs. The supply must generate high voltage with sufficient current to drive the separation and charge the shielding system. Loss of charge from corona and stray capacitance must be prevented if the full potential of the power supply is to be realized.

The generation of high voltage can be accomplished in many ways. Perhaps the simplest method is the van de Graff generator.<sup>10</sup> Briefly, charge is pumped from one roller to another roller held inside a metal sphere via a belt of dielectric material. The van de Graff generator is a constant current source, and therefore the voltage is limited by the loss of charge to the surrounding air and resistive load. Submerging the generator in transformer oil can dramatically reduce charge loss and improve the efficiency of the generator. Since the voltage is generated in a single step, charging metal shield rings to different potentials to shield the capillary may not be practical.

If a single commercial high voltage power supply is used, a string of high voltage resistors set up to divide the voltage will be needed to bias the shielding rings. Such a system would be most practical for voltages up to about 100 kV, and even then require careful insulation of the resistors and high voltage wires.

The Cockcroft-Walton voltage multiplier has been used to generate the high voltage for the two UHVCE systems developed thus far.<sup>6,7,12,14</sup> The instrumentation has already been thoroughly detailed elsewhere, and so will only briefly be discussed here. The multiplier is a convenient and inexpensive solution to several problems surrounding UHVCE. It produces successively higher d.c. voltages as the multiplier chain is extended, providing multiple voltage sources to bias the shielding rings. The electronics are simple and can be easily contained within modestly sized shielding rings so that dielectric stresses on the electronic components themselves can be minimized (Figure 24.5). The efficiency of the multiplier decreases as the number of stages is increased. This can be mediated somewhat by using large capacitors in the first stages and decreasing the capacitance of each successive stage. Using fast recovery diodes can prevent excessive losses from reverse current leakage. The

**FIGURE 24.5** (a) A schematic representation of the electronics in the individual modules that make up the Cockcroft–Walton voltage multiplier and shielding rings. The capillary spool can be seen in the photo (b), as well as the connections between modules (c). (Reprinted from Henley, W. H., PhD Dissertation, University of North Carolina, Chapel Hill, 2005. Copyright 2005. With permission.)

a.c. input frequency should be carefully selected for maximum efficiency of the Cockcroft-Walton generator.

### 24.2.2.3 HV Insulation

When the electric field at a metal surface becomes greater in magnitude than the dielectric strength of the surrounding material, ionization of that material will occur. This phenomenon is called corona when it occurs in air. It is undesirable because it is a source of potential voltage loss and can lead to an electric arc. The strength of the electric field is dependent on the radius of curvature of the metal shielding ring. For every 30 kV of potential, the radius of curvature must increase 1 cm to prevent corona. Potentials of 500 kV require a radius of curvature of over 33 cm. Such large diameters can be avoided if material of sufficient dielectric strength and thickness is used to surround a more modest diameter. The first UHVCE instrument was surrounded by a tank of transformer oil. The oil proved difficult to work in. It absorbed moisture from the atmosphere and became slightly conductive, reducing the maximum attainable voltage.

The second UHVCE instrument<sup>6</sup> used thick coatings of plastics for dielectric insulation (Figure 24.5). All metal surfaces were painted with vinyl coatings. The electronic components were potted in thermoplastic polyethylene commonly available as “hot melt” glue. This material is inexpensive, has good dielectric properties, can be applied in thick coatings, and can be easily reworked with a scalpel and heat. Insulation between the shielding rings was provided by polyethylene caps. The insulation from the surrounding air was provided by an acrylic tube with many layers of polyester film. The polyester film had an exceptionally large dielectric strength ( $\sim 3 \times 10^6$  V/cm). Every effort was taken to prevent an ionizable path to ground. The high voltage end of the instrument housing was completely sealed with polyester/styrene casting resin except for the tiny injection port. The injection port was plugged with a polyetheretherketone (PEEK) injection rod (Figure 24.6) covered in silicone vacuum grease to exclude air from the seal.

### 24.2.2.4 Modes of Operation and Examples

Open tube UHVCZE can be used for the separation of small molecules, peptides, proteins, and protein digests.<sup>6,7,12</sup> Increasing the time that the analytes migrate will improve resolution and efficiency. One method of achieving this is to increase the length of the capillary, but when the maximum attainable voltage is limited, the electric field strength will be relatively low in long capillaries. UHVCE can improve these separations by maintaining a high field strength in a long capillary. Figure 24.7 shows two separations of a model peptide sample in a 566-cm-long capillary. The sample was first separated at 28 kV (close to the maximum conventional CE applied voltage) resulting in an electric field strength of only 50 V/cm. Leu-enk had an efficiency of 1 million theoretical plates and required approximately 328 min to migrate to the detector. Using the UHVCE power supply at 330 kV, the electric field strength was 580 V/cm. Leu-enk showed a 10-fold efficiency improvement at higher voltage, resulting in an efficiency of 10 million plates. Migration time was reduced to 28 min. Resolution between the analytes and impurity peaks can also be seen.

In open tube UHVCE, it is important to reduce analyte adsorption as much as possible. Analytes that adsorb to the fused-silica surface do not tend to show much improvement as the length of capillary and applied voltage are increased. Figure 24.8 shows a model protein separation that demonstrated a small amount of adsorption in a 50 cm long separation. Using UHV in a 501 cm capillary, resolution and efficiency are actually reduced, and migration time is proportionally longer.

Capillaries coated with aminopropyl species have been used to reduce the adsorption of peptides and proteins. UHVCE separations of peptides and proteins using these coating have been reported

**FIGURE 24.6** Schematic diagram showing the operation of the injection port for sampling at low voltage. (Reprinted from Henley, W. H., PhD Dissertation, University of North Carolina, Chapel Hill, 2005. Copyright 2005. With permission.)

with UV absorbance and ESI-MS.<sup>6</sup> Large improvements were seen in resolution and efficiency using UHVCE compared with shorter capillaries run at the same field strength at lower voltages.

If the capillary is filled with a suitable sieving matrix, polymers such as nucleic acids<sup>6</sup> and hyaluronic acid<sup>12,14</sup> can be separated using UHV capillary gel electrophoresis (UHVCGE). Figure 24.9 shows four separations of MegaBASE™ 4 Color Sequencing Standard using different lengths of 75  $\mu\text{m}$  i.d., 360  $\mu\text{m}$  o.d. acrylamide-coated capillary filled with MegaBACE™ Long Read Matrix (Amersham Biosciences). The applied voltage ranges from  $-9$  kV in the 60 cm capillary to  $-83$  kV in the 5.5 m capillary to maintain a constant field strength of 150 V/cm. The time has been rescaled for the longer separations by a factor of  $X$  (given in the legend) so that the resolution improvements at higher applied voltages can be easily seen.

Neutral analytes have been separated using UHV micellar electrokinetic chromatography (UHVMEKC).<sup>12,15</sup> This was demonstrated by the separation of oligosaccharide mixtures in a surfactant-containing buffer. Higher resolution was achieved using UHV than standard running voltages, and plate counts over 1 million plates were seen.

#### 24.2.2.5 Limitations

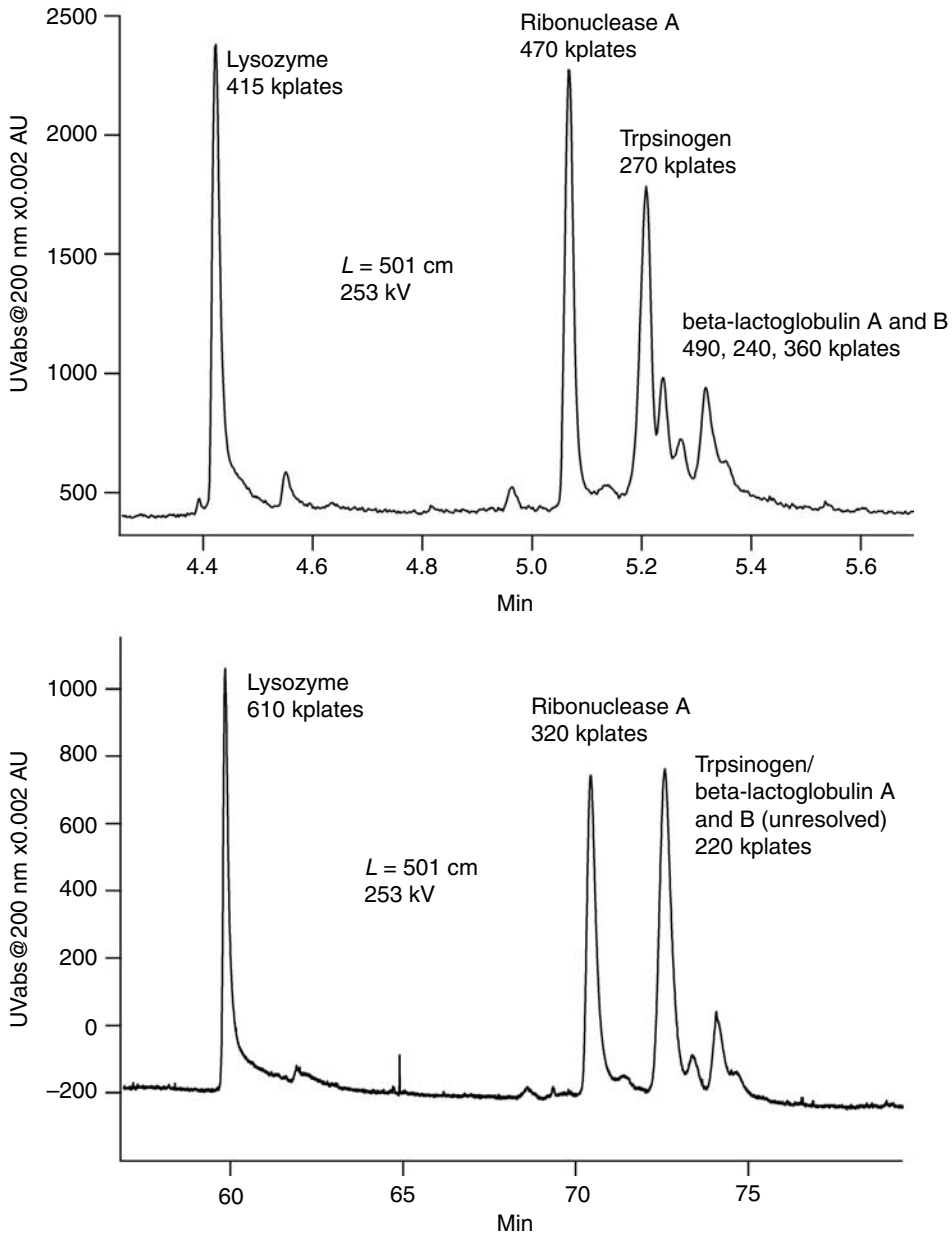

Despite the advantages offered by UHVCE, several problems still limit its application. The lack of available instrumentation and unfamiliarity with voltages in excess of 30 kV keep many potential applications from being explored. The dangers involved with working at such high voltages are more perceived than real, and safety can be assured by using a grounded Faraday cage with interlocks designed to protect the operator from high voltage discharges. Also, the stored energy in most high voltage systems is usually very small, much less than 50 J for the current UHVCE system.

**FIGURE 24.7** Separations of a model peptide sample run on the same capillary at conventional and UHV. The 10-fold increase in electric field strength improves efficiency and reduces separation time 10-fold. Resolution increase can be clearly seen by the closely migrating impurity peaks. (Reprinted from Henley, W. H., PhD Dissertation, University of North Carolina, Chapel Hill, 2005. Copyright 2005. With permission.)

#### 24.2.2.6 Methods Development Guidelines

Part of the advantage of UHVCE is that it allows the use of known separation systems that work well for similar analytes but are unable to completely resolve the analytes of interest using conventional voltages and capillary lengths. Several factors relating to the buffer system and capillary should be taken into consideration before attempting to use a separation system for UHVCE.

**FIGURE 24.8** Separation improvements are not realized in longer capillaries at higher voltages if analyte adsorption occurs. Shown here is a separation of proteins in short (a) and long (b) capillaries under the same electric field strength. Efficiency and resolution are actually reduced at UHV conditions due to analyte adsorption over the long capillary wall. (Reprinted from Henley, W. H., PhD Dissertation, University of North Carolina, Chapel Hill, 2005. Copyright 2005. With permission.)

#### 24.2.2.7 Buffer Selection

When selecting a buffer for UHVCE, the conductivity of the buffer must be as low as possible so that the electric field strength can be high without unacceptable Joule heating. The maximum field strength for a buffer/capillary system can easily be found by generating a current to field strength

**FIGURE 24.9** Separations of DNA sequencing standard rescaled in the time domain by factor  $X$  for comparison of resolution improvements at higher applied voltages. Longer lengths ( $L$ ) of capillary were used to maintain a constant 150 V/cm field strength. (Reprinted from Henley, W. H., PhD Dissertation, University of North Carolina, Chapel Hill, 2005. Copyright 2005. With permission.)

plot using a conventional power supply in a short piece of capillary. The onset of appreciable Joule heating can be found at the field strength where the plot begins to show nonlinear behavior.

High concentrations of salt are used in some buffers to prevent adsorption of analyte molecules (peptides and proteins<sup>17</sup> in particular) to the capillary wall. Zwitterionic molecules contain an equal number of positive and negative charges at a pH equal to their isoelectric point. They can be used to raise the ionic strength of the buffer without increasing the conductivity greatly. In UHVCE applications, they can sometimes be substituted for more conductive buffers to allow the use of higher field strengths while maintaining sufficient ionic strength to reduce analyte adsorption. It is important to note that the pI of the zwitterionic molecule may be several pH units different from their  $pK_a$  values. In cases where this occurs, they cannot be relied upon to buffer the solution effectively.

High concentrations of ions with small radii of hydration such as  $H_3O^+$ ,  $K^+$ , and  $OH^-$  should be avoided. These small ions are rapidly transported within the linear electric field of the capillary, resulting in high electric currents. For this reason, ions with lower mobility such as  $Li^+$  and  $CH_3COO^-$  should be substituted wherever possible.<sup>18</sup>

The buffer capacity can become important in separations of extended duration. For example, a CGE separation requiring 30 min on a 30 cm capillary will require 300 minutes on a 300 cm capillary if the same electric field strength is used. The 10-fold increase in analysis time results in 10-fold the amount of electrolysis products that must be dealt with by the buffer. The moles of  $OH^-$  at the cathode can be calculated from the electrophoretic current ( $i$ ):

$$it \frac{1}{F} = \text{molOH}^-, \quad (24.6)$$

where  $t$  is time in seconds and  $F$  is Faraday's constant. A significant pH shift can cause problems with reproducibility. Large capacity buffer vials can be used if the instrumentation has enough available space.

Buffer systems that do not adequately address problems of analyte adsorption will not be compatible with UHVCE in long capillaries.<sup>6</sup> Buffers that contain ions with significantly different mobilities from the analyte ions will also result in electrodispersion that will be exacerbated by long separation distances. Both of these problems can be avoided by examining the shape of the analyte bands in short capillaries at lower voltages. Peaks that show fronting or tailing indicate potential problems, whereas highly Gaussian peaks indicate compatibility with UHVCE.

#### 24.2.2.8 Capillary Selection

The length of the capillary should be determined by the desired degree of improvement over a known, lower voltage, separation. For example, if twice the resolution of a known system using 30 kV in a 50 cm capillary is desired, then 120 kV should be used in a capillary 2 m long. This separation will also require fourfold the time.

Joule heating can be avoided by simply reducing the power consumption of the capillary. Reducing the capillary diameter by half decreases the current fourfold. For the separation described above, a 50 cm length of capillary with half the diameter could be used at 120 kV without excessive Joule heating. In this case, the separation would require fourfold *less* time.

The inner diameter of the capillary cannot be decreased too greatly if UV absorbance is used for detection. Below  $\sim 50 \mu\text{m}$ , the pathlength is too short for sensitive detection. ESI-MS also requires a certain flow rate for optimal detection that may not be achievable in very narrow capillaries. LIF detection is well suited for use with narrow capillaries, but not every analyte can be labeled with fluorescent tags.

#### 24.2.2.9 Sample Separation Strategies

Unlike techniques that are limited to a narrow range of analyte properties, UHVCE is well suited for the analysis of complex samples containing analytes with a broad spectrum of properties (Figure 24.1). These samples include, among others, cell lysates, protein digests, or DNA sequencing preparations. The UHVCE analysis of samples should ideally start with a fairly concentrated sample containing low amounts of salt. High sample ionic strength can result in electrodispersion of the sample when used with low conductivity buffers. Dilute samples can be problematic if poor detection limits require excessively large sample injections.<sup>19</sup> This may or may not be solved using sample stacking techniques.

The best solution found thus far for the preventing peptide and protein samples from adsorbing to the capillary wall in UHVCE is electrostatic repulsion. This can be accomplished in bare silica capillaries by using very basic pH buffers where the deprotonated silanol groups and the majority of peptides and proteins are negatively charged. This method is not directly compatible with positive mode ESI-MS, but may work for UV absorbance detection or LIF.<sup>17</sup>

Various coatings that impart a positive charge to the surface can be used for low pH separations. Covalently bound coatings such as aminopropyltrimethoxysilane have been used with good success for UV detection and ESI-MS of peptides.<sup>20,21</sup> Other coating schemes based on the same principles have been used to varying degrees of success, and diisopropylaminopropylethoxysilane has shown remarkable stability to degradation from hydrolysis.<sup>6,22</sup> Cationic polymers such as PolyE-323<sup>23,24</sup> have been used to great effect for CE/ESI-MS for proteins and peptides. These coatings are easily applied to long capillaries and stable in buffers with organic modifiers.

The analysis or sequencing of DNA in CE and its advantages over standard slab gels has been well documented.<sup>25-40</sup> Preliminary study of UHVCE for DNA separations indicates that it may be best suited for high-resolution separations of relatively short sequences of DNA.<sup>6</sup>

Polysaccharides and other complex carbohydrates can be difficult to analyze for several reasons. The lack of charged moieties requires the use of a sieving gel or pseudo-stationary phase. Sieving gels can be quite useful for highly branched structures found in some of these analytes. UHVCGE or UHVMEKC has been shown to be useful for high-resolution analysis of these samples.<sup>12,14,15</sup>

## 24.3 FLOW COUNTERBALANCED CAPILLARY ELECTROPHORESIS

### 24.3.1 BACKGROUND

The effectiveness of capillary electrophoretic separations can be greatly affected by the magnitude and direction of the bulk fluid flow. As pointed out by Jorgenson and Lukacs,<sup>4</sup> analyte bands that migrate in the direction opposite to the EOF spend a greater amount of time in the electric field and thus are more affected than analytes that migrate with the EOF. Direct manipulation of the EOF or application of hydrodynamic (pressure driven) flow can be used to retard the migration of analytes to improve efficiency and resolution. Resolution improvement by the direct control of the EOF through the manipulation of radial electric fields has been shown at low pH and low ionic strength.<sup>41</sup> Cheng et al.<sup>42</sup> noted the potential of a counter flow to improve the resolution of analytes in a paper investigating the effect of a constant applied pressure from a sheath flow cuvette on separations of amino acids during CE separations. Pressure driven flows have also been used for the preconcentration of samples for capillary isotachopheresis with long preconcentration times in short capillaries.<sup>43–49</sup> Reduction of the EOF using surfactants and polymers to increase the viscosity of background electrolyte near the wall has also been demonstrated for resolution improvement.<sup>50–55</sup> Lucy and McDonald<sup>51</sup> used this technique to resolve the major isotopes of chlorine using CE. Several preparative scale purification techniques using a counter flow have been reported for enantiomers and other closely related species.<sup>56–63</sup> Another study used a counter flow to prevent buffer components that improve selectivity but increase the UV absorbance background signal from reaching the detector.<sup>64</sup>

A practical system for analytical scale high-resolution separations was first demonstrated by Culbertson and Jorgenson.<sup>65</sup> Narrow diameter capillaries and LIF detection were used to resolve analytes with extremely small differences in mobility such as peptide isomers. Misleveling of the buffer reservoirs, using a siphoning action to provide a counter flow in large diameter capillaries, was also reported with modest resolution improvements.<sup>66</sup>

Band broadening caused by the counter flow limited high-resolution FCCE to narrow bore capillaries and LIF detection for over a decade. Recently, the use of large diameter capillaries packed with bare silica particles to flatten the parabolic flow profile of the counter flow has been demonstrated.<sup>67</sup> Packed capillary FCCE should not be confused with capillary electrokinetic chromatography (CEC). Packing material used in FCCE serves no chromatographic purpose and does not act as a stationary phase. The purpose of the packing material is simply to prevent band broadening in large bore capillaries so that UV absorbance detection can be used to detect unlabeled analytes.

### 24.3.2 THEORETICAL ASPECTS

The power of FCCE lies in the ability to maintain analyte bands within a high electric field strength for a long period of time. A counter flow is applied that pushes the bulk solution in the direction opposite to the analyte's migration, extending the duration of the separation. For a given length ( $L$ ) of capillary with applied voltage ( $V$ ), the electric field strength ( $E$ ) is simply

$$E = \frac{V}{L}. \quad (24.7)$$

The time ( $t_m$ ) required for an analyte band to migrate a distance equal to the length of the capillary ( $L$ ) can be determined from the following equation:

$$t_m = \frac{L}{E(\mu_e + \mu_{EOF})}, \quad (24.8)$$

where  $\mu_e$  is the analyte's electrophoretic mobility and  $\mu_{EOF}$  is the mobility of the EOF. Suppose that a counter flow is applied opposite to the direction of the analyte's net migration so that the analyte band now requires fourfold the time to transverse the same length of capillary. The electric field strength, length of capillary, and mobilities of the analyte band and EOF remain unchanged, but now the effective distance ( $L_{\text{eff}}$ ) traveled by the analyte band is equal to  $4L$ . Neglecting any band broadening, an equivalent separation without a counter flow would require a capillary four times as long. In order to obtain the same electric field strength, four times the voltage would have to be applied. This can be thought of as the effective voltage ( $V_{\text{eff}}$ ) that can be determined from the known electric field strength:

$$E = \frac{V}{L} = \frac{V_{\text{eff}}}{L_{\text{eff}}}. \quad (24.9)$$

Since the resolution between two analyte bands scales with the square root of the applied voltage, fourfold the effective voltage would generate twofold the resolution. For example, consider two analyte bands that transverse a 30 cm capillary in an average time of 30 s with 30 kV applied. If the resolution between the bands is 0.5, then a capillary 120 cm long with 120 kV applied would be needed to obtain a resolution of 1.0. The same resolution can be obtained using the 30 cm capillary with 30 kV applied if a counter flow is applied so that the analytes transverse the same distance in 120 s.

EOF is generated at the wall of the capillary, resulting in a flat flow profile that limits band broadening to that caused by longitudinal diffusion. This broadening can be expressed as a variance ( $\sigma_B^2$ ) using Einstein's equation:

$$\sigma_B^2 = 2Dt, \quad (24.10)$$

where  $D$  is the diffusion coefficient of the analyte and  $t$  is time. The application pressure results in a hydrodynamic flow. Flow velocity is greatest in the center of the capillary due to drag at the capillary wall and a parabolic flow profile is the result. Analyte bands diffuse laterally across this flow profile and broaden to a degree proportional to its magnitude (Taylor dispersion). Culbertson and Jorgenson<sup>65</sup> derived an equation for the degree of band broadening for FCCE in an open tube. In addition, the maximum allowable diameter of the capillary was determined from the following expression:

$$\sigma_c^2 = \frac{d_c^2 v_{\text{pa}}^2 t}{96D} \leq 2Dt = \sigma_B^2, \quad (24.11)$$

where the broadening of the analyte bands from hydrodynamic flow is expressed as a variance,  $\sigma_c^2$ , which should be less than or equal to the band broadening caused by longitudinal diffusion alone. The diameter of the open capillary ( $d_c$ ) can be calculated from the average velocity of the hydrodynamic flow ( $v_{\text{pa}}$ ) required to counterbalance the electrokinetic migration of the analyte band and the diffusion coefficient of the analytes ( $D$ ). For the analytes investigated, open tubular capillaries 5–10  $\mu\text{m}$  were deemed acceptable.<sup>65,68</sup> Narrow bore capillaries have a limited optical pathlength and LIF detection is usually required for sensitive detection.

Band broadening from hydrodynamic flow in packed capillaries is independent of capillary diameter, allowing the use of capillaries with a pathlength large enough for UV absorption detection.

A similar equation for band broadening in packed capillary FCCE can be derived, as can a similar method of calculating the required particle diameter ( $d_p$ ) to minimize band broadening.<sup>6,67</sup> Briefly, the total broadening is expressed as a variance ( $\sigma_{\text{total}}^2$ ), which is the sum of the contributions of longitudinal diffusion and hydrodynamic flow:

$$\sigma_{\text{total}}^2 = \sigma_B^2 + \sigma_C^2 = 2Dt + \frac{d_p^2 v_{pa}^2 t_b}{10D}, \quad (24.12)$$

where  $t_b$  is the time during which the counter flow is applied. Using the same strategy as expression 11, the maximum particle diameter can be calculated. The efficiency for FCCE in packed capillaries can be found using the following equation:

$$N = \frac{10D(tv_{ek})^2}{20D^2t + d_p^2 v_{pa}^2 t_b}, \quad (24.13)$$

where  $v_{ek}$  is the average electrokinetic velocity for the analyte bands and  $N$  is the efficiency in theoretical plates.<sup>6,67</sup> High efficiencies can be most easily obtained by using small diameter particles and long separation times.

### 24.3.3 PRACTICAL IMPLEMENTATION

#### 24.3.3.1 Instrumentation

The instrumentation required to perform FCCE is relatively simple. The power supply can be any commercially available HVDC power source, but an ideal power supply would have dual polarity, 0–30 kV at several 100  $\mu$ A, with safety interlocks and computer control capabilities. The maximum voltage needed is determined by the desired electric field strength and length of the capillary. In order to allow for some margin of error in control of the counter flow, the minimum length of capillary should be at least three to four times the physical width of the desired separation window. These margins allow for the analyte bands to be maintained within the inner half of the capillary so that they are not pushed out on either side of the capillary, with detection occurring in the center of the capillary.

The source of the counter flow, or pumping system, is determined by the velocity of the analyte band and the backpressure required to reverse or stop its forward migration. Where the analyte bands migrate slowly in an open tube, the pumping system may be as simple as a misleveling of the buffer vials. Rapidly migrating analyte bands in narrow open capillaries may require a compressed gas driven system such as that shown in Figure 24.10.<sup>65,68</sup> Packed capillaries require much greater pressures and so an high-performance liquid chromatography (HPLC) pump or syringe pump capable of generating the desired fluid velocity must be used (Figure 24.11).<sup>6,67</sup> If an HPLC pump is used, some consideration should be given regarding the volumetric flow rate needed to maintain a stable pressure. Typically, flow rates for HPLC columns range in the mL or  $\mu$ L per minute range. The flow rate for FCCE will be much smaller, typically nL/min. The use of a “splitter” capillary to divert the majority of the flow volume back to the pump’s buffer reservoir can save many liters of running buffer. This may be especially important for buffers containing expensive reagents. Syringe pumps have limited capacity and the flow rate will therefore determine the maximum separation time. One notable exception to this is the Haskel International Inc. (Burbank, CA) DSHF-300 Air Driven Fluid Pump. This is a syringe-style hydraulic pump capable of producing up to 50,000 psi of liquid pressure via a 300-fold amplification of applied gas pressure. The advantages of this pump include its stable applied pressure over a volumetric flow rate ranging from no flow at all to a few mL per minute. It has a low stroke volume of a few mL, but it automatically recycles and refills itself at the end of a piston stroke, maintaining a fairly constant pressure with built in check valves.

**FIGURE 24.10** Open tube FCCE using a gas pressure driven pumping system. (Reprinted from Culbertson, C. T. and Jorgenson, J. W., *Analytical Chemistry* 1994, 66, 955–962. Copyright 1994 American Chemical Society. With permission.)

**FIGURE 24.11** Packed capillary FCCE using high pressure from a hydraulic pump controlled by a pneumatically actuated valve. (Reprinted from Henley, W. H., et al., *Analytical Chemistry* 2005, 77, 7024–7031. Copyright 2005 American Chemical Society. With permission.)

Ideally, the velocity of the counter flow should be exactly equal and opposite to the velocity of the analyte band so that band broadening from pressure driven flow is minimized. The practical implementation of such a system requires a detector capable of imaging the entire width of the separation window such as a linear diode array or charge-coupled device (CCD) camera.

Single point detectors using UV absorbance or LIF detection require that the analyte bands pass through the detection point in order for data to be collected. Therefore, analytes are first allowed to migrate past the detection point electrokinetically. Then a pressure great enough to push them backwards past the detector is applied via a computer-controlled valve. Once the analytes have been sufficiently pushed back, the pressure is released and the cycle is repeated. The electrophoretic voltage is maintained during the entire course of the separation, so the analytes are continuously separating electrokinetically, even while being pushed backwards by the counter flow. An alternative scheme using constant pressure with intermittently applied voltage would only resolve the analytes while the voltage was applied.

Valves for controlling the back pressure must actuate quickly, be rated to the desired pressure, and ideally be computer controlled. As long as the pressure remains constant, dead volume is usually not a major concern. If the valve is constructed from metal, it must be electronically isolated from the electrophoretic system or else electrolysis processes may corrode and destroy the valve, in addition to ruining the separation. Several suitable valves are manufactured by Valco Instrument Co. Inc. (VICI) (Houston, TX).

When making the connection between the capillary and pumping system, it is very important to consider the flow of electrophoretic current and the effect it may have on components of the system. Figure 24.12 shows two ways of connecting a packed separation capillary to the high-pressure pumping system. A stainless steel Swagelok® compression fitting forms a union between the fused-silica capillary and a piece of PEEK tubing. The configuration in Figure 24.12a results in electrolysis products entering the capillary and spoiling the separation. Even though the metal fitting is electrically floating, it is not isolated from the electrophoretic current. Current flows as ions through the capillary and through the PEEK tubing, but the highly conductive metal fitting offers a low resistance path for electrons to travel. The result is that electrolytic processes occur at the surface of the metal near the exit of the capillary and the entrance to the PEEK tubing. An easy way to avoid this is to simply push the capillary into the PEEK tubing so that the metal fitting is truly electrically isolated from the electrophoretic current (Figure 24.12b).

### 24.3.3.2 Capillary Packing

Packing the capillary with nonporous bare silica can greatly reduce the amount of band broadening observed at similar counter flow linear velocities. Figure 24.13 shows the temporal variance of an

**FIGURE 24.12** In order to prevent electrolysis products from entering the capillary at the connection of the capillary to high-pressure counter flow system, metal surfaces must be floating and isolated from the path of the electrophoretic current. (Reprinted from Henley, W. H., PhD Dissertation, University of North Carolina, Chapel Hill, 2005. Copyright 2005. With permission.)

**FIGURE 24.13** A comparison between the band broadening seen in a pack capillary and open tubular capillary under similar counter flow linear velocities shows much less broadening in the packed capillary. (Reprinted from Henley, W. H., et al., *Analytical Chemistry* 2005, 77, 7024–7031. Copyright 2005 American Chemical Society. With permission.)

R-(–)-epinephrine peak using a 50  $\mu\text{m}$  open tubular capillary (OTC) and a 75  $\mu\text{m}$  capillary packed with 4.1  $\mu\text{m}$  nonporous bare silica particles. The diameters of the capillaries were chosen so that they would have approximately the same dead volume and electrophoretic current. It is easy to see from the plot of temporal variance versus counter flow linear velocity that much less broadening is seen in the packed capillary as compared with the large diameter open tube.

The preparation of the packed capillary for FCCE using UV absorbance detection is not difficult, but it differs in several aspects from the methods used to prepare capillary HPLC or UHPLC columns.<sup>69</sup> For chromatography, capillaries are typically run with mobile phases flowing in the same direction as the capillary was packed. For FCCE, the alternative application and release of pressure flowing opposite to the flow of the EOF causes large voids to develop within the packed bed. Consolidation of the capillary can be achieved via sonication under hydrodynamic flow.<sup>70,71</sup> Briefly, dry silica particles are tapped into one end of an OTC. Heat from an electric arc is used to sinter them together and to the capillary wall. Pressure (up to 50,000 psi) from packing bomb is used to force a  $\sim 10$  mg/mL slurry of packing material into the open end of the capillary. After the bed is packed, an inlet frit is sintered at the head of the bed using a heated tungsten wire. The pressure is released, and the capillary is cut to length. The capillary, except for the fritted ends, is placed into a water bath and sonicated for  $\sim 5$  min. Pressure is then applied to the capillary in the direction opposite to that in which it was originally packed. A  $\sim 5$ –10% reduction in the length of the packed bed should be observed. A new frit is then sintered using a heated tungsten wire while the capillary is still under pressure. Sonication can be repeated with pressure applied from the opposite end if further consolidation is desired. Figure 24.14 shows how the consolidation of the packing material reduces band broadening caused by the counter flow. The same capillary was used for measurements of an R-(–)-epinephrine peak using 3.1  $\mu\text{m}$  nonporous bare silica packing.<sup>6,67</sup>

### 24.3.3.3 Modes of Operation and Examples

Open tube FCCE can be performed in capillaries of relatively large diameter if the analyte bands migrate slowly and only a modest improvement in resolution is desired. Misleveling of buffer vials can provide a simple way of improving the resolution for analyte bands that are almost, but not quite resolved under standard conditions.<sup>66</sup> Band broadening will occur but usually not to a great extent over short durations.

**FIGURE 24.14** Reducing the interparticle porosity of the capillary packing can decrease the amount of band broadening caused by the counter flow. Data taken from migration of *R*-(-)-epinephrine using 3.1  $\mu\text{m}$  nonporous bare silica packing. (Reprinted from Henley, W. H., et al., *Analytical Chemistry* 2005, 77, 7024–7031. Copyright 2005 American Chemical Society. With permission.)

Open tube FCCE in narrow capillaries using zone electrophoresis is useful for resolving analytes that can be tagged with fluorescent labels for LIF detection. Culbertson<sup>72</sup> demonstrated resolution of the peptide fragment YAGAVVNDL and YAGAVVNDI (Figure 24.15), which only have an electrokinetic mobility difference of 1.0033.

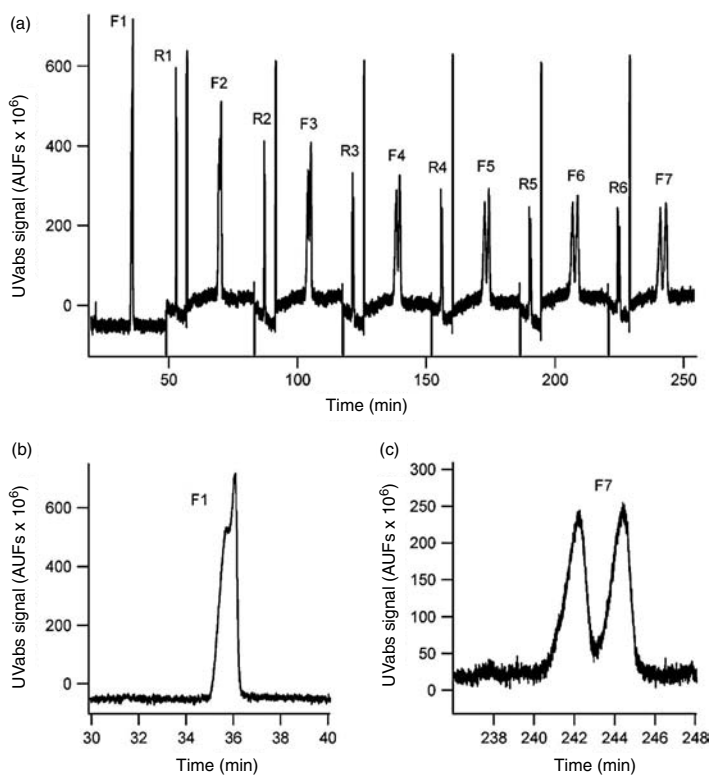

Open tube FCCE using micellar electrokinetic chromatography (MEKC) can be used to obtain high resolution for charged or neutral analytes. High-resolution separations of TRITC-labeled phenylalanine with different numbers of hydrogen atoms replaced with deuterium atom showed resolution between analytes with differences of a single neutron (0.16% mass difference). The relative levels of deuterium substitution could also be determined from the peak areas. The ability of FCCE with MEKC to separate these isotopomers is believed to be based on slight differences in hydrophobicity caused by the influence of the heavier deuterium atom.<sup>68</sup>

Packed capillary FCCE can be used with larger diameter capillaries with sufficient pathlength for sensitive UV/Vis absorption detection. UV detection allows analysis of nonfluorescent analytes and sample impurities. Most organic and some inorganic compounds absorb UV or visible light to some degree, and therefore packed capillary FCCE can be used for a much larger range of analytes than open tubular FCCE.

Separations of racemic samples of several basic and acidic pharmaceuticals using packed capillary FCCE have been reported previously.<sup>6,67</sup> Figure 24.16 shows the separation of the enantiomers of fenoprofen using  $\beta$ -cyclodextrin as the chiral pseudo-stationary phase. The top portion of the figure (a) shows the entire separation. The analyte peak is allowed to electrokinetically migrate pass the detector (forward pass) and then pushed backwards under hydrodynamic flow (reverse pass). Seven cycles with forward passes (F1–F7) and six reverse passes (R1–R6) can be seen in Figure 24.16a. Figure 24.16b shows the first electrokinetic pass in front of the detector. This part of the electropherogram represents the resolution (0.34) and efficiency (21,000 plates) that would result from traditional CE under these separation conditions. Figure 24.16c shows the final pass in front of the detector, where the analyte bands have broadened by a small degree, but are approaching baseline resolution with greatly increased separation efficiency (320,000 plates). Table 24.1 gives a list of acidic and basic pharmaceutical compounds separated with packed capillary FCCE. Electrokinetic only migration times, total number of passes, along with resolution and efficiency improvements are given.

**FIGURE 24.15** Open tube FCCE with LIF detection showing the resolution of YAGAVVNDL and YAGAVVNDI. (Reprinted from Culbertson, C.T., p. 264, 1996, University of North Carolina, Chapel Hill, NC. Copyright 1996. With permission.)

Several isotopomer separations have been reported for packed capillary FCCE. Deuterium-substituted phenylalanine showing no resolution during the first forward pass was almost baseline resolved after an 11 h separation time.<sup>67</sup> Figure 24.17 shows a packed capillary FCCE separation of bromine-79 and bromine-81 using UV absorbance detection. After 6 h of run time (Figure 24.17b), a distinct notch is seen in the bromide ion peak. The separation was maintained for over 60 forward passes requiring over 1100 min, and clear separation of the isotopes can easily be seen.<sup>6,67</sup>

Before attempting MEKC in packed capillaries, an examination of the properties of the micelles under high pressures should be considered. Unpublished work suggests that at the high pressures required for reversing the analyte bands, the properties of the micelles may change, resulting in an unstable system.

## 24.3.4 METHODS DEVELOPMENT GUIDELINES

### 24.3.4.1 Handling Extended Separation Times

The high resolution and efficiency obtained in FCCE separations comes at the expense of extended separation time. Although the buffer within the capillary is replenished by the counter flow,<sup>60</sup> care should be paid to ensure sufficient buffer capacity for reservoirs with fixed volume. Measurements of the electrophoretic current can be used to calculate the expected pH change in each buffer reservoir for a given separation time. In addition, steps should be taken to prevent electrolysis products from entering the capillary. Figure 24.11 shows a long coil of PEEK tubing connected between the capillary and the grounded electrode. This coil has sufficient length and volume to prevent gas bubbles or UV absorbing electrolysis products from entering the separation capillary for many hours under typical counter flow rates.

Automation of the valve control using a computer program is not only useful for ensuring that the analyte band stays within the capillary but also lets the operator leave the instrument running

**FIGURE 24.17** A separation of bromine isotopes using packed capillary FCCE. (Reprinted from Henley, W. H., et al., *Analytical Chemistry* 2005, 77, 7024–7031. Copyright 2005 American Chemical Society. With permission.)

autonomously for hours at a time. There are many different ways to automate the control of the system, but a few basic principles should be followed for reliable operation. After injection of the sample, the electrokinetic migration velocity of the analyte band can be determined by the time it takes to travel the distance to the detector. After allowing the band to travel some distance beyond the detector, the counter flow can be applied (while maintaining the applied voltage). The time required for the analyte band to be pushed back in front of the detector can be used to calculate the analyte band velocity under hydrodynamic flow. These two parameters can be used to calculate the position of the analytes at any given point in the FCCE separation cycle. The progress of the separation should be checked every few hours to correct any timing errors. Adjustments will have to be made for long separations due to variations in pump pressure, EOF velocity, and buffer viscosity caused by temperature changes or buffer depletion.

#### 24.3.4.2 Band Broadening Prevention

One of the main advantages of FCCE is that published buffer conditions that may not completely resolve certain analytes in a traditional CE system can be used to fully resolve the analytes by giving them more time to separate. This can save method development time when analyzing a variety of

compounds with similar characteristics. The main limitation on the timescale of an FCCE experiment is the degree to which band broadening reduces the analyte signal strength, and therefore the counter flow velocity should be kept as low as possible.

Adsorption of the analyte to the capillary wall or bare silica packing material must also be prevented to avoid signal loss. Electrostatic repulsion works well for negatively charged species in basic buffer with bare capillaries. Amine or other basic analytes can be analyzed at low pH in bare capillaries if a competitive inhibitor such as triethylamine is added to the running buffer. The use of dynamic coatings such as polymers or surfactants in the running buffer to reduce adsorption of analytes is probably best suited to open tubular FCCE as increased viscosity may result in high back pressures in packed capillaries. Permanent, covalently bound coating should be used only after their long-term stability has been confirmed, and analyte band migration time should be closely monitored.

Electrodispersion can be a major source of band broadening in FCCE due to the long separation times. Close matching of the electrophoretic mobilities of the analyte bands and running buffer can reduce electrodispersion greatly. Gaussian-shaped peaks usually indicate a compatible sample/buffer whereas fronted or tailed peaks indicate potential problems. Furthermore, the ionic strength of the running buffer should be closely matched to that of the sample.

In addition, in packed capillary FCCE, care must be taken to ensure that the packing material is fully consolidated. Voids in the packed bed will dramatically increase the observed broadening as seen in Figure 24.14.

#### 24.3.4.3 Determining the Best Separation Strategy

The first thing to consider when designing an FCCE separation strategy for a particular sample is the desired method of detection. Both open tubular FCCE and packed capillary FCCE have their advantages and drawbacks. Open tube FCCE uses a slightly less complicated instrumental setup (Figure 24.10) than packed capillary FCCE (Figure 24.11). While not difficult, the equipment and skills needed to pack capillaries with bare silica particles can represent a considerable investment. The high sensitivity of LIF detection makes open tube FCCE the method of choice for analytes that can be easily labeled with fluorescent tags such as peptides and protein fragments.

FCCE in packed capillaries can be used for many more types of analytes. Direct or indirect UV/Vis absorbance detection can be used to detect everything from monoatomic ions like  $\text{Br}^-$  to basic and acidic pharmaceuticals.

Pseudo-stationary phases can be used to improve the resolving power of either type of FCCE. MEKC works well in narrow diameter open tubes for separating neutral analytes based on their hydrophobicity differences. Chiral selectors such as cyclodextrins can be used with either method. Other methods of detection such as noncontact conductivity and modes such as CEC have yet to be explored but may prove useful in the future.

## 24.4 SYNCHRONOUS CYCLIC CAPILLARY ELECTROPHORESIS

### 24.4.1 BACKGROUND

Synchronous cyclic CE, as the name implies, uses a series of electrodes placed at regular intervals around a closed loop to “chase” analyte bands around a continuous separation channel. Voltage switching is synchronized to maintain analytes of a particular mobility within the separation channel for a long period of time.<sup>73</sup> A similar concept had been applied in chromatography using two chromatographic columns and timed valve changes to continuously separate analyte bands.<sup>74</sup> The problems connecting separation channels on the extremely small scale of capillary electrophoretic systems prohibited the implementation of SCCE until several years later.<sup>75</sup>

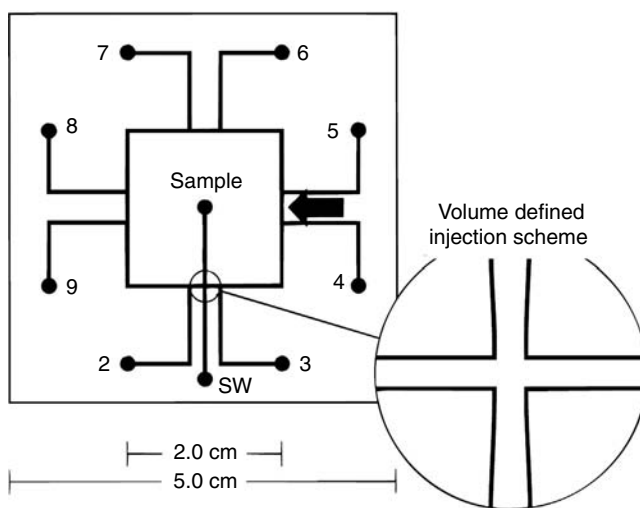

### 24.4.1.1 Microchip SCCE

Burggraf et al.<sup>75–77</sup> reported the first practical SCCE system using microfluidic technology. Photolithographic techniques can be used to cheaply manufacture microfluidic structures with channels one to several hundred microns in dimension. The interconnection of these channels can be used to create networks with negligible dead volumes. The first pattern used for SCCE was four overlapping, 2-cm channels arranged in a square. An additional channel intersecting the middle of a main channel was used to perform electrokinetic injections. Several other designs have since been reported by Manz's group.<sup>78,79</sup> Figure 24.18 shows the layout for an SCCE that was used to separate fluorescently label amino acids and human urine.<sup>79</sup>

### 24.4.1.2 Capillary SCCE

The use of polyimide coated fused-silica capillaries for SCCE with low dead volume connections was first reported by Zhao et al. in 1999.<sup>80,81</sup> Fused-silica capillaries offered several advantages over the microchip-base SCCE systems. The capillaries provided longer separation distances for the analyte bands. While the geometry of the connections on a microfluidic device cannot be easily changed during an experiment, the use of adjustable gaps between the capillaries provides very low dead volume. In addition, conventional UV-Vis absorption detection was feasible for SCCE for the first time using capillaries 50  $\mu\text{m}$  in diameter. A basic schematic representation of the instrumental setup is shown in Figure 24.19.<sup>80</sup>

Another device has been reported, the “electrophoretotron” that used two capillaries with different polarity surface treatments. The capillaries were connected in a loop and a single power supply was used to apply a fixed potential across the two capillaries. The different polarity surface treatments cause the EOF to flow in a continuous loop around the capillaries. Injected analytes would continuously travel around the loop under the influence of the EOF.<sup>82</sup> Such a device may prove useful for CEC separations of neutral analytes. However, any separation of charged species in one capillary will be almost negated in the second capillary due to the change in the polarity of the electric field.<sup>73</sup>

**FIGURE 24.19** Schematic representation of capillary-based SCCE system used to resolve isotopomers and enantiomers. (Reprinted from Zhao, J., et al., *Journal of Microcolumn Separations* 1999, 11, 431–437. Copyright 1999 John Wiley & Sons, Inc. With permission.)

## 24.4.2 THEORETICAL ASPECTS

### 24.4.2.1 Absolute versus “Effective” Voltage

The electric field strength is determined by the applied potential difference divided by the distance over which it is applied. SCCE is similar to FCCE in that the effective separation voltage can be much higher than the actual, physically applied voltages. For a single cycle, the effective voltage is twice that of the applied voltage. For an analyte band transversing  $n$  cycles, the effective voltage ( $V_{\text{eff}}$ ) is

$$V_{\text{eff}} = 2nV_{\text{applied}}, \quad (24.14)$$

where  $V_{\text{applied}}$  is the applied voltage. Using Equation 24.2, an equation for the expected resolution between two analyte bands for a given applied voltage can be derived:

$$R_s = 0.177(\mu_1 - \mu_2) \left( \frac{2nV_{\text{applied}}}{D((\bar{\mu}_e + \mu_{\text{EOF}}))} \right)^{1/2}. \quad (24.15)$$

### 24.4.2.2 Band Broadening Mechanisms

There are several sources of band broadening in SCCE to consider. Longitudinal diffusion occurs in all CE separations. As seen in Equation 24.10, it is mainly governed by separation time and the analyte’s diffusion coefficient.

Turns in the separation channel create another source of band broadening.<sup>83–87</sup> As the analyte bands migrate around a turn, the portion of the band on the inside of the turn travels a shorter distance than the portion of the band on the outside of the turn. In addition, the electric field is concentrated near the wall of the inside of the turn, increasing the rate of band broadening. Taylor dispersion then

smoothes out the distorted band shape. The dispersion created by a turn in the separation channel can be described as a variance

$$\sigma_{\text{turn}}^2 = \frac{(\Delta l)^2}{X} = \frac{(2\theta w (1 - \exp(-t_D/t_t)))^2}{X} \quad (24.16)$$

where  $\Delta l$  is the difference in length traveled around the inside and outside of the turn,  $\theta$  is the angle subtended in radians,  $w$  is the width at the top of the separation channel,  $t_D$  is transverse diffusion equilibrium time,  $t_t$  is the turn transit time, and  $X$  is a constant  $\cong 12$  when  $t_D$  is large.<sup>83</sup> The smaller radius of curvature found in microchip-based channels exacerbate this phenomenon, which is typically not a concern in capillary-based SCCE.

Broadening at the connections (corners on microchip-based SCCE) between the separation channels is another important source of band broadening and sample loss in SCCE. The total broadening can be expressed as a variance,  $\sigma_{\text{total}}^2$

$$\sigma_{\text{total}}^2 = \sum_{i=\text{sides}} \sigma_i^2 + \sum_{j=\text{corners}} \sigma_j^2 = \sigma_{\text{migr.dist}}^2 + n\sigma_{\text{corner}}^2, \quad (24.17)$$

where  $n$  is the number of corners the band travels through,  $\sigma_{\text{migr.dist}}^2$  is the variance from the total migration distance, and  $\sigma_{\text{corner}}^2$  is the broadening caused each time a band travels through a corner or connection of channels.<sup>75</sup>

### 24.4.3 PRACTICAL IMPLEMENTATION

#### 24.4.3.1 Power Supply and Voltage Switching

Power supplies for microchip-based SCCE and fused-silica capillary-based SCCE mainly differ in the number of power supplies and in the magnitude of the applied voltage. The small size found in most microchip-based SCCE systems limits the separation channel length and so relatively small potential differences are needed to generate high electric field strengths ( $\sim 2$  kV/cm). In contrast, capillary-based SCCE use approximately 50 cm lengths of capillary, and so power supplies generating up to 30 kV and a few hundred microamperes are typically used. The configuration of the separation channels determines the number of HV electrodes needed. The actual number of HV supplies needed can be reduced if relays are used to switch the potential between different electrodes. The fused-silica capillary-based SCCE instrumentation reported used a single 30 kV HV supply with four HVDC relays.<sup>80</sup> The first chip-based SCCE system used four HV power supplies at 2.5 kV and eight HV relays to control the voltage switching.<sup>75,76</sup> Later work with chip-based SCCE used six 10 kV HV supplies and thirteen HV relays.<sup>79</sup> Different geometries with shorter capillary channels were also studied. A triangular arrangement resulted in the fewest HV supplies needed.<sup>78</sup>

#### 24.4.3.2 Connection of Fused-Silica Capillaries

While the connection of the separation channels used in microchip-based SCCE can be manufactured with almost no dead volume using photolithographic techniques, connection of fused-silica capillaries is challenging. Zhao et al.<sup>80,81</sup> report the use of a controllable gap using a cross flow connection and a tight fitting Teflon sleeve (Figure 24.20). The gap between the capillaries offers several advantages over other methods. In order to allow the flow of electrophoretic current, the gap is opened, which also allows fresh buffer to flow into the capillary network and old buffer to be removed. While the analyte bands migrate through the gap, the gap is tightly closed, reducing the dead volume dramatically. This system can be implemented with solenoid, piezoelectric, hydraulic, or even manual actuation. Careful preparation of the capillaries is required to ensure a tight, low loss

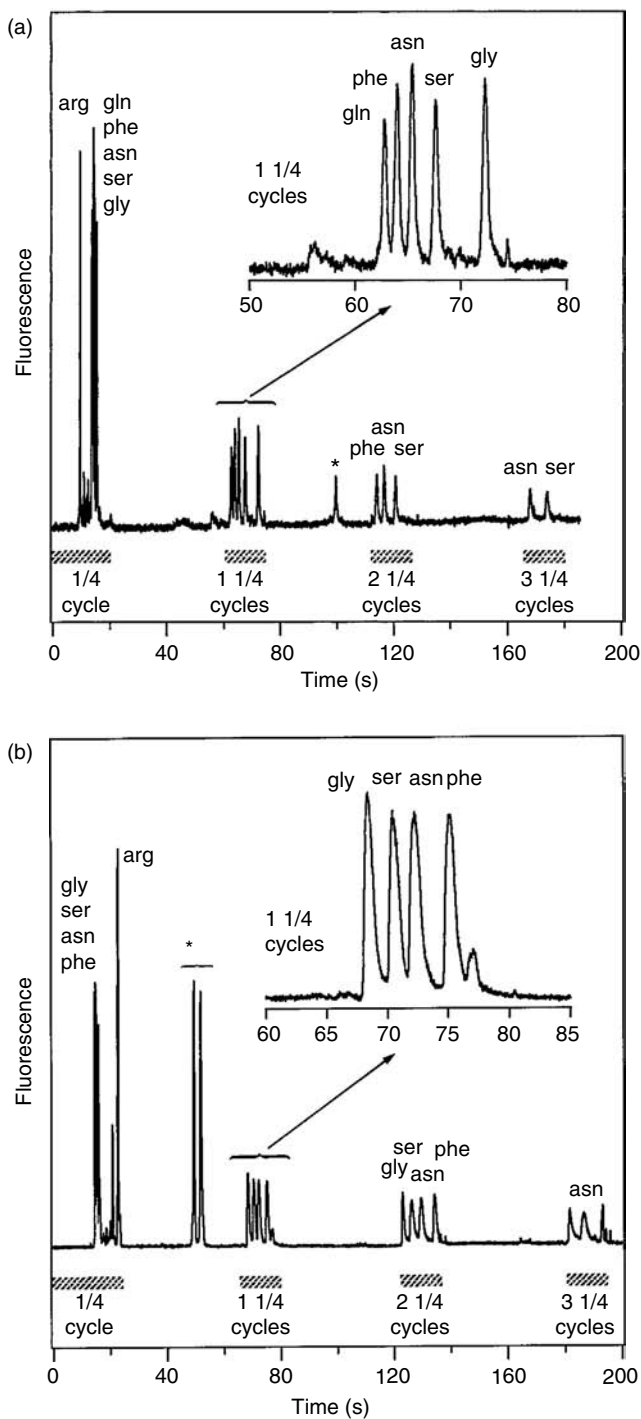

**FIGURE 24.20** Schematic diagram detailing the connection of the capillaries and the controlled gap for capillary-based SCCE. (Reprinted from Zhao, J., et al., *Journal of Microcolumn Separations* 1999, 11, 431–437. Copyright 1999 John Wiley & Sons, Inc. With permission.)

fit. Capillaries were cut to precisely equal lengths so that  $E$  fields and flow velocities would be equal in each length of the four capillaries. The ends of the capillaries were polished flat using a jeweler's lathe and fine grit sandpaper to ensure a perfectly flat mating surface.<sup>80</sup>

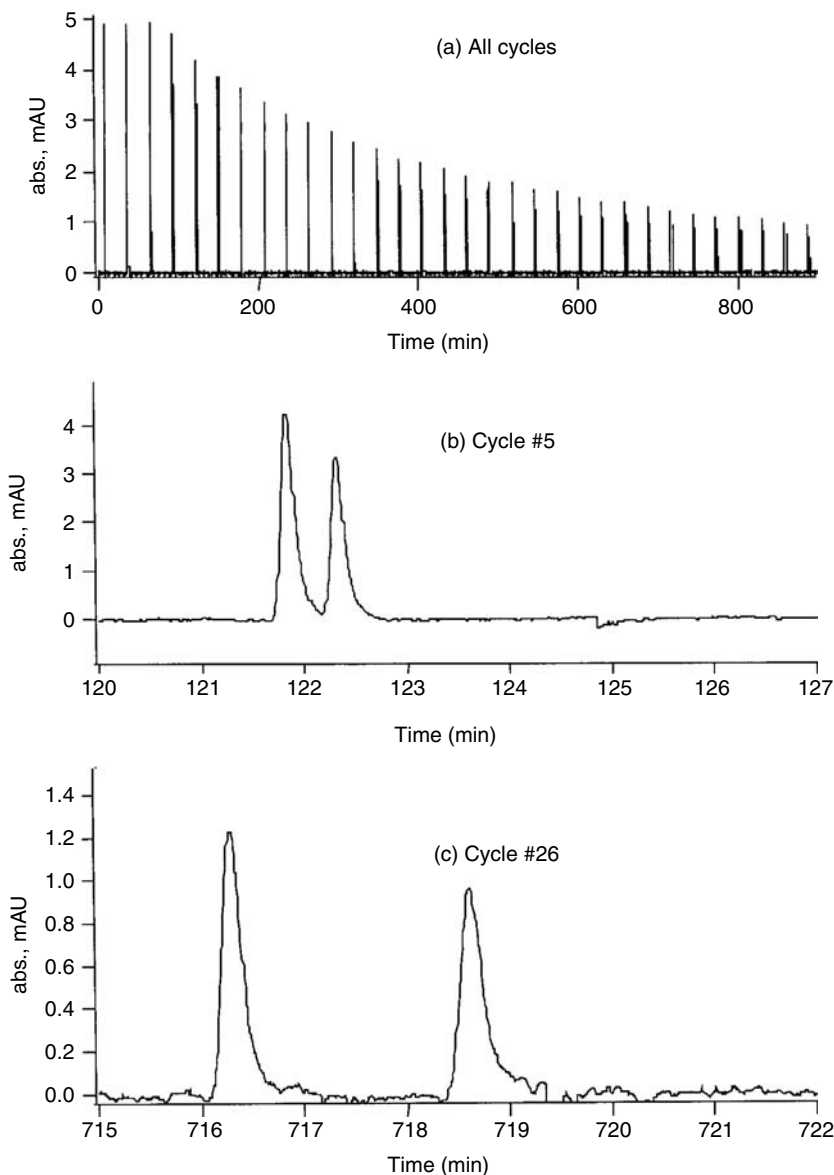

### 24.4.3.3 Modes of Operation and Examples

Capillary zone electrophoresis with microchip-based SCCE has been used to separate fluorescent dye from degradation products<sup>88</sup> and to separate fluorescein isothiocyanate (FITC) labeled amino acids.<sup>78</sup> Capillary zone electrophoresis (CZE) in fused-silica capillaries has been used to separate the racemic mixtures of ( $\alpha$ -hydroxybenzyl)methyltrimethylammonium and (2-hydroxy-1-phenyl)ethyltrimethylammonium with  $\beta$ -cyclodextrin as the chiral pseudo-stationary phase.<sup>81</sup> L-Phenylalanine and L-phenylalanine-ring-D5 (the hydrogens in the aromatic ring were substituted with deuterium)<sup>81</sup> and another separation of the closely related amino acids phenylalanine and tyrosine have been resolved using CZE with capillary-based SCCE.<sup>80</sup>

MEKC has been implemented in both microchip-based SCCE separations and capillary-based SCCE separations. Figure 24.21a shows a microchip-based SCCE separation using MEKC of FITC-labeled amino acids.<sup>79</sup> The same chip was also used to resolve FITC-labeled components of human urine using MEKC in addition to performing an MEKC-based immunoassay of serum theophylline levels.<sup>79</sup> MEKC using capillary-based SCCE has resulted in separations with as many as 100 million theoretical plates in 15 h of run time. A separation of L-phenylalanine and L-phenylalanine-ring-D5 is

**FIGURE 24.21** (a) MEKC separation of FITC-labeled amino acids using microchip-based SCCE. (b) CGE separation of FITC-labeled amino acids using the same microchip-based SCCE device. (Reprinted from von Heeren, F., et al., *Analytical Chemistry* 1996, 68, 2044–2053. Copyright 1996 American Chemical Society. With permission.)

**FIGURE 24.22** MEKC separation of phenylalanine and phenylalanine-ring-D5 using capillary-based SCCE. (Reprinted from Zhao, J. and Jorgenson, J. W., *Journal of Microcolumn Separations* 1999, 11, 439–449. Copyright 1999 John Wiley & Sons, Inc. With permission.)

shown in Figure 24.22. These two analytes have only a 0.4% mobility difference and were separated in only 14 h.<sup>81</sup>

CGE separations have been reported using microchip-based SCCE. Figure 24.21b shows an SCCE with CGE separation of FITC-labeled amino acids.<sup>79</sup> SCCE with CGE has also been used with another microchip design for the separation of a PhiX174/Hae III DNA ladder. Separations with difference synchronization times were used to isolate different DNA fragments.<sup>78</sup>

#### 24.4.3.4 Methods of Detection

Laser-induced fluorescence detection is a logical choice for high-resolution SCCE when performed on microfluidic chip-based systems. High laser power can result in photobleaching, decreasing the analyte signal every time it passes through the beam.<sup>75,76,79</sup>

UV absorbance can easily be done on capillary-based systems using capillaries at least 50–75  $\mu\text{m}$  in diameter. It is a universal method of detection that can be used with high sensitivity with most analytes. The short pathlength provide by the shallow channels make UV absorbance detection difficult to implement on microfluidic systems. In addition, microchip-based systems fabricated from glass instead of fused silica absorb significant amounts of UV, further complicating its implementation. In future experiments, detection methods may include direct conductivity measurements (microchip-based SCCE) and contactless conductivity methods (capillary-based SCCE).

#### 24.4.3.5 Limitations

Theoretically, the ability of SCCE to separate analytes is limited only by longitudinal diffusion. In practice, broadening from the dead volume connecting the separation capillaries and adsorption of the analytes to the capillary wall ultimately limit the efficiency of the separation. Microchip-based SCCE also loses efficiency from broadening around tight turns.

SCCE, similar to FCCE, is a method in which each cycle reduces the range of mobilities that can be analyzed. The result is that the peak capacity of the separation will be reduced during each subsequent cycle. This effect is most notable when short channels and low voltages are used.<sup>78</sup>

The switching of potentials in SCCE causes analytes of the selected mobility to continuously travel around the separation loop in the same direction. Analytes that migrate at higher mobilities are lost at the corners and flushed into the waste reservoirs. Analytes of lower mobility that do not make it into the next separation channel before the potentials are switched will travel in the reverse direction. This can cause data analysis problems for complex samples when these backward migrating peaks pass in front of the detector again. This has been observed in several microchip-based separations including the SCCE separation of fluorescein isothiocyanate and its degradation products,<sup>88</sup> the MEKC and CGE with SCCE separations of FITC-labeled amino acids and human urine,<sup>79</sup> and SCCE of double-stranded DNA in a sieving matrix.<sup>78</sup> While this phenomenon is not much of a problem with relatively simple samples, data analysis may be confusing and complicated for complex samples such as cell lysates.

### 24.4.4 METHODS DEVELOPMENT GUIDELINES

#### 24.4.4.1 Handling Extended Separation Times

The selection of the buffer components is very important in SCCE. Just as in FCCE and UHVCE, careful attention must be paid toward the amount of analyte adsorption to the channel walls. At extended separation times, losses from adsorption will add to reduce the signal to noise value greatly. Although the separation channels are flushed with fresh buffer during the SCCE separation, buffering capacity must be fairly high for long separation times if the reservoir size is small. This is a bigger problem with microchip-based SCCE where typical reservoir volumes are less than 1 mL. Capillary-based SCCE typically uses 20 mL buffer reservoirs and buffering capacity problems are usually not observed.

Similar to FCCE, automation of SCCE voltage switching can greatly improve the reliability and usability of the SCCE system. Zhao et al.<sup>80</sup> report the use of software that determined the rising and falling signal of the detected analyte above a predetermined threshold value during each

cycle and recalculated switching times to ensure that the analyte bands stayed within the separation channels.

Longer separation channels have a few advantages over shorter channels when separation times are long. Longer channels allow longer separation distances without as much broadening and sample loss associated with channel connections and corners. In addition, longer separation channels maintain a higher peak capacity during extended run times, and the analyte bands can broaden considerably without being cut off at the edges.

#### 24.4.4.2 Band Broadening Prevention

Band broadening prevention strategies for SCCE are similar to those used in UHVCE and FCCE. Known formulas can be used for buffer components if little peak tailing is seen under standard CE separations. Electrostatic repulsion from channel walls that share the same electrical charge as the analytes can reduce broadening greatly.

The electrophoretic mobilities of the buffer ions should closely match those of the sample ions to prevent broadening from electrodispersion. Similarly, the ionic strength of the buffer should be greater than or equal to that of the sample.

Several strategies for reducing dead volume at the channel connections have been reported. The use of T-shaped junctions at the middle of the separation channels (Figure 24.19) has been employed in an effort to reduce losses at the corner connections of the separation channels. Experimental observation indicated that broadening was more significant than that seen in previous designs with reservoir connections at the corners.<sup>79</sup> Recently, Manz et al.<sup>78</sup> have reported the use of side channels that are much shallower ( $\sim 1/8$ th depth) than the separation channel in an effort to reduce losses at the connections of the channels.

The use of narrower rounded turns for microchip-based SCCE is reported for reducing band broadening at the corners.<sup>78</sup> This approach has been shown to reduce the broadening seen for turns in other microfluidic chip designs.<sup>83,86,87,89,90</sup> Other, more exotic approaches to reducing dispersion at the turns of channels on microfluidic devices have been reported. One technique using a pulsed UV laser to modify the surface of plastic chips at the turn to increase the EOF by up to 4%. This technique was shown to reduce band broadening at the turns.<sup>91</sup>

#### 24.4.4.3 Sample Separation Strategies

Amino acids and peptides are easily labeled with fluorescent dyes. CZE, CGE, or MEKC in capillary or microchip-based SCCE can typically resolve these analytes. Microchip-based SCCE offers higher sensitivity for very small samples, and higher electric field strengths can be used without Joule heating problems. Capillary-based SCCE offers a much higher peak capacity and the use of UV absorbance detection of unlabeled analytes.

Isotopomers are best separated using capillary-based SCCE due to the extremely long separation times required. The components of the buffer must be carefully selected so that their ionic strength and ion mobility are very close to that of the analytes and adsorption to the capillary wall is prevented. MEKC can be used in some cases to separate isotopomers more quickly than CZE, most likely due to small changes in hydrophobicity caused by deuterium substitution.

Resolution of the enantiomers in a racemic mixture will require the use of a chiral selector such as a cyclodextrin. Fluorescently labeled analytes can be detected at very low concentration using microchip-based SCCE, and unlabeled analytes can be easily detected with UV absorption using capillary-based SCCE. The long separation times available with capillary-based SCCE allows the use of less than optimal chiral resolving agents, whereas a more selective chiral selector is needed in microchip-based SCCE.

## 24.5 CONCLUDING REMARKS

The three techniques presented in this chapter demonstrate different approaches to improving the resolution and efficiency of CE separations. All three methods work by increasing the time and distance that the analyte bands electrophoretically migrate under a high electric field strength, but the different ways in which each method accomplishes this goal determine their useful application.

UHVCE uses the direct application of extremely high voltages on long capillaries, and it allows the examination of analytes that span the entire range of mobilities found within the sample. Samples containing complex mixtures of proteins, peptides, nucleic acids, and many others display a wide range of mobilities and UHVCE is well suited to their analysis.

FCCE and SCCE use conventional voltages on relatively short capillaries, but they maintain analytes with a narrow range of mobilities within the capillaries for very long periods of time. Because high-resolution analysis is limited to such a narrow range of mobilities, FCCE and SCCE are best suited for the analysis of difficult to resolve pairs such as closely related peptides, enantiomers, and isotopomers. The ultimate utility of SCCE and FCCE depends on the ability of the experimenter to eliminate sources of band broadening. The amount of broadening observed in SCCE depends mainly on the design of the instrumentation. Band broadening in FCCE is inherent to the magnitude of the counter flow required to reverse the migration of the analyte bands.

The analysis of extremely complex samples such as cell lysates can be simplified through a combination of these methods. Preliminary high-efficiency, high-resolution analysis with UHVCE can be used to elucidate areas of interest within the sample. After the mobilities of the analytes of interest have been determined, FCCE or SCCE can then be used for much more detailed analysis of particular bands. The analysis of complicated biological samples remains an area where the implementation of these techniques can provide new insight.

## 25.1 INTRODUCTION

Forensic science is defined as the application of science to the law. It is the goal of the forensic scientist to identify and compare physical evidence and use the resulting observations to aid in solving criminal or civil matters. From its inception, forensic scientists have recognized the potential of capillary electrophoresis (CE) as a useful tool to assist in the analysis of a wide array of trace evidence samples [1,2]. This is particularly true for applications in forensic biology. In this discipline, biological fluids (blood, hair, semen) left behind at a crime scene are probed to establish the *essential facts* of the crime. Sample analysis is performed via extraction and analysis of the genetic material within these samples. The key to the procedure is targeting specific locations in the genome containing polymorphisms (different allelic forms) that permit differentiation between individuals. The statistical probability

of an individual inheriting any given polymorphism can then be used to assess the evidence and compare it with known samples from victims and suspects.

In the early years of DNA analysis, the separation and sizing of DNA was accomplished by slab gel electrophoresis. However, since 1998 CE has gradually taken over slab gel techniques in this field because of its ease of automation, minimal sample consumption (which is of utmost importance in the field), and its high-throughput capabilities.

## 25.2 BACKGROUND

Although seldom used for genotyping in current forensic applications, slab gels set the precedent for the development of CE. Slab gel systems had an advantage in forensic analysis in that multiple samples could be run simultaneously, allowing easy comparisons and rapid analysis. The ability to compare different samples on the same gel was particularly useful in early procedures involving restriction fragment length polymorphisms (RFLPs) and multilocus probes. With the RFLP techniques, DNA fragment sizes ranged up to 20,000 bases and results were based on the presence or absence of bands within different size ranges. Separations took place on large format agarose gels and genetic loci were detected using Southern blotting with radioactive probes. As a result, a complete analysis could take several weeks because of the time involved in repetitive DNA transfer, hybridization, and exposure to radioactive film [3].

With the advent of the polymerase chain reaction (PCR), there was a complete paradigm shift. The PCR permits a few copies of a DNA sequence to be amplified to millions of copies [4], thus increasing sensitivity and eliminating the need for radioactive probes. DNA fragment sizes were reduced to a few hundred bases, and the total time for an analysis dropped to a single day. With PCR, sample quantities were sufficient for detection via simple silver staining processes; however due to the smaller size of the alleles, higher resolution acrylamide gels were required. As the exceptional capabilities of the PCR in DNA typing became apparent, law enforcement personnel began to take advantage of the expanded speed and sensitivity that the new technique had to offer. Consequently, an increasing number of evidence samples began to be submitted to laboratories for testing.

Therein arose a new concern. How were laboratories going to be able to handle the bulk of samples received in a timely manner? An analytical technique was needed that could provide as good or better results than those obtained via slab gel systems in a standardized and automated fashion. This technique was to be CE.

The principle governing both slab gel and CE techniques is the same: the separation of a series of analytes based on size selective sieving through a gel or polymer network under the influence of an electric field. The slab gel matrix permits a size-dependent separation of fragments since larger DNA fragments contain an invariant charge-to-size ratio due to their sugar-phosphate backbone. However, slab gels require manual operations such as the preparation of the gel and the loading of samples. Automated CE systems eliminated these tedious tasks and substituted replaceable, entangled polymer solutions for the rigid cross-linked acrylamide gels. Also, the improved heat dissipation of the fused-silica capillary permits much higher voltages to be used, reducing the run time of the analysis [5]. Laser-induced fluorescence detection also improved throughput by allowing multiwavelength analysis [6]. Soon, the forensic science community became interested in this robust technology and began to adopt it for a variety of analyses. In particular, CE systems can be used for DNA quantification, genotyping, sequencing, and mutation detection.

## 25.3 THEORETICAL ASPECTS

### 25.3.1 THE CAPILLARY AND THE SIEVING MATRIX

In 1988, it was shown that DNA single nucleotide separation could be achieved using cross-linked polyacrylamide gel filled capillaries coupled with UV/Vis detection [7]. These chemical gels provided

size selective separation of DNA molecules based on their ability to migrate through transient pores created in the polymer matrix. Unfortunately, cross-linked gel filled capillaries had a limited lifetime due to the ready formation of voids in the gel during electrophoresis [8]. There were also concerns with carryover from one run to the next, an important point when precious evidentiary samples were being run. The solution to this problem was the development of CE systems with entangled polymer buffers such as polyacrylamide, hydroxyethylcellulose, and polyethylene oxide [9]. With proper control of polymer molecular weight and concentration, these buffers provided equivalent separation to cross-linked gels with the added advantage that they permitted refilling and reuse of the capillary. This property allowed the same capillary to be used up to 100 times before replacement.

An additional problem with these novel sieving polymers was the effect of the electroosmotic flow (EOF) on migration time reproducibility. For optimum results, the polymer network must not only separate the DNA fragments but also eliminate wall effects such as adsorption and osmotic flow. This is an important issue as the primary function of the method is to precisely determine the size of the DNA fragments. Variations in migration time due to slight differences in EOF can negatively affect estimation of fragment size. For this reason, linear polydimethyl acrylamide “POP” became the polymer of choice for these separations because of its relatively low viscosity and its capability to eliminate EOF [10,11].

Another critical issue in the development of the separation was the choice of buffer composition. The optimal buffer should produce low and stable currents and be able to separate DNA under both denaturing—where the formation of secondary structure of the sample is halted by denaturing agents such as heat, formamide, or urea [12,13]—or nondenaturing conditions—where secondary structure formation is desired to study subtle differences in DNA sequences [14,15].

For the majority of genotyping applications such as sequencing and fragment length determination, denaturing conditions are preferred as resolution is superior and there is a predictable relationship between fragment size and migration time. Buffers such as trishydroxymethylaminomethane (Tris) and *N*-tris[hydroxymethyl]methyl-3-aminopropanesulfonic acid (TAPS) are commonly used as they produce low currents and can buffer at physiological pH. A commonly used buffer for sequencing and genotyping applications consists of 100 mM TAPS at pH 8.0 with 5% pyrrolidinone and 8 M urea as denaturants [11]. Four to six percent polydimethyl acrylamide at a controlled molecular weight is added to sieve the DNA and eliminate EOF. Uncoated fused-silica capillaries of 50  $\mu\text{m}$  are typically used as this diameter provides a good compromise between resolution, sensitivity, and resistance to clogging.

### 25.3.2 INJECTION

For most applications in forensic DNA analysis, electrokinetic injection is used. This injection mode provides improved peak shape and intensity as a result of field amplified sample stacking. The stacking process results when the DNA sample is prepared in low ionic strength solutions. The application of an electric field accelerates the DNA to the sample/buffer interface where it concentrates because of the drop in field strength at that point. Because this process is highly dependent on the ionic strength of the sample solution, great care must be taken to keep salt concentrations low. Unfortunately PCR amplifications occur at relatively high-salt concentrations (70–100 mM KCl) and various buffers are often added to stabilize DNA for long-term storage. Thus, the sample must be diluted or dialyzed before injection as smaller buffer ions have higher electrophoretic mobility and interfere with the injection of the DNA.

Sample injection is an important issue in forensic analysis as there should be a semi-quantitative relationship between peak height and sample concentration. This relationship helps the analyst assess the quality of the sample and its preparation. It also helps define the relative level of different contributors to a mixture. The removal of salts through dialysis or the unintentional addition of higher quantities of salt can produce peak intensities that are less representative of sample quantity and affect the aforementioned relationship.

In a typical injection, 1–2  $\mu\text{L}$  of a completed PCR is diluted in 10–20  $\mu\text{L}$  of formamide. Water can also be used but the formamide produces complete denaturation of the sample without further processing. High purity, low conductance formamide must be used to avoid loss of peak intensity or other injection artifacts.

### 25.3.3 DETECTION

Laser-induced fluorescence is the most common method of detection for DNA analyses due to its high sensitivity and multiplex capabilities. Typically argon-ion lasers are used with excitation wavelengths of 488 and 514 nm. Detection occurs using a charge-coupled device (CCD) that collects the fluorescence emission produced by the various dyes bound to the DNA molecules. There are three basic methods for detection of the DNA using these dyes: intercalation, amplification with dye-labeled PCR primers, or incorporation of dye-labeled bases into the DNA sequence during replication. For single channel detection of native DNA, intercalating dyes produce excellent results [16]. These dyes may simply be added to the CE buffer and the DNA is labeled as it moves through the gel toward the detector. For genotyping of denatured DNA, dye-labeled primers are used [17] while dye-labeled bases are used in DNA sequencing [18].

The specific dyes used for genotyping and DNA sequencing are designed to simultaneously absorb at a single laser wavelength but emit at a variety of different wavelengths. Rhodamine and fluorescein derivatives are commonly used. Using these dyes, multiple loci can be amplified and genotyped without interfering with each other by simply labeling each set of PCR reactants with a different dye. Current commercial systems have the capability to detect as many as five different dyes simultaneously on a single CE capillary. Special software is used to eliminate problems with dye overlap by applying virtual filters and various calibration procedures [17].

### 25.3.4 SIZE ESTIMATION

As mentioned previously, the primary function of the separation in genetic analysis is the estimation of fragment size. Multichannel fluorescence systems typically reserve one channel for use as an internal standard. The internal standard consists of multiple peaks throughout the size range of the analysis and is used by the computer to permit a precise estimate of unknown fragments in the other dye channels. Computer algorithms can then be used to produce a size estimation of the unknown DNA fragments in the other dye lanes. The samples can be further processed by comparison of these data with an external standard that consists of all known mutations. Using both sets of standards, it is possible to produce size estimates with a precision of better than 0.17 base pairs (bp) making the system capable of distinguishing single base differences at sizes up to 350 bp [19]. It is important to note at this point that the size estimates produced by these techniques can be influenced by temperature or sequence effects, and thus careful control of temperature and denaturant concentration is important in order to maintain precision [20,21].

## 25.4 PRACTICAL APPLICATIONS IN FORENSIC BIOLOGY

The major application of CE in forensic biology is in the detection and analysis of short tandem repeats (STRs). STR markers are preferred because of the powerful statistical result that is possible with these markers and the large databases that exist for convicted offenders' profiles. Other related applications include the analysis of haploid markers in the Y chromosome and in mitochondrial DNA (mtDNA). Nonhuman DNA testing can also be performed depending on the circumstances of the case. The techniques involved include genotyping, DNA sequencing, and mutation detection.

### 25.4.1 STRs

The analysis of STR loci in DNA is the most common method for the determination of human identity and can indisputably distinguish between two or more unrelated individuals if sufficient loci can be detected [22]. STR loci occur in noncoding regions of the human genome and consist of short segments of DNA 2–7 bp in length such as AATG, which are repeated consecutively multiple times. The number of repeats at a given locus can vary between individuals and there is a statistical probability that a given individual will have a set number of repeats at a particular STR locus. It has been estimated that over 100,000 STR loci exist in the human genome and research continues in an effort to determine their exact function [23]. Among this large number of STRs, the forensic community in the United States has established a set of 13 loci (Table 25.1) [24,25] that can be used to develop a genetic profile for the identification of individuals in criminal casework. To process the results from each analysis, large database known as Combined DNA Index System (CODIS) has been set up. This database stores profiles from convicted offenders and unsolved casework. Similar databases have been set up in Europe, Japan, and other countries. The information in these databases can be used to detect and apprehend serial offenders by permitting rapid exchange of information between crime laboratories [26–28].

STRs can be targeted for PCR amplification by preparing primer sequences that bind to more conserved sequences flanking the variable STR regions. The chemistry and protocols necessary for identifying each set of STRs are included in one or a combination of kits provided by companies such as Applied Biosystems and Promega. These kits (Table 25.2) have been subjected to strict validation processes to ensure the quality of the data [19,29–31]. The kits permit multiplex PCR amplification of up to 16 loci (including the sex determination gene) simultaneously from a single sample (Figure 25.1). The different loci included in the kit contain multiple alleles and are separated by size and dye label. The repeat motifs are 4–5 bases in length and the motif sequence can repeat itself up to 51 times (Table 25.1). To help define the size and migration time of each known allele an external standard known as an allelic ladder is run subsequent to each set of samples and used to more precisely define the identity of each peak (Figure 25.2).

**FIGURE 25.1** AmpFLSTR Identifier<sup>™</sup>16-plex amplification results. The electropherogram shows 15 STR loci as well as the amelogenin (sex determining) marker. Individual STR loci are separated by amplicon size and dye label. Each row represents a different dye marker: 1, the 6-FAM labeled loci; 2, VIC labeled loci; 3, NED labeled loci; 4, PET labeled loci; an internal standard labeled in rox is also run simultaneously but is not shown. (Courtesy of Ada Nuñez, Florida International University.)

**FIGURE 25.2** AmpF/STR™ Identifiler kit allelic ladder. A separation of the most common alleles for each STR loci. The STR analysis software utilizes this ladder as an external standard to assign the correct alleles to evidence samples such as is illustrated in Figure 25.1. Notice the presence of two base variant alleles (from the normal four base STR repeat) at the D21, D18, D19, and FGA loci. There is also a one base variant allele located in the THO1 locus. (Courtesy of Ada Nuñez, Florida International University.)

One of the major issues in the separation of these large multiplex sets by CE is the potential presence of variant alleles that differ from the standard 4 base repeat unit by 1 or 2 bp. Single base resolution and high precision are necessary over the range of fragment lengths up to 350 bp in order to reliably detect these variant alleles and distinguish them from artifacts, spikes, and noise.

Another issue that is unique to this application is the role of the PCR in defining system sensitivity. Amplification of DNA concentrations less than 100 pg (about 17 cells) can produce stochastic intensity fluctuations leading to peak imbalance and occasional loss of signal (allele dropout). Low level mixtures may also be present in the electropherogram further complicating the interpretation of the data [32,33]. The ability to produce clear and unambiguous electropherograms is critical in criminal casework since DNA evidence may be the only information tying the suspect to the crime. Loss of peak intensity can complicate data interpretation. As a result, rigid rules have been developed for interpretation of signals below an intensity threshold that can be defined by the ability to reproducibly amplify DNA and detect it at a level above the system's limit of quantification [34].

For mixtures such as those often encountered in sexual assault cases, special techniques have been developed for isolation of male DNA (sperm heads) from female epithelial cells [35]. These procedures aid the interpretation of the data by removing most of the female contribution to the profile. This process, known as differential extraction, can be performed by selective digestion of the epithelial cells followed by isolation of undigested sperm heads through centrifugation. The sperm fraction is further digested and extracted using dithiothreitol (DTT). However in certain situations such as the case with vasectomized males or multiple assailants, isolation of individual profiles is more difficult. In these cases careful analysis of the results may be necessary to reach

**FIGURE 25.3** Mixed male/female DNA Profile. The amplification of a 1:1 mixture of male and female DNA using the Identifiler™STR multiplex. Note the presence of 2-, 3, or 4 alleles at each locus indicating the presence of 2-, 1-, or 0-shared alleles. Also, notice the 3:1 ratio of X to Y sex typing alleles in the third panel due to the mixture of XX and XY alleles. Analysis performed on an ABI310 Genetic Analyzer. (Courtesy of Stephanie King and George Duncan, Broward County Sheriff's Office Crime Laboratory.)

a conclusion. Figure 25.3 illustrates the electropherogram of a mixed profile. Note that the sample can be determined to be a mixture of male and female DNA based on the relative peak areas of the Amelogenin sex marker. In this case there is a 3/1 ratio of X- to Y-chromosome, suggesting a 1/1 mixture of male (XY) to female (XX) DNA.

Once the separation is complete, the data are analyzed using specialized software that assigns an allele repeat number to each peak based on the alleles identified by the previously run allelic ladder. Statistical analyses can be performed using relevant population frequencies to determine the overall probability of another individual having an identical DNA profile [36]. Because the different genetic loci used in determining the profile are inherited independently, the individual probabilities of having a particular set of alleles at one locus can be multiplied together for all loci producing a random match probability for the 13 CODIS loci of  $1 \times 10^{-15}$  [24]. For all intents and purposes, the data from a single source profile such as that shown in Figure 25.1 can be used to provide identification of a suspect [37]. Analysis of more complex samples such as those containing multiple contributors (Figure 25.3) or related individuals is less straightforward and requires in-depth statistical analysis [38–41].

#### 25.4.2 MINI STRs

Large STR multiplex sets are used for most forensic evidence samples. However, biological fluids or materials left behind in a crime scene may be degraded because of exposure to a variety of harsh

**FIGURE 25.4** (See color insert following page 810.) A comparison between a 9947 control DNA sample (a) and a degraded DNA sample (b) extracted from a recovered bone fragment. There is an evident loss of signal at the larger size loci in sample b (arrow) due to sample degradation. The sample is extracted and amplified DNA prepared using the Promega Powerplex STR multiplex kit and consists of 16 separate genetic loci labeled with three different dyes and separated via capillary gel electrophoresis using the ABI 310 genetic analyzer. (Courtesy of Kerry Opel, International Forensic Research Institute, Florida International University.)

conditions and/or due to the presence of various contaminants that have been mixed with the sample [42,43]. In both cases, the result may be a partial DNA profile (Figure 25.4) in which some alleles are missing from the profile or are present below a laboratory's interpretational threshold [44,45]. Characteristically, the larger alleles lose intensity due to increasing decomposition of the template into smaller fragments. The resulting partial electropherograms are far less definitive than a full profile since fewer loci are available for statistical analysis. This leads to an increase in the probability of finding a random unrelated individual in the general population with a matching profile.

In these situations, one approach has been to perform further testing using mtDNA sequencing. Since there are multiple copies of mitochondrion in each cell, the likelihood of obtaining a result is greatly increased when compared to nuclear DNA. However, mtDNA analysis involves difficult and expensive analytical procedures, and because it is inherited solely through the female line, maternally related individuals will all have the same profile and statistical results are much less conclusive.

In recent years, investigators driven by this issue have developed a viable alternative—the use of mini STRs. Mini STRs are reduced size STR amplicons that can be obtained by redesigning the amplification primers in such a way that they bind closer to the STR repeat regions [46–48]. To keep the fragment size as short as possible only one or two STR loci can be used in each dye lane. These shorter amplicons can be detected when the original template is too fragmented to properly amplify (Figure 25.5).

Many of these STR markers targeted by modified primers are the same as those already established for the CODIS database [46]. Concordance studies between the mini STR and the commercially available STR primers have been performed and some discrepancies (0.2%) have been observed in the allele calls. These, however, can be explained by the fact that the primers from the mini STRs bind at different locations than those of the original STRs, thus insertions/deletions can affect primer

**FIGURE 25.5** Mini STR amplification. The electropherogram illustrates the analysis of an extracted and amplified bone sample. The electropherogram consists of four panels showing three STR loci and an internal lane standard run simultaneously and detected with four different dyes. Unlike the larger multiplexes illustrated in previous figures, only one locus appears in each dye lane in an effort to keep the amplified products as short as possible. (Courtesy of Kerry Opel, International Forensic Research Institute, Florida International University.)

binding resulting in an apparent discrepancy in allele size [49]. This problem is being addressed through alternative primer designs, and researchers are continuing to identify new mini STRs to increase the information content of STR assays [50].

### 25.4.3 MITOCHONDRIAL DNA ANALYSIS

In situations in which minimal DNA can be recovered from a sample due to severe degradation or lack of recoverable DNA, mtDNA can be exploited due to its relatively small size and presence in multiple copies within the cell [51]. The mitochondrion is a self-replicating organelle that is able to synthesize its own DNA [52]. The DNA is circular and contains 16,569 bp [53]. It contains both coding and noncoding regions, and it is in the noncoding hypervariable regions, HVI and HVII, where information relevant to forensic information is found [18,54]. These hypervariable regions have high-mutation rates that enable them to be a useful tool for human genetic analysis [55]. Owing to its small size, mtDNA does not contain STRs or other repetitive elements and instead analysis relies on variations in sequences [51,56]. Mutation detection takes place through the analysis of single nucleotide polymorphisms (SNPs); deletions, additions, and substitutions of various nucleotides in HVI and HVII. The treatment the samples receive before being loaded into the CE system is also different from that of the STRs. Because these samples are generally present at low copy number and are highly degraded, extensive use of control samples with strict isolation protocols is necessary in order to avoid cross contamination and maintain data reliability.

The samples are first amplified and the resultant native, unlabeled PCR products are quantified using CGE or microfluidic CGE with fluorescent intercalating dyes to determine input levels and

**FIGURE 25.6** Quantitative analysis of PCR-amplified mtDNA by microfluidic CE. Determination of the overall quality and quantity of the DNA before sequencing is important to assure high-quality results. The figure illustrates the detection of an mtDNA amplicon from the HVI region located between two internal standards used for sizing. The analysis is performed on an extracted blood stain by an Agilent 2100 bioanalyzer using fluorescent detection with an intercalating dye. (Courtesy of the DNA Analysis Unit II at the FBI Laboratory, Quantico, VA.)

sample quality for the subsequent sequencing reaction [16,57] (Figure 25.6). Sequencing reactions are then performed using the PCR template, and products are separated using denaturing CGE. The results are compared to a reference sequence to catalog the specific point mutations that are present [58] (Figure 25.7). The statistical analyses of these data are not as definitive as that obtained from STR typing since mitochondria are transmitted directly from mothers to their progeny and there is no admixing or shuffling of genetic information such as occurs in meiosis. Thus mtDNA analysis cannot produce the high-statistical certainty of identification produced in STR typing and instead is most useful as a means for maternal lineage determination [59,60]. However, in situations in which the only evidence available is badly degraded or where only a few cells containing DNA are present (such as the situation in which a single shed hair is recovered), mtDNA may be the only way useful genetic information can be obtained [51,61–63].

#### 25.4.4 Y-STRs

As with mtDNA, which provides maternal lineage, the Y-chromosome can be used to provide paternal lineage. The first Y-STR was discovered in 1992 [64]. Since then, a number of additional Y-STRs have been validated for use in the forensic field [65,66] and several commercial multiplex amplification kits are now available (Table 25.3). Initially used for paternity testing and rape case scenarios [67,68], Y-STRs are now being used to aid in missing persons investigations [69], genealogical research, and evolutionary studies [70–72]. Y-chromosome markers are particularly useful in the detection of small amounts of male DNA in the presence of an overwhelming abundance of female DNA. This type of STR loci are most useful when trying to isolate the male fraction from a DNA mixture (Figure 25.8) [73,74]. .

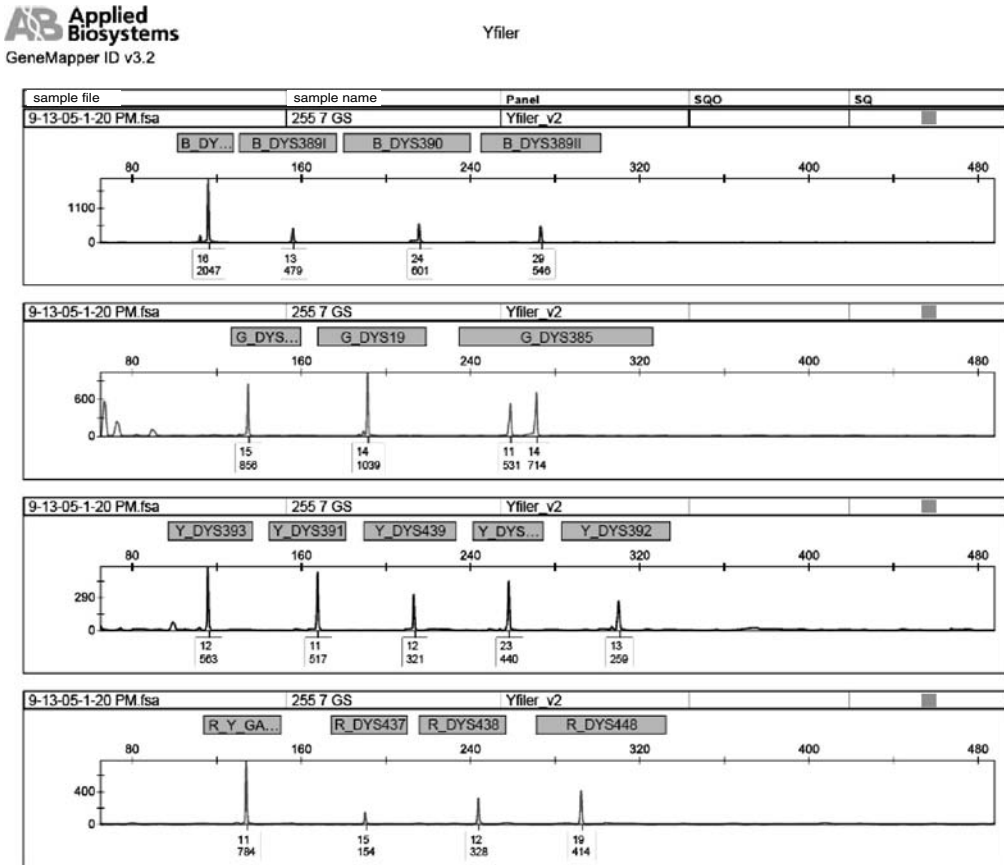

**FIGURE 25.7** (See color insert following page 810.) Mitochondrial DNA profile of an HVII sequence from a hair shaft. A repetitive analysis of the same hair sample is used to compare and align the sequences. The nuclear DNA in hair is often badly degraded and difficult to amplify. mtDNA provides an alternative procedure that can provide a DNA haplotype for forensic DNA profiling based on point mutations detected in the sequence when compared to a reference sample. Analysis performed on an ABI 310 Genetic Analyzer. (Courtesy of the DNA Analysis Unit II at the FBI Laboratory, Quantico, VA.)

**FIGURE 25.8** A Y-STR profile of the mixture in Figure 25.3 using the ABI Y Filer™Y chromosomal STR multiplex. Note that the DY385 locus has two alleles due to a duplication of the sequence on the Y chromosome. Analysis performed using an ABI 310 Genetic Analyzer. (Courtesy of Stephanie King and George Duncan, Broward County Sheriff's Office Crime Laboratory.)

An example of such a scenario might be a fingernail scraping from a female victim or the detection of a mixed DNA profile from the handle of an automobile. The profile depicted in Figure 25.9a results from an extract taken from a knife handle that includes DNA from the male suspect along with two female profiles. Use of the Y profile (Figure 25.9b) permits isolation of just male DNA, although it should be noted that all of the suspect's male relatives from his paternal lineage would also have the same Y-haplotype. Statistical analysis of the result involves performing an estimate of the frequency of a given profile in a database. Frequency estimates for Y profiles are much less specific than those obtained with autosomal STRs as individual allele frequencies cannot be multiplied together. Nevertheless, the data provide important information regarding the potential placement of an individual at a crime scene.

#### 25.4.5 SINGLE NUCLEOTIDE POLYMORPHISMS

The various types of point mutations detected via mtDNA sequencing can also be targeted in nuclear DNA. SNPs are particularly useful in ethnicity testing and in the analysis of highly degraded or compromised samples [57,75,76]. In the human genome SNPs occur every 1000–2000 bp, thereby

systems have limited numbers of alleles and therefore many more loci are required to perform a full genetic profile than is the case with STRs. In fact, about 50 SNPs would require analysis to achieve the same level of statistical uniqueness developed with 13 STRs [78]. In addition, SNPs cannot easily be used in mixture studies as fragment sizes overlap making it difficult to isolate multiple contributors to a profile. SNPs can be detected using a single base primer extension assay in which a special primer is designed to target a known SNP location [81]. A polymerase is then added and used to probe the site of the polymorphism (the next unincorporated base pair) through the addition of a terminal fluorescently labeled dideoxynucleotide (ddNTP). The SNP assay can be multiplexed by simultaneously labeling multiple numbers of these loci and using changes in primer length to permit all locations to be detected simultaneously. Like mtDNA sequencing and mini STRs analysis, SNPs can be valuable in the recovery of information from degraded DNA. Figure 25.10 illustrates the comparison of results from the standard STR typing of a degraded DNA sample followed by SNP typing of that same DNA extract. The SNP amplicons are much shorter and provide additional genetic information to assist in the identification of the partial STR profile.

#### 25.4.6 MUTATION DETECTION

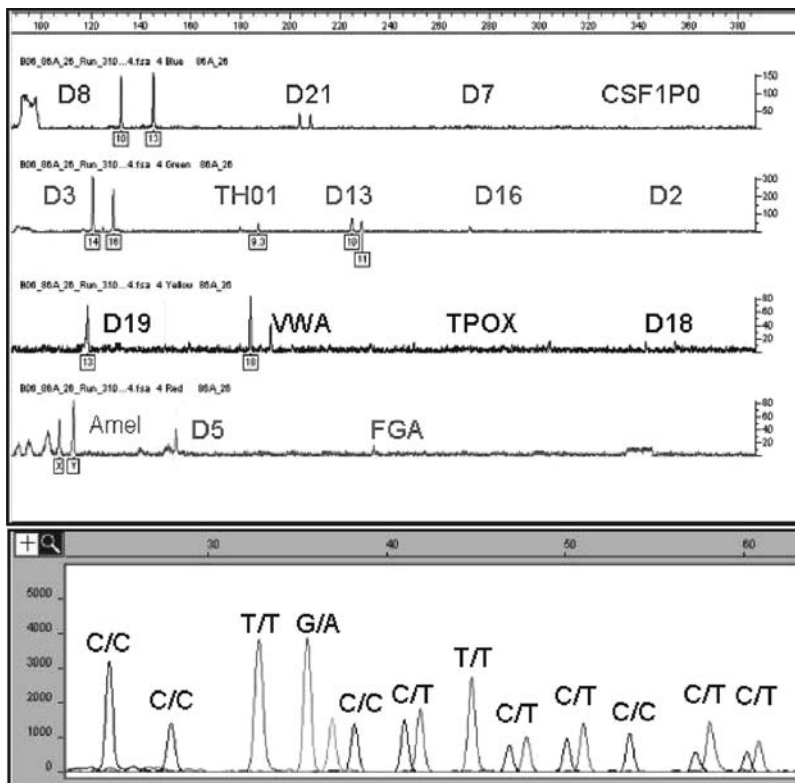

Although more commonly used in oncology and detection of genetic diseases [82–84], mutation detection techniques can provide useful information in forensic analysis. Sequence polymorphisms resulting from one or more base pair changes in PCR-amplified DNA fragments can be exploited through differences in melting points, heteroduplex formation, or conformational variations. A variety of different CE procedures exist to detect these differences, including single-stranded conformational polymorphism (SSCP), heteroduplex polymorphism, and constant denaturant CE. Using these techniques, DNA fragments of the same or similar length that would otherwise comigrate can be differentiated based on mobility differences resulting from the effect of temperature, denaturant concentration, or rehybridization effects. These types of mobility assays have been used in paternity disputes [85] and in ABO allele discrimination [86]. These techniques are relatively inexpensive to perform and can be highly sensitive to slight differences in sequence [87] making them highly useful in the detection of previously unknown mutational events.

#### 25.4.7 NONHUMAN DNA

Nonhuman DNA can provide crucial information in a variety of crime scenarios [88]. Items found at a crime scene, such as animal hair, plant material, fungal spores, and soils, may all contain recoverable DNA. Genetic markers such as STRs have been isolated from these types of materials and a number of different loci have been validated for use in criminal casework [89,90]. For other items such as microbial DNA, soil and plant materials, sequence information may not exist, and various exploratory procedures must be used to recover genetic information.

##### 25.4.7.1 Animal DNA

Feline and canine STR analyses have been used in forensic casework [91–94] and specific kits have been developed to determine the genetic fingerprint of both animals [95,96]. Canine genetic material has also been analyzed via CE using mtDNA sequencing [97]. As with human samples, canine DNA can help link a suspected animal to crimes such as bite attacks or mauling. Similarly, it can also be used to exclude the animal from implication in attacks or unlawful deaths [98]. More commonly, however, dog hair and other animal hair has been found associated with victims at crime scenes [94,99]. Figure 25.11 illustrates an electropherogram of a suspect dog hair that might be used to associate an animal with the victim of an abduction. Genetic analysis of this material provides further information on the circumstances of the crime and can connect the victim to a particular

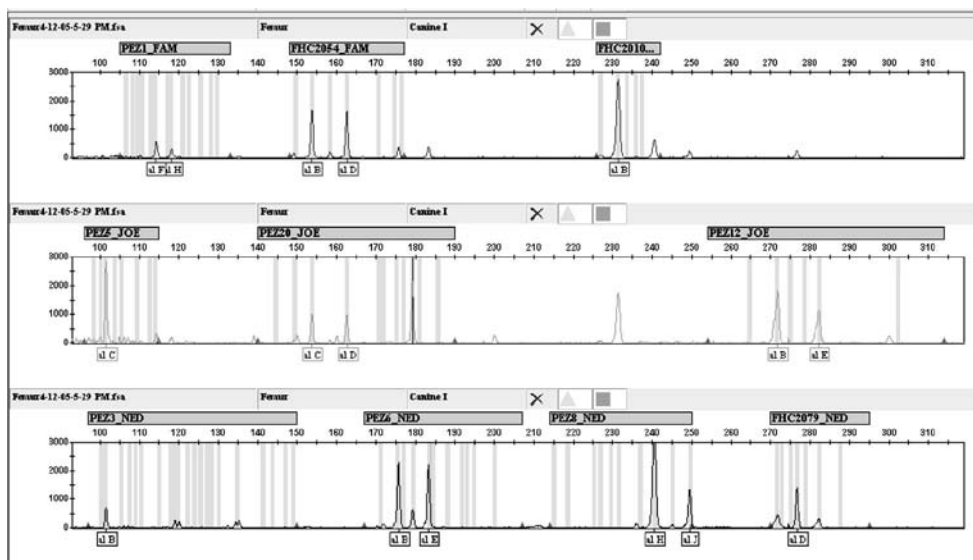

**FIGURE 25.10** (See color insert following page 810.) The recovery of information from degraded DNA using the Identifiler™STR multiplex and an SNP multiplex, both analyzed using the ABI 310 genetic analyzer. The top electropherogram depicts a degraded sample amplified via STRs. The bottom profile depicts a SNP multiplex on the same sample. The STR profile is blank for many larger alleles such as D7 CSF, D16, D2, TPOX, D18, and FGA. The smaller sized SNP fragments permit recovery of additional genetic information from the sample. (From Vallone, P.M., Decker, A.E, and Butler, J.M., The evaluation of Autosomal SNP assays, *Chemical Science and Technology Laboratory, National Institute of Standards and Technology, Div.831.*)

location or suspect. Although more commonly used for lineage analysis, other genetic material such as equine and bovine DNA could also be used in criminal casework [100].

#### 25.4.7.2 Botanical DNA

Plant DNA analysis has been increasing over the past couple of years because of its ability to pinpoint the origin of drug-related plant material [101,102]. Plant STRs are not yet well characterized; however, other molecular methods can be combined with capillary gel electrophoresis to establish the identity of plant species [103]. These techniques include amplified fragment length polymorphism (AFLP), random amplification of polymorphic DNA (RAPD), and other similar random primer annealing techniques used for mutation detection.

AFLP is a molecular tool in which the DNA is cut by a combination of restriction enzymes for subsequent amplification utilizing relatively nonspecific primers that are tagged with a fluorescent dye [104,105]. These primers will anneal only to the fraction of the cut fragments that contain a short complimentary sequence, leaving behind those that do not. Since DNA sequences vary, the cut

**FIGURE 25.11** Canine STR analysis. Ten canine markers were successfully amplified and analyzed after extracting DNA from a single dog hair. (Courtesy of Lilliana Moreno, Forensic DNA Profiling Facility, Florida International University.)

sites produced by the selected restriction enzymes will vary between the different plant materials submitted for analysis. The result is a set of DNA fragments of different sizes and intensities that can be related to a particular plant cultivar. The specific fragments can be isolated and detected by capillary gel electrophoresis. Various computer software are then used to define and catalog the differences between samples. AFLP has proven to be a particularly valuable tool for establishing plant identification and for tracing plant material back to its original source [106]. Figure 25.12 illustrates the analysis of a seized marijuana sample using AFLP with multichannel fluorescent CE detection.

### 25.4.7.3 Microbial DNA

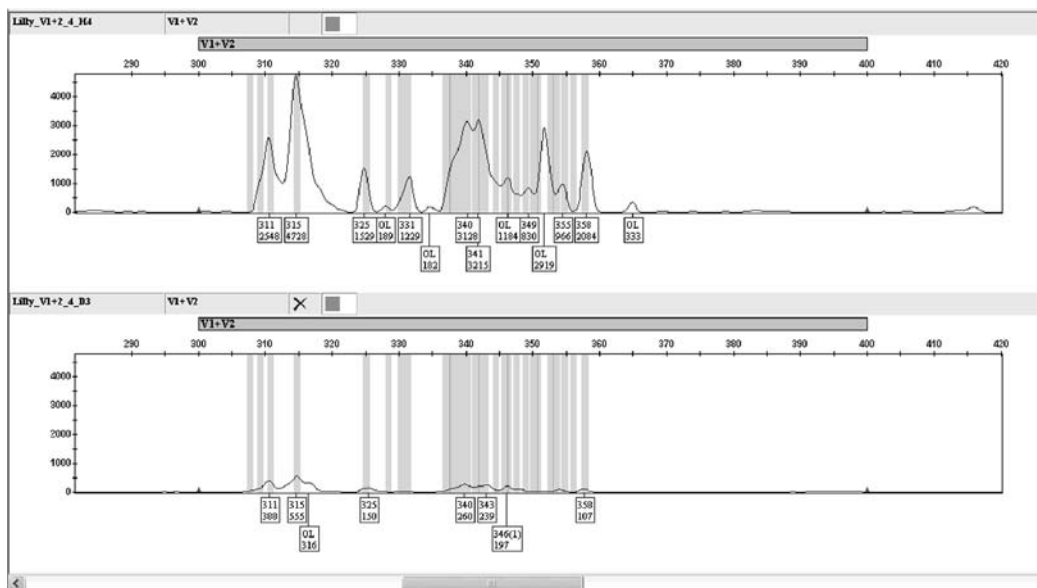

Recent events involving the use of microbes as bioterrorists' weapons have intensified research in the developing field of microbial forensics. This new field couples law enforcement efforts with existing procedures to identify patterns in disease outbreaks, determine the pathogen involved, control its spread, and trace the microorganism back to its source [107]. A variety of techniques are currently being used as tools for the classification and identification of microorganisms and these procedures can also be used to assist investigators in the detection of criminal acts. While most of the reported incidents to date involve hoaxes with nonpathogenic material, the consequences of such an attack require that laboratories be properly prepared to meet the threat. In addition, these same techniques can also be used to examine trace evidence such as soils left behind following a criminal act [108,109]. A number of molecular techniques for microbial detection and analysis are listed below.

Terminal restriction fragment length polymorphism (TRFLP) uses end-labeled primers that will bind to specific primer sequences used when amplifying DNA by PCR [110,111]. After digestion of the PCR products with restriction enzymes, the samples are loaded into the CE system for separation.

**FIGURE 25.12** Genetic analysis of a marijuana sample using AFLP. The sample consists of amplified DNA fragments characteristic of the plant overlaid on top of an internal lane standard used to size the individual fragments. Analysis performed on an ABI 310 genetic analyzer. (Courtesy of Ira Lurie, Yin Shen, and Bruce McCord.)

**FIGURE 25.13** Soil microbial DNA profile. The 16S rRNA gene hypervariable region V1\_V2 was amplified using ALH technique. The different DNA fragments identified in the figure depict the different microbes present in the soil. These data can then be used to aid in the identification of soils associated with a crime scene and to help answer important questions such as has a body been moved from its current location. Analysis performed using an ABI 310 genetic analyzer. (Courtesy of Lilliana Moreno, Forensic DNA Profiling Facility, Florida International University.)

This method has been extensively used in conjunction with the small ribosomal subunit (16S rRNA) to establish differences between microbial entities [112,113] and was the technique first used in the analysis of microbial communities for forensic purposes [108]. Subsequent researchers in microbial forensics examined a method known as amplicon length heterogeneity (ALH), which is commonly used in microbial ecology. ALH bases its profiles on differences in length within select hypervariable domains of the 16S rRNA genes. DNA extracts from different microbial communities are amplified using universal primers that bind outside of the variable region and are capable of hybridizing to the majority of target organisms. The output is a pattern of peaks that provide, just like STRs, a unique pattern that is used to differentiate microbial communities (Figure 25.13). Unlike TRFLP, this highly reproducible method does not require restriction endonucleases but is based on the natural variation in sequence lengths of specific regions within the gene [114,115]. Because of its ubiquitous nature, soil can be a valuable evidence in crime scene investigations; however, it is seldom used because the physical analysis is complicated and requires experts in the field of geology. A novel approach utilizing ALH-PCR to discriminate between soils for forensic purposes has been developed and tested and provides a promising foundation for the future of the application [109].

## 25.5 CONCLUSIONS

Capillary electrophoresis technology has become an indispensable tool for forensic scientists in the biology field since it is able to provide valuable information to aid in the process of law enforcement. The primary application of the technique is in the qualitative analysis of STRs. Isolation of STR mixtures is also possible using relative peak heights. Other applications of CE include quantitative analysis of PCR products, mtDNA sequencing, and mutation detection for the analysis of plant and bacterial DNA. Based on the performance of the methods illustrated above, it is reasonable to expect future researchers and practitioners to continue working to exploit the capabilities of this robust scientific technique and its application to criminal investigations.

## ACKNOWLEDGMENTS

The authors would like to thank John Butler, Dee Mills, Alice Isenberg, Kate Theisen, Pete Vallone, Ed Buse, Ada Nuñez, Kerry Opel, Ira Lurie, Stephanie King, Yin Shen, and George Duncan for their contributions to this work. Major funding from the National Institute of Justice is also gratefully acknowledged. ## 26.1 INTRODUCTION

The movement of soil colloidal particles was the first description of electrophoresis as early as 1809. However, Arne Tiselius (~1937) was the first to construct a successful instrument useful for the separation of serum protein by electrophoresis using the boundary separation principle. Because of the clinical significance of this type of separation, many improvements and refinements followed, such as utilizing paper, cellulose acetate, gel, and more recently capillaries in order to speed up and better separate (into distinct zones) the different proteins. The electric current can be utilized in the clinical applications to accomplish not just separation but other tasks:

1. It can be utilized to move fluids (through the electroosmotic flow, EOF). This feature is very useful for analysis in the microchip and in capillary electrochromatography (CEC) where the additions of pumps to move and mix fluids are not feasible.
2. It can be used to concentrate dilute compounds directly during the electrophoretic step (through stacking) as it will be discussed later. This feature is very important for analysis of clinical compounds present in biological fluids at very low concentration.
3. It can be used to separate, quantify, and identify different compounds in clinical samples using different electrophoretic principles.

Capillary electrophoresis (CE) is a general analytical technique for separation and quantification of a wide variety of molecules including those of clinical interest, utilizing narrow bore capillaries under high voltage. It separates various compounds not only based on charge but also based on size, hydrophobicity, and stereospecificity as discussed in Chapters 1, 2, 19. The flexibility of this technique stems from its ability to incorporate easily in the separation buffer different additives, that can interact with some of the analytes relative to others to alter their velocity so as to achieve the desired separation. These additives give the CE great ability to separate numerous clinical compounds in the same instrument using nonexpensive capillaries. Thus, most of the clinical tests can be adapted to CE; however in practice, some are better suited than others for analysis by this method.

The clinical/biological field and pharmaceutical industry are the main areas that are benefiting most from the application of the CE. Most of the clinical tests can be analyzed by CE as well by other techniques, such as high-performance liquid chromatography (HPLC) or slab gel electrophoresis (SGE). However, the CE offers certain advantages for clinical analyses notably a high plate number, a characteristic that is useful when dealing with complex samples containing numerous compounds such as serum or urine. The CE also offers rapid analysis time and a low cost per test with full automation. These characteristics were the driving forces for adopting the CE for completing the human genome sequence project.

However, the CE in clinical analysis requires more thoughtful planning to achieve a good separation compared with other methods. For example, many steroids cannot be separated in free zone electrophoresis. Many of these are neutral or weakly charged compounds and migrate with EOF. They separate much better by the addition of a micellar compound, such as sodium dodecyl sulfate (SDS) to achieve separation by micellar electrokinetic capillary chromatography (MEKC). The CE has some challenges such as poor sensitivity of detection, problems with the sample matrix, and adsorption to the capillary walls as it will be discussed later here and Chapter 13. However, with careful planning these obstacles can be resolved. Many applications can fall under the umbrella of clinical applications; however, tests that have routine applications in the clinical field will be discussed more in detail in this chapter.

### 26.1.1 SPECIAL ASPECTS OF CE IN CLINICAL ANALYSIS

The clinical field is a very vast one encompassing molecules of different physical and chemical characteristics. The sizes vary from small ions such as Na and K to very large ones such as protein and DNA. It encompasses compounds that are very abundant in concentration such as albumin

(~30,000 mg/L) to compounds very low in concentration such as prostate-specific antigen (~4  $\mu\text{g/L}$ ). It encompasses compounds with different solubility and hydrophobicity. Thus, the analysis of these different compounds requires different strategies and represents different degrees of difficulties. Some analyses work well and easily with capillary zone electrophoresis (CZE) (e.g., serum proteins), size separation (e.g., DNA) while others are difficult to adapt to any form of CE. The lower the concentration is the more difficult the analysis becomes.

### 26.1.2 ADVANTAGES OF CE IN THE CLINICAL FIELD

The main advantage of the CE in clinical analysis is the flexibility of the separation so that the same instrument can be utilized to separate numerous biological compounds. It is easy to add different additives to the separation buffer to induce a change in the velocity of some of the compounds leading to a better separation. The principle of the separation can easily be changed from free solutions to hydrophobicity separation (MEKC), size separation, chiral, isofocusing to suit a particular group of compounds as described under Chapters 1, 2. The second important advantage is the high plate number in CE generated in the capillary due to the flat profile, compared with the laminar flow in HPLC, without dealing with the high pressure or the high cost of the HPLC packed column. A third feature is the ability to perform separations without the need to use large volumes of organic solvents. Organic solvents, which are used often in HPLC, are becoming more expensive to purchase and more difficult, under many state laws, to store and dispose of. This eventually may compel shifting of many separations from HPLC to the CE.

### 26.1.3 LIMITATIONS OF CE IN THE CLINICAL FIELD

On the other hand, CE suffers from a few problems. Unlike HPLC, CE is greatly affected by sample matrix (i.e., salts and proteins) [1–4], which are very high in biological samples. Another major problem in clinical analysis is the suboptimal detection sensitivity. The third problem is sample interaction with the capillary walls. To utilize the CE successfully for practical separation of clinical samples it is important to understand how these factors affect the CE and the different maneuvers needed to overcome them.

## 26.2 PRACTICAL ASPECTS OF CE IN CLINICAL ANALYSIS

### 26.2.1 BACKGROUND

Many applications fall under the umbrella of clinical applications. For the sake of simplicity, these can be divided into two general areas. One is the research, which is performed occasionally for gaining basic scientific information. The other area is the routine analysis for patient care and diagnosis such as detection of monoclonal gammopathies to detect specific tumors. This test is performed often. In research, the need is for the flexibility and versatility with good separation with emphasis on detection of compounds at low concentration. In routine work, the emphasis is more on good reproducibility (precision) with minimum amount of analytical steps. The different forms of CE can fulfill both goals. For example, the ability to add different additives to the buffer allows for great selectivity and versatility, for example, from separation based on charge to separation based on hydrophobicity, or to size. On the other hand, the MEKC form of the CE offers ability to simply inject the sample directly on the capillary without any treatment.

### 26.2.2 SAMPLE MATRIX EFFECTS

Many compounds can be analyzed easily from pure standard solutions, tablets, or from samples with clean matrix. However, the analysis of the same compounds from biological sources poses many

more difficulties. This is because of the effects of both the high salt and high protein content of the biological samples on the separation in CE.

Although the sample, in most instances, constitutes a very small portion of the overall volume in the capillary once injected (<1%), the matrix of the sample has profound effects in CE. This is due to two main factors: contribution of the sample to the total current conductance and also due to its interaction with the capillary walls (especially proteins). On the basis of how the sample is prepared and how the separation buffer is selected, sample matrix effects can be either favorable or detrimental to the analysis [5]. Peak shape, separation, quantification, and reproducibility are affected greatly by sample matrix.

A simple, but limited, solution to overcome the problems of high salt and protein content is to dilute the sample. However, this not only lowers the salt and the protein content but also decreases the concentration of the analytes of interest too!

### 26.2.3 HIGH SALT CONTENT IN THE SAMPLE

Conductivity differences between the analyte zones and the pure background electrolyte (BGE) zones can lead to local electric field strength differences that, in turn, can distort the shape of the analyte bands yielding asymmetric peaks and result in reduced separation efficiencies [1,3,5]. Sample desalting is not easy to perform. If it is necessary, this can be accomplished through special columns or after sample extraction. However, samples with high salt content can be analyzed directly provided the separation buffers have high ionic strength [3]. These aspects will be discussed more in detail later on.

### 26.2.4 HIGH PROTEIN CONTENT IN THE SAMPLE

High protein content in the sample can mask the absorption of the compounds of interest especially those with low concentration. Proteins can bind to many molecules and alter their migration. They can also cause peaks asymmetry [1,5]. However, more importantly they adsorb to the capillary walls and change the zeta potential and the characteristics of the capillary. Notably, the reproducibility suffers greatly from protein adsorption. High protein content in the sample eventually ruins the capillary because of their adsorption to the walls. Since proteins tend to adsorb more on the capillary inlet, cutting off a few millimeters of an old capillary inlet sometimes can restore back the separation. Excess protein such as in serum samples can be removed by deproteinization before the CE step. If the molecule of interest is a small to medium in size (<5000 Da) acetonitrile (2 V acetonitrile: 1 V of serum) is an effective means to remove the protein while providing ability to concentrate (stacking) the analyte as described below.

If the molecule of interest is neutral or weakly charged then the sample can be analyzed directly without removing the protein or any treatment using MEKC. Analysis by MEKC can tolerate proteins since the surfactants in the MEKC solubilize them.

### 26.2.5 WIDE VARIABILITY IN CONCENTRATION

The recent interest in proteomics placed great emphasis on analyzing proteins and peptides that are present in very low concentration. Serum and many biological fluids contain numerous different proteins (~10,000) the majority of these are in very low concentration. However, at the same time, very few proteins (mainly albumin, globulins, and transferrin) are present in these fluids in very large concentrations. If these abundant proteins are not removed first, they make the analysis very difficult because they overload the capillary. Several methods can be used to remove these proteins and enrich the ones of interest; some are commercially available as kits. In general, several separation or binding steps are used to remove or enrich these proteins (e.g., size exclusion, anionic exchange chromatography, hydrophobic chromatography, and solid-phase ligands binding) [6,7]. For analysis

of small molecules, sample deproteinization is necessary but easy to perform. This removes the proteins but leaves the small molecules in the supernatant.

### 26.2.6 PRECISION

In general, but not in all cases, the HPLC tends to give slightly better reproducibility than the CE. The reproducibility in CE depends greatly on the capillary surface and to some extent on the number of steps for sample preparation. A thorough wash with diluted sodium hydroxide or phosphoric acid removes the adsorbed proteins from the capillary surface and improves the reproducibility. Furthermore, the reproducibility improves by employing internal standards, peak area rather than peak height, effective mobility rather than migration time, and frequent calibration [8]. The MEKC can decrease or eliminate the extra steps for sample preparation. It allows direct injection of serum on the capillary thus indirectly improving precision.

### 26.2.7 COATED VERSUS NONCOATED CAPILLARY

A noncoated (untreated) capillary is sufficient for most routine CE analysis, especially when it is used with high ionic strength buffers. It is less expensive and offers good precision. However, for the analysis of proteins and peptides present in low concentrations, a coated capillary gives a much better theoretical plate number for proteins [9]. This is true of the capillaries and also for microchips [10]. Such capillaries are also important for performing isofocusing and isotachopheresis (ITP) to eliminate the EOF and are more suitable for the detecting microheterogeneity. The coating can be covalently (permanently) bound or hydrodynamically by adding the coating material to the buffer. The walls can be modified to possess either positive or negative charges or neutral. Linear polyacrylamide was the first polymer used for permanent coating but it was not very stable. Other coatings were prepared with other polymers such as dextran, fluorinated aromatic hydrocarbons, and hexamethyl disiloxane poly(dimethyl acrylamide). Some of the covalently coated capillaries have a very short life. Several dynamic coatings have been described, for example, Polybrene-poly(vinyl sulfonate), Polybrene, poly(methoxyethoxyethyl)-ethylenimine, poly(diallyldimethylammonium chloride), and starch derivatives [11–13]; some of these are commercially available as kits. An interesting dynamic coating (adsorbed surfactant) was described based on washing the capillary with special surfactant such as dimethylditetradecylammonium bromide and didodecyldimethylammonium bromide. The coating binds and remains tightly bound enough for next several samples eliminating analytes adsorption [14].

### 26.2.8 STACKING OF COMPOUNDS OF CLINICAL INTEREST

Because of the need for better sensitivity of detection in CE, sample concentration is crucial for the widespread and practical use of this technique. Sample concentration can be accomplished by several physical means outside the capillary, such as by liquid- and solid-phase extraction; but more easily in CE by concentration on the capillary directly (stacking). Stacking is a general term referring to the contiguous concentrated zones resembling a “stack of coins.”

Several methods for staking including the theoretical aspects have been described [15–18]. Few of these methods are general while others are specific and more suitable for certain types of compounds. In most of the stacking techniques, discontinuous buffers of different kinds are employed as the basic means for altering the charge of the analytes or the field strength of the sample zone [15]. Thus, the same analyte molecules present at the different edges of the band move at different velocities in such a way that leads to sample concentration. Buffer discontinuity can be brought about simply by altering the sample conductivity or pH so as to be different from that of the separation buffer. Sometimes this can occur unintentionally [16].

Two general types of stacking are used often in CE for clinical compounds. The first is the high field strength stacking. In this method, the sample is diluted in the same separation buffer but at 10 times dilution. Thus, the sample molecules are subjected to higher field strength than that of the electrophoresis buffer. Thus, they accelerate in this region but slow at the interface of the sample and the buffer. This method can be used for large and small molecules. The second type is acetonitrile stacking. Mixing acetonitrile with the sample (2:1 v/v) is used mainly to remove proteins. However, the presence of acetonitrile in the sample (not in the buffer), has several important additional advantages. For example, (1) it counteracts the deleterious effects of salts, (2) it yields better stacking for small molecules than that obtained in dilute buffers, and (3) it allows larger volumes of sample (in some cases half of the capillary volume) to be injected. The overall effect is an increased sensitivity of small and medium molecules (<5000 Da). The stacking occurs in both the hydrodynamic and the electromigration injection. The sodium chloride present in serum at about 150 mmol/L together with the acetonitrile used in the deproteinization both bring about 10–30 times sample concentration. The mechanism of the stacking is pseudotransient ITP [19]. Thus, biological samples having high salt and protein content are well suited to CZE analysis after treatment with acetonitrile.

ITP [15], especially transient ITP, are used for small and large molecules stacking. In this technique, the sample is mixed with appropriate leading and terminating ions [16] as described in Chapter 13. This technique is used to selectively enrich low-abundance compounds (e.g., peptides in the absence of any bioaffinity interactions) [20]. This method is more difficult in practice, but it offers the benefits of speed and very high concentration.

Neutral molecules analyzed by MEKC require special and more difficult stacking methods [18]. They concentrate based on stacking either by having regions of difference in the electric field or by sweeping, that is, picking and accumulating of analytes by the pseudostationary phase that penetrates the sample [18].

## 26.2.9 COMPOUNDS DIFFICULT TO ANALYZE BY CE

In spite of few attempts, glycoproteins, carbohydrates, and lipids are difficult to analyze by CE. Carbohydrates and glycoproteins are important in the immunological recognition, control, and attack of pathogens and in protein folding. Carbohydrates do not have strong absorption in the UV and most do not have strong charges. They are analyzed at very high pH and require labeling mostly with fluorescent reagents. The analysis of carbohydrates by CE-MS has been reviewed [21].

Lipids are important since they are part of the cell membrane and the lipoproteins have important diagnostic values in coronary heart disease. Lipids too do not have strong absorption and lack strong charges; in addition to that, they are hydrophobic. Lipoproteins have been analyzed by MEKC [22]. CZE was used to separate the isoforms of low-density lipoprotein (LDL) particles in human serum based on charge/volume ratios of the particles. LDL, dense LDL, were analyzed by CE [23]. A CE-MS method incorporating SDS for separating very-low-density lipoprotein (VLDL), LDL, high-density lipoprotein (HDL) has been described [24].

## 26.2.10 COMPOUNDS SUITED FOR ANALYSIS BY CE

Some of the clinical compounds are better suited than others for separation by this technique. In general, polar compounds possessing a strong charge and present in high concentration are most suited to analysis by CE (e.g., proteins, hemoglobins and their chains, some peptides, and drugs). Enzymes and DNA are also suited for analysis by CE even though they are not present in high concentration. The DNA is amplified first and then analyzed elegantly by CE using sensitive detection fluorescent dyes while enzymes are analyzed through the accumulation of products (catalytic activity on the substrates). Following sections discuss those clinical compounds that have been well studied by CE and analyzed often for patient care.

## 26.3 PROTEINS

Proteins are important not only for their function but also for their diagnostic significance. Proteins maintain structural integrity and perform different functions such as catalytic, hormonal, or receptors. The function of many of the proteins of clinical interest remains not well understood nevertheless these proteins remain to be important. The CE is useful for quantification, purity check, and detection of microheterogeneity of proteins.

Proteins and peptides are composed of amino acids, which are zwitterions carrying both positive and negative charges. Thus proteins possess different isoelectric points. These proteins acquire a charge based on the buffer they are dissolved in and move toward the opposite electrode depending on the net charge. Usually, slightly alkaline buffers ( $\text{pH} > 8.0$ ) are chosen for separation of proteins. Under these conditions, the majority of proteins are negatively charged moving toward the anode but they are pulled toward the cathode by the EOF. They can be also separated at acidic buffer conditions ( $\text{pH} < 3.0$ ) (i.e., carrying a positive charge). However, because of the absence of the EOF at this pH, the separation requires a much longer time. Different proteins tend to behave differently in CZE depending on their net charge. For example, basic proteins tend to bind to the capillary wall and give distorted peak shape especially when they are in low concentration. To improve their separation by CE, different additives, high salts, or coated capillaries are used to decrease the binding to the walls.

The advantages of CE over agarose gel (AG) electrophoresis for analysis of proteins are the speed, automation, small sample volume, and avoidance of many staining/destaining steps. This led some companies to design instruments dedicated only to protein analysis by CE. Furthermore, other manufacturers designed special CE instruments to perform capillary isoelectric focusing (CIEF) with absorption imaging detectors in order to focus, concentrate, and separate better the different proteins as discussed in Chapter 19. These instruments can detect protein microheterogeneity better than the common CZE instruments. Here are some clinical applications of proteins and peptides measurement by CE.

### 26.3.1 SERUM PROTEINS

The interest in serum proteins stems from their diagnostic significance. Few thousands of different proteins are present in the serum arising from the different cells and tissues; however, mostly at very low level—way below the CE detection limits. A few of these proteins are present at high enough concentration to be detected directly by CE. These proteins separate into a few bands ( $\sim 5$ – $12$ ), which are not pure or single proteins but a group of several proteins. Serum proteins are analyzed routinely on a daily basis in most large hospitals to detect several disorders such as renal failure and infections; but most importantly, monoclonal gammopathies.

In CZE, serum proteins have been separated using different buffers (e.g., Tris and Tricine), but mostly borate, with pH of 8–11 [22,25–29]. Serum protein separation can be completed by CE in about 2–10 min in contrast to 1–2 h for agarose electrophoresis (AG) (Figure 26.1). The correlation coefficient between CE and AG for the separated bands is good [30–32]. Some commercial instruments use multicapillaries of narrow diameter ( $25 \mu\text{m}$ ) to increase the throughput of the analysis. The narrow capillaries produce better resolution than the wider capillaries with a much shorter migration time [28]. This is true for all CE separations.

### 26.3.2 IMMUNOFIXATION (IMMUNOSUBTRACTION)

Serum immunoglobulins are composed of heavy and light chains and classified based on their reaction with specific antibodies into the classes of IgG, IgA, IgM, IgD, and IgE. These can be secreted in high concentration as some of clones of cells become malignant. Multiple myeloma, Waldenstrom's disease, and light chain disease all represents different malignancies of plasma cells and can cause increased levels of these proteins (paraproteins). The identification of the type of

**FIGURE 26.1** Comparison of the CZE to agarose gel (AG) electrophoresis for a patient with a streptococcal infection: (a) CZE and (b) AG. (I: internal standard; P, prealbumin; A, albumin; a1,  $\alpha_1$  globulin; a2,  $\alpha_2$  globulin; T, transferrin; C, complement; G,  $\gamma$ -globulins; N, neutral compounds). Arrows in the  $\gamma$ -region indicate oligobands. (From Shihabi, Z., *Electrophoresis*, 17, 1607, 1996. With permission.)

these different paraproteins is important for the proper patient treatment. These paraproteins are detected and classified with immunofixation, a laborious procedure performed in gel electrophoresis. Immunofixation is an important part [32] of working up an unknown monoclonal band. CZE has been adapted to perform the immunofixation method based on reacting serum proteins with specific antibodies. The Antigen-antibody complex can be separated from the free antibody or antibodies based on binding to a solid matrix or simple separation in the capillary. The sample is assayed before and after the binding [30,32]. The difference between the two “immun subtraction” represents the specific type of the monoclonal abnormal serum protein. This simple method has been shown to be reliable.

### 26.3.3 CRYOGLOBULINS

Cryoglobulins analysis is an important but unfortunately a neglected test in clinical practice because of the difficulty of the test. Cryoglobulins are special type of immunoglobulins that reversibly precipitate from serum at cold temperatures [33]. They can be associated with skin lesions (purpura), glomerulonephritis, and peripheral neuropathy, or malignancy [8]. These are divided into two general

categories. First, a small fraction (about 5–10%) that are pure monoclonal antibodies (type I) and which representing malignancies. The second type, which is the majority ~95%, are immune complexes (mixed cryoglobulins) representing immune stimulation due to infection or presence of autoantibodies. The latter group is further divided based on if the cryoprecipitate contains a monoclonal rheumatoid factor (type II) or polyclonal rheumatoid factor (type III) immunoglobulins [33]. The mixed cryoglobulins can precipitate in the different tissues of the body such as the kidney and the extremities causing vasculitis.

Cryoglobulins are detected, quantified, and phenotyped all simultaneously by precipitating an aliquot of the serum at 4°C, centrifuging, and dissolving the precipitate in a buffer followed by electrophoresis using the same conditions as those for serum proteins (Figure 26.2) [34]. Cryoglobulins are well suited for analysis by CE. The main advantages are the higher sensitivity, the use of small volumes of serum, speed (15 min vs. 2 h), and improved quantification compared to the AG method. We have used the CE for routine cryoglobulins analysis for our patients for over a decade with good success [21].

#### **26.3.4 URINARY PROTEINS**

Usually urine proteins are present at about 10–100 times lower concentrations compared with serum but in the presence of numerous interfering UV-absorbing compounds. This renders urinary proteins to be more difficult to measure directly by CE when compared with serum. The majority of urine samples require concentration (based on the protein content) before the CE analysis. They are concentrated through special commercial “membrane concentrators” followed by washing with saline solution or using chromatographic column [32] to decrease the interfering UV-absorbing materials. The urine contains several proteins of clinical interest, especially Bence-Jones proteins, which are important for detecting plasma cell malignancies and for diagnosis of nephropathy. Very few urine samples that are very high in proteins can be analyzed directly without any preparation. The same buffers and conditions for serum proteins are basically used for the analysis of urine protein [35].

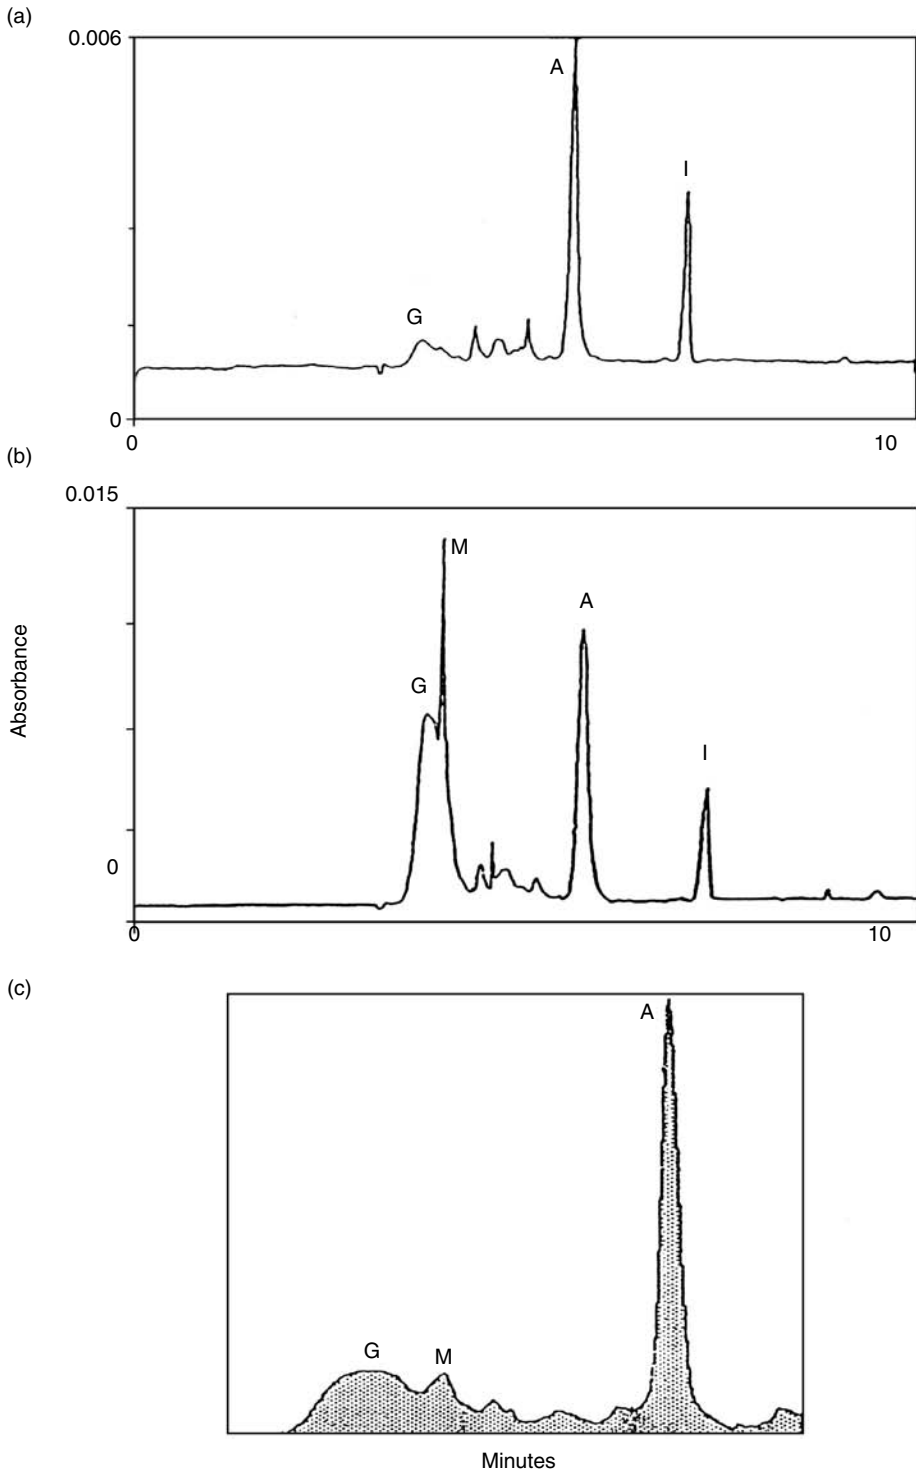

#### **26.3.5 CEREBROSPINAL FLUID PROTEINS**

The main clinical significance of cerebrospinal fluid (CSF) protein electrophoresis is for the detection of the oligoclonal bands, which are present in multiple sclerosis in the gamma region. Similar to urine, proteins in the CSF are present fluid in very low concentration (100 times less than serum). For the majority of the samples, a 10- to 20-fold concentration is preferred before analysis by CE (by the same membrane concentrators used for urine). CSF protein separation can be accomplished in less than 10 min with CE versus 2 h for AG with the ability to detect oligoclonal banding by this technique [36].

### **26.4 ENZYMES**

Since enzymes are essentially proteins, they can be measured in CE by direct light absorbency like other proteins or by their enzymatic activity. The CE offers versatility for enzyme measurement: the enzyme itself, the substrates, or the products (Figure 26.3) all can be measured in CE. Most of the enzymes in biological fluids are present in very low concentration so that they cannot be determined by direct light absorbency. The catalytic activity is much more sensitive and more versatile. Catalytic activity is more suited for enzymes with low activity because the reaction product can be amplified with time. The catalytic activity can be measured in several ways: (A) incubation in the capillary that is used as a microreactor [37–39]; (B) online, postcapillary reaction (more difficult); and (C) incubation outside the capillary that is more common. If a long incubation step is needed then it is more convenient to perform the incubation outside the instrument. After the incubation step, the reaction is stopped preferably by the addition of acetonitrile (rather than acid) (Figure 26.3), which

**FIGURE 26.2** Serum electrophoresis of a patient with type II cryoglobulins (650 mg/L): (a) serum CZE, (b) Cryoglobulins by CZE, and (c) cryoglobulins by AG (see legend of Figure 26.1). (From Shihabi, Z., *Electrophoresis*, 17, 1607, 1996. With permission.)

**FIGURE 26.3** Glutathione transferase activity: rat heart tissue homogenate 25  $\mu\text{L}$  were mixed with 50  $\mu\text{L}$  of 1-Cl-2-dinitrobenzene (0.2 mg/mL, pH 6.6) and 25  $\mu\text{L}$  of reduced glutathione (2 mg/mL) and incubated for 10 min at 37°C. The reaction is stopped with 200  $\mu\text{L}$  acetonitrile, mixed, and centrifuged. (a) At 0 min and (b) at 10 min of incubation (P, product of the reaction; G, glutathione peak). (Separation buffer: 250 mM borate, 50 mM Tris, pH 8.0 at 10 kV, 214 nm, 20 s injection on a capillary 30 cm  $\times$  50  $\mu\text{m}$  (ID)).

can remove the proteins, decreasing the UV absorption, and concentrate the analyte (by stacking) at the same time.

Proteolytic enzymes and those enzymes with low activity or with expensive substrates are well suited for analysis by CE in this manner. The proteolytic enzymes can be detected simply based on their absorption in the UV range in CE. Several enzymes have been analyzed by CE, such as chloramphenicol acetyl transferase [40], glutathione peroxidase, glutathione transferase

**FIGURE 26.4** Enzymatic activity of breast tumor homogenate activity for Cathepsin D (106 pmol/mg protein) at different periods of incubation: (a) 0 min; (b) 10 min; (c) 20 min; and (d) at 20 min in the presence of pepstatin. (P, split peptide; I, Iothalamic acid). (From Shihabi, Z.K. and Kute, T.E., *J. Chromatogr. B*, 683, 125, 1996. With permission.)

(Figure 26.3), ornithine transcarbamylase [40], angiotension converting enzyme [41], Cathepsin D (Figure 26.4) [42], and elastase [43].

The advantages of CE for analysis of enzymes are the use of small volumes, versatility, and ability to avoid the extra steps of indicator reactions. We found in some instances, for example, analysis of glutathione transferase it is easier to assign enzymatic activity units (IU) based on the CE because both the substrate and the products can be monitored at the same wavelength. Unfortunately, researchers did not take full advantage of the CE for enzyme analysis. In practice, kinetic spectrophotometric methods remain to be most widely used for routine work while the CE is reserved for those difficult and specialized tests.

## 26.5 HEMOGLOBIN

### 26.5.1 HEMOGLOBIN VARIANT

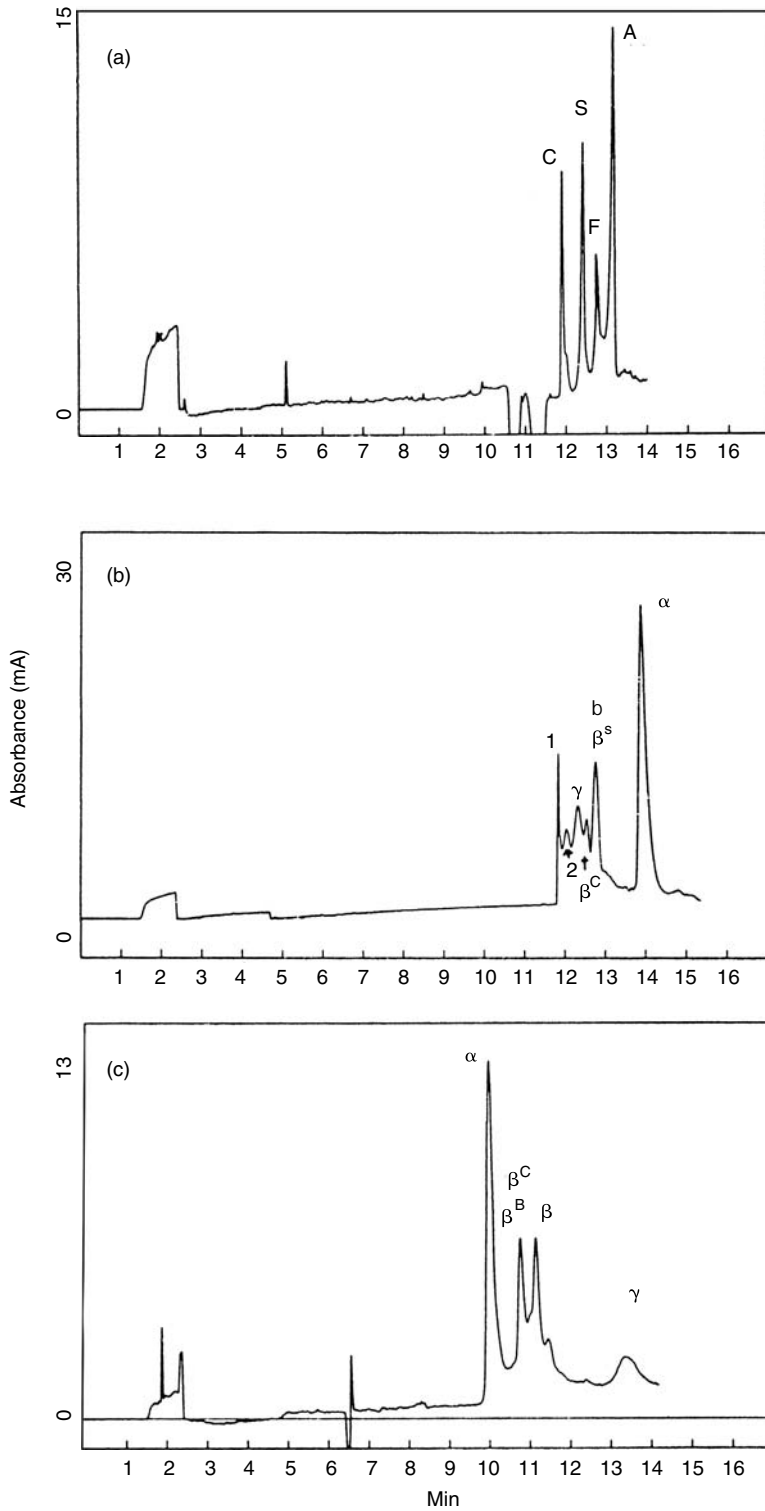

Hemoglobin (Hb) carries the vital oxygen to the different tissues. Its concentration is used clinically as an indicator of the different types of anemia. Hemoglobin is a tetramer composed of  $2\alpha$  chains and  $2\beta$  chains. The  $\beta$  chain is more susceptible than the  $\alpha$  chain for amino acid substitution (mutations), which results in different variants often present in special populations. Most of the variants are harmless and of research interest. However, few such as Hb S are associated with severe anemia, decreased capacity to carry oxygen, and altered red blood cell shape. The most encountered variants of hemoglobin are A, F, S, C, and E. Hemoglobin electrophoresis is carried out for two purposes: detection of Hb variants and detect the presence of thalassemias (decreased synthesis of one of the Hb chains).

Because of the small charge difference of the isoelectric point (pI), Hb variants do not separate well by CZE. For good separation of hemoglobin variants by CZE, a high buffer concentration, a narrow capillary (20–30  $\mu\text{m}$ ) (i.d.), and coated (hydrodynamically treated) capillary are chosen. Tris, Tricine, and arginine buffers at pH 8–8.4 give a good separation [27,44,45] (Figure 26.5), which resembles very closely to that of the alkaline separation by AG.

Although CE instruments are not well designed for CIEF, many variants can be separated better by this technique. In addition to the common variants, G Philadelphia, A2, and Bart's can all be separated by CIEF [46–48]. The separation by CIEF compares well with gel isoelectric focusing and with HPLC. The variants have also been analyzed by both CE and CIEF equipped with special absorption imaging detectors. These types of detection devices eliminate the extra steps needed to move the peaks, after the focusing step, to the detector and can simultaneously detect several capillaries with better precision and faster results than CE instruments. HB A<sub>2</sub>, which is increased in  $\beta$ -thal, is better quantified by CE compared with AG electrophoresis [44]. Hemoglobin analysis by CE has been reviewed recently [49–51].

### 26.5.2 HEMOGLOBIN A<sub>1C</sub>

Hemoglobin HbA<sub>1C</sub> is very important clinically because it is used to follow the control of blood glucose over extended periods of time in patients with diabetes. It measures the amount of glucose bound to hemoglobin (glycated Hb). Unlike blood glucose, HbA<sub>1C</sub> is more stable and represents the average glucose in the past 3 months (the average life of the red blood cell). Clinical labs perform this test routinely on a daily basis because of the widespread of incidence of diabetes and the need to modify the glucose level or modify the patient treatment. A dedicated HPLC instrument solely for this test is sold commercially. However, the cost/test is relatively expensive. For analysis of this hemoglobin by CE, a coated capillary either dynamically [52,53] or permanently is required [54]. Both CZE [52,53] and isoelectric focusing [54,55] are used for its analysis.

**FIGURE 26.5** Separation of a mixture of the common Hb variants using the same diluted sample and same CE conditions for the intact Hb molecules and the HB chains (4 s injection, 214 nm). (a) Intact Hb molecule; (b) Hb chains under acidic conditions; and (c) Hb chains under basic conditions. Peak 1, albumin; peak 2, unknown. (From Shihabi, Z.K. and Hinsdale, M.E., *Electrophoresis*, 26, 581, 2005. With permission.)

### 26.5.3 GLOBIN CHAINS OF HEMOGLOBIN

The globin chains are useful for investigating the presence of thalassemias that lead to decreased globin synthesis (either  $\alpha$  or  $\beta$  chain). This could be minor (without much clinical consequences) or major (severe or life threatening) symptoms, depending on the number of genes involved. The deviation of the ratio of  $\alpha/\beta$  in the patient from that of the normal ( $\sim 1:1$ ) indicates the presence of thalassemia. The thalassemia represents a decrease in the synthesis of either  $\alpha$  or  $\beta$  chains. The  $\alpha$ -thalassemia is common in people of the African origin while the  $\beta$ -thalassemia is common in those of Mediterranean sea origin. These chains are analyzed by cellulose acetate, which is a laborious technique requiring extraction with acetone, denaturation by high concentration of urea, and strip staining. Few CE methods used similar protocol to the cellulose acetate methods with analysis in phosphate buffer either at pH 11.8 or at pH 2.5–4.5 [56,57]. We simplified the CE by using direct Hb hemolysates without extraction or denaturation simply by analyzing the diluted red blood cells at high alkaline pH 12.6 [58] or low acidic pH 2.15 (Figure 26.5). These buffers with high or low pH induce the chain denaturation and at the same time separate the heme and serum proteins from the chains. Thus method is extremely simple and very rapid since it does not require sample treatment, staining or destaining. Furthermore, the common variants of the  $\beta$  chains, such as  $\beta$ S,  $\beta$ C, and  $\beta$ E, are also separated from each other. Thus, this method gives further confirmation of the Hb variants separation by CZE.

### 26.6 PEPTIDES AND POLYPEPTIDES

Peptides and polypeptides are similar to protein in structure but smaller in size. Many of the peptides are biologically active compounds with different functions, such as adrenocorticotrophic hormone (ACTH), angiotension, substance P, or glutathione. Most of these peptides are present at very low concentration. However, peptides can also arise from the digestion of purified proteins *in vitro* especially as a step during protein characterization and can be present in high concentration.

After sequencing the human genome, there is a great interest in peptide analysis as a means to identify those proteins coded by the different genes discovered recently. Peptide analysis by CE can be used for quality control or purity check in the pharmaceutical industry. In this respect, the CE is well suited for this purpose. After protein hydrolysis, the different peptides can be separated by HPLC or CE and analyzed by the mass spectra. On the other hand, peptides can be present naturally in different biological fluids such as in serum or spinal fluid. In most of the biological fluids, they are usually present in low concentration among high concentration of interfering substances. Thus, the analysis becomes much more difficult. Sample concentration before or on the capillary becomes vital for the analysis. We used acetonitrile to concentrate some peptides, for example, glutathione, insulin chains (Figure 26.6), and enkaphlin [59,60]. However, for those peptides in very low concentration they require much more concentration either by other types of stacking [61] or by chromatography [62]. For better analysis, coated capillaries are preferred [9,10]. Analysis of peptide has been reviewed recently [63,64].

### 26.7 CE AND PROTEOMICS

Proteins are synthesized as a result of the transcription and translation steps of the information stored in the DNA. However, because of post-translational modification, during development and disease, proteins primary structure can be modified greatly and so the function. In cells or tissues, there are usually a large number of proteins that vary widely in their physicochemical properties, including molecular weight, pI, solubility, and folding. Many factors that affect the synthesis can result in many subtle variations, for example, due to sugar binding or SH interaction, which can account for the wide variations between different individuals.

**FIGURE 26.6** Effect of stacking for some natural peptides on sensitivity of detection (A, angiotensin; I, insulin B chain; C, impurity in the insulin B chain; and E, Leu-enkephalin; (a) at 1.5% loading of the capillary and (b) at 30% (stacking in acetonitrile). (From Shihabi, Z.K., *J. Chromatogr. A*, 1996, 744, 231. With permission.)

At the present time, proteomics is an area far from the routine work; however, this probably will change in the near future because of the importance and the accelerated research. We have witnessed the rapid change from research to routine work for DNA analysis. DNA fragments now are routinely analyzed for viral detection; and for leukemia's typing. Finding proteins (biomarkers) that play key roles in the development, malfunctions of cells or tissues is a helpful for early detection and diagnosis of diseases as well as searching for new targets for production of new drugs. There is a great interest in identification and quantification of multiple proteins, including those in very low concentration that constitute or control a particular biological process. Thus, techniques providing high sensitivity and high peak capacity are still greatly demanded for the analysis of biological samples.

At the present time, most of the studies for proteomics employ 2D gel or HPLC-MS. The CE-MS has some promise in this area because of the speed and high plate number [65]. However, Huang et al. [66] have summarized some of the problems involved with separation of protein by CE as part of the proteomics “poor reproducibility, low-sample loading capacity, and low throughput due to ineffective interfaces between the separation and MS systems.” Size separation is often used in protein characterization in gel electrophoresis. This separation works very well in CE for the DNA strands; however, it is more difficult for serum proteins. It is based on adding polymers such as different cellulose derivatives, dextrans, or linear polyacrylamide to the buffers to retard the migration of the large peptides. The proteins have to be denatured and carry the same charge (in SDS) [67]. Several companies offer special kits suitable for this purpose.

Several pure proteins have been purified and checked for their purity, microheterogeneity, or diagnostic significance by CE. In this case, coated capillaries are preferred for this separation. Many of the proteins can be analyzed by CE; however, sensitive detectors such as fluorescence are necessary [68–70]. Examples of proteins studied by CE separately or in a profile are transferrin isoforms, which are important as markers of alcoholism [71],  $\alpha$ -1 antitrypsin [72], recombinant human erythropoietin glycoforms that stimulates erythropoiesis [73], plasminogen tissue activator [74], prions [75], urothelial carcinoma proteins in urine [76,77], and numerous urinary proteins [78].

### 26.7.1 NUCLEIC ACIDS (DNA)

This is an area that represents the best application of CE in the clinical/biological field as discussed in Chapters 12, 16 and 25.

## 26.8 SMALL MOLECULE ANALYSIS

### 26.8.1 DRUG ANALYSIS

Therapeutic drug monitoring is an expanding area for both the clinical and the pharmaceutical industry as discussed in Chapter 4.

### 26.8.2 ENDOGENOUS COMPOUNDS

Many metabolites both ionizable and nonionizable can be measured by different forms of CE such as CZE, MEKC, and chirality. Metabolites with strong UV absorption such as nucleotides, phenolic amino acids, and their metabolites are easy to measure by CE. However, some of these require concentration and clean up before the CE step [5]. This can be achieved by traditional concentrating methods, such as solid phase and solvent extraction; or by concentration on the capillary (stacking). Examples of small molecules that have been analyzed by CE are nucleotides [79,80], amino acids, catecholamines [81–83], and sugars [84,85]. Below is a more detailed discussion of some of these compounds.

### 26.8.3 AMINO ACIDS

Amino acid analysis can be performed for detecting all the amino acids or for few specific ones. Regardless of the type of method, analysis of amino acids is a difficult task because the majority of the amino acids lack a strong chromophore and they resemble each other in structure, which makes the separation very difficult. Thus, they need extra reaction steps to be derivatized pre- or postseparation. Furthermore, physiological fluids like serum contain many interfering compounds such as peptides and the uncommon amino acids. Amino acid analysis can be requested for a wide variety of purposes such as clinical (diagnostic), nutritional, or for basic structure determination.

1. *Specific amino acids*: Analysis of a few or specific amino acids is useful and easy to perform. This often requested in the detection of inborn errors of metabolism (phenylketonuria or maple syrup disease). In these cases, the abnormal amino acids are present in high concentration that makes the analysis simple. Several amino acids have been determined by CE for this purpose, such as tyrosine, proline, and phenylalanine.
2. *Amino acids arising from protein hydrolysate*: This analysis is used often in food industry as well in basic biochemistry. It is important in determination of the structure of protein and in the assessment of the nutritional value of different proteins. Here the analysis of about 20 amino acids is sufficient. This type of analysis is relatively more difficult than that for a single amino acid.
3. *Quantification of free amino acids in serum, urine, or other physiological fluids*: The separation here is complicated by the presence of many interfering substances, such as small peptides and uncommon amino acids. This analysis is requested often for screening purposes.

Traditionally amino acid analysis is carried out by specialized column chromatography instruments (amino acid analyzers). These instruments are quite expensive. More recently, general HPLC with specialized columns have been adapted to run this analysis. Many workers have attempted analysis of amino acids by CE using different pre- and postreactions to enhance their detection. Both free CZE and MEKC have been used with different degrees of success similar to that of amino acids detection by HPLC. The separation of amino acids is better achieved in coated capillaries and also better with MEKC. Derivatization, especially with fluorescent agents, offers much better sensitivity. Several additive agents such as urea, cyclodextrin, and tetrabutyl ammonium salts improve the separation. Chiral amino acid separation based on MEKC has been developed to analyze and quantify both D- and L-amino, which can be useful for detecting bacterial contamination [86,87]. On-capillary derivatization of amino acids in serum with laser-induced fluorescence (LIF) detection has also been reported [88]. Amino acid by CE has been reviewed [89–92]. The analysis of amino acids from biological fluids by CE without interference and with good reproducibility remains a challenge. A dedicated CE instrument for amino acids separation might someday be commercially available.

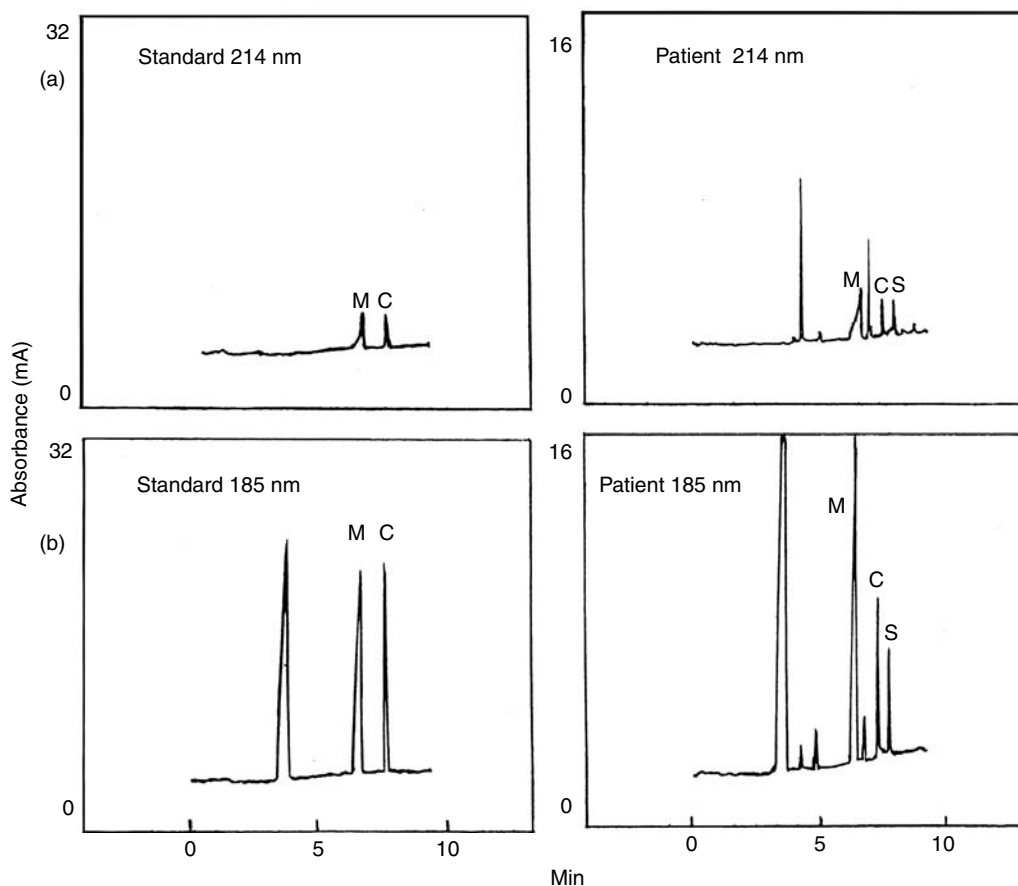

#### 26.8.4 ION ANALYSIS

Many organic and inorganic ions are components of the biological fluids and cells. Most of these have clinical and physiological importance. A change in their normal level is associated with different disorders. Inorganic ions in the serum are important for maintaining cell viability, muscle excitability, osmotic pressure, and regulating the pH. Thus they prevent muscle, renal, and heart malfunctions. Organic acids are intermediates in the metabolism of many compounds in the cell. Clinically they are important for detection of inborn errors of metabolism, infection, and different metabolic disorders, such as diabetes. Some of the ions are not easy to measure regardless of the method. These ions resemble each other, lack strong absorbency and may be present in low concentration. Depending on the type of the ion, they are analyzed by several techniques [e.g., HPLC, automated clinical analyzer, gas chromatography (GC), atomic absorption, or mass spectra]—all technically very involved. Many inorganic ions are measured routinely in clinical labs. In practice, the common inorganic ions, such as Na, K, Ca, can be measured more conveniently and rapidly in the clinical labs by ion-selective electrodes built into highly specialized instruments.

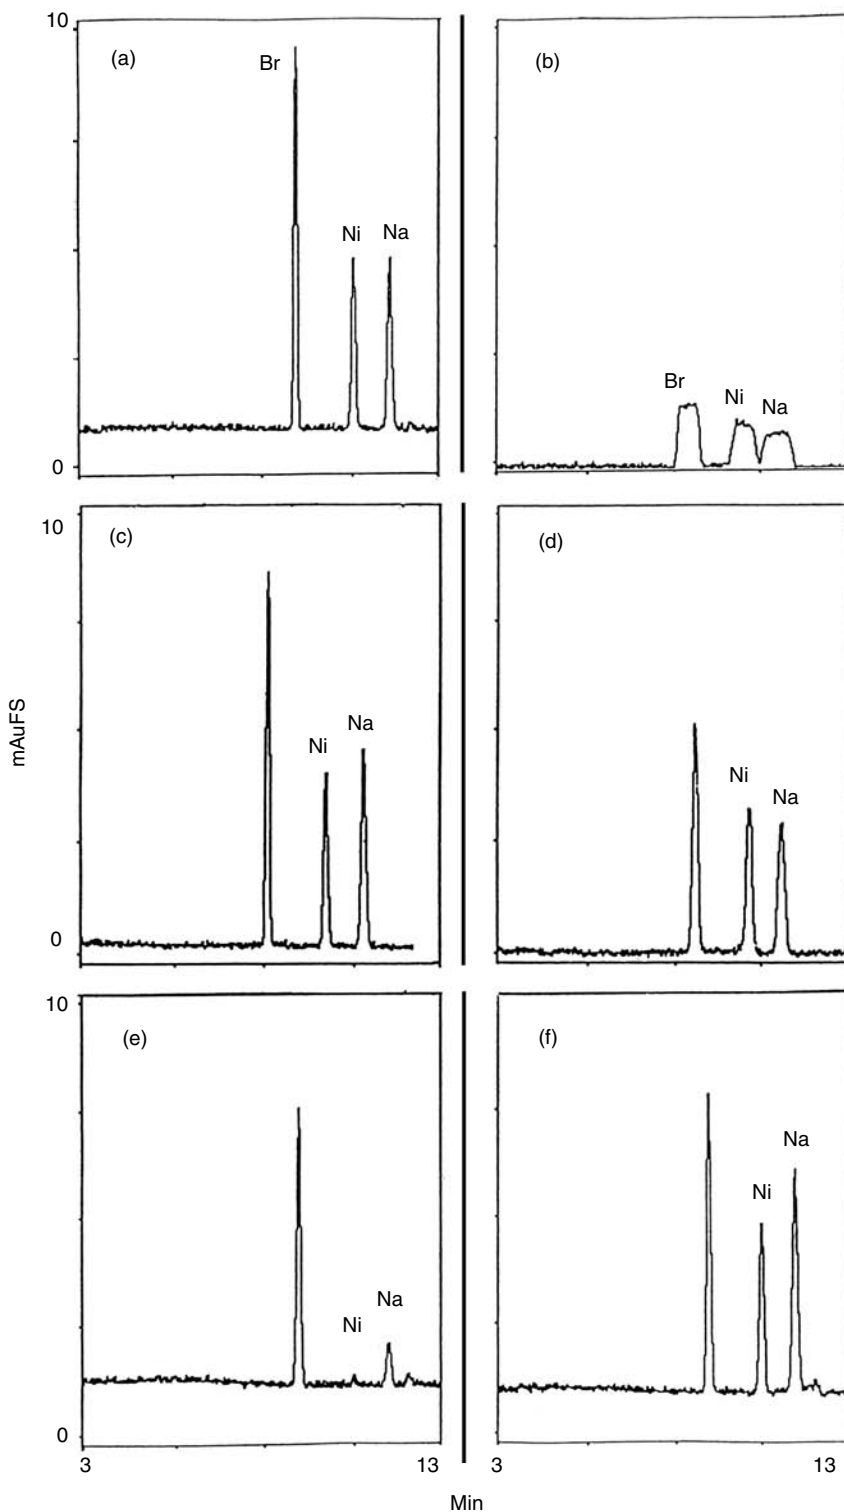

The CE is quite suited for analysis of these ions too. Because of their relative charge to the small mass, they tend to migrate rapidly in this technique giving fast separation with very high theoretical plate numbers at a low cost per test. Both cations and anions can be analyzed in the same run. The separation can be based on simple free solution CE or based on a suitable chelating additive. In general, cations are measured in a low pH electrolyte containing a UV active species (imidazole

or benzylamine), while anions are measured after reversing the EOF and also after adding a high mobility UV active species.

Organic acids are more difficult to measure compared with inorganic ions. Usually, these are measured by the GC or HPLC. However, CE offers speed, precision, and specificity over other methods. Many of these compounds have been measured by CE directly, or by indirect UV absorbency after the addition of a UV-absorbing compound such as benzoate, naphthalene, sulfonate, imidazole, or benzylamine. For example, oxalate and citrate (Figure 26.7), which are important in stone formation, have been measured after urine dilution by both direct and indirect UV detection [93–95]. Lactate, pyruvate, ascorbate, and oxalate were measured by CE in serum and in cerebrospinal fluids of patients in  $\sim 10$  min [96,97]. Methylmalonic acid, which is a sensitive measure of vitamin B<sub>12</sub> deficiency, preceding any clinical symptoms or changes in the serum level, has been determined in urine by CE after sample extraction and concentration [65,98]. Some of the uncommon ions such as nitrite and nitrate can be measured easily with CE (Figure 26.8) [99]. Plasma NO<sub>2</sub> and NO<sub>3</sub> were analyzed after sample dilution using absorbance at 214 nm [100] and after serum deproteinization with acetonitrile (Figure 26.8). We found the CE is much faster and less expensive for nitrate analysis when compared with the enzymatic methods. CE has been applied for the determination of arsenic acid and its related compounds using indirect detection in ammonium formate buffer [101]. Few

**FIGURE 26.7** Effect of the wavelength on citrate detection by CE. (a) Standard of malonic acid (500 mg/L) and standard of citric acid (1000 mg/L) with detection at 214 nm; and patient urine at 214 nm; (b) same as top but detection at 185 nm (C, citric acid; S, Succinic acid; M, malonic acid. (From Shihabi, Z., et al., *J. Liq. Chromatogr.*, 24, 3197, 2001. With permission.)

**FIGURE 26.8** Nitrite (Ni) and nitrate (Na) (6 mg/L), analysis by CE, added to (a) water without acetonitrile, (b) 0.9% NaCl without acetonitrile, (c) 66% acetonitrile in water, and (d) 66% acetonitrile in 0.9% saline. (e) Serum from an individual with low levels of nitrite and nitrate (for spiking), deproteinized with acetonitrile (66% acetonitrile final concentration), and (f) the same serum spiked with nitrite and nitrate (6 mg/L, 66% acetonitrile final concentration). (From Friedberg, M. A., et al., *J. Chromatogr. A*, 781, 491, 1997.)

ions, such as Fe, Ni, Zn, citrate, and oxalate, have been determined in urine based on transient ITP [102]. Hydrogen peroxide that is involved in many biological reactions has been measured after acetonitrile stacking [103].

## 26.9 CONCLUDING REMARKS

The CE can be adapted to the separation of numerous compounds of clinical interest with some compounds being more suited than others. It offers different advantages in the clinical field notably, speed, high plate number, automation, and low operating cost. It is a good complement to other separation techniques. At the same time, the CE has few limitations, such as poor detection limits and the effect of the sample matrix on the separation. Understanding the principles behind these limitations allows better strategies to encounter them. Biological samples usually have a high content of protein and salts with a very wide range of concentrations for many compounds. This requires special attention to how the samples can be treated, how the separation buffer is chosen, and how the capillary is treated. The practical aspects and the special conditions for the separation of biological samples are described. The CE has matured enough that there are several companies putting on the market specialized fully automated instruments dedicated to special functions or special clinical compounds such as serum protein separation, DNA analysis, or isofocusing of proteins. Numerous applications of CE in the clinical field are described especially in the area of proteins, hemoglobin, enzymes, and ions. Since the operating costs are much less than that of the HPLC, and it does not require any appreciable amounts of organic solvents, application of CE in the clinical field is expected to expand. The CE-MS is being refined for applications in the area of proteomics. There remains a need for simpler methods of isofocusing in capillaries and simpler methods for size separation for proteins. Further researches concerning amino acid analysis, dyes that bind to proteins to improve the detection limits and improve the specificity are needed. The analysis of proteins by CE probably will expand in the future as the separation and detection of microheterogeneity are improved.

## 27.1 INTRODUCTION

Improving the concentration detection limit is the goal of much analytical research and development. While miniaturization leading to lower mass detection limits is by no means trivial, it is at least conceptually obvious how to proceed. On the other hand, approaches to better concentration detection limits often require considerable creativity. In some cases, better detectors offer lower detection limits. Because properties of molecules differ, it is difficult to be globally accurate in a statement of relative merits of detectors, but experience shows that the inherent detection limits for compounds that are well suited for each detector are fluorescence < electrospray ionization mass spectrometry (ESI-MS) ~ electrochemistry < optical absorbance. It is worth noting that low detection limit is correlated with the selectivity of the detector. In fact, in real samples of sufficient complexity (are there any real samples that are not complex?), Nagels<sup>1-4</sup> has shown that detection limits correlate

with the selectivity of the detector. The reason that detection limits correlate with the selectivity of the detector is that the limitation in real analyses is interferences from chemical constituents of the sample. These may be perceptible peaks in an electropherogram, or they may be a “baseline” of poorly resolved, multiple unknown components that vary from sample to sample. When this is the case, attempts to improve the detection limit by increasing the concentration of all the components in a sample will fail.

The high-resolution capability of capillary electrophoresis (CE) coupled with recent progress in comprehensive two-dimensional separations give a glimmer of hope that some day all components of a sample will be resolved, and then detection limits will be dictated by the inherent detector properties. If this is the case, then the act of concentrating all of the components in a sample will lead to better detection limits. A consideration of the peak capacity problem, however, tells us that we have a long way to go to realize this goal. We must, therefore, consider ways to improve analytical methods based on CE and related techniques for real samples knowing that there are more components in a sample that our most well-designed separations system can resolve. What is required is a method that concentrates selectively the desired analytes, and does not concentrate, or better yet, that dilutes undesired components of a sample.

Microextractions have the capability to concentrate selectively compounds with particular chemical properties, and to reject solutes with other particular chemical properties. Microextractions function on a small volume scale. As the volumes involved in microextraction and CE can be (but are not necessarily) the same, and given the capability of microextraction to concentrate analytes selectively, microextractions are a natural choice for improving virtually any CE (micellar electrokinetic chromatography, MEKC; capillary electrochromatography, CEC; etc.) method.

## 27.2 MICROEXTRACTION APPROACHES

This chapter will describe two approaches to microextraction: solid-phase extraction (SPE) and solid-phase microextraction (SPME). It is not a comprehensive review. Rather certain key elements of each approach and how it interfaces to the separations step will be described. As SPE is more intuitively understood, and SPME perhaps less so, there is a focus on SPME. SPME has been reviewed from several different perspectives.<sup>5–17</sup>

SPME was first developed in Pawliszyn's laboratory and applied to gas chromatography (GC).<sup>18</sup> The technique has been commercialized and is available through Supelco (now part of the Sigma/Aldrich company in the United States). The technique has some marvelous attributes—it is more than a different way to carry out a separation. Figure 27.1 shows in schematic form the basic idea as originally conceived. An SPME probe is simply an inert rod or fiber (e.g., an optical fiber) coated with any of a number of types of materials such as the highly polar poly(acrylic acid) or the highly nonpolar poly(dimethylsiloxane). The probe tip can be immersed directly in the sample or head space sampling may be preferred. The most common application is to gas chromatography (GC). The probe is inserted into the injection port where the high temperature and gas flow desorb and carry away the analytes. The commercial device incorporates the SPME probe into a syringe barrel. This both protects it and makes the injection into a GC seamless. Recently, a commercial device, also from Supelco, has become available for interfacing with high-performance liquid chromatography (HPLC).

One property of SPME that distinguishes it from other types of extraction is the phase ratio (organic or extracting phase volume/sample volume). The phase ratio in SPME can be very small (e.g., 1/1000). When the phase ratio is small, then the number of moles of an analyte extracted can be small in comparison to the total number of moles in the sample. Unlike in bulk extraction where most of the analyte can be extracted from a sample, in SPME it is possible that a negligible fraction of the analyte in a sample is extracted. Because of this, the quantity extracted will reflect the “free

**FIGURE 27.1** Scheme of SPME. (a) An SPME probe with an extracting phase as a film on the end of a rod or fiber, and a liquid sample in a container. (b) Extraction by immersion of the probe in a sample or by headspace sampling. (c) Desorption in the inlet of a GC column.

concentration” of the analyte, not the “total concentration.” For example, it is possible to determine total drug concentration from blood serum using a bulk extraction. On the other hand, an SPME experiment can be configured so that the “free” drug concentration is measured. In a sense SPME is to bulk extractions what pH measurements are compared to titrations with base.

Another remarkable property of SPME can be realized with volatile solutes. It turns out to be faster (and more selective) to extract volatile solutes with headspace extraction rather than by immersing the SPME probe into the sample. Gaining speed from headspace extraction seems counterintuitive — after all, headspace analysis involves an extra step (sample—vapor phase—extracting phase vs. sample—extracting phase). The reason that headspace can be faster (more rapid progress toward equilibrium; more analyte extracted in a given time) is that the rate-limiting step in the extraction is typically solute getting out of the sample. The flux of analyte in this case is related to a mass transport coefficient (that depends on diffusion and fluid flow if present) for the analyte in the sample and also to the surface area through which the analyte flux goes. The probe tip-sample surface area is the area across which the rate-limiting flux occurs in the direct immersion case. In the case of headspace analysis, the sample-vapor phase surface area is the area across which analyte flux occurs. The latter area is far larger than the former, so headspace extraction proceeds faster than direct immersion.

Another advantage of SPME over bulk extractions especially and over SPE to a lesser degree is the variety of extraction phases that can be made, and the ease with which phases can be developed and used in research laboratories. In bulk extraction, there are certainly differences among organic solvents in their ability to extract analytes. However, using one organic solvent in preference to another is not a powerful method to control the extraction selectivity. In SPE, chromatographic particles are used. Here, there is a variety of choices. However, preparation of a new phase is time consuming at best, and difficult to do and difficult to analyze at worst. In contrast, making a film of polymer or other type of material on a surface can be very easy. Thickness can be controlled by simple means using dip coating.

SPME does have drawbacks. One potential drawback is the equilibration time. Probes typically equilibrate with sample on the timescale of tens of minutes to an hour or more. In many applications, it is not necessary to wait for equilibrium, thus the extraction step need not take a long time. However, by making the extraction yield depend on kinetic as well as equilibrium phenomena, there will be more matrix effects to consider. Things like viscosity, percent solids, and the presence of species that can foul the probe surface have an influence on a kinetically limited extraction, whereas they do not on an equilibrium extraction. SPME is ideally suited to GC. The fit with liquid-based techniques

is not as simple. Desorption must be into a solution or liquid film requiring some thinking about the chemistry, while in GC, there is nothing really to think about except the details: elevating the temperature in the gas phase will release the extracted analytes into the column. Desorption in CE (and HPLC) often involves a solvent that can itself dissolve in the film, so desorption can be faster than adsorption—on the minutes timescale. On the other hand, it takes some effort to mate a purely organic extract with CE.

Finally, there are some secondary considerations in SPME that, if properly handled, can improve analysis. SPME probes are reusable, which is great from a cost and environmental burden perspective, but as a consequence carryover is a concern. Washing (or heating for volatile solutes) is essential between applications. Modifying the sample, for example, by adding salt, can influence analyte yield. Unlike in SPE or bulk extraction, it is not necessary to choose between a polar and a nonpolar phase. Phases with both properties, e.g., Carboxen/PDMS exists. Carboxen is a porous carbon that adsorbs polar and nonpolar solutes, and PDMS is quite nonpolar.

SPE is conceptually simpler than SPME. Sample is passed through a packed bed. The bed strips the analyte from the sample. A desorbing solvent is then passed through the bed and passed on for analysis. Commonly used phases are C18 and polystyrene/divinylbenzene (PS/DVB), but others more selective are also used as will be discussed below. It is difficult to generalize, but despite the nominally similar size of the objects used for SPME and SPE (mm length scale, 100  $\mu\text{m}$  diameter scale) the phase ratio (extracting phase/sample) is larger in SPE than SPME because of the porosity of most materials used in SPE. Consequently, it is not typically the case that the extraction reveals the “free” concentration of an analyte. Also because of the porosity and thinness of the extracting layer, for example, in a C18 material, the presence of the support (nominally the same in an optical fiber-based SPME and a silica-based SPE) can be more evident in SPE. Some skill is required to prepare CE- or capillary HPLC-scale packed beds. There are practical advantages of SPE, too. Packed beds are a natural match to flowing fluid, so adsorption and desorption are easily carried out by solvent switching. There is a considerable history of adsorbent selectivity that can be applied to new problems. As the typical particles are small, adsorbent layers are thin and mass transport outside of the particles is rapid because the fluid flow augments diffusion, equilibration times (equivalent roughly to the C term in the van Deemter equation) are short.

The defining features of SPME are mostly film-based, and the film volume is markedly smaller than the sample volume. SPE is typically particle-based with a larger phase ratio. However, these terms are not precise, and they are used differently in the literature. Also, there are some approaches that simply do not fall easily into one category or the other. This writer is not enthusiastic about creating unique terms for even finer distinctions between techniques, so this will be avoided here. The terms SPME and SPE will be used generally, though not exclusively, as the original authors used them. When all else fails, or for general comments, the abbreviation SP(M)E will be used.

SPME has been applied to CE and related techniques, first by Li and Weber<sup>19</sup> offline and then by Nguyen and Luong<sup>20</sup> with online back extraction both in 1997. The approach possesses a number of potential advantages, not the least of which is the obvious applications to the chip format in which film and gel (as in sol-gel) formation are possible. Another advantage is that desorption can often be followed by stacking or a variant of it obviating the problem of bandspreading induced by the desorption step. The size scale of CE and SPME are also similar, so the fit is natural from a conceptual perspective. On the other hand, there are engineering difficulties that include among other things how to manage the many fluids required (adsorption, desorption, separation, column rinsing, SPME rinsing), and how to incorporate fluid flow and electrokinetic flow. There are several very useful reviews cited above that are considerably broader than the current overview that provides examples of SPME-CE and related techniques. The remainder of this chapter draws from the primary literature in the hope of presenting the sort of detailed understanding that makes this approach to analytical chemistry understandable, and allows the novice to anticipate problems and recognize opportunities.

## 27.3 PREPARATION OF SPME PROBES

### 27.3.1 COMMERCIAL SPME PROBES

Several workers use commercial SPME probes in conjunction with CE and related techniques. In all cases, probes were conditioned both before first use and between uses. Poly acrylate (PA) probes were conditioned in 50:50 methanol/water (30 min)<sup>21</sup> or the desorption solvent, for example, acetonitrile.<sup>22</sup> A carboxen/PDMS probe was cleverly conditioned by exposing it to GC inlet conditions (300°C for 2 h).<sup>23</sup> The solutes in this case were halophenols. Obviously, this treatment would not be useful for ionic compounds, for example, cations in a PA phase (although if the cation were a low molecular weight protonated nitrogen base, it may work). Thirty minutes in methanol for a PDMS/divinyl benzene (DVB) probe proved suitable.<sup>24</sup> Other workers<sup>25</sup> used a 30 min initial conditioning for four different types of probes, and used a 20 min conditioning between analyses. The theme is clear. A 30 min exposure to a suitable solvent will work to condition SPME probes for use in CE both before and between analyses.

### 27.3.2 FILMS AND FIBERS

Others interested in the development of SPME *per se* prepare their own probes. It is not necessary to start from scratch. One group<sup>20</sup> purchased a particular optical fiber from Polymicro and used dimethylformamide (DMF) to strip off a layer of nylon. This revealed a layer of PDMS underneath. Of course, PDMS is a well-studied and understood extraction phase, so this is a very clever route to something home made, and thus suited to a particular experiment, but commercially available. Another approach uses a differently coated optical fiber. The polyimide coating on an optical fiber was removed using 98% sulfuric acid at 120°C for 15 h. (*Note:* Hot, concentrated sulfuric acid is extremely corrosive and must be treated with utmost respect. Use the absolute minimum quantity to carry out the task. Use an apparatus in which both the containers of sulfuric acid and the fiber are held in place reliably and securely.) Following this treatment, the clean surface could react with aminopropyltriethoxysilane (APTES) to form an amine (ammonium in neutral or acidic solutions) surface. The surface could also be exposed to a solution of pyrrole and ammonium persulfate in 1:1 water/isopropanol for forming a poly(pyrrole) surface.<sup>26</sup> When interfacing with CE, handling the probe is a problem. Typically, CE does not involve a device for injection, rather the injection is made directly into the separation capillary with no other mechanical device (even if a mechanical device such as an autosampler is used, at most the mechanical assistance in the injection *per se* is something to pierce the septum enclosing the sample). Thus, unlike HPLC and GC, interfacing requires creativity. This topic will be taken up below. Here, though, it is appropriate to describe an approach that permits both modification of a surface and adaptation of the probe to a device. Whang and Pawliszyn<sup>27</sup> developed a method to create a probe suitable for CE, and that fits into the commercial, syringe-like holding apparatus (see Figure 27.2). The probe thus formed is placed into the syringe-like apparatus that is commercially available after the probe with which it came is removed. While the field of SPME has been dominated by a handful of phases spanning a wide range of polarity, there are other phases with excellent properties. Poly vinylchloride (PVC), appropriately plasticized, is the basis for ion-selective electrodes. In a sense, SPME experiments have been done on this material for decades, but without that explicit purpose in mind. Valenta et al.<sup>28,29</sup> has described the fact that the polarity of plasticized PVC depends on the plasticizer. Zhang et al. has demonstrated that the polarity also depends on the ratio of plasticizer to polymer.<sup>30</sup> Li and Weber<sup>19</sup> have used this material in SPME-CE. The probes are based on a stainless steel rod. A primer coating of poly(vinylchloride-*co*-vinyl alcohol-*co*-maleic acid) permits a coating of plasticized PVC (dip coat from tetrahydrofuran). The probes are reusable. The polymer also plays a role in the selectivity with of extractions based on molecular recognition. A barbiturate receptor in plasticized PVC extracts barbiturates more selectively the lower the polarity of the plasticizer.

**FIGURE 27.2** Preparation of an SPME probe for CE.<sup>27</sup> (a) A 245  $\mu\text{m}$  diameter PA coated optical fiber 3 cm long. (b) Strip the PA from 2 cm. (c) Glue a 10 cm long piece of fused silica capillary (100  $\mu\text{m}$  ID, 245  $\mu\text{m}$  OD) to the distal 0.8 cm of the exposed 2 cm. (d) Cut at a point 1.0 cm from the end of the capillary. (e) Etch with HF (*Note:* use in a hood. Breathing HF is harmful.) to about 40  $\mu\text{m}$  diameter. (f) Dip coat X3 in 3% poly(acrylate).

Porous materials can be used for SPME. Carboxen particles have been mentioned above. A monolithic porous polymer has been prepared for SPME. Wei et al.<sup>31</sup> made a porous polymer monolith with monomers methacrylic acid, ethylene glycol dimethacrylic acid, and a toluene porogen. The material was prepared inside a 250  $\mu\text{m}$  capillary, which had been previously derivatized with a methacrylic acid-containing silane. Following polymerization at 60°C for 16 h, the monolith was washed with methanol, a popular choice for conditioning. Application (which is described more below) uses flow through the medium, so perhaps this is more properly called micro-SPE. However, the authors call it SPME, and it is an interesting approach, so it is being described here. Zhou et al.<sup>32</sup> used molecular recognition to assist in the SPME. A conjugate of the well-known small molecule host, calix-[4]-arene, with a silane yields a reactive ethoxy silane that is functionalized with the calixarene. A sol of this and tetraethoxysilane with a porogen (-OH terminated silicone oil) was prepared. A fiber was dipped into the sol several times, then the sol was given time to react to form the gel. Control probes were made in which the calixarene-modified silane was not present. These probes were used for head space extractions, then back extraction and analysis with CE. The calixarene probe was more effective for propranolol than the control.

### 27.3.3 PACKED BEDS

Packed beds, as mentioned above, are sometimes described as SPME, and indeed, it may be accurate—that is the extracting phase may reach or approach equilibrium with a sample without extracting a significant amount of analyte on average from the sample passed through the packed bed. Typically, a small piece of a filter material is used as a “frit” to block particle flow at the boundary between a capillary holding the particles and another capillary.<sup>33</sup> If the particles are large enough with respect to the downstream capillary diameter, then there is no need for a frit or other device to contain the particles. In Reference 34, 10  $\mu\text{m}$  particles were introduced into a 180  $\mu\text{m}$  capillary as a very dilute suspension at modest pressure. The bed was formed where the 180  $\mu\text{m}$  capillary met a restrictor that was 50  $\mu\text{m}$  in diameter.

## 27.4 INTERFACING SP(M)E WITH CE AND RELATED TECHNIQUES

### 27.4.1 GENERAL CONSIDERATIONS

Interfacing SPME with CE is not as straightforward as interfacing SPME with GC or as interfacing SPE with CE. Because of the difficulty of interfacing, a lot of work has been done with offline “interfacing.” The general issues faced when considering interfacing (in general) are as follows:

*Preconcentration:* A good extraction/back extraction cycle not only results in a cleaner sample, but analytes are concentrated in the process. Obviously, this argues for using the smallest possible back extraction solvent volume. If this volume needs to be manipulated by hand, that is, if it is not a volume resulting from a programmed mechanical device or by switching on a chip, then the minimum volume of the back extraction solvent will probably be about 1  $\mu\text{L}$ .

*Kinetics:* An effective extraction/back extraction cycle is fast. Slow extraction or back extraction requires that the designer of the system be cognizant of the details. Slow extraction can obviously lead to poor yield. Operating in a kinetic regime means that many more parameters influence the outcome in comparison to operating with the extraction at equilibrium. Slow back extractions have the same problem. In addition, a slow back extraction online can add to bandspreading.

*Fluid management:* Depending on the design of a system there may be five different fluids needed for an analysis: sample, back extraction solution, running buffer/electrolyte, extraction phase rinsing, and column rinsing/conditioning solution. These liquids need to be managed appropriately for a successful outcome of a single analysis and for good reproducibility.

On balance, the design of a system is a trade-off between the complexity of mechanization/automation versus the savings of time (and improvement in reproducibility) once the effort to automate/mechanize has been made. Because the effort to create online systems is considerable, there has been significant effort in offline systems. Both offline and online systems are covered below. The section on “online” systems includes methods that have at least one online step.

### 27.4.2 OFFLINE

Both in-sample and headspace approaches have been used in conjunction with CE. The forward extraction, as is typical for SPME, can take an hour or more to equilibrate. The yield of the extraction is improved by the addition of salt (typically NaCl). As the probe is intended to reach equilibrium with the sample and not extract a large fraction of the moles of analyte in the sample, the volume of sample can be immaterial. The first SPME-CE paper used offline extraction and back extraction.<sup>19</sup> Management of the back extraction solution was made easier by keeping it in a piece of Teflon<sup>®</sup>. The general scheme is shown in Figure 27.3.

Using such a system, the back extraction solution can be kept to a few microliters. In most instances, however, the back extraction is into a much larger volume of 20–200  $\mu\text{L}$ .<sup>21–24,31,32</sup> In most cases, the back extraction medium is not highly ionic. This permits stacking, electric field-induced concentration at the interface between the relatively high conductivity running buffer and the relatively low conductivity back extraction solvent. The option to stack means that it is less urgent to use a small volume of back extraction solvent.

In most of the articles cited above, the authors measured the desorption kinetics. These turn out to be remarkably consistent—with about 90% recovery (from the probe) in minutes ( $\sim 3$ –10 min). This is interesting, because at least two modes of back extraction are used. In one, a solvent more “organic” than water is used (e.g., methanol or acetonitrile). On the other hand, the ionic nature of

**FIGURE 27.3** Off-line extraction and back extraction with back extraction solution management.<sup>19,21</sup> (a) extraction with SPME (dark portion = extracting phase, diagonal hatching = sample). (b) Separately, inject a small volume (few  $\mu\text{L}$  of back extraction solvent into a Teflon<sup>®</sup> tube sized to have a diameter just larger than the diameter of the SPME probe. (c) Insert the probe into the back extraction solution-containing probe. The solution will spread between the wall of the tube and the extracting phase. (d) Following the back extraction, remove the SPME probe. Using an empty syringe, move the droplet, which re-forms when the probe is removed, at will.

the analyte is switched by changing the pH of the back extraction solvent from the value existing in the sample.

There is one report of an offline SPME (or perhaps more properly SPE) extraction system for CE analysis in which the offline extraction is automated.<sup>31</sup> The extraction medium is a monolith placed in the loop position of a six-port loop injector. An injector loop upstream contains a large loop with sample. The sample from the loop in the upstream injector is passed through the extraction medium for a controlled time at a controlled flow rate. Following a rinse, the back extraction solvent is then pumped through the monolith into a collection vial. This system has the advantage of the reproducibility of an automated system, and simultaneously avoids the complexity of the interfacing process.

### 27.4.3 ONLINE

When the separation medium is online, it may be within the separation path or not. Figure 27.4 shows the two most common arrangements. One pair of arms (horizontal or vertical) is for sample management, while the other pair (vertical or horizontal) is for the separation. The tubing need not be of the same diameter in each arm or branch. If the SP(M)E medium is in the center of the cross arrangement (Figure 27.4a), then obviously the SP(M)E medium is “online” during the separation. Elution from the SP(M)E material occurs in the separation column. This places severe demands on the effectiveness of the back extraction and the volume of back extraction solvent. Of course, stacking may be used to address problems of having an initial back extraction zone that is too large in many cases. The back extraction must be complete in the arrangement, too. If it is not, the peaks will tail, or worse, the separation will be impossible. If the SP(M)E medium is in one branch of the cross, then the demands on the back extraction are not as severe. Incomplete back extraction is permitted. A flow-gate type of injection is possible to assure narrow zones. On the other hand, the back extraction solution can be directed onto the separation column if stacking, sweeping, or other online reconcentration is possible. Variations on these themes exist as well.

This sort of cross arrangement has been used by several workers. Peptides were trapped, separated by CE, and detected by ESI-MS using an arrangement as shown in Figure 27.4b.<sup>34</sup> This paper demonstrated the creation of the online SP(M)E in a PDMS chip. Once every 10 s a 1 s injection was made from the back extraction solution. It appeared that the peptides eluted from the SP(M)E

**FIGURE 27.4** (a) A cross arrangement for online extraction and back extraction with the extraction medium centered in the cross. (b) Reaction medium in one arm.

[very high surface area hypercrosslinked poly(styrene)] over about a 3 min period. In a similar way (Figure 27.4b), a short capillary packed with small fibers (Zylon) was used for the extraction of tricyclic antidepressants.<sup>35</sup> Samples could be driven through the extraction medium at a high flow rate (80  $\mu\text{L}/\text{min}$ ). Back extraction volumes varied, but were in the range of 2  $\mu\text{L}$ , of which 4 nL were injected onto the CE column. An alternative arrangement similar to Figure 27.4b has only three arms. The “waste” line for the extraction and the running buffer source (positive electrode in “normal” polarity) capillary are the same.<sup>36</sup> This leads to interesting possibilities for flow control, as pressure flow going through the SP(M)E medium splits—a predictable amount going to waste, and a predictable amount going onto the separation column.

A cross like Figure 27.4a has been used for affinity capture by Guzman.<sup>37</sup> In this case, each of the four arms is outfitted with a valve as well, so the flow is completely controllable. As mentioned above, however, it is important to desorb the analytes into a small volume and rapidly. Guzman uses 100 nL of desorption solution (pH 3.4 glycine buffer or acetonitrile) to dissociate the antibody–analyte complexes. A cross with medium centered in it was fabricated on a chip.<sup>38</sup> In this paper, the goal was manufacturing, not applying, the SP(M)E. A small packed bed served as the hydrophobic medium. Laser-induced fluorescence was used for detection of the “analyte,” fluorescein. Interestingly, the beam was split so that the luminescence from the fluorescein in the extraction chamber could be seen. Evidence of rapid and complete desorption was obtained in this way.

It is possible to construct a system in which there is only one pair of “arms”—that is with an extraction medium and a separation capillary in series. In an example of this, Yates and coworkers<sup>33</sup> extracted proteins and then desorbed them into a zone of methanol introduced with a 45 s electrokinetic injection.

The previous works have been based on beds of particles or fibers. Films, that is, with a construction similar to commercially available SPME probe tips, can be used online. The first publication in this area was half online. The sample extraction was carried out offline, but desorption and analysis was managed online.<sup>20</sup> In this and other papers, the extraction fiber is constructed as in Figure 27.2. A fiber with analytes adsorbed is inserted into the injection end of the capillary. The injection process involves introducing not sample but a desorption solution. The flow may be stopped to allow for desorption (recall that it can take several minutes), then restarted for separations. In a similar vein, Whang and Pawliszyn<sup>27</sup> created a system in which fibers with extracted analytes were moved to a capillary for desorption/analysis. In this case, though, the desorption solution is injected into the capillary before inserting the SPME fiber into the end of the capillary. Also in this case, the fiber is attached to a syringe for ease of handling. While it is an advantage in some sense, the use of a low (organic/aqueous) phase ratio does limit the number of moles extracted from a sample. As this places limitations on the follow-up analysis (mass detection limit), there is some advantage to keeping the SPME tip “long.” The “active” extracting tips are typically  $\sim 1$  cm in length. One may wonder about the effect of creating an annular space filled with analyte on bandspreading in CE. Stoyanov and Pawliszyn<sup>39</sup> have shown that the problem is not too large. Because the cross-sectional

area of the annular space created by inserting the probe into the injection end of the capillary is small compared with the full cross-sectional area of the capillary, the field is higher in the annular space than the capillary. This requires that the velocity of the analytes slows down when they reach the full capillary (having come from the annular space). The result is a compression of sorts that helps keep the injection-induced bandspreading to a minimum.

Another way to fight the potential bandspreading from the desorption/injection process is to perform isoelectric focusing rather than  $C(Z)E$ .<sup>26</sup> The focusing effect of the separation technique undoes any bandspreading resulting from the desorption injection process.

Despite clever approaches, the online desorption/injection from SPME is not a “natural” fit. An approach that holds promise for macromolecular analytes is to use microdialysis as an intermediate step. Liu and Pawliszyn<sup>40</sup> achieved this by back extracting and moving analytes electrokinetically into the lumen of a microdialysis probe, then inject from the lumen into the separation capillary. The beauty of this is that the sample stays in the (small) microdialysis probe volume, but electrolyte and current can pass through the walls of the microdialysis probe.

Some general practical comments are in order. Care must be taken to make good butt connections when coupling capillaries. Band spreading can result from poor connections. Many applications of SP(M)E-CE are partly offline, or involve physically working with capillaries. Also, solvents of various sorts are used for desorption. Therefore, there is abundant opportunity for the formation of bubbles. It is a good idea at some point in the process to use pressure to flush the system before using electrokinetic forces for separations. Many publications discuss moving fluid where desired using both pressure and electroosmotic flow. Because flow control generally needs to be quantitative, it is often necessary to have valves or pressurized electrolyte containers to facilitate predictable fluid flow.

## 27.5 RANGE OF APPLICABILITY

The range of analytes accessible to SP(M)E/CE is wide. Drugs, pollutants (and very hydrophobic ones like polyaromatic hydrocarbon, PAHs), proteins/peptides have all been determined using the methods described herein. There does not seem to be any sacrifice in separation modes, either. CE, capillary isoelectric focusing, MEKC, nonaqueous CE can all function with some form of SP(M)E. Methods of detection are similarly broad, encompassing at least the three most common: optical absorbance, laser-induced fluorescence, and MS. It is perhaps foolish to attempt to generalize, but it does seem that an improvement in concentration detection limits of about 100-fold can be realized through SPME in conjunction with CE.

## 27.6 CHALLENGES FOR THE FUTURE

### 27.6.1 SELECTIVITY

Many analyses are for a few similar molecules, or a class of molecules. In such cases, selectivity is highly desirable in the extraction. Selectivity in SPME has been reviewed.<sup>41</sup> Information is also available at the Supelco website (this author is not and has never been funded by Supelco, and this author has no financial interest in Supelco) [http://www.sigmaaldrich.com/Brands/Supelco\\_Home/Spotlights/SPME\\_central.html](http://www.sigmaaldrich.com/Brands/Supelco_Home/Spotlights/SPME_central.html).

Ultimately, molecular selectivity is desirable. Calix-[4]-arenes improved the extraction of propranolol. Antibodies can be used for affinity separations. Li et al.<sup>42</sup> have demonstrated selectivity for barbiturates using a specially designed receptor molecule. The need for more selectivity is made clear by the following common observation. Recall that SPME extractions can take a long time to reach equilibrium. Is it worthwhile to wait for equilibrium? It can be as mentioned above, it should be more reproducible. But interestingly, for many samples extracted by direct immersion of the probe into the sample there is no detection limit advantage to longer extractions because interferences

are extracted along with analytes. More research and development on selective phases is certainly needed.

### 27.6.2 DESORPTION/INJECTION

There remains, despite some very clever approaches, a need for a seamless union of SPME and CE. This may ultimately come with lab-on-a-chip developments, as the goal of much of this sort of research is complete analysis. In other words, rather than the necessary voltages, pumps, valves, and pressure sources being a bother (as it is to a worker using commercial CE, commercial SPME, commercial valves, etc.) it is a research opportunity for the courageous chemists and engineers designing chips. This prognosis, then, points out a need for the development of extraction phases (with selectivity, see above) that can be emplaced in the microfabrication process. This is an important area for future work.

### 27.6.3 SMALLER PROBES

There is room to make smaller, thinner probes to manage microanalysis. Interfacing them brings new challenges, but also may obviate some problems. Smaller, thinner phases with faster equilibration times may improve the desorption/injection process.

## 27.7 CONCLUDING REMARKS

The combination of SP(M)E and CE is a good idea. CE suffers from poor concentration detection limits; microextractions provide for preconcentration. There is apparently no inherent sacrifice that must be made in separations mode or detection mode in order to make SP(M)E work with CE and related techniques. The biggest advantage occurs when the extraction is fairly selective: then the act of concentrating the analytes (and not concentrating interferences) improves the concentration detection limit for the method. Examples of where this is the case would be in head space extractions, and extractions based on selective or affinity phases. The engineering of the extraction and back extraction online is still awkward, but improving.

## 28.1 INTRODUCTION

Since their discovery in 1990, aptamers have gained increasing attention due to their high affinity and specificity for a wide range of target molecules.<sup>1-5</sup> While aptamer applications are growing exponentially, the time and difficulty of the process used to isolate aptamers are limiting widespread adoption. Recently, the high resolving power of capillary electrophoresis (CE) has been used to select high-affinity aptamers.<sup>6,7</sup> This offers a number of advantages over conventional selection protocols due to the dramatic enrichment rate and selection stringency made possible by CE. These advantages result in a significantly faster and simpler process allowing high-affinity aptamers to be obtained

in several days rather than the weeks to months typical of pre-existing procedures. This chapter discusses the significance of CE-SELEX and describes details of the selection process.

## 28.2 BACKGROUND

The word aptamer comes from the Latin root “aptus” meaning “to fit.” This is appropriate since aptamers are single-stranded deoxyribonucleic acid (ssDNA) or ribonucleic acid (RNA) sequences that fold into unique structures allowing them to bind target molecules with high affinity and selectivity. Aptamers are typically 70–120 bases long, containing primer sequences on both ends to facilitate polymerase chain reaction (PCR) amplification. As shown in Figure 28.1, depending on their sequence, single-stranded nucleic acids can fold into a variety of loops, hairpins, and bulges to generate a wide range of structures. The plethora of structures available make nucleic acids an attractive combinatorial library since sequences can be isolated with affinity for virtually any molecular target.

While the large number of structures available in a library of even relatively short nucleic acids allow aptamers to be isolated for a wide range of targets, it also raises the question of how to identify high-affinity sequences out of so many possibilities. This was addressed in 1990 with the introduction of a process for isolating aptamers that has been referred to as SELEX (Systematic Evolution of Ligands by EXponential enrichment),<sup>8</sup> *in vitro* selection<sup>9</sup> or *in vitro* evolution.<sup>10</sup> The process has been described in detail in a number of excellent reviews.<sup>1–5</sup> As illustrated in Figure 28.2, a structurally diverse library containing approximately  $10^{13}$ – $10^{15}$  ssDNA or RNA molecules is incubated with the target molecule. The nucleic acids contain a 30–80 base random sequence region flanked by two primer regions. Sequences with affinity for the target are separated from nonbinding sequences using filtration, affinity chromatography, or panning. Binding sequences are PCR amplified, purified, and made single stranded to generate a new nucleic acid pool suitable for further rounds of enrichment. This process is continued until the pool converges on a collection of sequences with high affinity for the target. Typically, 8–15 selection cycles are required to generate a pool containing a significant abundance of high-affinity aptamers. Individual aptamers are then cloned and sequenced from this final pool for further characterization.

Aptamers have been obtained for hundreds of targets.<sup>1–5</sup> Low nanomolar to picomolar dissociation constants are typical for large protein targets. Aptamers of therapeutic interest have been isolated for a number of drug targets including HIV components,<sup>11,12</sup> the influenza virus surface

**FIGURE 28.1** Secondary structure of a DNA aptamer selected using CE-SELEX to have affinity for neuropeptide Y. (From Mendonsa, S. D., Bowser, M. T., *J. Am. Chem. Soc.*, 127, 9382–9383, 2005.)

**FIGURE 28.2** Schematic representation of the SELEX process. A random sequence ssDNA library is incubated with the target molecule. Binding sequences are selected using a filter or affinity separation, PCR amplified, purified, and made single stranded, generating a new pool suitable for further cycles of enrichment. High-affinity aptamers are typically obtained after 8–15 rounds of selection.

glycoprotein hemagglutinin,<sup>13,14</sup> and the amyloid conformer of the prion protein.<sup>15,16</sup> Macugen, a treatment for age-related macular degeneration (AMD), is the first aptamer-based drug to gain Food and Drug Administration (FDA) approval and is now available to the public.<sup>17</sup> There are a number of other promising therapeutic aptamers in clinical trials.<sup>18</sup>

Aptamers have an even more diverse role in diagnostics.<sup>19,20</sup> Highly specific aptamers have been used as affinity probes in CE<sup>21–23</sup> and proteomic microarrays.<sup>24–28</sup> Aptamers have been incorporated into fluorescent switches and beacons.<sup>29,30</sup> They have been incorporated into chromatography<sup>31–33</sup> and capillary electrochromatography<sup>34–40</sup> stationary phases. They have even been used as the sensing element of cantilever-based detectors.<sup>41</sup> Clearly, the combination of high affinity and selectivity provided by aptamers can be applied to a wide range of analytical techniques.

The high affinity and selectivity of aptamers draw obvious comparisons with antibodies.<sup>19</sup> Although similar in many respects, aptamers hold several advantages. Once their sequence is known, aptamers are cheaply synthesized with little variation between batches. Modifications such as fluorescent tags and non-natural bases can be easily incorporated into the synthesis. Isolating aptamers does not require animals. Aptamers can therefore be obtained for molecules that are toxic or do not stimulate an immune response. Aptamers are not restricted to use in physiological conditions. The structure and affinity of aptamers can be easily manipulated by changing buffer conditions, heat, pH, and so forth. Aptamers will often refold into their original structure once returned to non-denaturing conditions. The relatively small size of aptamers allows them to penetrate tissues more easily, which is attractive in therapeutic applications. Furthermore, their smaller size allows tighter packing and higher loading capacities when attached to stationary surfaces in chromatography or microarrays.

## 28.3 THEORY

### 28.3.1 CE-SELEX

Recently, the high resolution power of CE has been used to isolate high-affinity aptamers (see Table 28.1 and references therein). This process has been referred to as CE-SELEX.<sup>6,7</sup> The CE-SELEX process is illustrated in Figure 28.3. The target molecule is incubated with a nucleic

**TABLE 28.1**  
**Comparison of Aptamers Selected Using CE-SELEX with Those Selected Using Conventional SELEX Protocols**

Target	CE-SELEX		SELEX	
	$K_d$ (nM)	Cycles	$K_d$ (nM)	Cycles
IgE	$23 \pm 12^7$	4	$6^{53}$	15
HIVRT	$0.18 \pm 0.07^{11}$	4	$1^{54}$	12
Neuropeptide Y	$300 \pm 200^{42}$	4	$370^{55,*}$	12
PFTase	$0.5^{45}$	1	n/a	
mutS	$3.6 \pm 0.5^{56}$	3	n/a	
Kinase C- $\delta$	$122^{57}$	9	n/a	—
Ricin	$58 \pm 19^{44}$	4	$105 \pm 41^{44}$	9

\*RNA aptamer.

**FIGURE 28.3** Schematic representation of the CE-SELEX process. A random sequence ssDNA library is incubated with the target molecule. Binding sequences are separated from nonbinding sequences using CE, PCR amplified, purified, and made single stranded, generating a new pool suitable for further cycles of enrichment. High-affinity aptamers are typically obtained after 2–4 rounds of selection.

acid library. Several nanoliters of this incubation mixture are injected onto a capillary and separated using free zone CE. Nonbinding oligonucleotides migrate through the capillary with the same mobility, regardless of their length or sequence. Complexing the target changes the size and/or charge of binding sequences causing them to migrate as a separate fraction. These binding sequences are collected as a separate fraction at the outlet of the capillary. As in conventional SELEX selections, the fraction containing binding sequences is amplified, purified, and made single stranded for further rounds of enrichment. The process is repeated until no further improvement in affinity is observed between rounds.

### 28.3.2 LIBRARY SIZE

In general, as many independent sequences as possible should be included in the initial library. This maximizes the probability that high-affinity aptamers are present in the initial pool. Presumably, sequences with the highest affinity for the target are characterized by more complex, and

**FIGURE 28.4** Effect of injection size on the peak shape of a 2.5 mM ssDNA library separated using CE. Injection parameters were (a) 1 psi, 5 s; (b) 1 psi, 3 s; and (c) 0.5 psi, 3 s. Using a 1 psi, 3 s injection,  $1.8 \times 10^{13}$  sequences were loaded onto the capillary. The arrow shows the position on the electropherogram where collection of binding sequences was stopped. CE conditions: TKG buffer, pH 8.3, UV detection at 254 nm, 50.2 cm, 50  $\mu$ m i.d., 360  $\mu$ m o.d. capillary, 30 kV separation voltage. (From Mosing, R. K. et al., *Analytical Chemistry*, 77, 6107–6112, 2005.)

therefore rare structures than moderate binders with lower selectivity. The number of possible independent sequences in an oligonucleotide library is given by  $4^n$ , where  $n$  is the number of bases in the random region. Total coverage of all potential sequences becomes quickly unmanageable. For example, a moderate length library containing a 60 base random region contains over  $10^{36}$  independent sequences. In conventional selections,  $10^{13}$ – $10^{15}$  sequences are often used in the initial round of selection as a compromise between an adequate coverage of sequence space and practical constraints. CE selection puts further constraints on library size. Injection volume in CE is limited to several nL. Considering this, the concentration of the library must be in the low mM range to inject  $10^{13}$  sequences onto the capillary. This high concentration of ssDNA introduces significant band broadening, making separation of aptamers from nonbinding sequences more difficult (see Figure 28.4). In some cases, the concentration of the library must be lowered to ensure that bound sequences are well separated from nonbinding sequences. Therefore, choosing the optimum library size in CE-SELEX is a trade-off between maximizing sequence diversity and achieving adequate resolution to separate aptamers from nonbinding sequences.

### 28.3.3 SEQUENCE LENGTH

Nucleic acid libraries are typically made up of 70–120 base ssDNA or RNA molecules. These single-stranded oligonucleotides contain a 30–80 base random sequence region flanked by two primer regions. The random region should contain at least 30 bases so that it is long enough to form common structural motifs such as hairpins, bulges, pseudoknots, and g-quartets. Longer sequences add diversity to the pool by providing more positions along the sequence where these motifs can be located. The upper limit to sequence length is often determined by synthetic limitations. Yield and purity drop off dramatically during synthesis of oligonucleotides longer than 100 bases.

### 28.3.4 MODIFIED NUCLEIC ACID LIBRARIES

Fluorescently labeled libraries can be used to facilitate detection during selections. Laser-induced fluorescence (LIF) detection is orders of magnitude more sensitive than UV-absorbance detection making it much easier to reliably observe peaks for the unbound sequences during selections. Fluorescent labels are easily incorporated at the 5' end of ssDNA during initial synthesis. Fluorescent

labels can be incorporated into sequences generated during the selection process by using a 5' labeled forward primer during PCR.

If the final application of the aptamer includes attaching a fluorescent label (e.g., an affinity sensor), it is advantageous to incorporate the label during selection. Postselection modification of the aptamer could modify its structure, and consequently affect affinity or selectivity.

### 28.3.5 TARGET CONCENTRATION

An advantage of CE-SELEX is the flexibility to manipulate the selection stringency by varying the target concentration in the incubation mixture. Target concentrations as low as 1 pM have successfully been used in CE-SELEX selections.<sup>6</sup> Considering the injection volume this resulted in  $10^{13}$  ssDNA molecules competing for binding sites on 10,000 target molecules. This level of stringency is difficult to obtain using conventional macroscale separations. More recent selections have used higher target concentrations.<sup>7,11,42</sup> There is some concern that extreme competition promotes the selection of aptamers that bind target sites that do not optimally bind nucleic acids.

### 28.3.6 CAPILLARY INNER DIAMETER

One of the easiest ways to increase the injection volume, and therefore number of sequences, is to increase the inner diameter of the CE separation capillary. This increase in loading capacity must be balanced with the potential for Joule heating. Joule heating is generally avoided in CE due to the additional band broadening it causes. This is not the major concern in CE-SELEX since peaks are already broad due to destacking caused by the ionic strength of the nucleic acid library. In CE-SELEX, the concern is that Joule heating can change or even eliminate the structures that allow aptamers to bind their targets. Melting temperatures as low as 40°C are not uncommon for some of the structural motifs found in aptamers. Therefore, strict temperature control and elimination of Joule heating are critical for selections to be successful.

### 28.3.7 CAPILLARY LENGTH

Capillary length should be optimized in much the same way as in typical CE separations. An additional factor to consider is that longer capillaries force the complex to stay intact for a longer period of time before collection. Note that even if equilibrium is reached during incubation before injection, as soon as the separation begins the target-aptamer complex migrates into buffer that does not contain the uncomplexed target. Therefore, the off-rate must be on the order of minutes for the complex to migrate through the capillary intact. This can be used to increase the stringency of the selection. Longer capillaries will promote selection of aptamers with slow off rates, which generally have higher affinity for the target.

### 28.3.8 CAPILLARY COATINGS

Coatings are typically used in CE to prevent analyte interactions with the capillary wall.<sup>43</sup> These wall interactions can give rise to severe peak tailing, degrading resolution. In CE-SELEX, interactions between the oligonucleotide library and the capillary wall are minimal since both are negatively charged. Interactions between the target and the wall are more common. These should be avoided since it is unclear how adsorption onto the capillary surface will affect binding sites on the target. Typically, a CE analysis of the target alone is performed before attempting a selection. If a symmetrical peak is observed, this indicates that interactions between the target and capillary wall are minimal. Tailing would suggest that wall interactions are taking place and that buffer conditions or the capillary surface should be modified.

### 28.3.9 BUFFER COMPOSITION

There are a number of important considerations when choosing the incubation and separation buffers. The end use of the aptamer is most important when choosing the incubation buffer. The selection protocol enriches sequences that bind best under these specific conditions. There is no guarantee that the selected aptamers will bind the target under different conditions. Therefore, the incubation buffer should mimic the conditions that the aptamer will be used in as closely as possible. The separation buffer should be similar to the incubation buffer, taking constraints of the CE separation into consideration. High ionic strength buffers give rise to Joule heating and should be avoided. Divalent ions such as  $\text{Ca}^{2+}$  and  $\text{Mg}^{2+}$  interact strongly with the fused-silica walls of uncoated capillaries, affecting electroosmotic flow (EOF). The incorporation of buffer additives to modify the separation should also be avoided since this introduces the possibility of selecting aptamers with affinity for the additive, not the target.

### 28.3.10 NEGATIVE SELECTIONS

Great care must be taken when performing conventional filter or chromatography-based SELEX to avoid isolating aptamers with affinity for the stationary surfaces to which they are exposed to during selection. Negative selections are often necessary to prevent this. Before incubation with the target the library is passed through a filter or the raw stationary support to eliminate sequences that have any background affinity for these stationary surfaces. While effective, this procedure decreases the diversity of the nucleic acid pool before selection even begins.

Negative selections have not proven to be necessary in CE-SELEX selections. No aptamers have been identified that exhibit affinity for the capillary surface. This has been equally true for selections performed using uncoated or neutrally coated capillaries.<sup>6,7,11,42</sup> This greatly simplifies the SELEX procedure and removes one of the significant pitfalls of aptamer selection.

## 28.4 PRACTICAL APPLICATION

Mendonça et al.<sup>6,7</sup> were the first to isolate aptamers using CE-SELEX. They used CE to isolate aptamers with low nM dissociation constants for immunoglobulin E (IgE) after as few as two rounds of selection. This was a significant improvement over conventional selections, which typically take 8–15 rounds. Since then CE-SELEX has been used to isolate aptamers for a range of targets including human immunodeficiency virus reverse transcriptase (HIV-RT),<sup>11</sup> neuropeptide Y (NPY),<sup>42</sup> ricin,<sup>44</sup> protein farnesyltransferase (PFTase),<sup>45</sup> and MutS<sup>46</sup> (see Table 28.1). Berezovski et al.<sup>45</sup> were able to isolate aptamers with subnanomolar dissociation constants for PFTase after a single round of CE-SELEX selection, demonstrating the extreme enrichment provided by CE.

Aptamers selected using CE-SELEX exhibit similar if not better affinity for their targets than aptamers selected using conventional methods (see Table 28.1). Mosing et al.<sup>11</sup> used CE-SELEX to isolate aptamers with dissociation constants for HIV reverse transcriptase as low as 180 pM, fivefold better than aptamers selected using nitrocellulose filtration. Tang et al.<sup>44</sup> directly compared CE-SELEX with conventional selections by isolating aptamers for ricin using both methods. They found that after four rounds of CE-SELEX 87.2% of the nucleic acid pool bound ricin while even after nine rounds of conventional selection only 38.5% of the pool bound target.

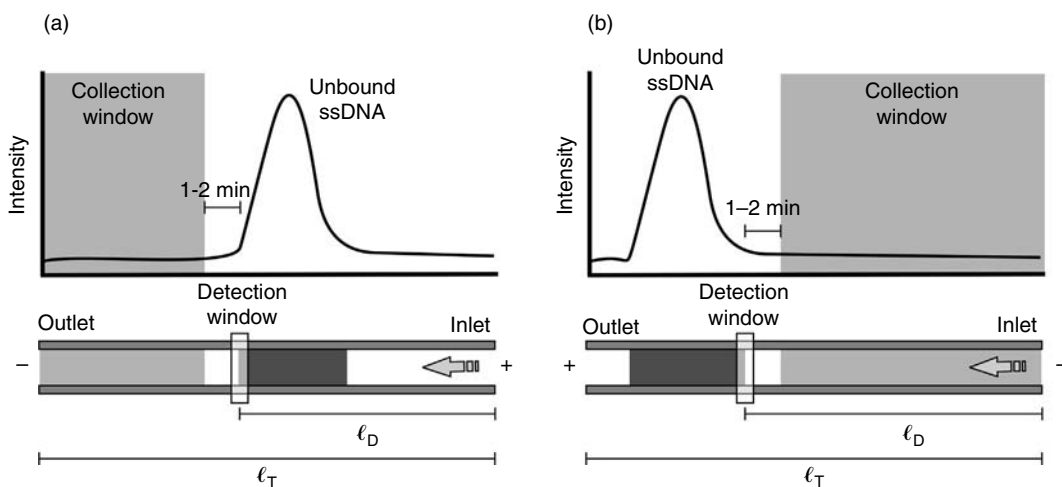

Target size is a potential limitation to CE-SELEX. The target must be large enough to significantly shift the mobility of the aptamer upon binding for fraction collection to be successful. To test this limitation, Mendonça and Bowser<sup>6</sup> used CE-SELEX to isolate aptamers for NPY. NPY is a 36 amino acid peptide with a molecular weight of 4272 g/mol, significantly smaller than the ssDNA in the nucleic acid library (~25 kDa). Aptamers with 300 nM dissociation constants for NPY were isolated, similar to RNA aptamers previously selected using conventional methods. These results demonstrated for the first time that CE-SELEX can be used to select aptamers for targets smaller

than the library itself. It is important to note that the target did not need to be attached to a stationary phase or a large affinity tag as is necessary to perform conventional SELEX selections against small molecules.

## 28.5 METHODS DEVELOPMENT GUIDELINES

### 28.5.1 IDENTIFICATION OF THE COLLECTION WINDOW

For CE-SELEX experiments to be successful, there must be adequate separation between the aptamer–target complex and nonbinding sequences. Initial experiments should be performed to assess the probability that resolution will be sufficient and determine the migration window of the analyte–target complex. This is complicated by the low abundance of binding sequences in early rounds of selection and the low concentration of target used in selections. Both these factors prevent direct detection of aptamer–target complex during selections. Before attempting selections, the nucleic acid library and target should be analyzed by CE separately to determine their migration times. In almost all cases the aptamer–target complex will migrate at a time between the target and unbound oligonucleotides. For large targets it can be assumed that the complex will migrate closer to the free target peak. Note that in almost every case the aptamer complex will have a mobility that is less negative than the unbound sequences (see Figure 28.5). It is difficult to imagine many targets with a more negative charge density than ssDNA or RNA that would give rise to an aptamer–target complex with a more negative mobility than unbound oligonucleotides. If the target and unbound sequences are not separated then it is unlikely that the aptamer–target complex will be sufficiently resolved for successful fraction collection. In this case separation buffer, voltage, injection time, capillary coatings, capillary length, and/or inner diameter should be modified to achieve resolution.

**FIGURE 28.5** Schematics illustrating the procedure for fraction collection in CE-SELEX. (a) When using an uncoated capillary that generates EOF the aptamer–target complex will migrate earlier than the unbound ssDNA. Equation 28.2 should be used to calculate the time required for an analyte that reached the detection window 1–2 min before the leading edge of the unbound ssDNA peak to reach the outlet of the separation capillary. (b) When using a coated capillary that does not generate EOF the aptamer–target complex will migrate after the unbound ssDNA. Equation 28.2 should be used to calculate the time required for an analyte that reached the detection window 1–2 min after the trailing edge of the unbound ssDNA peak to reach the outlet of the separation capillary.

### 28.5.2 FRACTION COLLECTION

Once an adequate separation is achieved, and the migration window of the aptamer–target complex has been identified, CE-SELEX selections can begin. Before selection the nucleic acid library is heated to 72°C for 2 min and allowed to cool to room temperature. This ensures that all sequences fold into their stable room temperature conformations. The library is then incubated with the target (50–500 pM) for 20 min at room temperature to allow binding to occur. It is important to keep the target concentration lower than that of the nucleic acid pool to promote competition for binding sites. An aliquot of the incubation mixture is injected onto the CE capillary and the separation voltage is applied.

The strategy for fraction collection is shown in Figure 28.5. Figure 28.5a shows a typical selection using an uncoated capillary in the presence of EOF. EOF pulls the negatively charged nucleic acid library toward the cathode. The aptamer–target complex is generally less negative and therefore will migrate earlier than the unbound sequences. All sequences that migrate before the unbound nucleic acid peak should therefore be collected. Sequences are collected during the CE separation directly into the outlet vial containing a small volume (~50 µL) of separation buffer. The volume of buffer in the collection vial should be small to facilitate PCR amplification after fractions have been collected. To account for run-to-run variability, the collection window should be set to end a certain period of time (e.g., 1–2 min) before the leading edge of the unbound sequences migrates off the end of the capillary. This time can be adjusted based on the resolution anticipated between the aptamer–target complex and the unbound sequences. As shown in Figure 28.5a, the on column detection of CE facilitates this fraction collection strategy. As there is a length of capillary after the detection window, it takes a certain period of time for analytes to reach the outlet of the capillary after they have been detected. The time that an analyte will reach the outlet of the capillary ( $t_{\text{out}}$ ) is given by

$$t_{\text{out}} = \frac{\ell_{\text{T}}}{\ell_{\text{D}}} (t_{\text{det}}), \quad (28.1)$$

where  $t_{\text{det}}$  is the time required for the analyte to reach the detector,  $\ell_{\text{T}}$  is the total length of the capillary, and  $\ell_{\text{D}}$  is the capillary length to the detector. To account for variation in migration time between CE separations the separation is monitored until the front of the peak corresponding to the unbound sequences is observed. Equation 28.1 can then be used to calculate the time it would take an analyte that reached the detector 1–2 min earlier to reach the outlet of the capillary. The separation is stopped at this time. The vial at the capillary outlet is removed and any sequences remaining on the capillary are washed to waste using a pressure rinse.

Figure 28.5b illustrates the fraction collection procedure when using a coated capillary that eliminates EOF. The polarity of this separation has been reversed since in the absence of EOF nucleic acids will migrate toward the anode. The aptamer–target complex will migrate after the unbound oligonucleotides if it is less negative. In this case, the separation is monitored until the end of the peak corresponding to the unbound sequences is observed at the detector. Equation 28.1 is used to estimate the time it would take an analyte that reached the detector 1–2 min later than the trailing end of this peak to reach the outlet of the separation capillary. At this time the separation voltage is turned off and the vial at the capillary outlet is replaced with a collection vial containing a small volume (~10–50 µL) of PCR buffer. A pressure rinse is used to collect any sequences remaining on the capillary into this vial.

### 28.5.3 PCR AMPLIFICATION

After fraction collection, binding sequences are PCR amplified using standard procedures. Care must be taken during this amplification step due to the extremely low concentration of ssDNA collected. The precise melting, annealing, and extension temperatures are determined by the lengths of the primers and the sequences in the library. The reverse primer should be biotinylated at the 5' end

to facilitate the purification procedure (described in the following section). If the initial library was fluorescently labeled, the forward primer should be similarly labeled at the 5' end.

Note that PCR facilitates release of even high-affinity aptamers from their targets. The first step of the PCR process is a melting stage where the sequences are brought to  $\sim 90^{\circ}\text{C}$ . This melting eliminates all secondary structure from the ssDNA, removing the aptamer's affinity for the target. Once released, the target is quickly diluted in the PCR buffer, making reformation of the aptamer–target complex unlikely.

Successful PCR amplification can be confirmed using standard gel electrophoresis protocols (2% agarose, ethidium bromide). A single solid band of the proper length with little smearing should be observed. Careful controls should be carried out to ensure that the amplified DNA is from the collection and not the result of contamination.

#### 28.5.4 PURIFICATION

PCR amplification generates double-stranded DNA (dsDNA). ssDNA must be recovered for binding sequences to fold into their proper binding structures. Complementary sequences are biotinylated during PCR to facilitate ssDNA recovery. The dsDNA is passed through a streptavidin column. After a short incubation period, the column is rinsed with streptavidin binding buffer ( $10 \times 500 \mu\text{L}$ , 10 mM Tris, 50 mM NaCl, and 1 mM ethylenediamine tetraacetic acid, EDTA) to remove excess PCR reagents. The column is then heated to  $37^{\circ}\text{C}$  in the presence of 0.15 M NaOH to separate the dsDNA without disrupting the biotin–streptavidin complex. The single-stranded forward sequences are eluted from the column while the complementary sequences remain attached to the stationary phase through the biotin–streptavidin interaction.

The ssDNA is immediately neutralized (0.15 M acetic acid) to avoid degradation:  $40 \mu\text{L}$  of 3 M sodium acetate and 1 mL of 100% ice-cold ethanol are added to initiate ethanol precipitation to further purify and concentrate the ssDNA. The solution is incubated at  $-80^{\circ}\text{C}$  for 1 h to ensure complete precipitation. The solution is centrifuged at 14,000 rpm for 15 min at  $4^{\circ}\text{C}$  to pellet the ssDNA precipitate. The supernatant is discarded leaving approximately  $50 \mu\text{L}$  at the bottom of the vial. The following steps are repeated three times to wash the ssDNA pellet:

1. Add 1 mL of ice cold 70:30 ethanol/water
2. Centrifuge 14,000 rpm for 25 min at  $4^{\circ}\text{C}$
3. Discard the supernatant leaving approximately  $50 \mu\text{L}$  of solution remaining in the bottom of the vial

The samples are then dried in a speed vac at  $60^{\circ}\text{C}$  for 25 min or until dry. The resulting DNA pellet is resuspended in  $30 \mu\text{L}$  of buffer, generating a new ssDNA pool suitable for further rounds of enrichment. In the next selection cycle  $10\text{--}15 \mu\text{L}$  is used. The remaining portion is used to assess the affinity of the pool for the target. An aliquot is also stored for further characterization or cloning and sequencing once the selection process is complete.

#### 28.5.5 DISSOCIATION CONSTANT ESTIMATION

The affinity of the nucleic acid pool for the target is measured after every round of selection to monitor the progress of the enrichment. Affinity of the library for the target should increase as the selection progresses. Selection cycles should continue until no further improvement in affinity is observed between rounds. Dissociation constants in the low nM to pM range are typically observed at the completion of the CE-SELEX process.

Dissociation constants can be estimated using affinity capillary electrophoresis (ACE).<sup>47</sup> In these experiments, a constant concentration of the nucleic acid pool is titrated with increasing concentrations of target. Use of fluorescently labeled sequences is recommended since LIF detection

allows detection of much lower concentrations. After incubation, each solution is analyzed using CE. The intensity of the peak corresponding to the unbound sequences decreases as the target concentration increases and the equilibrium is shifted toward the aptamer–target complex. If the condition that the nucleic acid concentration is much lower than the target concentration is met, the dissociation constant ( $K_d$ ) can be determined by fitting the peak intensities to the following equation:

$$\frac{I_0 - I}{I_0} = \frac{c}{K_d + [\text{target}]}, \quad (28.2)$$

where  $I_0$  is the height of the unbound nucleic acid peak in the absence of target,  $I$  is the height of the unbound nucleic acid peak in the presence of target,  $c$  is a constant, and  $[\text{target}]$  is the concentration of the target.

### 28.5.6 CLONING AND SEQUENCING

Once the affinity of the nucleic acid pool has plateaued, individual sequences can be cloned and sequenced from the pool for further characterization. The final pool is PCR amplified for eight cycles to ensure that all sequences are double stranded. Primers should not be 5' labeled with biotin or a fluorescent tag since this will prevent ligation of the sequences into the cloning vector. dsDNA is ligated into a pGEM vector and transfected into DH5 *Escherichia coli* and colonies are raised.<sup>7,11</sup> Plasmids from approximately 30 (or more) colonies are chosen at random and the sequences of individual clones are determined using the T7 promoter sequence.

### 28.5.7 APTAMER CHARACTERIZATION

Once the sequences of individual aptamers are obtained, it is relatively inexpensive to have sufficient quantities for further characterization synthesized. In conventional selections, sequence patterns or motifs are commonly observed in the aptamers recovered from cloning. This suggests that the selection has converged on certain sequence elements that are important for binding the target. Software programs such as ClustalW are readily available for identifying these motifs in large numbers of sequences.<sup>48</sup> Only the random region of the sequences should be entered when using these programs. Otherwise, the homology of the primer regions will dominate the analysis. Contrary to conventional selections, sequence motifs are rare in aptamers selected using CE-SELEX.<sup>6,7,11,42</sup> This suggests that the heterogeneity of the pool remains high even after the selection has converged on a collection of high-affinity aptamers.

Common structural elements can be identified using mFold, a program that predicts secondary structure of ssDNA or RNA.<sup>49</sup> For this analysis, it is necessary to include the primer regions since they most likely contribute to the overall structure of the nucleic acid. This analysis is useful in identifying common structural elements in aptamers even if they are generated by differing sequences.

Sequencing and synthesis allow the affinities of individual aptamers to be determined. Dissociation constants can be estimated using ACE as described above. Affinity of the aptamer should be compared with that of the unselected library or a nonsensical sequence such as polyT as a control experiment. Selectivity should be assessed by measuring the affinity of the aptamer for molecules similar to the target. Affinity should be measured under a range of conditions and in the presence of potential interferents depending on whether the aptamer is to be used as a therapeutic or diagnostic agent. Activity assays should be performed if the aptamer was designed to inhibit the function of the target to determine if the aptamer interferes with the active site.

## 28.6 ADVANTAGES OF CE-SELEX

CE-SELEX provides a number of benefits over traditional SELEX methods. The high resolving power and efficiency of CE generates high rates of enrichment allowing aptamers to be isolated after 2–4 rounds of CE-SELEX selection. Conventional selections typically require 8–15 selection cycles, a process that can take weeks to months to complete. CE-SELEX performs selections in free solution, dramatically reducing the potential for nonspecific interactions with stationary surfaces. CE-SELEX generates a large number of independent aptamer sequences, producing many lead compounds for therapeutic or diagnostic applications. The abundance of high-affinity sequences in the final nucleic acid pool is nearly 100%. In comparison, it is not uncommon for half of the sequences selected using conventional techniques to not demonstrate affinity for the target. Finally, CE-SELEX is much more compatible with libraries that incorporate non-natural nucleic acids to improve aptamer stability. These non-natural nucleic acids often contain hydrophobic functional groups, which promote nonspecific interactions with hydrophobic filter materials, such as nitrocellulose, commonly used in conventional selections.

## 28.7 FUTURE WORK

CE-SELEX has been used successfully to isolate aptamers for a variety of targets (see Table 28.1). While these initial proofs of concept experiments are promising, a more detailed study of the selection process is now needed. CE-SELEX has made the selection process dramatically faster. This will allow fundamental experiments assessing the effect of variables such as library concentration, target concentration, and incubation time to be performed for the first time. The 4–6 weeks that are necessary to complete a conventional selection have made these experiments unfeasible until now.

CE-SELEX opens the door to further advances in automating the selection process. Several researchers have developed automated SELEX instruments based on conventional selection protocols.<sup>50–52</sup> These experiments have demonstrated that automation greatly improves the throughput of aptamer selection. The electrophoretic selection of CE-SELEX suggests that development of an automated microfluidic SELEX device may be possible. Considering the dramatic improvements in the time required for separation, amplification, and purification, which can be obtained by performing these processes on the microscale, it is not difficult to imagine a fully automated microfluidic device capable of performing the entire SELEX process in as little as several hours.

## 29.1 INTRODUCTION

Of the numerous applications of capillary- or microflow-based analyses, especially those involving biological assays, there perhaps is none more fitting than employing microflow techniques to study the circulatory system. In fact, the dimensions of the microcirculation so closely match those of microbore capillary tubing and the channels in microfluidic devices, it is rather amazing that such analytical tools and devices have not been in use to study the events in the bloodstream to a greater extent. Here, a brief introduction to the microcirculation is given such that the nonexpert is able to understand better why microflow techniques are an excellent tool to study *in vivo* processes that occur in the bloodstream. Next, real examples will be given in order to demonstrate how such devices are effective as tools to increase our understanding of the processes occurring in the bloodstream.

## 29.2 BACKGROUND

One of the key features of employing microbore tubing in a microflow system or a microfluidic device to study events occurring in the microcirculation is that the studies can be performed in a controlled

environment. That is, *in vivo*, the circulation is very dynamic. Not only do vessel diameters change (due to vasodilation) but also do the linear rates of the bloodstream, the viscosity of the blood, and hematocrit.<sup>1</sup> There are also slight changes in pH,<sup>2</sup> oxygen tensions,<sup>3</sup> and concentrations of molecules in the bloodstream. Finally, there are also changes that occur at the cellular level that can affect the overall cellular function. Common examples are cell aging and cellular oxidant status that can affect the cell's membrane properties.<sup>4</sup>

The use of a microflow system enables quantitative determinations to be performed in an environment where the many variables mentioned above can be controlled.<sup>5</sup> An excellent example is the linear rate of the blood flow. *In vivo*, it has been shown recently that red blood cells (RBCs) have the ability to control vessel diameter due to their ability to release adenosine triphosphate (ATP) upon shear-induced deformation.<sup>6–8</sup> This ATP is a recognized stimulus of nitric oxide (NO) production in certain cell types including the endothelium<sup>9</sup> and platelets.<sup>10</sup> NO is a potent vasodilator, resulting in the increase of vessel diameter and an increase in blood flow.<sup>11–13</sup> The ability to study the effect of linear rate on the release of ATP from RBCs would be difficult in an animal model because, as the ATP is released (resulting in subsequent NO-induced vasodilation), the vessel diameter would increase, thus changing the overall linear rate of the blood flow through the vessel. By performing such studies on a controlled *in vitro* platform (microbore tubing), the ATP can be measured rather easily via chemiluminescence, but the linear rate will remain constant (because microbore tubing does not dilate).

Another advantage of performing measurements involving the bloodstream using microflow technologies is that blood is a complex sample and, as such, often requires some type of preparation prior to the measurement portion of the analysis. Examples of such preparation schemes using microfluidic devices have been described for automated, high-speed genotyping from droplets of blood<sup>14</sup> and separation of plasma from a flowing blood sample.<sup>15</sup> There also exists numerous examples of cell sorting on microfluidic devices.

Finally, and what may prove in the immediate near future to be the most important aspect of investigating the bloodstream with microflow techniques is the finding that many processes in the bloodstream are actually activated due to the flow itself.<sup>8,16,17</sup> It has long been accepted that endothelium-derived NO is actually stimulated due to a shear stress placed upon the endothelium.<sup>11–13</sup> However, it is also becoming increasingly clear that other events in the microcirculation are also stimulated due to the forces placed upon certain cells when flowing through open tubes (vessels). These same forces can be applied to cells in an *in vitro* format in a microflow system and the resultant cellular response can be quantitatively measured or monitored.<sup>18</sup> In order to better understand the importance of flow for the induction of many cellular events *in vivo*, it is necessary to understand the properties of blood flow *in vivo*.

### 29.2.1 COMPONENTS OF THE CIRCULATION INVESTIGATED WITH MICROFLUIDIC TECHNIQUES

The microcirculation is generally considered to be the blood flow through vessels having diameters that are less than 100  $\mu\text{m}$ . Specifically, this set of vessels consists of capillaries, arterioles, and venuoles. There do exist other classifications within this range of vessels (e.g., meta-arterioles are often defined as those vessels whose diameters range between 10 and 25  $\mu\text{m}$ ). However, capillaries can be defined to have diameters below 25  $\mu\text{m}$  while arteriole diameters range between 25 and 100  $\mu\text{m}$ .<sup>1</sup> However, there exist many different cell types that are determinants of microcirculatory maintenance. Their traditional roles and potential new roles being that are being discovered through microanalytical techniques follow.

#### 29.2.1.1 Erythrocytes

Many researchers consider the microcirculation to be a very important component of the circulatory system due to its 60,000 miles of architecture (vessels) that deliver the different cell types in the

**FIGURE 29.1** Proposed mechanism for the involvement of RBCs and platelets as determinants of vascular caliber in the microcirculation.

bloodstream to the tissues and organs in the human body. Of these cell types, erythrocytes or red blood cells (RBCs) are deemed important due to their classic task of delivering oxygen to the various tissues and organs *in vivo*. RBCs are generally considered as one of the more nonexciting cell types in the circulation. They do not possess a nucleus, mitochondria, or any other key type of organelle. Recently, however, RBCs have gained some attention in the literature due to their association with NO, both as a carrier of the molecule<sup>19,20</sup> and as a potential determinant in NO production.<sup>7,21</sup>

RBCs, when traversing microvascular beds such as in the pulmonary circulation, are subjected to mechanical deformation. Previously, it was reported that, in the isolated perfused rabbit lung, RBCs obtained from either rabbits or healthy humans were a required component of the perfusate in order to demonstrate flow-induced endogenous NO synthesis in the pulmonary circulation. Importantly, it was reported that the property of these RBCs that was responsible for the stimulation of NO synthesis was their ability to release ATP in response to mechanical deformation. Moreover, it was reported that the release of ATP from RBCs of rabbits and humans increased as the degree of deformation increased.<sup>6,22,23</sup>

These reports suggested a novel mechanism for the control of vascular caliber (Figure 29.1). In this construct, as the RBC is increasingly deformed by increments in the velocity of blood flow through a vessel and/or by reductions in vascular diameter, it releases ATP that stimulates endothelial synthesis of NO resulting in relaxation of vascular smooth muscle and, thereby, an increase in vascular caliber. This vasodilation results in a decrease in vascular resistance as well as a decrease in the stimulus for RBC deformation and ATP release. Indeed, it has been proposed that RBC-derived ATP contributes to vascular resistance in both the pulmonary and systemic circulation.

The finding that ATP is released from RBCs in response to mechanical deformation suggests that variables such as vascular diameter and flow rate may be important determinants of ATP release as these cells traverse the intact circulation. An understanding of the contribution of these parameters individually and in combination to ATP release from RBCs in the microcirculation, and in particular in resistance vessels, is of paramount importance for the comprehension of the role of the RBC as a determinant of vascular caliber.

### 29.2.1.2 Platelets

Other formed elements in the bloodstream that are considered crucial are the platelets. Platelets are non-nucleated cells in the bloodstream that are approximately 2  $\mu\text{m}$  in diameter. The main role of platelets involves hemostasis, the prevention of excessive blood loss following vascular

injury. The actions of platelets take place in a dynamic environment: flowing blood. As such, the larger and more numerous RBCs occupy the axial portion of the vessel forcing platelets toward the peripheral endothelial lining.<sup>24</sup> Platelets normally circulate without adhering to undisturbed vascular endothelium. Upon vascular insult, subendothelial collagen is exposed that acts as the primary stimulus for platelet activation. However, several other endogenous agonists also exist such as thrombin, ADP, thromboxane A<sub>2</sub>, serotonin, and epinephrine, which also promote platelet activation.<sup>25</sup> Platelet activation initiates a change in the platelet shape, thus promoting adhesion to the vascular walls and the subsequent recruitment of additional platelets. NO has been widely shown to mediate this process by activating soluble guanylate cyclase (GC) which initiates a protein kinase G (PKG) dependent pathway.<sup>26</sup> In this construct, NO becomes an important determinant in platelet adhesion *in vivo*.<sup>10</sup> If uncontrolled, these adhered platelets become a major constituent of thrombus formation and subsequent vessel blockage.

Recently, platelets have been reported to have unique properties in disease states other than cardiovascular problems. For example, a procedure used in multiple sclerosis, plasma replacement therapy, involves removing such formed elements as RBCs and leukocytes from the patient's plasma and then replenishing new plasma with the previously removed cells. The plasma contains the platelets so, in addition to obtaining new plasma, the patient also receives new platelets. Interestingly, the platelets of people with multiple sclerosis have been shown to be more susceptible to hyperactivity, often aggregating more easily than the platelets of healthy people that do not have multiple sclerosis.<sup>27</sup> The importance of this platelet activity is that platelets are known to create NO upon activation and people with multiple sclerosis have been shown to have high levels of NO and NO metabolites in their cerebral spinal fluid and urine.<sup>28,29</sup> This trait of platelets (prone to activation and aggregation) is also known to exist for patients that have cystic fibrosis.<sup>30</sup> Finally, patients with diabetes also have platelets that are known to be activated more readily than healthy, nondiabetic patients.<sup>31</sup> Exemplifying the importance and complexity of the relationship between platelets and NO is that NO has the ability to inhibit platelet activation.<sup>10</sup>

Interestingly, platelets have the ability to create bioavailable NO in the bloodstream in multiple ways other than by activation. For example, NO can be synthesized inside of the platelet by one of multiple isoforms of NOS<sup>32,33</sup> or from the denitrosation of *S*-nitrosothiols (*S*-nitrosoglutathione or *S*-nitrosoalbumin) enzymatically<sup>34</sup> or by copper-containing proteins.<sup>35</sup>

### 29.2.1.3 Endothelial Cells

Endothelial cells form a single layer within the blood vessels comprising the circulatory system. They separate the flowing blood within the lumen from the vessel wall. While they are present in both arteries and capillaries they have significantly different properties depending on the vessel size. Endothelial cells are involved in many biological roles some of which include vasoconstriction, blood pressure, inflammation, and transfer of materials into and out of the circulatory system. Research of vascular disease has significantly increased the culturing of endothelial cells that are dominantly obtained from the bovine aorta, bovine adrenal capillaries, rat brain capillaries, human umbilical veins as well as other sources. Once cultured, a simple protocol for cell dissociation involving trypsin can be followed to subculture the cells, reseeding them for future divisions or integrating them into microfluidic devices for *in vivo* mimic studies.

## 29.3 THEORETICAL ASPECTS

### 29.3.1 UNIQUE FLOW PROPERTIES OF THE BLOODSTREAM

Collectively, the formed elements that comprise blood in the microcirculation have the properties of a non-Newtonian fluid. As such, flow properties encountered in open tubes are not necessarily

found when the fluid contains components such as RBCs or platelets. Many properties of blood flow in a vessel *in vivo* are difficult to mimic in a section of microbore tubing or a channel in a microfluidic device. For example, the overall pressure drop across an open tube can be described by the expression shown in the following equation.

$$q = \frac{\Delta P r^4 \pi}{8 \mu L}$$

Here, the overall flow  $q$  is dependent on variables such as the pressure applied across the tube ( $\Delta P$ ), the radius ( $r$ ), length ( $L$ ) of the tube, and the viscosity ( $\mu$ ) of the solution. Unfortunately, this equation must be modified somewhat because blood is a non-Newtonian fluid having some pseudoelasticity. Therefore, at similar applied pressures, blood will flow faster than a typical Newtonian fluid. Furthermore, *in vivo*, the vessel diameter (due to dilation and constriction of the resistance vessels) is dynamic and constantly changing. Moreover, the viscosity of blood is very difficult to measure because the hematocrit of blood changes depending on the diameter of the vessel in which it flows. Because of this, blood viscosity *in vivo* is often reported as an “apparent” viscosity. Finally, in the bloodstream, blood flow is somewhat pulsatile, especially in the venous side of the circulation. In sum, it is difficult to know the exact linear rate of the blood flow or a pressure drop at any one point in the microcirculation.

Another aspect of blood flow *in vivo*, and one that plays a major role in such circulation complications such as atherosclerosis and stroke, is that cells will partition themselves into certain areas of the flowing stream. For example, RBCs will typically travel in the middle of the open tube where the convective forces are at a minimum. However, platelets, being smaller in size, then become forced to flow more toward the wall. In fact, a close examination of the components of blood at the wall of the vessel or tube will show that there is actually a cell-free layer (often called the skimming layer) along the wall. This phenomenon was first noticed in the 1920s by Fahraeus and Lindqvist today bears the name of their discoverers.<sup>1</sup>

Interestingly, it may also be a key to a potential new role for the RBC, namely, the ability to participate in the control of vascular caliber in the intact circulation. Furthermore, it is these flow properties that enable such formed elements as the platelets to participate in the repair of damaged endothelium.

## 29.4 APPLICATIONS

### 29.4.1 DISEASE BIOMARKERS

Although tissue analysis is an outstanding point to begin for many experiments in search of biomarkers, the bloodstream represents one of the more accessible tissues from which to extract samples. An example of microfluidic technology helping to determine such a biomarker was recently reported by Carroll, where the amount of ATP released from RBCs that were exposed to shear-induced mechanical deformation.<sup>4</sup> Specifically, RBCs obtained from healthy control subjects were pumped through microbore tubing having diameters that approximated those of resistance vessels *in vivo*. The ATP released from these deformed RBCs was measured using the well-known luciferin chemiluminescence assay for ATP. When compared to RBCs obtained from patients having type II diabetes, the control patients release approximately two times the amount of ATP ( $190 \pm 10$  nMvs.  $90 \pm 10$  nM, respectively) as the RBCs obtained from the patients with type II diabetes (Figure 29.2). Such a screen could be an important marker for adult onset diabetes because one could screen the ATP release, archiving the results for the patient, and subsequently monitor any decrements on perhaps an annual basis.

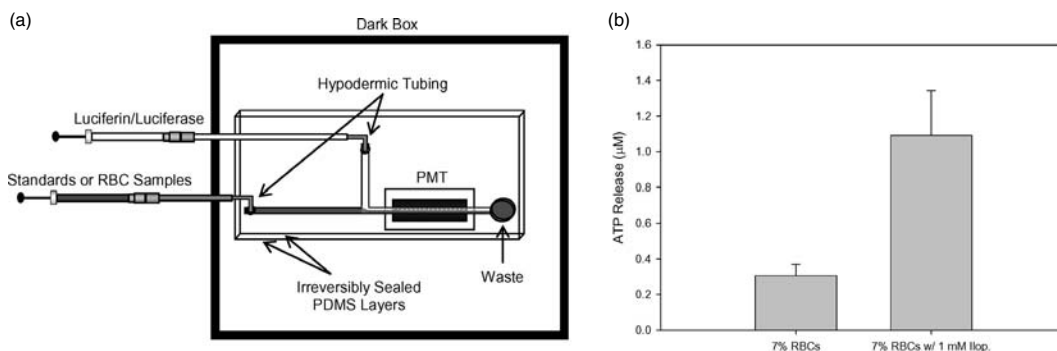

**FIGURE 29.2** Determination of ATP release from the RBCs of diabetic ( $n = 7$ ) and nondiabetic ( $n = 7$ ) patients is shown. The RBCs were pushed through microbore tubing that had an inside diameter of  $50 \mu\text{m}$ . The error bars represent standard errors about the mean. The values shown in the figure differ significantly ( $p < 0.001$ ).

#### 29.4.2 HIGH-THROUGHPUT DRUG EFFICACY INVESTIGATIONS

A microfluidic device has been utilized to explore the mechanism by which vasodilation occurs and the effects of iloprost, a known vasodilator. Iloprost is a second generation prostacyclin analog that has been shown to directly affect vasorelaxation *in vivo* by increasing the amount of ATP released from RBCs transversing the circulatory system. ATP is then free to stimulate the production of NO from endothelial cells resulting in the production of guanosine monophosphate, which is known to relax smooth muscle cells surrounding resistance vessels. This study incorporates the methodology of the previous research and examines the effect of iloprost on the release of ATP from RBCs when forced through a microchannel to mimic the circulation system. An irreversibly sealed poly(dimethyl)siloxane (PDMS) microfluidic device was fabricated from a 4 in. silicon wafer master that was obtained using standard negative photoresist lithographic processes (Figure 29.3a). The channel dimensions measured approximately  $100 \mu\text{m}$  wide by  $100 \mu\text{m}$  deep and were patterned from a negative photomask. This T-channel chip was irreversibly sealed to another PDMS chip absent of any channels after perforating sample introduction and waste ports. A displacement syringe pump and Tygon tubing was used to introduce samples via hypodermic steel tubing inserted into the channels. A 7% RBC solution treated and left untreated with iloprost was mixed with a luciferin/luciferase solution to examine the iloprost stimulated, RBC-derived ATP. The chemiluminescence for all samples and standards was measured in real time by a photomultiplier tube at a rate of 10 measurements per second for 30 s using software written in-house. The results from this study are shown in Figure 29.3b.

#### 29.4.3 MEASURING CELL-TO-CELL COMMUNICATION

Another advantage of microflow techniques to investigate the events occurring in the microcirculation is those involving multiple cell types in a controlled environment. For example, the ability to place endothelial cells in a microfluidic device and monitor the ability of platelets to adhere to these endothelial cells would be beneficial in studies pertaining to vessel blockage due to thrombus formation. Quite often, a thrombus is formed due to platelets, macrophages, and even RBCs adhering to the endothelial wall under certain conditions. The ability to quantitatively monitor those

**FIGURE 29.3** (a, b) Determination of ATP release from RBCs incubated with iloprost, a stable analog of prostacyclin, in a microfluidic format.

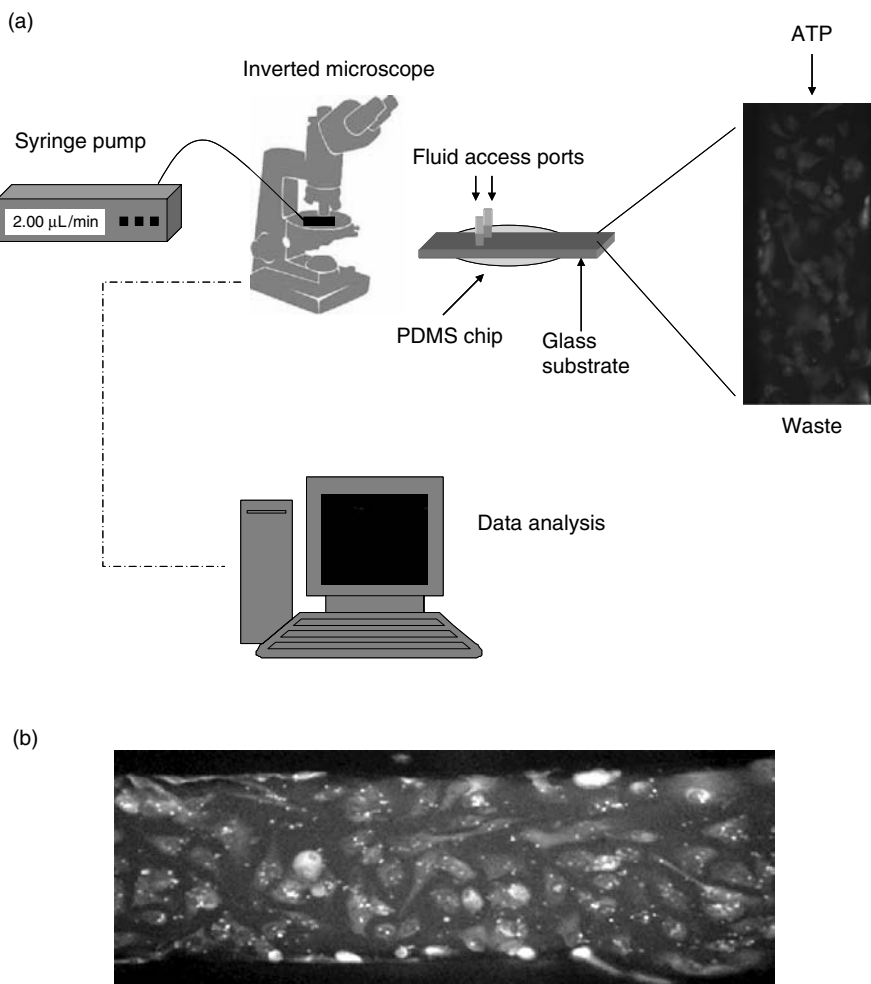

molecules involved in the thrombus formation or those molecules that prevent such adhesion events would be useful to the biomedical community. Figure 29.4a shows an endothelium coating in the channel of a microfluidic device.<sup>9</sup> The dimensions of this channel approximate those of resistance vessels *in vivo*. Figure 29.4b shows activated platelets flowing over an endothelium. Importantly, a close observation reveals that, in certain areas, platelet recruitment is occurring; that is, upon activation, platelets become somewhat sticky and adhere to each other in addition to the endothelial wall. In such a scenario, these platelets become determinants in the mechanism of vessel blockage. The ability to create a multicellular composition in a controlled environment will facilitate the investigations of thrombus formation, occurrence of stroke, and studies involved in discovering new thrombolytic materials.

## 29.5 METHODOLOGY

### 29.5.1 CELL HARVESTING

One of the inherent challenges for performing studies involving the circulation is that, due to an absence of a nucleus, RBCs and platelets cannot be cultured. Therefore, to work with a meaningful sample of RBCs, platelets, plasma, and so forth, one has to gather these cells from a mammalian subject prior to completing the analysis. The RBCs and platelets are both obtained from the whole blood of the animal or human. This means that approval from either an animal investigation committee or a human investigation committee is required before such harvesting can proceed. In addition, if the harvesting will involve a nonsurvival procedure (with an animal subject), it is likely that certain drugs will be employed that may be controlled substances or require a special license in order to be used in the procedure. Of course, the appropriate training will also be required prior to any harvesting procedures.

Once the necessary approvals are in place, the harvesting of the RBCs and platelets can proceed. This procedure for removal of cells from rabbits has been outlined in many publications. Rabbits can be anesthetized with ketamine (8 mL/kg, i.m.) and xylazine (1 mg/kg, i.m.) followed by pentobarbital sodium (15 mg/kg i.v.). A cannula is then placed in the trachea so that the animals can be ventilated with room air. A catheter is then placed into a carotid artery for administration of heparin and for phlebotomy. After heparin (500 units, i.v.), animals are exsanguinated and the whole blood collected in a 50 mL tube. Depending on the animal size, varying amounts of blood can be collected.

**FIGURE 29.4** (a) A PDMS chip was fabricated to contain  $100\ \mu\text{m} \times 100\ \mu\text{m} \times 2\ \text{cm}$  channels. bPAECs were cultured into the microfluidic channels, and the chip was reversibly sealed to a glass substrate, making sure to align the channel and the fluid access port. Solutions were perfused across the cells ( $2\ \mu\text{L}\ \text{min}^{-1}$ ) using  $75\ \mu\text{m}$  microbore tubing to connect the syringe pump to the microfluidic adaptor on the fluid access port. Fluorescence measurements were acquired using an Olympus IX71M microscope equipped with an electrothermally cooled CCD (Orca, Hamamatsu) and MicroSuite software (Olympus). (b) Platelets are shown adhering to an immobilized endothelium, even in the presence of flow. Such devices may be used in the future to investigate thrombus formation or other vaso-occlusive mechanisms.

### 29.5.2 SAMPLE PREPARATION

Once the RBCs or platelets are harvested from the subject, there still exists some sample preparation prior to the measurement portion of the analysis. For example, in order to purify platelets, the collected blood is centrifuged at  $500\ g$  at  $37^\circ\text{C}$  for 10 min. The platelet-rich plasma (PRP) is decanted for the subsequent isolation of platelets. Platelets are then isolated from the PRP by centrifugation (15 min at  $2000\ g$  at  $37^\circ\text{C}$ ) and washed three times in Tyrode-albumin solution (pH 7.4). The first wash contains heparin (2 U/mL) and apyrase (1 U/mL); the second wash contains only apyrase (1 U/mL); and the third wash contains Tyrode's solution without apyrase and heparin.

In order to purify the RBCs, the plasma and buffy coat (white cells) are removed for further purification (see above). RBCs are then resuspended and washed three times in a physiological salt solution [PSS; in mM, 4.7 KCl, 2.0 CaCl<sub>2</sub>, 140.5 NaCl, 12 MgSO<sub>4</sub>, 21.0 tris(hydroxymethyl)aminomethane, 11.1 dextrose with 5% bovine serum albumin (final pH 7.4)]. Cells should generally be prepared and studied on the day of use within 8 h of removal from animal or human subjects.

In addition to the cell purification, it is also important to remember that, *in vivo*, RBCs exist at various hematocrits throughout the vasculature, depending on the size of the vessel. For example, it is generally accepted that the average hematocrit of RBCs *in vivo* is approximately 40–45%. However, in resistance vessels, this value can decrease to levels as small as single-digit percentiles.

Endothelial cells are, in some ways, easier to work with than the RBCs and platelets because they can be grown in standard tissue culture flasks. However, even though these cells may be easier to obtain (committee approval is not required), preparing them for a quantitative investigation in a microflow system is challenging because one must immobilize these cells prior to investigation. For example, Kotsis has demonstrated the ability to culture endothelial cells from bovine pulmonary artery on the walls of a microbore tubing. Although these cells responded to an ATP bolus by producing NO, the preparation of the cell microflow reactors was tedious and met with a low rate of success. More recently, immobilizing these cells to the walls of a channel in a microfluidic device has been reported by multiple groups. Immobilizing the cells in the microfluidic device is advantageous because the chip device is planar (similar to standard tissue culture flasks), the channels are accessible thus allowing media to flow over the cells, and the cells can be easily monitored using standard microscopy (Figure 29.4a). There also exist different methods for cell immobilization.

Spence et al.<sup>36</sup> employed a method by which endothelial cells were vacuum delivered into a channel that was coated with fibronectin. Li et al.<sup>37</sup> described the use of a “trough” method for immobilizing a dopaminergic cell model. This method appears to be useful for cell types that have a tendency to cluster. Other methods have been described as well. In most cases, hydrodynamic pumping schemes have been employed for such immobilization determinations.<sup>38</sup>

### 29.5.3 DETECTION

Detection of the molecules produced, consumed, and secreted by the cells described here is challenging for two main reasons. First, the cell is dynamic and constantly tries to maintain balance. As such, molecules concentrations or speciation are usually changing. Second, the matrix in which these measurements are typically performed is very complex. Thus, the technique of choice needs to have some built-in feature that enables the analyst to overcome the matrix. To date, a variety of measurements have been employed to learn more about the roles of the cells in the microcirculation. Specifically, fluorescence, chemiluminescence, and amperometry have all been used extensively. Not surprisingly, all three of these detection schemes are readily employed in capillary electrophoresis-based determinations. Therefore, many of the measurements employ technology from the CE field. However, due to the cell matrix complexity, techniques are required to overcome potential interferences. For example, Kovarik et al.<sup>39</sup> employed a Nafion coating over a micromolded ink electrode for selectivity in detecting dopamine in the presence of an anion interferent (ascorbate). For similar reasons, Ku<sup>40</sup> employed the classic method of multiple standard additions to quantitatively determine the amount of NO released from activated platelets in a flowing stream.

### 29.6 FUTURE ASPECTS

The concept of performing studies involving the circulation in an environment that closely mimics blood vessels and its components is relatively new. Therefore, there has not been a great deal of studies involving actual blood flow in microflow systems. However, as pointed out in a recent review by Martin, Root, and Spence, the number of papers published over the past decade involving

biological cells and microfluidic devices is growing at a very rapid rate. One of the obstacles in performing cellular studies with cells typically found in the circulation is that many of these cells cannot be cultured; that is, they must be harvested. One of the initial steps in any analysis is obtaining the sample and obtaining the sample is not easy in these studies. However, the potential range of studies that still need to be investigated are immense.

One potential area where microflow studies of the circulation will be of major benefit involves studies involving glycosylation products. In a recent report, it was stated that nearly 80% of all proteins in the bloodstream were glycosylated. With such products being implicated heavily in such diseases as diabetes and cancer, it would seem logical to employ the systems described here with other separation schemes, detection schemes, or protocols in general to determine various biomarkers in a system that more readily mimics the circulation *in vivo*.

As eluded to above, one of the key features that this technology offers is the ability to perform important investigations early. For example, most biomarker detection is successful on plasma, serum, or other tissues after the disease of interest has already taken hold of the patient. By monitoring the bloodstream, one may be able to find certain biomarkers before the formation of tumors, vessel blockages, organ damage, and so forth. Moreover, it may also be possible to perform biomarker studies not only on patients already inflicted with a disease but also to perform such studies on healthy patients, creating an archive of their health and subsequently monitoring the decline in certain proteins, peptides, or metabolites.

## 30.1 INTRODUCTION

The usefulness and importance of capillary electrophoresis (CE) in food analysis is now well recognized and established, as shown with many applications in the study of substances of food concern, ranging from naturally occurring compounds to contaminants. This fact is corroborated by more than 650 papers published in the past 10 years,<sup>1</sup> including several review papers<sup>2-4</sup> and a handbook for method development in food analysis.<sup>5</sup> Also, the scope of applications is broad in terms of molecular size of food components, ranging from the analysis of small molecules such as organic acids (OA) or amino acids (AA) to the analysis of large biomolecules such as proteins, carbohydrates, or DNA.<sup>1</sup> An exhaustive review examining the latest developments in the application of capillary electromigration methods for the analysis of food components, as well as for the investigation of food interactions and food processing was recently published.<sup>2</sup> In addition, the analysis of organic contaminants in foods with emphasis on procedures for extracting and concentrating compounds such as pesticides, antibiotics, biological toxins, and pathogens was also reviewed.<sup>3</sup> Another important area in food analysis where CE offers good potential is food authentication. Several examples of food authentication were summarized in two review papers.<sup>4,6</sup> Consequently, the aim of this chapter is not a comprehensive review of the literature as this has been done in other works, but to present selected applications of CE that are most relevant to the analysis of different food components and food quality.

## 30.2 APPLICATIONS

### 30.2.1 CARBOHYDRATES

The analysis of carbohydrates by CE has been reviewed by several authors as scientific papers<sup>1,7–9</sup> or chapters of books.<sup>5,10</sup> In fact, Chapter 7 by Khandurina in this handbook deals specifically with this topic. Carbohydrates have traditionally been classified by food researchers into sugars and polysaccharides, although mixtures of them such as glucose syrups are also used, taking advantage of their respective characteristics. Sugars are utilized for their sweetening power, preservative action (osmotic pressure), and crystallinity in foodstuffs; polysaccharides provide foodstuffs with texture, body, and colloidal properties.

Currently, the assay of carbohydrates is a very important criterion for the quality control of drinks and foodstuffs, especially in dietary products. Assay of carbohydrates is also very important in the fields of monitoring of food-labeling claims, analysis of sweeteners, bulking agents, and fat substitutes as well as for establishing authenticity and in the fermentation monitoring in the production of alcoholic beverages.

A representative selection of applications is shown in Table 30.1, which illustrates the wide choice of food sample types that have been analyzed, with attention being paid to the CE mode, its running conditions, the derivatization technique and its conditions, as well as the detection method utilized.<sup>11–26</sup> Since carbohydrates lack both a charge and a strong ultraviolet (UV) chromophore, several derivatization techniques have been described during the development of the CE methodologies.<sup>11,27</sup> Wang et al.<sup>11</sup> reported an excellent detection limit of 420 amol for a standard mixture of monosaccharides previously derivatized with 3-aminophthalhydrazide and an online chemiluminescence detector with hexacyanoferrate as the postcapillary chemiluminescence reagent. A more conventional approach is the derivatization with a UV chromophore, although this does not give such good sensitivity as the chemiluminescence detection. Several chromophores have been utilized to derivatize carbohydrates such as 2-aminobenzoic acid,<sup>12</sup> 6-aminoquinoline,<sup>13</sup> 8-aminonaphthyl-1,3,6-trisulfonic acid,<sup>14</sup> 9-aminopyrene-1,4,6-trisulfonic acid (APTS),<sup>19,23</sup> *p*-nitroaniline,<sup>22</sup> and *p*-aminobenzoic acid.<sup>26</sup> While these methods lead to improved sensitivity and resolution, the complexity of derivatization limits its use.

Alternatively, methods for the analysis of underivatized carbohydrate have been developed. These methods include the use of high alkaline electrolyte to ionize the carbohydrates and make them suitable for indirect UV detection.<sup>15–17,20,24,28–30</sup> These techniques enabled to analyze acidic, neutral, and amino sugars without derivatization. Soga and Serwe<sup>18</sup> reported the separation of the standard mixtures of 28 carbohydrates (Figure 30.1)<sup>18</sup> including monosaccharides, disaccharides, acidic sugars, amino sugars, and sugar alcohols using indirect detection at high pH with 20 mM 2,6-pyridinedicarboxylic acid (PDC) for indirect UV detection and 0.5 mM cetyltrimethylammonium hydroxide (CTAH) for reversing the direction of the electroosmotic flow (EOF). The detection limits for fructose, glucose, and sucrose were in the range from 12 to 16 mg/L with pressure injection of 50 mbar for 6 s. The reader is referred to two additional reviews on carbohydrate analysis that have recently been published.<sup>31,32</sup>

### 30.2.2 AMINO ACIDS AND BIOGENIC AMINES

An overwhelming majority of foods contain AA, either in the free form (e.g., fruit juice) or in the form of protein (partially hydrolyzed or intact). Proteins are polymers of AA, and as such, represent the principal source of dietary AA for humans when enzymatically digested to liberate their constituents AA. Consequently, the determination of the AA content in food is important in a number of applications that include food as the sole source of nutrition (e.g., infant formula), prescribed fortified nutritional products (e.g., product enriched with glutamine), the verification of the absence of a specific AA in certain inborn errors of metabolism (e.g., phenylalanine in phenylketoneuria), as well as for regulatory concerns.

**TABLE 30.1**  
**Methods for the Analysis of Carbohydrate Samples by CE**

Type of Food	Detection Method	Sample Derivatization	CE Mode	Run Buffer	CE Conditions	References
Standard mixture of monosaccharides	Online chemiluminescence	Precapillary derivatization with 3-aminophthal-hydrazine and postcapillary reaction with 25 mM hexacyanoferrate in 3 M NaOH	CZE	200 mM borate (pH 10), 100 mM hydrogen peroxide	107 cm × 75 μm i.d. fused-silica capillary, 24 kV, 25°C	11
Mono- and disaccharides	UV absorbance 214 nm	Mono- and disaccharides derivatized with 2-aminobenzoic acid	CZE	50 mM sodium phosphate, pH 7	70 cm × 50 μm i.d. fused-silica capillary, 20 kV, 25°C	12
Peanut fungal pathogens and Baker's yeast	UV absorbance 254 nm	<i>N</i> -Acetylglucosamine and glucose derivatized with 6-aminoquinoline prior to analysis	CZE	100 mM sodium phosphate monobasic (pH 7)	80 cm × 20 μm i.d. fused-silica capillary, 18 kV	13
Cereals/corn	UV absorbance 235 nm	Reducing sugars derivatized with 8-aminonaphthyl-1,3,6-trisulfonic acid	CZE	250 mM phosphoric acid titrated pH 4.5 with triethylamine	67 cm × 50 μm i.d. fused-silica capillary, 20 kV, 30°C	14
Monosaccharides in orange juice	Indirect UV at 570 nm	Underivatized	CZE	70 mM NaOH, 2 mM naphthol blue-black, and 80 mM sodium phosphate (pH 12.5)	23 cm × 50 μm i.d. fused-silica capillary, 9 kV, 25°C	15
Monosaccharides in soft drinks, isotonic beverages, fruit juice, and sugarcane spirits	Indirect contactless conductivity detection	Underivatized	CZE	10 mM NaOH, 4.5 mM Na <sub>2</sub> HPO <sub>4</sub> , 200 μM CTAB	44 cm × 20 μm i.d. × 375 μm o.d. fused-silica capillary 2 kV, 30°C	16
Carbohydrates in alcoholic drinks/wine	ESI-MS	Underivatized	CE-MS	300 mM diethylamine (DEA). Sheath liquid: 2-propanol/water (80/20% v/v) with 0.25% DEA at 4 μL/min	70 cm × 50 μm i.d. fused-silica capillary, 20 kV, 25°C	17

*Continued*

**TABLE 30.1**  
**(Continued)**

Type of Food	Detection Method	Sample Derivatization	CE Mode	Run Buffer	CE Conditions	References
Mono- and disaccharides, amino sugars, and sugar alcohols in orange juice, apricot, sake, yogurts	Indirect detection 350 nm	Undersivatized	CZE	20 mM 2,6-PDC with 0.5 mM CTAH (pH 12.1)	112.5 cm × 50 μm i.d. fused-silica capillary, -25 kV, 20°C	18
Oligo- and monosaccharides in enzymatic polysaccharide digestion	Capillary array electrophoresis-LIF	Derivatized with 0.2 M 9-aminopyrene-1,4,6-trisulfonic acid trisodium (APTS) in 15% acetic acid and 2 M NaBH <sub>3</sub> CN in tetrahydrofuran	CZE	25 mM Lithium acetate (pH 5.0)	62 cm × 75 μm i.d. fused-silica capillary, 15 kV, 27 or 30°C	19
Mix of carbohydrates	Frequency based electrochemical	Undersivatized	CZE	0.1 M NaOH running electrolyte	Poly(dimethylsiloxane)/glass microchip with a channel 20-μm wide and 7-μm high. 50-μm wide copper electrode vs. Ag/AgCl	20
Carbohydrates in plants (lupine sample)	UV detection 220 nm	Derivatization with 12.5 μL of 0.15 M tryptamine dissolved in 10% propanol and heated at 90°C for 10 min + 4.5 μL sodium cyanoborohydride (0.3 g/mL), 90°C for 60 min	MEKC	100 mM Sodium tetraborate decahydrate, 35 mM cholic acid, and 2% 1-propanol, pH 9.7	760 mm × 0.05 mm i.d. fused-silica capillary, 30 kV, 30°C	21
Carbohydrates in infant and milk powder, rice syrup, and cola drink	UV-visible on-column LED 406 nm	Derivatization with 50 μL of glacial acetic acid, 100 μL of 0.036 M <i>p</i> -nitroaniline in methanol and 75 μL of 0.080 M NaBH <sub>3</sub> CN	CZE	0.17 M boric acid (pH 9.7)	72 cm × 50 μm i.d. fused-silica capillary, -20 kV, 27 or 30°C	22

Polysaccharides, <i>iota</i> , <i>kappa</i> , and <i>lambda</i> carrageenans	LIF	Derivatization with 2 $\mu$ L of 75% v/v acetic acid, 2 $\mu$ L 9-aminopyrene-1,4,6-trisulfonic acid (APTS) reagent (0.2 M in 15% v/v acetic acid) and 2 $\mu$ L of 1 M sodium cyanoborohydride in THF	CEC	2.5 mM ammonium acetate (pH 8.0)	60/67 cm $\times$ 50 $\mu$ m i.d. polyvinyl alcohol coated capillary, 30 kV, 50°C	23
Polysaccharides	Indirect DAD 210 nm	Underivatized	CEC	1% DMSO in 20 mM Tris, pH 8/ACN	Sulfonated polystyrene/DVB stationary phase. 300 $\text{\AA}$ , 45 cm (53 cm total) $\times$ 100 $\mu$ m, 10 kV, 20°C	24
Carbohydrates in sake	Indirect UV	Derivatized with phenylisocyanate Underivatized	CEC	THF with 2% water	Mixed Bed X400-PLGel C (40:60), 25(33) cm, 75 $\mu$ m; 25 kV; 20°C	24
Glucose, maltose, and maltotriose in nonalcoholic drinks/beverages	UV detection 280 nm	Pre-column derivatization 20 mg of NaBH <sub>3</sub> CN in 1 mL of methanolic solution of 250 mM <i>p</i> -aminobenzoic acid (PABA) and 20% AcOH	CZE	20 mM PDC, 0.5 mM CTAH (pH 12.1)	112.5 cm $\times$ 50 $\mu$ m i.d. fused-silica capillary, 30 kV, 15°C	25
			CZE	20 mM sodium tetraborate (pH 10.2)	57 cm $\times$ 75 $\mu$ m i.d. fused-silica capillary, 20 kV, 25°C	26

**FIGURE 30.1** Separation of 28 standard carbohydrates by CE. Peak assignment: (1) manuronic acid, (2) glucuronic acid, (3) galacturonic acid, (4) *N*-glycolylneuraminic acid (NGNA), (5) *N*-acetylneuraminic acid (NANA), (6) ribose, (7) mannose, (8) xylose, (9) glucosamine, (10) glucose, (11) galactosamine, (12) galactose, (13) fucose, (14) mannitol, (15) sorbitol, (16) xylitol, (17) inositol, (18) fructose, (19) rhamnose, (20) lactulose, (21) lactose, (22) sucrose, (23) galactitol, (24) *N*-acetylmannosamine, (25) *N*-acetylglucosamine, (26) *N*-acetylgalactosamine, (27) arabinose, and (28) raffinose, 200 mg/mL each. Experimental conditions: capillary, fused-silica 50  $\mu$ m ID  $\times$  112.5 cm (104 cm effective length); background electrolyte, 20 mM PDC, pH 12.1; injection, 6 s at 50 mbar; temperature, 20°C; indirect detection signal 350 nm, reference 275 nm. (Reprinted from Soga, T., and Serwe, M., *Food Chem.*, 69, 339–344, 2000. With permission from Elsevier Science-NL.)

Biogenic amines (BA) are bacterial degradation products of AA found in virtually all foods. They are also normal constituents in fermented foods, such as cheese, wine, and beer. Since excessive dietary intake of BA can lead to adverse physiological effects, such as migraine headaches (due to their toxicity), and because their presence is used as indicators of the degree of freshness or spoilage of food, it is important to analyze BA content for food quality. Histamine, putrescine, cadaverine, tyramine, tryptamine,  $\beta$ -phenylethylamine, spermine, and spermidine are considered to be the most important BA occurring in foods. The reader is referred to several reviews<sup>1,7–10</sup> that summarize the CE methodologies that have been developed for the determination of BA<sup>33–39</sup> and AA,<sup>40–42</sup> as well as some book chapters on the same topic.<sup>5,10,32</sup> The most significant reports and its separation conditions are given in Table 30.2.

BA is challenging in that it displays poor chromophore and fluorophore properties. A similar situation exists with AA because very few of them have a chromophoric moiety that allows for facile detection after separation; consequently, derivatization procedures to facilitate their detection are usually required. Fortunately, the presence of common functional groups (amine and carboxylic acid) chemical handles for derivatization schemes that render the BA and AA amenable to spectrophotometric and fluorimetric detection after separation.

**TABLE.30.2**  
**Methods for the Detection of AA and BA Separated by CE**

Type of Food	Detection Method	Sample Derivatization	CE Mode	Run Buffer	CE Conditions	References
AA growth medium	LIF	Derivatized with 3-(4-carboxybenzoyl)-2-quinoline-carboxaldehyde before analysis	MEKC	6.25 mM borate (pH 9.66), 150 mM SDS, 10 mM tetra-hydrofuran	107 cm × 75 μm i.d. fused-silica capillary, 24 kV, 25°C	43
Standards of AA	CCD spectrometer	Derivatized with FITC and 5-iodoacetamido fluorescein (5-IAF)	CZE	20 mM borate buffer at pH 10	Fused-silica capillary, 50 mm i.d., 360 μm o.d., length, 50 cm inner surface modified with γ-glycidoxypropyltrimethoxysilane (GOPTMS), applied voltage 17 kV	44
AA in alcoholic drinks/beer	Electrochemical	Derivatized with naphthalene-2,3-dicarboxaldehyde before analysis	CZE	Borate (pH 9.48)	80 cm × 20 μm i.d. fused-silica capillary, 18 kV	45
AA in beer and yeast	Contactless conductivity	Underivatized	CZE	2.3 M acetic acid, pH 2.1, 0.1% w/w hydroxyethylcellulose	80 cm × 50 μm i.d. fused-silica capillary, 30 kV, 25°C	46
Complex mixture of AA and blood	ESI-MS	Underivatized	CE-MS	Background electrolyte of 1 M formic acid	130 cm × 20 μm i.d. fused-silica capillary, 30 kV	47
AA standard mixture	ESI-MS	Underivatized	CE-MS	1 M Formic acid solution	100 cm × 50 μm i.d. fused-silica capillary, 30 kV, 20°C	48
Standard solution of AA and catecholamine	LIF	Derivatized with 5 mM NDA and 43 mM KCN	CZE	125 mM Borate buffer (pH 8.7)	65 cm × 50 μm i.d. fused-silica capillary, 10 kV/7 min, 20 kV/8 min	49
AA in soy sauce	UV-VIS at 214 nm	Underivatized	CZE	50 mM Phosphate buffer (pH 2.5)	Uncoated fused silica column, i.d. 50 μm, 150 cm (effective length 37.8 cm), 15 kV, 25°C	50

Type of Food	Detection Method	Sample Derivatization	CE Mode	Run Buffer	CE Conditions	References
BA (histamine, tryptamine, phenylethylamine, tyramine, agmatine, ethanolamine, serotonin, cadaverine, and putrescine) in red wines	DAD	Derivatization with 1,2-naphthoquinone-4-sulfonate	CZE	40 mM aqueous sodium tetraborate solution, pH 10.5, 2-propanol (25%, v/v)	67 cm × 75 μm i.d. × 375 μm o.d. fused-silica capillary, 30 kV, 25°C	51
BA in red and white wines	ESI-MS	Underivatized	CE-MS	25 mM citric acid (pH 2.0)	75 cm × 50 μm i.d. × 360 μm o.d. fused-silica capillary, 13 kV, 20°C	52
BA in fish and wine	LIF	Derivatized with OPA	CZE	50 mM borate buffer (pH 9.0) 20 mM MβCD, 25 mM SβCD 10% ethanol	47 cm × 50 μm i.d. × 360 μm o.d. fused-silica capillary, 25 kV, 25°C	53
Standards mix of AA	DAD at 205 nm	Underivatized	MEKC	20 mmol/L sodium borate buffer (pH 9.3) 140 mmol/L SDS 100 mM sodium phosphate (pH 2.0)	60 cm × 75 μm i.d. × 365 μm o.d. etched bare fused-silica capillary, 20 kV, 25°C	54
Standards of AA	UV detection at 200 nm	Underivatized	CZE	50 mM borate buffer (pH 9.5)	57 cm × 50 μm i.d. fused-silica capillary, 20 kV, 20°C	55
Standards of AA	Fluorescence	Derivatized with fluorescamine 2.5 mM	CZE	50 mM borate buffer (pH 9.5)	70 cm × 50 μm i.d. × 375 μm o.d. fused-silica capillary, 20 kV	56
AA in infant food	ESI-MS	Underivatized	CE-MS	300 mM formic acid or 100 mM triethylamine	fused-silica capillary, 20 kV	57
BA and AA in beer	LIF	Derivatized with 10 μL of 1 × 10 <sup>-3</sup> mol/L SAMF, 75 μm H <sub>3</sub> BO <sub>3</sub> buffer, pH 8.0	MEKC	25 mM boric acid running buffer (pH 9.0), containing 24 mM SDS, 12.5% v/v AcN	70 cm × 50 μm i.d. fused-silica capillary, 20 kV	58
Standards of BA	Indirect fluorescence	Underivatized	Microchip-CE CZE	30 mM phosphate (pH 9.4) 3% 2-propanol, 500 μM Rhodamine 110, pH 2.2	fused-silica capillary, 22.5 kV, 25°C Separation channel, 40 μm × 10 μm × 16 mm, 2000 V	59
AA in beer	Conductivity	Underivatized	CZE	50 mM AMP/10 mM CAPS, pH 10.8	60 cm × 25 μm i.d. × 360 μm o.d. fused-silica capillary, 25 kV	60

BA (histamine, putrescine, cadaverine, tyramine, spermidine, spermine, agmatine) in fish, cheese, meat products, vegetarian products	DAD at 210, 214, and 320 nm	Underivatized	CZE	20 mM sodium citrate buffer, 25 mM phosphate buffer, both BGE pH 2.5 and 6.5	56 cm × 50 μm i.d. fused-silica capillary, 10/25 kV, 25/35°C	61
AA (cysteine, cysteinyl-glycine, γ-glutamyl-cysteine, glutathione, and (γ-glutamyl-cysteinyl) 2-glycine (PC <sub>2</sub> )) in Durum wheat seeds	LIF	Derivatized with 400 μM 5-bromomethylfluorescein (5-BMF)	CZE	50 mM boric acid, pH 9.7–10.6 400 μM 5-BMF, 1 mM EDTA 1 μM GSH	57 cm × 75 μm i.d. fused-silica capillary, 30 kV, 30°C	62
Standards of aromatic	Electrochemical	Underivatized	Microchip-CZE	30 mM acetate buffer solution (pH 4.5)	Chip 86 × 20 × 2 mm × 75-mm long separation channel, 5-mm long injection channel, 1500 V	63
Stock solutions of AA	UV detection at 200 nm	Derivatized with phthalic anhydride 10 mM on-column	CZE	20 mM phosphate buffer, pH 10	40.5 cm × 50 μm i.d., fused-silica capillary, 24 kV, 25°C	64
BA (trimethylamine, putrescine, cadaverine, spermine, tryptamine, spermidine, phenylethylamine, tyramine) in fish, meat, and sausage	UV detection at 214 nm	Derivatized with 800 μL of a 1% (w/v) Dns-Cl in acetone solution	CZE	6 mM copper sulfate, 6 mM 18-crown-6-ether, and 4 mM formic acid (pH 2.7)	70 cm × 75 μm i.d. × 375 μm o.d. capillary tubing, 20 kV, 30°C	65
Mixture of BA standards (histamine, tyramine, cadaverine, and putrescine)	Spectrophotometric at 420 nm	5 mM 4-(4-sulfo-phenylazo)-1-hydroxy-2-naphthaldehyde sodium salt (AZO <sub>2</sub> )	MEKC	10 mM phosphate buffer, pH 7.8, 70% v/v ethanol, 0.3 mM Brij 35, 10 mM Na <sub>2</sub> SO <sub>4</sub>	48.5 cm × 50 μm i.d. fused-silica capillary, 20 kV, 35°C	66
AA in plant seeds	PDA	Underivatized	CZE MEKC	75 mM phosphoric acid (pH 1.85) 50 mM NaH <sub>2</sub> PO <sub>4</sub> 100 mM SDS (pH 7.0)	570 mm × 50 μm i.d., uncoated fused-silica capillary, 25 kV, 15°C (CZE); 25 kV, 20°C (MEKC)	67

Type of Food	Detection Method	Sample Derivatization	CE Mode	Run Buffer	CE Conditions	References
Standard mixtures of nine AA	UV-visible detection	In-column derivatization with OPA (50 mM) in borate buffer (pH 9.5, 50 mM)	CEC	100 mM phosphate buffer (pH 4.0)	Proline-coated column 75 cm × 75 μm i.d., -15 kV	68
BA in a sample of Thai fish sauce	Fluorescence emission, 488 nm excitation	On-chip derivatization with 25 μM dichlorotriazine fluorescein (DTAF)	Microchip CE	80 mM borate buffer (pH 9.2.)	Window of 40 μm × 40 μm	69
Mixture of AA (L-threonine and L-tyrosine) standards	Chemiluminescence detection (CL) with a on column coaxial flow detection interface	Underivatized	pCEC	MeOH/phosphate 20/80 (pH 8.0), 5 mM Cu(II) + 1 × 10 <sup>-5</sup> mol/L luminol pump flow rate, 0.01 mL/min; CL reagents, H <sub>2</sub> O <sub>2</sub> + NaOH media; CL reagent flow rates, 1.3 μL/min	<i>In situ</i> polymerization monolithic stationary phase (30 cm); capillary, 75 μm i.d. × 375 μm o.d., -4 kV; back pressure, 500 psi	70
BA (histamine, tyramine, putrescine, and tryptamine) in red wine	UV spectrophotometer	Derivatized with 10 mM OPA and 10 mM NAC and DNS-OH	MEKC	25 mM sodium borate buffer (pH 10.0); 25 mM sodium SDS; 5% v/v methanol	Channel widths/lengths of reaction chambers 120 μm × 2.3 mm (PRSM 1), 200 μm × 1.8 mm (PRSM 2), and 50 μm × 5.6 mm (PRSM 3). Glass microchips of soda lime silicate, 75 mm × 25 mm × 1 mm	71
AA in sake	Indirect UV	Underivatized	CZE	20 mM 2,6-pyridinedicarboxylic acid (PDC), 0.5 mM CTAH (pH 12.1)	112.5 cm × 50 μm i.d. fused-silica capillary, -30 kV, 15°C	72
AA in beer	UV at 210 and 270 nm	Underivatized	MEKC	25 mM Na <sub>2</sub> B <sub>4</sub> O <sub>7</sub> (pH 10.5) and 110 mM SDS	57 cm × 75 μm i.d. fused-silica capillary	73
Histamine in tuna fish samples	DAD	Underivatized	CZE	50 mmol/L phosphate (pH 2.5) 0.05% hydroxyethylcellulose	50 cm × 75 μm i.d. fused-silica capillary, 23°C	76

**FIGURE 30.2** Electropherograms of the polyamines standards spiked in Manila Mangos pulp and its blank. Conditions: Pre-column derivatization of the sample with FITC, 20 mM borate buffer, pH 9.5, 50 mM SDS, 30 kV, 25°C. Put = putrescine, Spd = spermidine and Spm = spermine.

Many reported methods for BA and AA involve pre- or postcolumn (or capillary) derivatization of these compounds before detection using 3-(4-carboxybenzoyl)-2-quinoline-carboxaldehyde,<sup>43</sup> 5-(4,6-dichloro-s-triazin-2-ylamino) fluorescein,<sup>44</sup> 1,2-naphthoquinone-4-sulfonate,<sup>45</sup> *o*-Phthalaldehyde (OPA),<sup>53,68,71</sup> fluorescamine,<sup>56</sup> and many other procedures reported in Table 30.2. OPA is disadvantageous in that it reacts only with primary amines, and the fluorescent derivatives are associated with significant instability. Dabsyl- and dansylchloride<sup>65</sup> are better in this respect as they react with both primary and secondary amino groups, and provide stable derivatives. Indirect UV,<sup>72</sup> indirect fluorescence detection,<sup>59</sup> conductivity,<sup>46,60</sup> and electrochemical detection<sup>45,63</sup> have been utilized after CE separation as well as mass spectrometry (MS).<sup>47,48,52,57</sup> Kvasnicka et al.<sup>74</sup> developed a direct, sensitive, and rapid (<15 min) CE method with conductometric detection for the determination of BAs in food products (salami, cheese, wine, and beer). Vargas et al.<sup>75</sup> reported the use of fluorescein isothiocyanate isomer 1 (FITC) for the derivatization of polyamines present in manila mangoes. The separation by CE with detection by laser-induced fluorescence (LIF) was critical to studying the levels of polyamines in Mexican manila mango and its relationship to storage at chilling temperature (Figure 30.2).

Nineteen AA were detected in beer samples derivatized with naphthalene 23-dicarboxaldehyde (NDA) and cyanide (CN<sup>-</sup>) by capillary zone electrophoresis (CZE) with electrochemical detection.<sup>45</sup> Under the optimum conditions, the limits of detection (LODs) for individual AA were between 84 and 893 amol. An interesting method recently developed by Ruiz-Jiménez and Luque de Castro<sup>65</sup> reported the determination of BA in nine solid food samples using a full-automated method based on pervaporation coupled online with CE and indirect UV detection. The pervaporator allowed leaching, formation of the volatile analytes, and their removal by evaporation and diffusion through a membrane. The isolated analytes were injected online into the CE system while the solid matrix remained in the pervaporator. With this approach, BA have been determined in fish, meat, and sausage, with LODs ranging between 0.2 and 0.6 µg/mL.

### 30.2.3 VITAMINS

The fat-soluble vitamins include vitamins A, D, E, K, and the carotenoids, which are precursors of vitamin A. The water-soluble vitamins are vitamins C, B<sub>1</sub>, B<sub>2</sub>, B<sub>3</sub>, B<sub>6</sub>, folacin, B<sub>12</sub>, biotin,

and pantothenic acid. Vitamin assay in foods are carried out for a variety of purposes: (1) to assure compliance with contract specifications and nutrient labeling regulation; (2) to provide quality assurance for supplement products; (3) to provide data for food composition tables; (4) to study changes in vitamin content attributable to food processing, packaging, and storage; and (5) to assess the effects of geographical, environmental, and seasonal conditions. Several scientific reviews<sup>77–78</sup> and book chapters<sup>6,10,32</sup> have been published for the analysis of vitamins by CE, and some separation details and the associated references can be seen in Table 30.3. CE methods for the determination of vitamins in food are limited to the determination of vitamin C in fruit,<sup>79,80</sup> vegetables,<sup>80,81,88</sup> and beverages,<sup>82–89</sup> niacin in the range of foods,<sup>90–93</sup> and thiamine in the samples of meat<sup>94</sup> and milk.<sup>95</sup>

As detailed in Chapter 3 by Terabe, micellar electrokinetic chromatography (MEKC) is a useful technique in the retention analysis of water-soluble compounds. The separation and analysis of lyophobic analytes, however, may be difficult in MEKC due to the strong affinity of lyophobic compounds to the micelle resulting in long separation times and poor resolution. An interesting approach for the simultaneous analysis of water- and fat-soluble vitamins by microemulsion electrokinetic chromatography (MEEKC) was proposed by Sanchez.<sup>96</sup> The separation of both water- and fat-soluble vitamins (B<sub>1</sub>, B<sub>2</sub>, B<sub>3</sub>, B<sub>6</sub>, B<sub>12</sub>, C, A palmitate, D, E acetate, and K) was obtained when the microemulsion was prepared with sodium dodecyl sulfate (SDS) as the surfactant, octane as the nonpolar modifier, butanol as the cosurfactant, and propanol as the second cosurfactant. Complete separation of all vitamins was carried out within 55 min; however, this approach was tested only in multivitamin formulation.

The electrophoretic profile of flavins in commercially available baker's yeast was reported by Cataldi et al.<sup>99</sup> An assay for riboflavin in common natural products was developed using LIF detection; benefiting from its intrinsic fluorescent nature, flavins could be selectively detected at very low concentrations using a middle basic running electrolyte (i.e., phosphate buffer at pH 9.8). In addition, a high sensitivity methodology was obtained with a minimal sample preparation by Aturki et al., who reported a rapid method for the separation and detection of tocopherols (TOHs) in vegetable oils by capillary electrochromatography (CEC) (Figure 30.3).<sup>101</sup> The method proposed was faster than the conventional chromatographic separation, with complete resolution of four TOHs achieved in less than 2.5 min with LODs of 1.25 mg/mL.

### 30.2.4 ORGANIC ACIDS AND INORGANIC IONS

Organic acids are among the most frequently assayed substances in food, occurring naturally in a variety of plant and animal substrates. OA present in food originate from biochemical processes, either from their addition or from the activity of some microorganisms (particularly yeasts and bacteria), and are important contributors to the sensory properties of foods. According to the regulations set forth by the Food and Drug Administration (FDA), OA can be used as acidulants (e.g., citric, fumaric, malic, and sorbic acid), antimicrobial additives (e.g., propionic acid), and sequestrants (e.g., tartaric acid).<sup>105</sup> On the other hand, inorganic ions (IA) in food are important from a health-related viewpoint. Cations such as Na<sup>+</sup> and K<sup>+</sup> are essential for the maintenance of a proper electrolyte balance, while excessive Na<sup>+</sup> levels is associated with high blood pressure. The divalent cations, Mg<sup>2+</sup> and Ca<sup>2+</sup>, are important for bone growth and are regulated in infant formulas. Other IA are used in food as additives, including nitrite as a preservative and color enhancer in meat, bromate to improve the strength of flour and reduce fermentation time, and sulfite as antimicrobial growth factor in food.

A scan of recent literature on the topic clearly reveals that CE is increasingly used for the analysis of OA and IA in food. These reports are summarized in Table 30.4, and excellent reviews about this topic can be found in the literature.<sup>106,107</sup> The detectors most frequently used for the OA analysis by CE are direct UV at 206–220 nm, and conductivity; while for IA, indirect UV and conductivity detection are the most often reported. Cortacero-Ramírez et al.<sup>109</sup> applied direct UV detection to analyze 19 OA in beer samples. The inner surface of the capillary was dynamically coated to facilitate a fast anodic EOF with the addition of a polycation (hexadimetre bromide,

**TABLE 30.3**  
**Methods for the Detection of Vitamins Separated by CE**

Type of Food	Detection Method	Sample Derivatization	CE Mode	Run Buffer	CE Conditions	References
Ascorbic acid in vegetables/blue berries	PDAD 254 nm	Underivatized	MEKC	0.05 M sodium deoxycholate, 0.01 M Na <sub>2</sub> B <sub>4</sub> O <sub>7</sub> , 0.01 M KH <sub>2</sub> PO <sub>4</sub> , pH 8.6	56 cm × 50 μm i.d. light path fused-silica column, 25 kV	80
Niacin in cereals, meat, fruit, vegetables, and selected foods	PDAD 254 nm	Underivatized	CZE	15% CH <sub>3</sub> CN, 85% 0.01 M KH <sub>2</sub> PO <sub>4</sub> , 0.01 M Na <sub>2</sub> HPO <sub>4</sub> (pH 7)	56 cm × 50 μm i.d. light path fused-silica column, 20 kV	91
Ascorbic acid in spinach, watermelon, potato, and tomato	DAD spectrophotometric	Underivatized	CZE	60 mM sodium dihydrogen phosphate, 60 mM NaCl, 0.0001% HDM (pH 7)	33.5 cm × 50 μm i.d. fused-silica capillary, -15 kV, 23°C	97
L-Ascorbic acid and D-isoascorbic acid in lemon, pineapple, sunkist, spinach	DAD 265 nm	Underivatized	CZE	0.2 M borate buffer (pH 9.0)	57 cm × 75 μm i.d. fused-silica capillary, 30 kV, 25°C	98
Alcoholic drinks/beer	UV absorbance, 210 and 270 nm	Underivatized	MEKC	25 mM Na <sub>2</sub> B <sub>4</sub> O <sub>7</sub> (pH 10.5) and 110 mM SDS	57 cm × 75 μm i.d. fused-silica capillary	73
Riboflavins vitamins in vegetables, wheat flours, and tomatoes and baker's yeasts	LIF at 442 nm	Underivatized	CZE	30 mM phosphate buffer, pH 9.8	84 cm × 75 μm i.d. fused-silica capillary, 30 kV, 15°C	99
Alcoholic drinks/wine	LIF at 442 nm	Underivatized	CZE	30 mM phosphate buffer, pH 9.8	84 cm × 75 μm i.d. fused-silica capillary, 30 kV, 15°C	100

**(Continued)**

Type of Food	Detection Method	Sample Derivatization	CE Mode	Run Buffer	CE Conditions	References
Vegetables oils/virgin olive, hazelnut, sunflower, and soybean	DAD at 205 nm	Underivatized	CEC	Methanol and acetonitrile (50/50 v/v) containing 0.01% ammonium acetate	33 cm × 75 μm i.d. × 375 μm o.d. fused-silica capillary, partially packed with ChromSpher C <sub>18</sub> (3 μm), -25 kV, 20°C	101
Ascorbic acid in soft drinks	Conductivity detection	Underivatized	CE	10 mM histidine/0.135 mM tartaric acid, 0.1 mM CTAB, pH 6.5, 0.025% HP-β-CD	60 cm × 50 μm i.d. × 360 μm o.d. fused-silica capillary, -15 kV	102
Riboflavin, flavin mononucleotide in wines, milk, yoghurt, and raw eggs	LIF	Underivatized	Microchips-CE	The same condition except, 0.06% HP-β-CD, 0.125 mM CTAB	PMMA microchips 90 × 6 mm, with a pair of antiparallel orientated electrodes (1 mm × 1.4 cm), and with a gap of 0.5 mm	103
Vitamin C in <i>Lupinus albus</i> L. var. <i>Multolupa</i>	UV detection	Underivatized	MEKC	1.08 g of deoxycholate in 50 mL of a 1:1 mixture of 0.02 M borate/phosphate, pH 8.6	30 mM phosphate buffer, pH 9.8	104

**FIGURE 30.3** CEC analysis of the TOHs content in different vegetable oils. (a) Virgin olive oil; (b) Sunflower oil; (c) Soybean oil. 1, BHT; 2,  $\delta$ -TOH; 3,  $\gamma$ -TOH; 4,  $\alpha$ -TOH.: 1, BHT; 2, d-TOH; 3, g-TOH; 4, a-TOH. Oil samples were diluted 5 times (10 times for sunflower oil) with the mobile phase and injected in the CEC system Butylated hydroxytoluene (BHT) was added as antioxidant to prevent the loss of TOHs. (Reprinted from Aturki, Z., et al., *Electrophoresis*, 26, 798–803, 2005. With permission from WILEY-VCH Verlag GmbH & Co.)

HDB) to the electrolyte. This resulting method was very useful because of the short time (22 min) for the analysis of 19 compounds, which makes this method suitable for screening in the brewing industry.

Recently, Suárez-Luque et al.<sup>111</sup> developed a method for the analysis of chloride, nitrate, sulfate, phosphate, and formic acid in honey samples by CE with indirect UV detection. The separation was achieved using 2 mM potassium dichromate and 0.05 mM tetraethylenepentamine (TEPA), pH 4.00. The detection limit was in the range between 0.03 and 20 mg/kg of the IA.

### 30.2.5 TOXINS, CONTAMINANTS, PESTICIDES, AND RESIDUES

Safety of food is a basic requirement of food quality. “Food safety” implies absence or acceptable and safe levels of contaminants, adulterants, naturally occurring toxins, or any other substance that may make food injurious to health on an acute or chronic basis. Most countries, therefore, have established official tolerance levels for chemical additives, residues, toxins, and contaminants in food products. Table 30.5 summarizes several CE reports that can be found in the literature that deal with the analysis of toxins, contaminants, pesticides, and residues. A number of reviews appearing

**TABLE 30.4**  
**Methods for the Analysis of OA and IA by CE**

Application	Detection Method	Sample Derivatization	CE Mode	Run Buffer	CE Conditions	References
Tartrate in spiked sample matrices; cocoa, jam, lemonade, sugar syrup, Madeira cake, and digestive biscuit	Direct UV at 214 nm	Underivatized	CZE	200 mM phosphate buffer (pH 7.5)	Neutral polyacrylamide coated capillary, 50- $\mu$ m i.d., 66 cm total length (56-cm effective length) and, -14 kV, 22°C	108
OA in malt beer	Direct UV at 210 nm	Underivatized	CZE	50 mM sodium phosphate (pH 8), 0.001% HDB, and 25% 2-propanol	57 cm $\times$ 75 $\mu$ m i.d. fused-silica capillary, -15 kV, 23°C	109
OA in milk powder, Cheddar cheese, and plain liquid yogurt	Indirect UV at 200 nm	Underivatized	CZE	4.4 mM KHP and 0.27 mM CTAB (pH 11.2)	105 cm $\times$ 75 $\mu$ m i.d. fused-silica capillary, -20 kV, 30°C	110
IA (chloride, nitrate, sulfate, phosphate) and formic acid in honey	Indirect UV at 254 nm.	Underivatized	CZE	2 mM potassium dichromate, 0.05 mM tetraethylene-pentamine (TEPA), pH 4.0	60 cm $\times$ 75 $\mu$ m i.d. fused-silica capillary, -27 kV, 25°C	111
Citric, isocitric, tartaric, and malic acids in natural and commercial orange juices	Direct UV	Underivatized	CZE	200 mM phosphate buffer (pH 7.50)	57 cm $\times$ 50 $\mu$ m i.d. fused-silica capillary, -14 kV, 25°C	112
OA in coffee	Direct UV at 200 nm	Underivatized	CZE	500 mM phosphate buffer (pH 6.25), 0.5 mM cetyltrimethylammonium bromide (CTAB)	57 cm $\times$ 50 $\mu$ m i.d. fused-silica capillary, -10 kV, 25°C	113
OA (tartaric, malic, lactic, succinic, and acetic acids) in white and red port wines	Indirect UV at 200 nm	Underivatized	CZE	5 mM 2,6-PDC, 0.5 mM CTAB (pH 5.0)	78 cm $\times$ 75 $\mu$ m i.d. fused-silica capillary, -10 kV, 18°C	114
Acetic, citric, fumaric, lactic, malic, oxalic, succinic, and tartaric acids, nitrate and sulfite ions in white and red wines	Direct UV at 200 nm	Underivatized	CZE	200 mM phosphate buffer (pH 7.50)	50 cm $\times$ 50 $\mu$ m i.d. neutral coated capillary, -14 kV, 20°C	115
OA (of tartaric, malic, acetic, succinic, and lactic) in wine	Direct UV, 185 nm Indirect UV, 254 nm	Underivatized	CZE	3 mM phosphate with 0.5 mM MTAB (pH 6.5) 7 mM phthalic acid, 2 mM MTAB, 5% v/v methanol (pH 6.1)	60 cm $\times$ 75 $\mu$ m i.d. fused-silica capillary, 15 kV, 25°C	116

IA and OA in sake	Indirect UV at 200 nm	Underivatized	CZE	20 mM 2,6-PDC, 0.5 mM CTAH, pH 12.1	112.5 cm × 50 μm i.d. fused-silica capillary, -30 kV, 15°C	72
Gibberellic acid in fermentation broth and commercial products	UV detection at 214 nm	Underivatized	MEKC	25 mM disodium tetraborate, pH 9.2, 100 mM SDS	57 cm × 50 μm i.d. uncoated fused-silica capillary, 30 kV, 25°C	117
IA (NH <sub>4</sub> <sup>+</sup> , K <sup>+</sup> , Ca <sup>2+</sup> , Na <sup>+</sup> , Mg <sup>2+</sup> , Cl <sup>-</sup> , NO <sub>3</sub> <sup>-</sup> , SO <sub>4</sub> <sup>2-</sup> ) in alcoholic and nonalcoholic beverages	Conductivity	Underivatized	μ-chip CE	10.5 mM His, 50 mM acetic acid, 2 mM 18-crown-6, pH 4.10 20 mM MES/His, pH 6.0 10 mM His, 7 mM glutamic acid, pH 5.75	Microchip 85 mm total length, 4 kV	118
Inorganic and organic anions in beverage drinks	Indirect UV at 240 nm	Underivatized	CZE	3 mmol/L 1,3,5-benzenetricarboxylic acid (BTA), 15 mmol/L tris(hydroxymethyl)aminomethane 1.5 mmol/L tetraethylethylamine (TEPA), pH 8.4	65 cm × 50 μm i.d. fused-silica capillary, -25 kV	119
Citric and lactic acid in food and beverages	Conductivity	Underivatized	μ-chip-CE	10 mM MES/His, 2 mM 18-crown-6 (pH 6) 10 mM 2-(cyclohexylamino) ethanesulfonic acid (CHES), 6 mM arginine electrolyte, pH 9 10 mM 3-(cyclohexylamino)-1-propanesulfonic acid (CAPS), 10 mM arginine buffer, pH 10 1 mM CuSO <sub>4</sub> + 1 mM L-tartaric acid, pH 5.1	Microchip 85 mm length, 3 kV	120
Malic acid in apple juice	PDA	Underivatized	CZE		56 cm × 50 μm i.d. polyvinyl alcohol-coated capillary, -20 kV, 30°C	121

**TABLE.30.5**  
**Methods for the Detection of Toxins, Contaminants, Pesticides, and Residues Separated by CE**

Type of Food	Detection Method	Sample Derivatization	CE Mode	Run Buffer	CE Conditions	References
Acidic pesticides (o-phenylphenol, ioxynil, haloxyfop, acifluorfen, picloram) in apple, grapes, oranges, tomatoes	UV ES-SM	Underivatized	CE-UV CE-MS	4 mM ammonium formate-formic acid (pH 3.1), 32 mM ammonium formate/acid formic buffer (pH 3.1)	60 cm × 75 μm i.d. fused-silica capillary, 25 kV, 25/15°C	127
AA herbicides (glufosinate and aminomethylphosphonic acid, the major metabolite of glyphosate) in agricultural soil samples	LIF	Derivatized with sulfoindo-cyanine succinimidyl ester (Cy5) and 1-ethyl-1-[5-(N-succinimidyl-oxy-carbonyl)-pentyl]-tetramethyl-indodi-carboamine (NIR-641)	CZE	(Cy5) 50 mM borate, 15% ACN (pH 8.0) (NIR-641) 150 mM borate, 15% ACN (pH 9.5)	57 cm × 50 μm i.d. fused-silica capillary, 25 kV, 25°C	128
Aniline metabolites (3-chloroaniline, 3-chloro-4-hydroxyaniline and 3-chloro-4-methoxyaniline) of chloropham in potato	LIF	Derivatized with 150 μL of 5 mM 5-(4,6-dichloro-s-triazin-2-ylamino) fluorescein (DTAF)	MEKC	20 mM boric acid, 30 mM SDS, and 10 mM Triton X-100 (pH 9.5)	57 cm × 50 μm i.d. × 375 μm o.d. fused-silica capillary, 25 kV, 25°C	129
Aflatoxins B <sub>1</sub> , B <sub>2</sub> , and G <sub>1</sub> and the cholera toxin stock solution	MPE-Fluorescence	Underivatized	CZE	20 mM Tris, 10 mM carboxymethyl-β-cyclodextrin buffer (pH 7.5)	20.4 cm × 2.1 μm i.d. capillary	130
Insecticide (pirimicarb) and fungicide (azoxystrobin) in soil and tomato	DAD	Underivatized	CEC	Acetonitrile/5 mM aqueous Tris 40/60 v/v (pH 8.6)	33 cm × 100 μm ID × 375 μm OD polyimide coated fused-silica capillary, 30 kV, 30°C	131
Substituted urea pesticides in orange and tomato	DAD	Underivatized	MEKC	4 mM borate and 35 mM SDS (pH 9.0)	60 cm × 75 μm i.d. polyimide-coated fused-silica capillary, 25 kV, 25°C	132

Pesticides (aldicarb, carbofuran, isoproturon, chlorotoluron, metolachlor, mecoprop, dichlorprop, MCPA, 2,4-D, methoxychlor, TDE, DDT, dieldrin, and DDE) in drinking water	UV detection	Underivatized	MEKC	50 mM SDS, 10 mM borate buffer, 15 mM $\beta$ -CD, 22% acetonitrile, pH 9.6	52 cm $\times$ 50 $\mu$ m i.d. fused-silica capillary, 25 kV	133
Bacterial endotoxins (lipopolysaccharides) in protein complexation	UV absorption	Underivatized	CZE	0.05 M Tris-HCl buffer, pH 8.5	28 cm $\times$ 50 $\mu$ m i.d. fused-silica capillary, 25 kV, 10°C	134
Fungicide validamycin A in rice plants	Indirect UV detection	Underivatized	CZE	10 mM aminopyrine, 2 mM ethylenediaminetetraacetic acid (pH 5.2)	60 cm $\times$ 75 $\mu$ m i.d. fused-silica capillary, 15 kV, 25°C	135
Herbicide, glyphosate (standard)	ESI-MS	Underivatized	CE-MS	Ammonium formate buffer (pH 2.5)	75 cm $\times$ 50 $\mu$ m i.d. fused silica capillary column, -15 kV, 25°C	136
Pesticides (pyrimethanil, pyrifenoxy, cyprodinil, cyromazine, and pirimicarb) in grapes and orange juice	UV and MS	Underivatized	CE-MS	0.3 M ammonium acetate/acetic acid (pH 4.0)	57 cm $\times$ 50 $\mu$ m i.d. fused-silica capillary, 25 kV, 25°C	137
Pesticides (carbendazim, simazine, atrazine, propazine and ametryn, diuron and linuron, carbaryl and propoxur), in drinking water and carrot	DAD at 200 nm	Underivatized	MEKC	20 mmol/L phosphate buffer (pH 2.5), 25 mmol/L SDS, 10% methanol	58.3 cm $\times$ 75 $\mu$ m i.d. $\times$ 375 $\mu$ m o.d. fused-silica capillary, -25 kV, 25°C	138
Antibiotics [Quinolone residues (danofloxacin, enro-floxacin, flumequine, ofloxacin, and piperimidic acid)] in chicken and fish	ESI-MS	Underivatized	CE-MS	60 mM (NH <sub>4</sub> ) <sub>2</sub> CO <sub>3</sub> (pH 9.2)	75 cm $\times$ 75 $\mu$ m i.d. $\times$ 375 $\mu$ m o.d. fused-silica capillary, 20 kV, 20°C	139

in the literature over the past half decade provide an excellent encapsulation of publications on these topics.<sup>122–126</sup>

Several drugs are frequently fed to domestic cattle because modern intensive animal breeding demands permanent suppression of diseases caused by viruses, bacteria, protozoa, and/or fungi. Therefore, residues of these drugs can be found in foods of animal origin such as milk, eggs, and meat. Kowalski et al.<sup>148</sup> reported the development and validation of CZE methodologies for eight antibiotics and one coccidiostatic (nifursol) residues in poultry and porcine tissues. They proposed a simplified clean-up procedure, including deproteinization by acetonitrile and liquid-liquid extraction with ethyl acetate, for drug substances at concentrations below 20 mg/kg in a variety of food types. Castillo and Vargas<sup>155</sup> reported a CE method for the simultaneous analysis of different kinds of antibiotic residues in bovine milk, which would allow for the routine monitoring of the presence of these compounds for quality control (Figure 30.4).<sup>155</sup>

On the other hand, contaminants are substances that have not been intentionally added to food. These substances may be present in food as a result of the various stages of their production, packaging, transport, or holding, or might result from environmental contamination. In this area, Palenzuela et al.<sup>151</sup> proposed an excellent CE method for the detection of bacterial contamination. The method was based on the interaction of ions with biocolloids that allows for their reliable separation of eight different types of bacteria by CE in only 25 min—a dramatic reduction in the analysis time resulted (7 h of enrichment vs. the 24–48 h typically required by culturing methods) compared with classical microbiological analyses.

In the field of pesticide residues in food, CE continues to gain ground and garner significant attention. However, one of the main drawbacks of CE is its low sensitivity in the monitoring of pesticide residue. Therefore, the use of different preconcentration strategies before the separation [e.g., solid-phase extraction (SPE), liquid-liquid extraction, etc.] or different stacking procedures in

the capillary column have been applied and recently reviewed.<sup>156,157</sup> Da Silva et al.<sup>138</sup> demonstrated the usefulness of sample stacking techniques for pesticide analysis with the separation of nine pesticides in complex matrices such as fruits and vegetables. Online preconcentration of the analytes during MEKC separation was established, providing LODs of 2.5 mg/L for all analytes in carrots. Moreover, the use of SPE, in combination with an online preconcentration strategy, allowed for the determination of pesticides at the 0.1 mg/L level in drinking water. Other toxic compounds such as mycotoxins<sup>130</sup> and bacterial endotoxins,<sup>134</sup> colorants,<sup>153</sup> and sulfonamide residues<sup>154</sup> have also been analyzed and reported using CE methodologies.

### 30.2.6 ANALYSIS OF PHENOLIC COMPOUNDS IN FOOD

Phenolic compounds (PCs) are a group of naturally occurring secondary metabolites present in plants, all of which possess one common structural feature—a phenol moiety, and behave as excellent antioxidants due to the reactivity of this group. PCs are of interest due to their potential contribution to the taste (astringency, bitterness, and sourness) and formation of off-flavor in food, including tea, coffee, and various fruits juices, during storage. Currently, PCs are divided into two types: simple phenols and polyphenols. Phenols are a widely found group of secondary plant metabolites (e.g., benzoic and cinnamic acid derivatives), and polyphenols have at least two phenol subunits—flavonoids are an example of a common polyphenol in plants. Some recent application of CE to the analysis of PCs in tea, wines, and other foods are summarized in Table 30.6. It should be noted that there is no need to derivatize samples of PCs because they are aromatic and, therefore, show intense absorption in the UV region. Several reviews have been published that can be used as a guide for the analysis of these compounds in food by CE.<sup>158–161</sup> In a recent review, Li et al.<sup>160</sup> discussed the strategies that have been used during the optimization of CZE for analysis of phytochemical bioactive compounds, and proposed the use of multivariate experimental designs to simplify this task. Blasco et al.<sup>162</sup> recently proposed a new and attractive route for fast, simultaneous detection of prominent natural antioxidants, including phenolics and nonphenolic antioxidants, using a CE microchip with electrochemical detection via a glassy carbon electrode. Separation of the pair of standard compounds (+)-catechin and ascorbic acid, (+)-catechin and rutin, as well as arbutin and phlorizdin was carried out in less than 400 s and later applied for the determination of these compounds in pear juice. An interesting method for the simultaneous separation and determination of selected PCs in six different collections of *Hypericum perforatum* (St. John's wort) was proposed by Hamoudová et al.<sup>163</sup> This method used an online combination of CZE with capillary ITP (CE-ITP) allowing detection limit as low as 60 ng/mL and total analysis time of less than 35 min.

Using a different mode of CE, MEEKC, and MEKC, Huang et al.<sup>181</sup> separated 13 PCs. The authors compared both methodologies and demonstrated that both MEEKC and MEKC methods possess the ability to analyze PCs in different food samples. The same authors also reported a method for the separation of the nine flavonoids most often found in grape wine, namely, apigenin, baicalein, naringenin, luteolin, hesperetin, galangin, kaempferol, quercetin, and myricetine, using a 35 mM borax, pH 8.9, 16.8 kV of applied voltage with an analysis time of within 16 min.<sup>182</sup> A high-pressure liquid chromatography (HPLC) method was also developed for the same group of compounds and later compared with the CZE. They concluded that both strategies were useful for the analysis of PCs. An electropherogram of the flavonoid separation can be seen in Figure 30.5.<sup>182</sup>

### 30.2.7 CHIRAL ANALYSIS OF FOOD COMPOUNDS

Most of the major nutritional organic components of food and beverage are chiral, including proteins, AA, carbohydrates, fats, and some vitamins. Many flavor and fragrance components of food and beverage are chiral as well. The significance of the enantiomeric composition of food components is that they can have a dramatic effect on aroma, taste, and nutritional value. Chiral separations for food components are useful for evaluating age, treatment, and storage effects; for control or

monitoring fermentation processes; to identify adulterated products; to understand and control flavors and fragrances; and for fingerprint complex mixtures.

AA in food naturally occurs as the L-AA form. However, the D-enantiomers can be found in food that have been exposed to microbial activity (fermentation, aging, etc.), highly processed food (those that have been exposed to extremes of pH, heat, etc.), and food that naturally contains D-AA. Excellent reviews have been published that deal with chiral separation by CE<sup>193–196,198</sup> and specifically those separations that are applied to food analysis.<sup>191,192,197</sup> Table 30.7 summarizes the most recently published scientific paper on chiral compounds present in food and beverages.

Nouadje et al.<sup>199</sup> proposed a method some years ago using  $\beta$ -cyclodextrins ( $\beta$ -CDs) and SDS to determine L- and D-AA previously derivatized with FITC. A number of AA, including L-proline, L-aspartic acid, D-Asp, L-serine, L-asparagine, L-glutamic acid, D-Glu, L-alanine, L-arginine, D-Arg, and the nonchiral  $\gamma$ -amino-*n*-butyric acid (GABA), were analyzed in orange juice. The buffer consisted of 100 mM sodium tetraborate, 30 mM SDS, and 20 mM  $\beta$ -CD at pH 9.4, with an applied voltage of 23 kV. It was shown that L-Arg, L-Asp, and GABA were the most important compounds for the classification of commercial orange juices to provide useful information about quality and the efficacy of processing. Simo et al.<sup>200</sup> reported the use of stepwise discriminating analysis for 26 standard samples of commercial orange juices (i.e., nectars, orange juices reconstituted from

Standards of aliphatic amines	Conductivity	Underivatized	On-chip CE	0.5 M acetic acid 5 mM of DM-β-CD 5 mM of (+)-18C <sub>6</sub> H <sub>4</sub> (pH 2.45)	60 cm × 50 μm i.d. × 375 μm o.d. fused-silica capillary, 15 kV, 22°C (PMMA), 90 mm × 16 mm	217
Standards of AA	UV-visible	Underivatized	CZE	20 mM ammonium acetate (pH 5) 2.5 mM vancomycin	35 cm × 50 μm i.d. × 375 μm o.d. fused-silica capillary, -15 kV, 20°C	218

Aromatic AA and L-mimosine in extracts of plant seeds and nonprotein AA	UV detection at 200 nm	Underivatized	CZE	60 mM phosphoric acid buffer, pH 2.5 containing 175 mM HP- $\alpha$ -CD 60 mM phosphoric acid buffer (pH 2.5) containing 2.3 mM HS- $\gamma$ -CD	502 mm $\times$ 50 $\mu$ m i.d. fused-silica capillary, 25.1 kV, 20°C, 25.1 kV, 18°C	219
Aromatic AA (phenylalanine, tyrosine, and tryptophan)	DAD	Underivatized	CZE	20 mM phosphate (pH 2.0), 0.5 mM S- $\beta$ -CD, and 0.55% dextran sulfate	55 mm $\times$ 25 $\mu$ m i.d. fused-silica capillary, 30 kV, 25°C	220
Flavonoids medicarpin and vestitone from transgenic legumes extracts	UV visible	Underivatized	CZE	2 mM hydroxypropyl- $\beta$ -cyclodextrin 20 mM hydroxypropyl- $\gamma$ -cyclodextrin 25 mM borate (pH 10.0), 10% v/v methanol	50 cm $\times$ 50 $\mu$ m i.d. $\times$ 375 $\mu$ m o.d. fused-silica capillary, 15 kV, 25°C	221
Standards mixture of AA	UV at 254 nm	Underivatized	CZE	100 mmol/L MES + 10 mmol/L His (pH 5.2) + 20 mmol/L MA- $\beta$ -CD + 2 mmol/L $\gamma$ -CD	Polyacrylamide coated capillary 80 cm total length (54 cm to the detector) $\times$ 75 $\mu$ m i.d., 24 kV	222
Chiral AA in orange juices and orange concentrates	LIF	Derivatized with FITC	MEKC	100 mM sodium tetraborate, 30 mM SDS (pH 9.4), 20 mM $\beta$ -CD	50 cm $\times$ 50 $\mu$ m i.d. fused-silica capillary, 20 kV, 15°C	223

concentrates, and pasteurized orange juices not from concentrates) and selected L-Arg, L-Asp, and GABA as the most important variable L-AA to differentiate the samples. With the use of  $\beta$ -CDs as the chiral selector to separate the L-AA, it was possible to classify correctly the 100% of the samples.

Carlavilla et al.<sup>202</sup> recently published a chiral MEKC-LIF procedure that allows fast and sensitive analysis of the 11 main L- and D-AAs typically found in vinegars. The separation of the 11 compounds could be achieved in a relatively short time (less than 20 min) with a LOD down to 16.6 nM. It was shown that using these profiles resulted in a very useful strategy for characterizing vinegars.

Gel-Moreto et al.<sup>211</sup> reported, for the first time, the complete separation of the 2*R*- and 2*S*-diastereomer of six selected flavanone-7-*O*-glycosides (naringin, prunin, narirutin, hesperidin, neohesperidin, and eriocitrin). CE measurements were done using 0.2 M borate buffer, 5 mM  $\gamma$ -CD, pH 10.0, and later applied for the separation of 2*S*- and 2*R*-diastereomers of eriocitrin and hesperidin in lemon juice. Another application of chiral analysis in food by CE was published by Liu et al.<sup>201</sup> They developed a method for the determination of 1-aminocyclopropane-1-carboxylic acid (ACC) in apple tissues based on the derivatization of ACC with 3-(2-furoyl) quinoline-2-carboxaldehyde (FQ) and the use of CE-LIF (488 nm). Optimal conditions for the separation of ACC were obtained using 20 mM borate buffer, pH 9.35, with 40 mM SDS and 10 mM Brij 35, allowing for the analysis of ACC in crude apple extracts to be done with an impressive LOD of 10 nM. Finally, Cinquina et al.<sup>76</sup> reported the determination of histamine in tuna fish samples. Histamine is a degradation product of the bacterial decarboxylation of the AA histidine, which is present at substantial concentration in fish tissues. A CE method and an HPLC method with diode array detection were compared showing that both techniques were associated with correlation coefficients that exceeded 0.999, and LODs of 1 and 2 mg/kg for HPLC, and 0.5 and 1 mg/kg for CE.

### 30.2.8 PROTEINS AND PEPTIDES

Proteins are one of the main components of foods and possibly one of the most challenging to analyze, not only because of the heterogeneity of the fractions but also because of their tendency to aggregate. Thus, it is not surprising that CE has evolved as an alternative technique to the classical gel electrophoresis for the analysis of proteins and peptides with the advantage that it allows for online detection and automation. In fact, the analysis of food proteins is one of the main applications of CE in food analysis, with most focus on the analysis of dairy proteins, followed closely by cereal proteins.<sup>2</sup> The third category includes other food proteins such as those from meat, eggs, and others.<sup>2</sup> Table 30.8 summarizes some selected applications for the analysis of food proteins by CE. For a comprehensive review, including applications up to 1999, the reader is referred to Frazier et al.<sup>5</sup> and to Cifuentes<sup>2</sup> for a more updated review including applications from June 2002 to June 2005. For specific reviews on food proteins of animal origin, the review by Recio et al.<sup>224</sup> describes CE methods of analysis for milk, egg, meat, and fish proteins and peptides, with special emphasis on dairy products. In addition, various hurdles associated with food analysis technology, such as the assessment of technological processes, quality, and authenticity control of animal foods, were considered.<sup>224</sup> Similarly, Bean and Lookhart<sup>225</sup> offer a specific review covering methods and applications for the separation of three major groups of food proteins: meat, dairy, and cereal proteins.

The first prerequisite for the analysis of proteins is their solubilization from the food matrix. Nonliquid food sources usually require homogenization before extraction to allow efficient recovery of proteins from the material.<sup>226</sup> For this purpose, milling, blending, homogenizing, and the use of ultrasound (sonication) are common methods. The homogenization step may be combined with extraction of the proteins using suitable extraction buffers, which may give a selective extraction of specific groups of proteins, often combining precipitation, filtration, and dialysis steps.<sup>226</sup> Defining a strategy for isolation of a protein or a group of proteins from a specific food matrix will usually encompass a choice of method chosen on the basis of known characteristics of the protein(s) that

**TABLE 30.8**  
**Food Proteins Analyzed by CE**

<b>Application</b>	<b>Detection Method</b>	<b>Sample Pretreatment</b>	<b>CE Mode</b>	<b>Run Buffer</b>	<b>References</b>
Caseins and whey proteins	UV at 214 nm	Milk, diluted (1:5) with 10 mM phosphate buffer (4.8 M urea, 0.2% Tween 20, pH 2.5), heating 5 min at 40°C	CZE	50 mM phosphate buffer (4 M urea, 0.1% Tween 20, pH 2.5), coated capillary	230
	UV at 214	Milk, diluted (1:5) with 5 mM sodium citrate (5 mM DTT, 6 M urea, pH 8.0)	CZE	10 mM phosphate or citrate buffer (0.05% MHEC, 6 M urea, pH 2.5), coated capillary	231
	UV at 214	Milk, diluted (1:5) with 167 mM Tris, 42 mM MOPS, 67 mM EDTA, 17 mM DTT, 10 M urea	CZE	20 mM sodium citrate buffer (0.05% MHEC, 6 M urea, pH 3.0), coated capillary	232
Caseins and whey proteins, denatured $\beta$ -lactoglobulin, para- $\kappa$ -casein	UV at 214	Milk, cheese, 167 mM Tris, 42 mM MOPS, 67 mM EDTA, 17 mM DTT, 8 M urea, 0.5 g/L MHEC	CZE	0.48 mM citric acid – 13.6 mM trisodium citrate in 4.8 M urea (pH 2.3), coated capillary	233
Caseins and whey proteins	UV at 214	Purified proteins, denatured by addition of 10% SDS and 7% DTT, heating 3 min at 100°C	MEEKC	3 mM sodium borate, 8.2 mM SDS (pH 9.5), uncoated capillary	234
Whey proteins, separation of $\beta$ -lactoglobulin variants A and B	UV at 214 nm	Milk, whey proteins prepared by casein precipitation diluted (1:4) with 8.25 mM borate buffer, 0.1% Tween 20, pH 8.0	CZE	0.05 M borate buffer, Tween 20 0.1%, pH 8.0, coated capillary	235
Cereal storage proteins	UV at 200 nm	Various cereals, extraction with 50% 1-propanol, glutens with 50% 1-propanol, 1% DTT	CZE	50 mM iminodiacetic acid IDA, 20% AcN, 0.05% HPMC	246
Sarcoplasmic/myofibrillar meat proteins	UV at 214	Meat, sarcoplasmic proteins extracted in bidistilled deionized water, myofibrillar extracted in 0.6 M NaCl/0.01 M phosphate buffer, 0.5% polyphosphates, pH 6.0, Biorad SDS sample buffer	MEKC	SDS-CE, nm, Bio-Rad SDS run buffer	247
Lysozyme from egg white	MS	Meat adulterated with chicken egg white	CE-MS	75 mM ammonium acetate/acetic acid, pH 5.5, coated capillary	249

include molecular weight or isoelectric point; however, some general strategies as outlined by Sorensen et al.<sup>226</sup> may be useful as a starting point before performing a CE analysis.

Similarly, the separation of proteins by CE is highly dependent on the characteristics of the proteins, especially the isoelectric points of the proteins and also information on the differences between the proteins to be separated are important.<sup>226</sup> The most important point to consider in the choice of buffer systems used in analyzing proteins is how to prevent or control the adsorption of proteins to the capillary wall.<sup>226</sup> Adsorption of the proteins to the silica surface of the capillary wall is the main reason for the observed efficiency loss, poor reproducibility in migration times, and low protein recovery.<sup>2</sup> This problem may be solved by the use of coated capillaries.<sup>226,227,228</sup> A coating polymer was demonstrated to provide good separations of acidic and basic proteins, including proteins from whey.<sup>227</sup> Coating regeneration was achieved by flushing the capillary between injections with an aqueous solution of the polymer.<sup>227</sup> Alternatively, the ionization of the silanol groups can be suppressed by working with background electrolytes (BGE) with low pH values or with a buffer pH above the pI of the sample protein and the use of dynamic coatings.<sup>226,228</sup> A comprehensive review of different dynamic and static capillary coatings for reducing protein wall adsorptions offered different alternatives for solving the problem.<sup>228</sup>

The separation of dairy proteins by CE has been generally carried out by CZE and has been exhaustively covered in several review papers,<sup>2,224,225,229</sup> thus Table 30.8 only presents the key methodologies that offer the reader an overview of their most distinctive features. Basically, dairy protein analysis has been performed in whole milk for the simultaneous determination of caseins and whey proteins, or in fractions isolated from milk after casein precipitation. The first approach being used when the quantitative determination of the major proteins is required for the calculation of casein/whey protein ratios or for authentication purposes where an analysis of the whole protein profile is required. In both cases, accurate quantitative data must be derived. However, few studies have addressed the analysis of both groups of proteins in a single run by presenting quantitative data based on calibration curves constructed with analytical standards and good recovery of all proteins from milk samples.

The first method reported to provide quantitative recovery of major whey and casein proteins in a single run was by Vallejo-Cordoba (Table 30.8).<sup>230</sup> With this method,<sup>230</sup> sample preparation was critical for the quantitative recovery of all proteins in their native state; while in most other methodologies, sample preparation included a strong denaturing reducing buffer.<sup>231,232,233</sup> Sample and run buffer contained the minimum concentration of urea (4 M) that allowed good casein solubility. Keeping urea to a minimum concentration was essential to prevent  $\beta$ -lactoglobulin denaturation and to minimize urea crystallization.<sup>230</sup> In addition, the nonionic detergent, Tween, was also used to help with maintaining caseins in solution. A typical electropherogram of whey proteins and caseins in fresh milk separated in a coated capillary at pH of 2.5 is shown in Figure 30.6.

Several groups have applied the method of de Jong et al.<sup>231</sup> with modifications to monitor milk proteins; these conditions not only allowed the separation of the individual milk proteins but also some of their genetic variants.<sup>7,232,233</sup> Although the original method offered by de Jong et al.<sup>231</sup> was the first method described for simultaneously determining casein and whey proteins, quantitative data were not presented. The original method of de Jong<sup>231</sup> included a reducing denaturing sample buffer at pH 8.5 and a running buffer at pH 2.5 or 3.0 containing a cellulose polymer. To minimize protein and capillary wall interactions, separation was carried out in a coated capillary. However, this method was later modified to minimize protein absorption by optimizing the sample and running buffer (Table 30.8).<sup>232,233</sup>

Finally, a third method<sup>234</sup> was based on MEKC, where proteins were separated after complete denaturation with SDS and DL-dithiothreitol in uncoated capillaries at pH 9.5. Although the method had the advantage of being very rapid (separation completed in less than 90 s), it was not quantitative (Table 30.8). The second approach reported for the analysis of dairy proteins was the analysis of the whey fraction after casein precipitation. Unlike the methods described earlier, separations were carried out in uncoated capillaries using polymeric additives, a high ionic strength, and high pH

**FIGURE 30.6** Typical electropherogram of proteins in fresh milk. (1)  $\beta$ -lactoglobulin, (2) bovine serum albumin, (3)  $\alpha$ -lactalbumin, (4) conalbumin (added internal standard), (5)  $\alpha$ -casein and (6)  $\beta$ -casein (From Vallejo-Cordoba, *B. J. Cap. Elec.*, 4, 219, 1997. With permission.)

separation buffer, which collectively reduced adsorption of proteins to the capillary wall.<sup>229</sup> Several examples of this strategy were reviewed,<sup>224,229</sup> however, few of these methods were demonstrated to be quantitative.<sup>229</sup> To this end, Olguin-Arredondo and Vallejo-Cordoba<sup>235</sup> presented a method that allowed the quantification of genetic variants of  $\beta$ -lactoglobulin (Table 30.8). Excellent resolution for variants A and B was observed under the established conditions (Figure 30.7).

Most applications for the analysis of dairy proteins are based on the methods described earlier (Table 30.8). However, since UV detection was used, the detection sensitivity of these methods is usually limited to proteins in the  $\mu\text{M}$  range.<sup>236</sup> Thus, to overcome this drawback, an on-capillary derivatization method with the fluorogenic reagent 3-(2-furoyl)quinoline-2-carboxaldehyde (FQ) and LIF was developed for the determination of dairy proteins.<sup>236</sup> This method allowed the determination of trace amounts of  $\beta$ -lactoglobulin in hypoallergenic infant formulas.<sup>237</sup> CE was used for the determination of added rennet casein and caseinate to processed cheeses<sup>238</sup> and for the simultaneous quantitative determination of bovine, ovine, and caprine casein fractions in Mexican unripened cheese (Panela).<sup>239</sup> CE was also useful for characterizing milk protein hydrolysates to investigate the molecular basis for differences in bioactivity,<sup>240</sup> for monitoring proteolysis of casein in packaged pasteurized milk during refrigerated storage in relation to hygienic and microbiological characteristics of starting raw milk,<sup>4</sup> and for peptide mapping in the investigation of milk protein genetic variants.<sup>242</sup>

Cereal proteins are important not only for their nutritional quality but also for their functional role in foods. The analysis of cereal proteins by CE has been covered in several reviews.<sup>228,243–245</sup> Cereal proteins are complex mixture of proteins that are often difficult to solubilize and separate. Because of this, a wide range of analytical techniques including CZE or sodium SDS-CE have

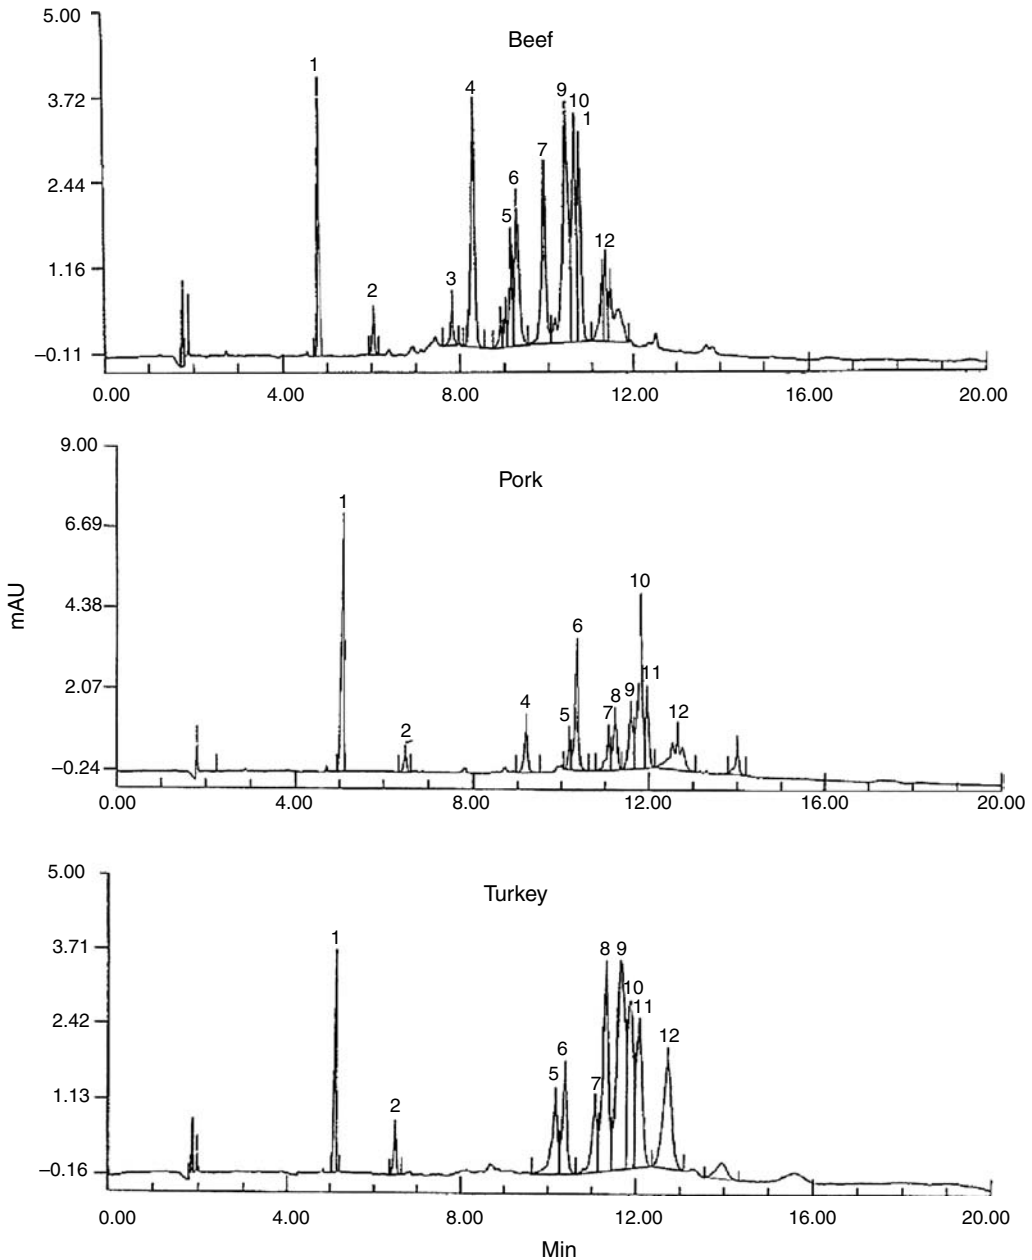

**FIGURE 30.7** Separation of  $\beta$ -lactoglobulin variants A and B in cow's milk. (From Olguin-Arredondo, H. and Vallejo-Cordoba, B., *J. Elec. Microchip Tech.*, 6, 145, 1999. With permission.)

been used.<sup>243</sup> These reviews also present the applications of CE for cultivar identification, classification, and prediction of quality.<sup>243–245</sup> Since the objective of most cereal protein applications was to qualitatively characterize protein profiles, most method development efforts were toward improving resolution, reproducibility, and speed of the analysis. A good example was an improved method that allowed rapid (2–8 min) separations of grain proteins for several cereals (wheat, oats, rice, barley, and rye) with high resolution and reproducibility using isoelectric buffers (Table 30.8).<sup>246</sup> These buffers allow the use of extremely high voltages, which in turn produces very rapid separations and resolution.<sup>246</sup> Also, it was shown that acetonitrile worked as well as urea in solubilizing maize and sorghum proteins, the most hydrophobic storage proteins. In addition, some cellulose polymer modifier was added to the buffer to prevent protein–capillary wall interactions.<sup>246</sup>

CE has also been successfully applied to the study of muscle proteins, and some of these applications have been recently reviewed.<sup>6,224,244</sup> Methods for the determination of muscle proteins were based on CZE, SDS-CE, or isoelectric focusing (CEIF).<sup>6,224,244</sup> Meat species identification was carried out by analyzing sarcoplasmic or myofibrillar proteins by a replaceable polymer-filled SDS-CE method (Table 30.8).<sup>247</sup> However, the analysis of sarcoplasmic protein profiles allowed better differentiation among beef, pork, and turkey meat (Figure 30.8).<sup>247</sup> The importance of sample preparation in the established method was highlighted since sarcoplasmic proteins extracted by simply homogenizing meat with cold bidistilled water were most useful for meat species identification when protein profiles were examined by linear discriminant analysis.<sup>248</sup> On the other hand, myofibrillar proteins extracted with 0.6 M NaCl/0.01 M phosphate buffer with 0.5% polyphosphates (pH 6.0) were not useful for raw meat species identification, although they may be of importance in the identification of heat-processed meats.<sup>248</sup>

The analyses of egg proteins by CZE, CIEF, or MEKC were reviewed by Recio et al.<sup>224</sup> In addition, an interesting application of CE coupled to mass spectrometry (CE-MS) was the detection of lysozyme from chicken and turkey egg white.<sup>249</sup> Since one of the problems of protein separations was the possible interaction with the capillary wall, a polymer coating compatible with CE-MS was developed, and the usefulness of this method was shown by the analysis of a minced meat extract containing chicken egg white as adulterant (Table 30.8).<sup>249</sup>

**FIGURE 30.8** CE-SDS electropherograms of sarcoplasmic proteins extracted from beef, pork and turkey meat. (From Cota-Rivas, M. and Vallejo-Cordoba, B., *J. Cap. Elec.*, 4, 197, 1998. With permission.)

**30.2.9 DNA AND MICROCHIPS**

Unlike food proteins, nucleic acids have no nutritional value but are characteristic of the various biological components in complex products. Thus, the analysis of nucleic acids in food allows control laboratories to determine the presence or absence of certain ingredients in complex products or the identification of specific single food components.<sup>250</sup> These analyses were based on nucleic acid probes, including the polymerase chain reaction (PCR), which made the detection of minute amounts

of nucleic acids and their sequence determination possible.<sup>250</sup> Also, as DNA is more thermostable than many proteins, analyses using nucleic acids are less liable to be disrupted by processing of foods. Thus, nucleic-acid-based technologies are developing rapidly and the use of suitable methods by food control laboratories has the potential to greatly simplify methods for food authentication.<sup>251</sup> The use of molecular techniques and CE has tremendously facilitated analytical procedures since this combination has the benefit of high specificity and sensitivity of molecular techniques coupled with the high resolving power and automation of CE.<sup>2</sup>

DNA-based analysis methods are highly dependent on the DNA extraction and purification techniques. In particular, the application of molecular methods to food samples requires stringent extraction and purification strategies, which ensure efficient recovery of nucleic acid and removal of the numerous compounds inhibiting PCR assay.<sup>252</sup> A comparison of DNA extraction methods for food analysis was recently reported that highlighted the efficiency of two different commercial kits.<sup>252</sup> Also, four different DNA extraction methods from maize flour in genetically modified organisms (GMOs) in foods were compared and the SDS/proteinase K method was chosen as the most convenient.<sup>253</sup> Thus, these studies highlighted the need for suitable DNA extraction methods to obtain highly purified nucleic acids without inhibitors before PCR-CE can be carried out.

PCR-based techniques combined with CE separations has resulted in powerful methods in two specific areas of food analysis, namely, food authentication and microbiology. PCR-CE applications for meat authentication were reviewed by Vallejo-Cordoba et al.,<sup>6</sup> while applications including other foods were reviewed by Cifuentes<sup>2</sup> and Kvasnicka.<sup>4</sup> An overview of the combined use of PCR and CE for the detection of transgenic foods, meat species identification, and microbial analysis discussing advantages and drawbacks of these combined techniques was presented.<sup>254</sup> Specific applications of food authentication consisted in the detection of GMOs<sup>255</sup> and the identification of meat species<sup>256</sup> or in beef sexing,<sup>257</sup> while food microbiology applications included the detection of food-borne pathogens,<sup>258</sup> food-spoilage bacteria,<sup>259</sup> and the characterization of toxigenic fungi in dry, cured meat.<sup>260</sup>

Commercial use of transgenic plants and other GMOs has raised several ideological and ethical issues in recent years. Therefore, this has created a demand for analytical methods that can detect and quantify the amount of GMO in foods.<sup>254</sup> A method that combines PCR and CGE-LIF was developed for the quantification of genetically modified Bt maize in foods.<sup>255</sup> The method developed was based on the coamplification of specific DNA maize sequences with internal standards using QC-PCR.<sup>255</sup> Different DNA isolation and amplification techniques, which are being used for detecting GMOs in foods, addressing quantitative aspects were reviewed.<sup>261</sup>

In the past, species identification in muscle foods routinely involved the detection of species-specific proteins when attempting to discern the origins of the material, but they were not without problems. The processing of foods by heating can cause denaturation of the proteins under study and, in addition, protein expression is usually tissue dependent. Thus, study in the past decade has seen DNA replace protein in species identification owing to the protein's instability at high temperatures, and to the fact that the DNA's structure is conserved within all tissues of an individual.<sup>251</sup> To this end, a PCR-RFLP method that used fluorescence sensor CE for DNA fingerprinting of pork, goat, and beef generated by restriction enzyme digestion following a fluorescent-labeling PCR amplification was reported.<sup>256</sup> This method was based on the amplification of the mitochondrial 12S rRNA gene with a unique primer pair and incorporated a fluorescent-labeling nucleotide with sufficient specificity to detect the three animal species. The method could reliably identify pork, goat, and beef and semiquantify any of these meats when they were present in meat mixtures at levels less than 1%.<sup>256</sup>

Although QC-PCR by CE for the determination of meat species has not been reported, this methodology was useful for quantitatively analyzing GMOs in foods. An alternative method, real time PCR (RT-PCR), is gaining popularity over QC-PCR for the quantification of GMOs in food samples, although these methods are still under development for the simultaneous detection of several transgenes. Also, the interlaboratory reproducibility of RT-PCR was very low since %RSD values of 40% were reported.<sup>255</sup> In addition, although instrumentation required for RT-PCR or QC-PCR-CE

may be costly for most food laboratories, CE is a more versatile technique because a wider range of analytes may be determined with the same instrumentation. Thus, QC-PCR-CE offers good potential for the quantitative determination of meat species or soy in heat-processed products.

Several of these food DNA-based analyses were recently translated to microchips as shown from the applications reviewed by Cifuentes.<sup>2</sup> An exemplary application of microchips was an improved PCR-RFLP method for fish species identification.<sup>262</sup> The objective of the improved method was to replace the gel-electrophoretic steps for fragment separation, detection, and analysis by employing a chip-based CE system (Agilent 2100 Bioanalyser) to analyze PCR-RFLP fingerprints. The use of this system allowed simultaneous postrestriction digestion analysis of 12 samples in under 40 min, which is a considerable time reduction over conventional gel-based methods. In addition, repeatability was less than 3%, allowing species identification without the need to run reference materials with every sample. Using DNA admixtures, discrimination of 5% salmon DNA in trout DNA was detected.<sup>262</sup> This improved lab-on-a-chip method was applied to the development of PCR-RFLP profiles on a commercial microchip electrophoresis instrument that can be used to identify a range of white fish species without the need for concurrent analysis of reference materials. The method was applied to a range of products and subjected to an interlaboratory study carried out by five UK food control laboratories. One hundred percent correct classification of single species samples and six of nine admixture samples was achieved by all the laboratories. The results indicated that the fish species identification could be carried out using a database of PCR-RFLP profiles without the need for reference materials.<sup>263</sup>

### 30.2.10 FOOD ADDITIVES

Food additives are substances added to food with the sole purpose of preserving it or improving its flavor and appearance. The extended use of additives has made necessary the development of new analytical procedures that are able to characterize them to ensure that food manufacturers comply with labeling regulations. A comprehensive review was reported by Boyce,<sup>264</sup> focusing on antioxidants, preservatives, colorings, and sweeteners added to food. In addition, an exhaustive survey of capillary electromigration methods to analyze natural antioxidants was presented together with some discussion of the use of these substances as functional foods.<sup>161</sup> Most recently, an updated overview on this subject was reported by Cifuentes.<sup>2</sup> In general, CZE and MEKC methods with UV detection were used for the analysis of food additives. A very useful application that demonstrated the versatility of MEKC for the simultaneous rapid separation of preservatives, sweeteners, preservatives, and colors in soft drinks was reported by Frazier et al.<sup>265</sup> Minimum sample preparation was required since soft drinks were only subjected to degassing by sonication. Resolution between all additives was achieved within a 15-min run using carbonate buffer containing an optimum SDS concentration at the micellar phase. By using the UV-visible range (190–600 nm), the identity of sample components was confirmed by spectral matching relative to standards.<sup>265</sup> Food additives that were used in this analysis included a range of seven synthetic food colors (quinoline yellow, sunset yellow FCF, carnosine, ponceay 4R, brilliant blue FCF, green S, and black PN), three artificial sweeteners (acefulfame K, aspartame, and saccharin) and two preservatives (benzoic and sorbic acid). Although this example required minimum sample preparation, sample matrix interference is directly related to food complexity. The analysis of eight colorants in milk beverages required prior sample pretreatment with a polyamide SPE column.<sup>266</sup> Baseline resolution of the carminic acid, a natural colorant, and seven synthetic dyes was achieved within 9 min by using a tetraborate buffer containing  $\beta$ -CD as additive. Also, the recoveries of the eight food colorants from milk beverages were better than 85% with detection levels of less than 0.5  $\mu\text{g/mL}$ .<sup>266</sup>

On the other hand, the development of a MEEKC allowed the determination of the same food colorants with most instances not requiring sample pretreatment. The effects of SDS surfactant, organic modifier (acetonitrile), cosurfactant, and oil were examined to optimize the separation. A highly efficient MEEKC separation method, where the eight colorants were separated with baseline

resolution within 14 min, was achieved by using a microemulsion solution of pH 2.0 containing 3.31% SDS, 0.81% octane, 6.61% 1-butanol, and 10% acetonitrile.<sup>267</sup> To this end, an electrolyte composed of tetraborate (TBS), Brij 35, and acetonitrile (ACN) was optimized for the separation of 11 dyes allowed in Brazil providing baseline separation in less than 9 min. The optimization procedure that provided baseline separation in less than 9 min was aided by a factorial design.<sup>268</sup>

Other applications of CE to analyze food additives include the determination of vitamin C and preservatives (benzoate and sorbate) by both conventional CE and microchip electrophoresis with capacitively coupled contactless conductivity detection.<sup>269</sup> The separation was optimized by adjusting the pH value of the buffer and the use of hydroxypropyl- $\beta$ -CD (HP- $\beta$ -CD) and CTAB as additives. For conventional CE, optimal separation conditions were achieved in a histidine/tartrate buffer at pH 6.5, containing 0.025% HP- $\beta$ -CD and 0.25 mM CTAB with a LOD ranging from 0.5 to 3 mg/L, whereas a histidine/tartrate buffer with 0.06% HP- $\beta$ -CD and 0.25 mM CTAB gave a LOD ranging from 3 to 10 mg/mL. By using a microchip electrophoresis format, a considerable reduction of analysis time was accomplished.<sup>269</sup>

Another useful application of CE is the determination of the preservative nitrate and nitrite ions in meat products.<sup>270</sup> It is known that nitrite causes methaemoglobinaemia and, with secondary and tertiary amines, yields the carcinogenic nitrosoamines. Owing to these toxic effects, it is important to develop new analysis methods for the simultaneous determination of the two anions reducing the matrix effect in meat samples. The method developed was based on the separation of the two anions in a capillary coated with polyethyleneimine (PEI). Since PEI is a cationic polymer, the EOF is reversed over a wide pH range and the fast separation of anions is achieved without the addition of any electroosmotic modifier to the Tris separation buffer at pH 7.5. The LODs of the method for nitrite and nitrate were 0.10  $\mu$ g/mL and 0.09  $\mu$ g/mL, respectively.<sup>270</sup>

Because of its aromatic properties, vanillin is the most widely used flavoring material in foods and beverages.<sup>271</sup> Vanillin is the main aromatic compound in natural vanilla, but it can also be synthesized from low-cost materials such as 2-methoxyphenol, eugenol, and lignin. On the other hand, ethylvanillin, which is commonly used as another synthetic compound, has much more flavoring strength than vanillin and is used in formulation and imitation products. Thus, a CE method was developed for the determination of vanillin, ethylvanillin, 2-methoxyphenol, and 2-ethoxyphenol, simultaneously in cocoa drink samples by using a photodiode array detector.<sup>270</sup> Separation was carried out in phosphate buffer containing CTAH at pH 10 with 10% acetonitrile. Vanillin and related compounds were determined in 7 min, with the LOD at 1.6  $\mu$ g/mL. Mean recoveries were 96.3–103.8%. With this method, it was possible to determine vanillin and ethylvanillin, which were originally contained as flavoring in cocoa drinks, but it was also found that vanillin and ethylvanillin were metabolized, respectively, to 2-methoxyphenol and 2-ethoxyphenol, by growth of *Bacillus firmus* causing an off-flavor.<sup>271</sup>

Artificial sweeteners are added to foods as a sugar substitute, particularly to low-calorie foods. Sucralose is one of these artificial sweeteners that was determined by CE in different food matrices.<sup>272</sup> A CE method was optimized chemometrically for the quantification of sucralose from different food matrices. Separation from food matrix components was obtained in a dinitrobenzoic acid/sodium hydroxide background electrolyte with a pH of 12.1 and detection was achieved at 238 nm by indirect UV. The method allows the detection of sucralose at >30 mg/kg making it suitable for implementation of the recently amended “Sweeteners for use in foodstuffs” European Directive.<sup>272</sup>

Antioxidants are often added to food to retard oxidative processes that cause food off-flavors. The most commonly permitted additives are butylated hydroxyanisole (BHA), butylated hydroxytoluene (BHT), tert-butylhydroquinone (BHQ), and the esters of gallic acid. Some of the applications of CE to synthetic antioxidants were reviewed by Boyce.<sup>264</sup> A recently reported method was the analysis of alkyl gallates and nordihydroguaiaretic acid (NDGA) by a microchip MEKC with pulsed amperometric detection. Simultaneous separation of the antioxidants propyl gallate (PG), octyl gallate (OG), lauryl gallate (LG), and NDGA was carried out in borate buffer, pH 9.7, containing SDS. The measured detection limits were in the range of 2–6 fmol of the analyte.<sup>273</sup>

### 30.2.11 FOOD QUALITY

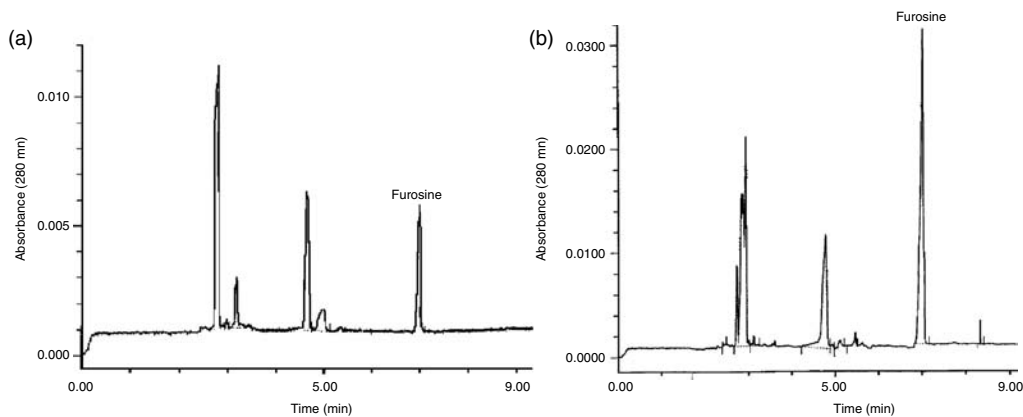

The versatility of CE makes it a very useful method for monitoring food quality from its different aspects, namely, nutritional, sanitary, compositional (including authenticity), and sensorial. Also, these technological processes such as heat treatment, roasting, freezing, drying, and so forth may affect different aspects of food quality, starting with changes in compositional and nutritional quality. While some recent applications of CE for evaluating food quality has been reviewed by Cifuentes,<sup>2</sup> the CE analysis of dairy proteins to determine the effect of different processing conditions, to follow proteolysis in different types of cheese, or to assess authenticity<sup>7</sup> represent, by far, the largest number of CE applications in food quality assessment. A comprehensive review of these applications has been presented by Recio et al.<sup>224</sup>

Capillary electrophoresis has been very useful for studying the effect of heat treatment on dairy proteins, particularly in the study of the interaction between carbonyl-containing compounds such as reducing sugars with amino groups. These types of interactions, known as Maillard reaction, have been found to be very important in food science and medicine. The Maillard reaction results in the formation of large protein aggregates as well as low molecular weight compounds known as Maillard reaction products (MRP) that impart various flavor, aroma, and color characteristics to foods. Thus, the formation of MRP not only affects food compositional quality but also impacts nutritional and sensorial aspects of quality. In this sense, CE methods were reported that allowed the determination of a broad spectrum of compounds ranging from large molecular weight aggregates, such as lactosylated milk proteins,<sup>274</sup> to small molecular weight compounds, such as furosine.<sup>275</sup> Deterioration due to Maillard reaction of milk powder upon storage was monitored by CE showing a native and a modified fraction of  $\beta$ -lactoglobulin.<sup>274</sup> The method used for the analysis of milk proteins was the one previously reported by Recio and Olieman.<sup>232</sup> In comparison to other methods, the CE method proved to be rapid, easy to execute, and sensitive for monitoring early deterioration of milk powders during storage due to Maillard reaction. The determination of the ratio of unmodified whey proteins to total whey proteins by CE was considered a suitable method to evaluate the loss in nutritional value of milk powders with reference to protein quality.<sup>274</sup>

A new CE method was established for the quantitative determination of furosine in dairy products. Sample preparation consisted of drying hydrolyzed samples, redissolving them in NaOH, and purifying them by SPE. The electrophoretic separation was carried out in an uncoated capillary using phosphate buffer containing the additive hexadecyl trimethylammonium bromide (HDTAB). The LOD for furosine was 0.5 ppm, a concentration that corresponds to 4.5 mg/mL of protein in milk samples. Electropherograms showing very well-defined peaks for furosine in UHT and evaporated milks are depicted in Figure 30.9. As expected, higher furosine concentration was determined for evaporated milk since it is the most severely heat-treated product. Thus, furosine determination by CE method may be used to assess the extent of protein damage caused by heating and as a useful indicator of the intensity of food processing conditions that cause the deterioration of the nutritive value.<sup>275</sup>

Another heat-induced marker formed as a result of the Maillard reaction is hydroxymethylfurfural (HMF). A MEKC method was developed for the determination of HMF in milk-based formulas by using an uncoated capillary and phosphate buffer (pH 7.5) containing SDS.<sup>276</sup> A similar compound, furfural, is also formed as a result of Maillard reaction and could be detected in distilled agave drinks such as Tequila and Bacanora by CE method. Furfural is formed during the cooking of agave heads before juice extraction, fermentation, and distillation. A MEKC procedure was carried out with phosphate buffer containing SDS at pH 7.5.<sup>277</sup> Typical electropherograms showing the furfural peak in Bacanora (Figure 30.10a) and Bacanora spiked with the analytical standard (Figure 30.10b) are shown. In addition, some CE-MS and CE-MS/MS applications for the study of Maillard reaction products were reviewed by Simo et al.<sup>249</sup>

Food authenticity is yet another food quality control parameter in addition to the parameters described earlier. Food fraud may involve substitution or addition of ingredients of inferior value

**FIGURE 30.9** Typical electropherograms of milk showing the furosine peak. (a) UHT milk containing 269 mg of furosine/100 g protein, (b) Evaporated milk containing 730 mg of furosine/100 g protein. (From Vallejo-Cordoba, B., et al., *J. Agric. Food Chem.*, 52, 5787, 2004. With permission.)

**FIGURE 30.10** Typical electropherograms of Bacanora (a), and Bacanora spiked with the analytical standard (b). (From Vallejo-Cordoba, B. and Gonzalez-Cordova, A. F., in *Hispanic Foods, Chemistry and Flavor*, ACS Series, 946, Tunick, M. H., and González de Mejia, E. Ed., 2007, p. 153. With permission.)

and/or quality required for normal or accepted processing or product formulation.<sup>6</sup> A comprehensive review of CE applications in food authenticity was offered by Kvasnicka.<sup>4</sup> Authenticity issues dealing with meat and meat products have been covered by Vallejo-Cordoba et al.,<sup>6</sup> and applications dealing with dairy products authenticity were reviewed by Recio et al.<sup>224</sup> Detailed knowledge on

raw materials constituting foods is essential, and this is especially true for the diverse foods and feeds made from cereal grains. Varietal identity and ability to predict dough properties of wheat consignments are largely dependent on protein composition. Whereas DNA analysis indicates genotype, protein composition provides information on variety and likely processing parameters. In this sense, the Australian industry has standard methods of protein and DNA analysis involving gel electrophoresis, CE, and most recently, Lab-on-a-chip equipment for protein analysis and microarrays for DNA composition.<sup>278</sup> The treatment of foods can be another issue in food authenticity; for example, meat may have been previously frozen and falsely represented as fresh, especially with fresh or chilled meat associated with higher prices than their frozen counterparts. Thus, fraudulent marketers may thaw frozen meat and sell it as chilled or fresh. Methods for the differentiation between fresh and frozen/thawed meat were based on the release of enzymes. Thus, the application of electrophoretically mediated microanalysis (EMMA) to determine  $\beta$ -hydroxyacyl CoA-dehydrogenase ( $\beta$ -HADH) activity in a model system and in meat samples was reported. The enzymatic assay and the separation of the reaction products were carried out in an uncoated capillary using a plug–plug reaction mode at variable potential. The  $\text{NAD}^+$  produced by  $\beta$ -HADH activity in juice extracted from previously frozen meat was at least three times the concentration of that produced in fresh meat (Figure 30.11).<sup>279</sup>

The most important issue in food quality analysis is food safety. Therefore, the development of rapid methods for the identification and quantification of bacterial contamination in foods is of utmost importance. Thus, a CE method with UV detection was proposed for the identification and quantification of bacterial contamination in food samples. The proposed method allowed for the effective separation of eight different types of bacteria in only 25 min. Electrophoretic resolution was improved by using cations in phosphate buffer (pH 7.0) that interacted with the bacterial surfaces changing its electrical properties and electrophoretic mobility. The validity of the method was established by comparison with the standard plate counting method,<sup>151</sup> where bacterial cells were separated as

**FIGURE 30.11** Electropherogram showing  $\beta$ -HADH activity by EMMA in extracted juice from beef. (a) Frozen thawed and (b) fresh. (From Vallejo-Cordoba, B., et al., *J. Cap. Elec. Microchip Tech.*, 8, 81, 2003. With permission.)

“biocolloids,” which under the influence of an electric field, move at a velocity that is proportional to their electrophoretic mobility. This means that under appropriate experimental conditions, different microorganisms exhibit a differential electrophoretic mobility.<sup>151</sup> Another approach for the identification of foodborne pathogens or food-spoilage bacteria consisted in multiplex-PCR-CGE-LIF procedures.<sup>258,259</sup> The main advantage of these techniques over conventional microbiological techniques is that it is possible to obtain fast and specific identification of microorganisms at the molecular/genetic level. One of the PCR-CGE-LIF protocols allowed for the simultaneous detection and differentiation of the genera *Leuconostoc* and *Carnobacterium*,<sup>258</sup> while a second protocol allowed the detection of *Staphylococcus aureus*, *Listeria monocytogenes*, and *Salmonella* spp.<sup>259</sup>

The determination of food fatty acids is important from the standpoint of food quality composition since fatty acid composition is required in nutritional labeling. Also, the quantification of *trans*-fatty acids, which are formed during oil hydrogenation, is particularly important since new regulations require their labeling to allow the consumer to make informed choices on their diet. Thus, a novel CE methodology using UV indirect detection at 224 nm for the analysis of *trans*-fatty acids in hydrogenated oils was reported. The electrolyte consisted of phosphate buffer (pH 7.0) containing sodium dodecylbenzenesulfonate, Brij 35, octanol, and acetonitrile, where, under optimized conditions, 10 fatty acids including C:12, C:13 (internal standard), C:14, C:16, C:18, C18:1c, C18:1t, C18:2cc, C18:2tt, and C18:3ccc were baseline separated in less than 12 min. The proposed method was used to monitor the formation of *trans*-fatty acids during hydrogenation of Brazilnut oil.<sup>280</sup> Similarly, the determination of short-chain free fatty acids, which are associated with lipolyzed flavors, is important for good sensory quality. However, the quantification of individual free fatty acids (FFA) in dairy products is particularly complicated, since FFA represent less than 0.5% of the total fat. FFA with chain lengths from 2 to 20 carbon atoms are present, and short-chain FFA with fewer than eight carbon atoms are extremely volatile. Because of these problems, the methods most frequently described for the analysis of FFA in milk and dairy products involve fat extraction, separation of FFA from the bulk of the extracted lipid, and injection of the fraction containing FFA directly in the gas chromatograph, or fat extraction, derivatization, and gas chromatography of the methyl esters formed.<sup>282</sup> To circumvent these problems, an attractive alternative was the use of CE, particularly in a MEKC mode. To this end, the release of short-chain free fatty acids was monitored from milk fat during hydrolysis with lipase by using MEKC.<sup>282</sup> Sample buffer containing CD and methanol allowed for the solubilization of FFA, followed by separation in an uncoated capillary with Tris buffer containing *p*-anisate as chromophore and trimethyl  $\beta$ -CD at pH 8.0. Indirect UV detection at 270 nm was used<sup>282</sup> and excellent separation was observed for FFA C<sub>4</sub>–C<sub>12</sub> in a FFA standard mixture (Figure 30.12a) or in milk fat lipolyzed with lipase (Figure 30.12b).

### 30.3 CONCLUDING REMARKS AND OUTLOOK

The versatility of CE in food analysis was clearly shown by the numerous, wide ranging methods and applications presented. Moreover, the efficiency and rapidity of CE separations were the main advantages that make this technique an attractive alternative in food analysis laboratories. CE is still far from being as well established as chromatographic techniques, although it certainly has gained popularity as an alternative to conventional gel electrophoresis for the analysis of food proteins, most likely due to the quantitative nature of CE, high resolving power, and speed of analysis. However, for the analysis of trace component determination for an organic contaminant, low sensitivity and low reproducibility of quantitative analysis are issues that need to be addressed. Perhaps the greatest potential of CE was found in food diagnostics for quality assurance and authenticity, with most recent approaches involving Lab-on-chip equipment. Authenticity issues such as meat and fish species, GMOs, and cereal variety identification and quantification are challenging problems where DNA-based CE methods in microchip-based formats offer opportunities for development. Similarly, DNA-based CE methods for microorganism identification is another niche that may be explored.

## 31.1 INTRODUCTION

In the past 25 years, capillary electrophoresis (CE) has conquered a solid position in the scientific community, supported by vast literature compiling the intricacy of its theoretical aspects and the diversity of its applications (Chapter 1 by Landers brings an introductory panel on CE technology). Several relevant characteristics of CE such as high resolution, high efficiency, and speed of analysis in addition to excellent mass sensitivity, low consumption of reagents, and small sample volumes are in perfect tuning with the demands of environmental analyses. Moreover, whenever limits of detection (LOD) are favorable, the direct injection of complex samples is possible without being detrimental to the column integrity, which in turn contributes to preclude time-consuming sample preparation, typical of environmental procedures. Another particularity of the CE technique is the variety of separation mechanisms that can be practiced in a single capillary column, allowing the simultaneous assessment of distinct classes of pollutants in a given sample.

## 31.2 SEPARATION STRATEGIES

The CE determination of broad classes of atmospheric pollutants and water and soil contaminants has been reviewed regularly.<sup>1-7</sup> This chapter focuses on separation strategies for environmental analysis involving the two most commonly used CE modes: capillary zone electrophoresis (CZE) and electrokinetic chromatography (EKC).

### 31.2.1 CZE

CZE separations are based solely on the differences in the electrophoretic mobilities of *charged species*, either in aqueous or nonaqueous media (this latter often referred to as nonaqueous capillary electrophoresis, NACE). In CZE, the migration of a species within the capillary column is the net result of mass transport phenomena and chemical equilibria. Two modes of migration are possible, that is, under suppressed electroosmotic flow (EOF), achieved at low pH buffers or by the use of surface modified capillaries, and in the presence of EOF; in the latter, two possibilities arise: separations under co- and counter-EOF, depending on the relative mobility of the analyte and EOF itself. With the proper control of electrolyte composition (buffer type regarding both co- and counterions, buffer pH and concentration, as well as additives), the analyte mobility can be altered. Flow characteristics are also dependable on the electrolyte composition as well as on the capillary surface condition.

Organic solvents are among the most commonly used additives in CZE. Several other additives (complexing agents to discriminate metal cations, quaternary alkylammonium salts as flow reversers in the separation of small anions, and neutral cyclodextrins [CDs] as chiral selectors) are listed in the literature as modifiers in CZE separations. In contrast, separations with charged CDs or mixtures of neutral and charged CDs are often classified as EKC methodologies (*vide* next section). Considering that low-molecular mass additives represent in fact borderline cases between CZE and EKC systems, arbitrary assumptions will be made in this chapter with the purpose of classifying the literature methodologies. Cyclodextrins either neutral, charged, or mixtures of both will be considered secondary phases in EKC separations whereas other complexing agents (ethylenediaminetetraacetic acid [EDTA], *o*-phenanthroline, crown ethers, etc.) will be classified as additives of CZE electrolytes.

Quaternary alkylammonium salts, used as flow reverser additives in the separation of small anions, will fall technically into the EKC definition, since the surfactant micellization is anticipated due to the electrolyte ionic strength in which the separation is conducted (*vide* section on small ions analysis).

CZE is, therefore, suitable for the determination of explicitly charged small ions, whose mobilities already differ by some extent or might be modified by additives, as well as ionizable organic environmental pollutants (for instance, compounds containing carboxylic acid, phenol, or amine functionalities). Cations are generally separated under co-EOF whereas anions with low to moderately low mobility are separated counter-electroosmotically. Examples of the CZE analysis of small ions in methanol (MeOH)-modified borate electrolytes include the speciation of mercury [inorganic Hg(II), methyl-, ethyl-, and phenylmercury] in water and dogfish muscle<sup>8</sup> and the direct ultraviolet (UV) determination of anions ( $\text{Br}^-$ ,  $\text{I}^-$ ,  $\text{NO}_2^-$ ,  $\text{S}_2\text{O}_3^{2-}$ ,  $\text{CrO}_4^{2-}$ ,  $\text{NO}_3^-$ ,  $\text{SCN}^-$ ,  $\text{Fe}(\text{CN})_6^{4-}$ ,  $\text{MoO}_4^{2-}$ , and  $\text{WO}_4^{2-}$ ) in effluents of a power plant.<sup>9</sup> For ionizable compounds, the analyte acquires an electrophoretic *effective mobility* (summation of ionic species mobilities weighted by the species availability at a given pH). The selective inspection of 21 aromatic amines in groundwater and soil sample using low pH phosphate buffer in capillaries modified by 1,3-aminopropane is a representative example of the CZE mode for ionizable compounds.<sup>10</sup> Another example is the determination of the priority phenols in spiked wastewater samples using ammonium acetate buffer modified by *N*-methyl formamide/acetonitrile (ACN) mixtures.<sup>11</sup>

### 31.2.2 EKC

Electrokinetic chromatography separations are those put into practice with electrolytes containing a *secondary phase* that migrate with a particular velocity distinct from that of the analyte. The fundamental requirement for EKC separations is that either the analyte or the secondary phase must be charged under the electrolyte medium pH. As pointed out previously, for charged analytes forming adducts with small molecules, there is a blurred distinction between CZE and EKC separation principles.

#### 31.2.2.1 MEKC

Micellar electrokinetic chromatography (MEKC) is a particular EKC mode where the secondary phase is composed by micellized surfactant (MEKC is discussed in detail in Chapter 3 by Terabe). Solute differential retention occurs as a result of a partition mechanism between a dispersed phase defined by the total volume of micelles and the remaining aqueous phase. MEKC modes of elution comprise normal, restricted, and reversed MEKC, based on the relative migration of the analyte and secondary phase apparent velocity.

The anionic surfactant sodium dodecylsulfate (SDS) is by far the most commonly used surfactant in micellar separations. Examples of the use of simple buffered/SDS systems in environmental applications include the simultaneous analysis of 10 *N*-methylcarbamate pesticides and their hydrolytic phenolic metabolites in river, well, and pond water (pH 8 phosphate/borate buffer/SDS),<sup>12</sup> and the analysis of insecticides (imidacloprid and its metabolite 6-chloronicotinic acid) in air samples collected from a greenhouse cropped with tomatoes (pH 8.5 ammonium chloride/ammonia buffer/SDS).<sup>13</sup>

The use of SDS in MEKC poses two important shortcomings regarding the nature of the compounds eligible for separation: hydrophilic compounds, especially anionic in character (electrostatic repulsion), are poorly retained even at high SDS concentrations, whereas hydrophobic compounds are highly retained even at low SDS concentrations and little selectivity is, therefore, provided.

The alternative use of cationic surfactants (quaternary alkylammonium salts) is recommended to increase retention of highly hydrophilic compounds. Cationic surfactants reverses the EOF. As the cationic micelles migrate electrophoretically against the anodic EOF, an extended migration window results. An example of MEKC separation using cationic surfactants is the analysis

of various *s*-triazines, including five chloro-, three methoxy-, and five alkylthio-*s*-triazines in tetradecyltrimethylammonium bromide (TTAB) electrolytes.<sup>14</sup>

For the MEKC analysis of highly hydrophobic compounds, several strategies have been proposed: the use of organic additives (short-chain alcohols, acetonitrile, tetrahydrofuran, dioxane, and dimethylsulfoxide are among the most studied), and the addition of large amounts of urea and glucose have been reported. A few examples of solvent-modified electrolytes within the environmental context include (i) separation of seven polynuclear aromatic hydrocarbons (PAHs) in borate/SDS/ACN for inspection of deliberately contaminated soils submitted to biological decontamination process and spent machine oil;<sup>15</sup> (ii) determination of 11 triazines in groundwater using as optimized electrolyte, borate/phosphate/SDS/1-propanol;<sup>16</sup> (iii) the analysis of 21 mono- and dinaphthalenesulfonates, as well as their hydroxy- and amino-derivatives in river water, with borate/SDS/ACN;<sup>17</sup> and (iv) determination of homologues and isomers of linear alkylbenzene-sulfonates (LAS) in household products and sewage sludge samples using borate/phosphate/ACN electrolytes.<sup>18</sup>

Other strategies to cope with hydrophobic compounds include the addition of neutral surfactants or neutral CDs to SDS micelle systems, use of bile salts, and by exploring solvophobic association with tetrahexyl- or tetraheptylammonium ions (added as perchlorate salt [THxAP] or bromide salt [THpAB]) or dioctylsulfosuccinate (DOSS).

In the separation of aromatic sulfonates, 10 electrolyte compositions were investigated with low and high pH buffers containing SDS, Brij35, and octylamine. Twenty-one compounds could be separated and the contents of aromatic sulfonates in an industrial effluent were determined.<sup>19</sup> Other examples of mixed micelle systems applied to compounds of environmental relevance include (i) the analysis of eight azo dyes, mono-, and disulfonated compounds with Brij35/SDS electrolytes;<sup>20</sup> (ii) the separation of 16 arylamine isomers with Tween80/SDS/cholate systems (lake water near industrial area);<sup>21</sup> (iii) the analysis of eight aromatic compounds (phenol derivatives and PAH) with Tween20/SDS electrolytes;<sup>22</sup> and (iv) the separation of six phenylureas and chlorsulfuron pesticides with PEG400/SDS systems.<sup>23</sup>

Although the target function of neutral CDs is to exert chiral selection in the EKC separation of optical isomers, they have often been used as auxiliary complex ligands as a means of improving resolution of closely eluting achiral positional and structural related compounds or to reduce significantly apparent retention factors. The separation of seven positional and structural naphthalenesulfonate isomers (pH 3.0 phosphate buffer/ $\beta$ -CD)<sup>24</sup> and five 2,4-dinitrophenylhydrazine (DNPH)-aldehyde derivatives in vehicular emission (pH 9.0 borate buffer/SDS/ $\beta$ -CD)<sup>25</sup> are examples of neutral CD-mediated separations.

Studies involving bile salts in EKC separations include (i) determination of *s*-triazines and quats in well water samples;<sup>26</sup> (ii) separation of the 16 priority pollutant PAHs for inspection in ambient air samples;<sup>27</sup> (iii) characterization of the electrophoretic behavior of 56 aromatic compounds (phenoxy acid herbicides, phenylalkanoic acids, aromatic carboxylic acids, aromatic sulfonic acids, azo and other dyes, and nitrogen-containing aromatic acids) for further assessment of extraction and sample clean-up procedures using spiked water and soils;<sup>28</sup> and (iv) recovery of synthetic dyes from spiked water and soil matrices.<sup>29</sup> Another interesting application of MEKC with diverse bile salts is the prediction of ecotoxicity of aromatic compounds.<sup>30</sup>

The use of carboxylic and dicarboxylic acids, SDS, bile salts, organic solvents, and alkylammonium ions was explored to study the separation of LAS homologues and positional isomers,<sup>31,32</sup> as well as alkylether sulfate oligomers.<sup>33</sup> The MEKC separation of mixtures of the surfactant classes coconut diethanolamide, cocamido propyl betaine, and alkylbenzene sulfonate was studied in either low pH phosphate or high pH borate or dipentylamine buffers containing as surfactants deoxycholate or SDS, organic solvents (methanol, acetonitrile, *n*-propanol, and *n*-butanol), and anionic solvophobic agents (DOSS, fatty acids).<sup>34</sup>

The use of DOSS/ACN mixtures in the separation of 9-fluorenylmethyl chloroformate (Fmoc)-derivatized anilines was investigated for inspection of lake water.<sup>35</sup> While the organic modifier

allowed the solubilization of the hydrophobic solutes and maintained the DOSS surfactant in its monomeric form by inhibiting micellization, the DOSS surfactant associated with the FMOC anilines to a varying degree led to their differential migration and separation. Seven conventional chromatographic ion-pairing agents including tetraalkylammonium series and alkanesulfonic series were tested comparatively in a recent study involving the separation of 13 PAH in methanolic/ACN matrices.<sup>36</sup>

Alternative and more complex surfactants continue to be explored as a resourceful option for MEKC separations. *In situ* generated micelles, which are anionic complexes formed by alkyl- or steroidal-glycoside surfactants and borate ions, the use of sodium 10-undecylenate (SUA) and sodium 10-undecylsulfate (SUS) oligomers as well as surfactants composed of two ionic groups and two lipophilic chains, such as sodium 5,12-*bis*(dodecyloxymethyl)-4,7,10,13-(tetraoxa)-1,16-hexadecanedisulfonate (DBTD), bilayered aggregates such as vesicles and liposomes, and bilayer micelles are a few examples.

*In situ* generated micelles have been applied to the inspection of aniline pesticidal metabolites in lake water.<sup>37</sup> The separation of 16 PAH in SUA oligomer electrolytes was reported.<sup>38</sup> Creosote-contaminated soil samples were extracted by accelerated solvent extraction using methylene chloride–acetone mixtures. The extracts were further fractionated by gel permeation chromatography before analysis. The EKC chromatogram of a creosote-contaminated soil fraction shows the resolution of at least 50 peaks. The separation of the 11 priority phenols in river and sea water<sup>39</sup> was demonstrated in MEKC with DBTD surfactants, whereas examples of the use of liposomes as carriers include the separation of benzene derivatives and phenols.<sup>40</sup>

High-molecular mass surfactants such as butyl acrylate-butyl methacrylate-methacrylic acid copolymer sodium salts, starburst dendrimers, poly(amidoamines), and diaminobutane-based poly(propyleneimine) as well as cationic polyelectrolytes (ionenes) had all been presented as successful secondary phases for aromatic compounds. The determination of 10 nitrophenols in glycine buffers modified by  $\beta$ -CD (0–10 mmol L<sup>-1</sup>) and polyvinylpyrrolidone (PVP) (0.5–2.5% w/v) is an example of application of polymer-based electrolytes to rain, tap, and process water.<sup>41</sup>

### 31.2.2.2 Other EKC Modes

#### 31.2.2.2.1 CD-EKC and CDCD-EKC

Single negatively and positively charged CDs (e.g., sulfobutyl ether  $\beta$ -CD, SB- $\beta$ -CD, sulfated CD, carboxymethylated  $\beta$ -CD, and methylamino substituted  $\beta$ -CD) or even mixtures of neutral and charged CDs are frequently employed in EKC separations as secondary phases. The separation mechanism is simply defined by host–guest interactions once micellized surfactants are absent. The enantiomeric separation of polychlorinated biphenyls using mixtures of several neutral and charged CD derivatives is a fine example of the EKC with charged CDs impact in environmental analysis.<sup>42</sup> Other examples include the use of a mixture of SB- $\beta$ -CD and the neutral methyl- $\beta$ -CD in borate buffer for the analysis of 16 PAH in contaminated soils extracted by supercritical CO<sub>2</sub><sup>43</sup> and the use of SB- $\beta$ -CD in the analysis of 25 chlorinated and substituted phenolic compounds (including the 11 priority phenols).<sup>44</sup> A complexation model was used for investigating the effect of pH and CD concentration on the electrophoretic mobility. The latter method was applicable for quantifying the level of pentachlorophenol in contaminated soil samples.

#### 31.2.2.2.2 MEEKC

Microemulsion electrokinetic chromatography (MEEKC) is a relatively new technique that accomplishes electrokinetic separations using buffers containing surfactant coated oil droplets (Chapter 4 by Altria and coworkers presents further details on the MEEKC technique). The potential of MEEKC for the separation of priority endocrine disrupting compounds in industrial and domestic wastewater treatment effluents and sludges has been investigated.<sup>45</sup> Using reverse migrating microemulsion, that is, negative polarity at the electrode inlet and a pH 2.8 phosphate buffer containing octane, butanol,

and SDS, further modified by propanol, the separation of the breakdown products of alkylphenolic detergents, a few synthetic estrogens, and the plastic monomer bisphenol A was demonstrated.

#### 31.2.2.2.3 *Calixarene EKC*

Calixarenes are conical-shaped macrocyclic oligomers whose inner cavity can accommodate several guest molecules and, therefore, can serve as a viable option to replace CDs in EKC separations. Environmental examples of the use of calixarene as EKC secondary phases include the separation of chlorinated phenols, benzenediols, and toluidines.<sup>46</sup> Sulfonated calixarenes have also been used as chromophores in the indirect detection of aliphatic amines.<sup>47</sup>

#### 31.2.2.2.4 *Suspension EKC*

The use of suspended chromatographic silica-based particles in SDS buffers was first demonstrated as secondary phases in the EKC separations of phenol derivatives.<sup>48</sup> Applications of polymer and silica-based particles to several other pollutants have been reviewed recently.<sup>49</sup>

#### 31.2.2.2.5 *Ion-exchange EKC*

The use of polymer ion additives such as poly(diallyldimethylammonium chloride) (PDDAC) and (diethylamino)ethyl-dextran (DEAE-dextran) has been successfully proposed to promote dynamic interactions with certain moderately hydrophobic solutes such as naphthalenesulfonate and naphthalenedisulfonate isomers.<sup>50</sup> The fundamentals and scope of ion-exchange EKC with ionic polymers for the separation of small ions of potential importance in the environmental context have been reviewed.<sup>51</sup>

### 31.3 SENSITIVITY ENHANCEMENT STRATEGIES

The small pathlength defined by the capillary internal diameter coupled with the need of a small injection volume to preserve the high-resolution features of CE place a strong demand on the detection capability. This is especially problematic for absorbance detectors (LOD in the order of  $10^{-5}$  to  $10^{-6}$  mol L<sup>-1</sup>), considered unsuitable for many environmental applications, where trace level occurrence or matrix complexity issues are generally of concern.

Several approaches to enhance sensitivity in CE have been devised: some are based on sample preconcentration procedures, others rely on special cell geometries and alternative detectors. Both areas have been subjects of intense investigation as described in Chapters 9 by Sweedler and coworkers, 13 by Burgi and Giordano, 14 by Ewing and coworkers, and 27 by Weber.

#### 31.3.1 PRECONCENTRATION SCHEMES

The sensitivity enhancement strategies based on sample manipulation are further subdivided into offline and online procedures (Chapter 13 by Burgi and Giordano). Liquid-liquid extraction (LLE) with a variety of solvents of selected properties and solid-phase extraction (SPE) (Chapter 27 by Weber) with a large assortment of chromatographic stationary phases of distinct chemistries are among the most often performed offline strategies for environmental applications as reviewed recently.<sup>4,5</sup> An interesting example of homogeneous LLE is the pH-induced phase separation of water samples (rain, river, and spring water) treated with perfluorooctanic acetate (PFOA<sup>-</sup>) surfactant in different water-miscible solvents for the preconcentration of five PAH.<sup>52</sup> At the optimal conditions (above 99% recovery), a 40 mL sample aliquot-containing THF and PFOA<sup>-</sup> was treated with HCl to separate 30  $\mu$ L of sedimented phase. The sedimented liquid phase was then mixed with 30  $\mu$ L DMSO before analysis. Limits of quantification (LOQ) in the range  $10^{-10}$  to  $10^{-9}$  mol L<sup>-1</sup> and enrichment factors up to 125,000-fold were obtained. An example of SPE is the use of C<sub>18</sub>-bonded silica and polystyrene-divinylbenzene (PS-DVB) disks for the enrichment of four triazines and three degradation products of atrazine in drinking and well water samples with recoveries better than 93%

and LOD in the range of 0.02–0.30 mg L<sup>-1</sup>.<sup>53</sup> Several other LLE and SPE procedures are compiled in the application tables (Section 31.4).

Online preconcentration strategies involve the insertion of large sample volumes in the capillary and can generally be classified into two categories. One category involves the criterious manipulation of the analyte electrophoretic velocity. A collection of strategies grouped by the name of stacking and transient isotachopheresis (tITP) belong to this category. Field-amplified sample stacking of arsenic species in environmental reference materials<sup>54</sup> and organonitrogen pesticides in drainage water<sup>55</sup> as well as the tITP preconcentration of iodide in seawater samples<sup>56</sup> are fine examples of these procedures.

The other category explores the analyte ability of interacting with secondary phases. Stacking of micelles and sweeping are representative of this group (fundamental aspects of these strategies were introduced in Chapter 3 by Burgi and Giordano). Stacking of micelles was employed to pre-concentrate dioxin-related compounds<sup>57</sup> and in the analysis of nonsteroidal anti-inflammatory drugs in mineral water,<sup>58</sup> whereas sweeping was employed for the online concentration of bisphenol A and alkylphenols.<sup>59</sup> Stacking of micelles and sweeping were contrasted in the analysis of phenylurea herbicides in tap and pond water<sup>60</sup> and in the multiclass pesticide analysis of drinking water.<sup>61</sup>

Combinations of online procedures are often employed in environmental applications. Examples include the analysis of trace metal ions in factory wastewater by a combination of cation-selective exhaustive injection (CSEI) (a form of stacking, CZE format) and sweeping.<sup>62</sup> In this latter case, sweeping was promoted by dynamic complexation with EDTA, used as carrier. The same CSEI principle has also been applied to the analysis of quaternary ammonium herbicides<sup>63</sup> and environmentally relevant aromatic amines<sup>64</sup> in water, both followed by sweeping with SDS.

Hyphenation of automatic continuous flow systems (such as SPE, dialysis, gas diffusion, evaporation, direct leaching, etc.) to CE and the coupling of automatic sample preparation devices into commercial CE equipments have been devised as a means to simplification and miniaturization of analytical procedures. An automatic online SPE device for the multiresidue extraction of seven pesticides has been described.<sup>65</sup> Four river samples were spiked with the test mixture at three different levels presenting recoveries from 90% to 114%.

An elegant example of SPE method based on ion-exchange retention was used for inline preconcentration of inorganic anions.<sup>66</sup> A single capillary containing a preconcentration zone (adsorbed layer of cationic latex particles) and a separation zone (fused-silica modified by adsorption of a cationic polymer) was used. Analytes were retained in the preconcentration zone and eluted isotachopheretically into the separation zone by means of an elutropic gradient. This approach was used to determine nitrate in Antarctic ice cores at the 2.2–11.6 µg L<sup>-1</sup> level.

### 31.3.2 ALTERNATIVE DETECTION SCHEMES

For the absorbance-based detectors, alternative cell geometries have been designed to extend the optical pathlength such as the Z-shaped cells, bubble cells, rectangular cells, and multireflection capillaries.<sup>6</sup> Although manufacturing and manipulation of these special cells can pose a few operational problems, sensitivity enhancement of tenths of fold have been reported. The determination of the herbicide metribuzin and its major conversion products in soil is an example of the use of bubble cells,<sup>67</sup> whereas the UV-detection of derivatized carbonyl compounds in rain is an example of the use of Z-shaped cells<sup>68</sup> in environmental analysis.

Alternative detection schemes for environmental analysis such as those based on laser-induced fluorescence (LIF), chemiluminescence, conductivity, amperometry, and mass spectrometry (MS) have been reported.

#### 31.3.2.1 Fluorescence Detection

Some pollutants are natively fluorescent such as PAH and metabolites as inspected in biota.<sup>69</sup> Others must be derivatized to fluoresce such as aniline species metabolized from pesticides<sup>70</sup> and

low-molecular mass amines labeled as fluorescein isothiocyanate (FITC) derivatives for further inspection of atmospheric aerosol samples reaching  $50 \text{ pg mL}^{-1}$  ( $10^{-9} \text{ mol L}^{-1}$ ) level.<sup>71</sup>

An interesting variant for labeling procedures is the so-called *in-capillary derivatization* reactions, which explores differences in the electrophoretic mobilities to merge distinct zones of analyte and labeling reagent under the effect of an electric field. Molina and Silva<sup>72</sup> explored the possibilities of LIF detection for in-capillary derivatization of nitrogen compounds (herbicides and biogenic amines).

Indirect fluorescence detection is another possibility for nonfluorescent compounds. In this particular case, a fluorophore co-ion is part of the electrolyte system. The simultaneous determination of cations (EDTA complexes) and anions in pond water by indirect fluorescence detection based on the displacement of fluorescein is an example.<sup>73</sup> The use of fluorescein at pH 9.5 as electrolyte was also reported in the determination of anionic organophosphorus herbicides [glufosinate, glyphosate, and its major metabolite aminomethylphosphonic acid (AMPA)] in groundwater,<sup>74</sup> with LOD in the  $\mu\text{mol L}^{-1}$  range.

### 31.3.2.2 Chemiluminescence Detection

Biogenic amines, labeled with *N*-(4-aminobutyl)-*N*-ethylisoluminol (ABEI) in the presence of *N,N*-disuccinimidyl carbonate (DSC) in methanolic medium, were determined in lake water sample by an EKC method using online chemiluminescence detection.<sup>75</sup> Parameters affecting the separation process (pH, SDS concentration, applied voltage, and injection time) and chemiluminescence detection sensitivity [ $\text{H}_2\text{O}_2$  concentration in the buffer and the postcolumn reagents  $\text{K}_3\text{Fe}(\text{CN})_6$  and NaOH concentrations] were examined in detail. Detection limits in the  $1.2 \times 10^{-10}$  to  $3.5 \times 10^{-8} \text{ mol L}^{-1}$  range were obtained.

### 31.3.2.3 Electrochemical Detection

Among the electrochemical detection schemes for CE, conductometric methods have gained great visibility especially for the determination of the high-equivalent conductivity inorganic species. Conductivity detection in CE is performed either by galvanic contact or in a contactless mode (CCD). The galvanic contact mode is further subdivided into on-capillary detection without decoupling and off-capillary, after grounding the separation applied voltage. Most contactless methods use oscillometric techniques. Wet deposition in the 1983–2006 period and related atmospheric chemistry in the metropolitan area of Sao Paulo, Brazil, using CZE-CCD methods has been investigated.<sup>76,77</sup> Electrolytes composed of MES-His (pH 6.2) modified by 18-crown-6 ether for the cation analysis (ammonium, magnesium, sodium, calcium, and potassium), and cetyltrimethylammonium bromide (CTAB) for the anion analysis (sulfate, nitrate, chloride, acetate, and formate) were employed. Limits of detection spanned from 10 to  $100 \mu\text{g L}^{-1}$ . An interesting approach employing dual-opposite end injection and CZE-CCD to determine cations and anions in the same run has been devised.<sup>78</sup> A single electrolyte containing all necessary modifiers was employed (MES/His containing 18-crown-6 ether and CTAB) allowing simultaneous detection of 13 anions and cations in less than 6 min with detection limits in the range of  $7\text{--}30 \mu\text{g L}^{-1}$  (except fluoride and phosphate). The method was applied to the inspection of ions in rain, surface, and drainage water and the results were contrasted with ion chromatography showing excellent agreement.

Despite the high sensitivity of amperometric detection, its use in environmental applications has not been exploited accordingly. Nevertheless, a few examples include the MEKC analysis of herbicides in tap water<sup>79</sup> and the CZE and MEKC analysis of aromatic amines in contaminated water samples.<sup>80</sup>

Electrochemical detection of 19 chlorophenols in river samples was performed using a graphite-epoxy working electrode at a potential of 800 mV versus Ag/AgCl.<sup>81</sup> A palladium metal union was used to decouple the electric field from the electrochemical cell and a compensating pressure was

applied during the EKC analysis. Detection limits from one to three orders of magnitude lower than UV-detection were achieved ( $10 \mu\text{g L}^{-1}$ ).

#### 31.3.2.4 Mass Spectrometry Detection

Mass spectrometry (MS) is one of the most powerful detection techniques employed in environmental screening due to the intrinsic structural information and high sensitivity it provides. With the advent of effective interfaces, soft ionization modes (electrospray ionization, ESI, and atmospheric pressure chemical ionization, APCI) and increased affordability of CE-MS instruments, the hyphenated technique has become widespread.

In CE-MS, the use of NACE or mixed aqueous-organic solvent systems is advantageous as non-volatile buffers are usually avoided. CZE-MS with volatile buffers has been employed in a variety of environmental applications such as the inspection of drug residues in river water (pH 5.1 ammonium acetate),<sup>82</sup> detection of explosives (nitroaromatic and cyclic nitramine compounds) in soil and marine sediment samples (ammonium acetate at pH 6.9 modified by SB- $\beta$ -CD),<sup>83</sup> and the identification of reactive vinylsulfone and chlorotriazine dyes in spent dyebaths and municipal wastewater treatment plant receiving dyehouse effluents (ammonium acetate at pH 9 modified by 40% ACN).<sup>84</sup> Other examples of volatile electrolyte systems include the use of a pH 3.0 formic acid/ammonium formate system in 50% methanol for the CZE-ESI (sheath liquid: 9:1 MeOH:20 mmol L<sup>-1</sup> acetic acid)-MS (ion trap) analysis of quaternary ammonium herbicides in contaminated irrigation water and spiked mineral water,<sup>85</sup> and pH 9.1 ammonium acetate/ammonium hydroxide/MeOH or pH 11 ammonium hydroxide systems by CZE-ESI (50% isopropanol)-MS (ion trap) for the inspection of methoxy phenols and aromatic acids in biomass burning aerosol samples.<sup>86</sup> When concentrations are rather high CE-MS can still be used as a means of confirming the pollutant presence. An example of such approach includes the determination of LAS in wastewater from treatment plants and coastal waters of Cadiz (Spain) receiving untreated domestic wastewaters by CZE-UV (ammonium acetate at pH 5.6 containing 30% isopropanol) followed by confirmation of the  $[\text{M-H}]^-$  ions by ESI (sheath liquid: 80% isopropanol and 0.1% ammonia)-MS (quadrupole).<sup>87</sup>

Particularly in MEKC separations, the presence of high amounts of SDS in the buffer is detrimental causing low ionization efficiency. A number of approaches have been presented to overcome this shortcoming such as the use of high-molecular mass surfactants and anodically migrating micelles as well as partial filling techniques. Examples of this latter approach have been compiled within the pesticide analysis context.<sup>88,89</sup> More recently, technological improvements in the interfacing systems were shown to be more tolerant to the usage of nonvolatile buffers as demonstrated by the MEKC-ESI-MS separation of triazines<sup>90</sup> and the MEKC-APCI-MS analysis of aromatic amines and alkylphthalates.<sup>91</sup>

### 31.4 REPRESENTATIVE APPLICATIONS

The literature comprises a larger number of methodologies employing electromigration principles, diverse preconcentration strategies, and a variety of detection schemes for pollutant standards combined as test mixtures and for real samples. Tables 31.1 through 31.9 compile representative applications of CZE and EKC methods to the most important classes of pollutants in different environmental compartments.

#### 31.4.1 PESTICIDES

Pesticide is a generic term used to describe compounds employed in the control, prevention, and elimination of plagues that attack crops and herds. Pesticides are associated with their persistence and toxicity and due to their widespread use in agriculture, these compounds are important sources of environmental contamination.

**TABLE 31.1**  
**Selected Applications of Electroseparation Methods for Pesticides in Environmental Samples**

Compounds	CE Mode	Matrix	Preconcentration Procedure (Recovery)	Optimal Electrolyte	Detection (LOD)	References
<i>Multiclass pesticides</i>

Pesticides encompass a large assortment of organic compounds, several of which are positional, geometrical, and optical isomers, with differing degrees of ionization, polarity, and water solubility. Many exhibit spectrochemical, electrochemical, or other functional properties suitable for detection. Unless the pesticide class is explicitly charged, single- and multiclass pesticide analyses are usually assessed by EKC modes. Several excellent review articles have covered the literature on pesticide analysis by CE in the past 5 years.<sup>92–96</sup>

The analytical feasibility of electromigration methods for pesticides has been endorsed by fundamental studies with standards and analyses of spiked and real samples. An example of fundamental study is the determinations of  $pK_a$  (CZE: citrate/phosphate buffers and carbonate buffers covering the pH range from 2.05 to 12.45) and  $pI$  (CIEF kit from Beckman Coulter) of 12 hydroxy-*s*-triazines standards.<sup>97</sup>

The majority of CZE methodologies for pesticides employs simple buffers at varying pH,<sup>70,98–100</sup> volatile electrolytes<sup>101,102</sup> (usually aiming at CZE-MS applications),<sup>103</sup> solvent modified buffers,<sup>85,104,105</sup> and electrolytes for special detector schemes (indirect fluorescence detection, for instance).<sup>74</sup> Table 31.1 compiles the details of a few CZE methodologies applied to pesticide analyses, classifying the application by the pesticide class and the environmental compartment assessed.

For the EKC mode, pesticide standards are either combined in multiresidue mixtures<sup>106–108</sup> or differentiated by classes: pyrethroids,<sup>109</sup> *s*-triazines,<sup>14,90,99,110</sup> carbamates,<sup>88,111</sup> phenoxyacids,<sup>112</sup> quaternary ammonium salts,<sup>63,113</sup> phosphonic acids,<sup>72</sup> and urea-derived pesticides.<sup>114</sup> MEKC methodologies include buffered systems containing SDS,<sup>99,107</sup> cationic,<sup>14,110,111</sup> or nonionic surfactants<sup>72</sup> and additives such as organic solvents<sup>63,106,113,114</sup> and CDs for chiral separations.<sup>106</sup> The use of poly-SUS for pyrethroids,<sup>109</sup> DOSS for herbicide mixtures,<sup>108</sup> and alkylglycoside chiral surfactants for phenoxy acids<sup>112</sup> have also been reported. Several examples of EKC methodologies applied to single class<sup>12,13,16,53,55,60,63,67,109,114–121</sup> and multiclass<sup>26,61,65,122–124</sup> pesticide residues in real samples are detailed in Table 31.1. Figure 31.1 illustrates the electromigration separation of herbicides.

**FIGURE 31.1** EKC separation of triazines and quats herbicides. (a) Standard solution and (b) spiked well water. Electrolyte:  $10 \text{ mmol L}^{-1}$  sodium tetraborate,  $25 \text{ mmol L}^{-1}$  SDS, 15% ACN, and  $40 \text{ mmol L}^{-1}$  sodium perchlorate. Other conditions: +30 kV; direct UV detection at 220 nm. Peak labels: simazine (SM), atrazine (AT), paraquat (PQ), and diquat (DQ). (Modified from M.I. Acedo-Valenzuela et al., *Anal. Chim. Acta*, 519, 65–71, 2004. With permission.)

### 31.4.2 PAH, PCB, AND PCDD

Polynuclear aromatic hydrocarbons are listed by the U.S. Environmental Protection Agency (U.S. EPA) and European Community as priority pollutants due to their mutagenicity and carcinogenicity. PAHs can be formed during natural processes or emitted by anthropogenic activity.

PAHs are characterized by a multitude of structurally similar congeners with inherently neutral and highly hydrophobic character. Therefore, they are not suitable for CZE analysis and as a result, only EKC-based methodologies have been devised in the literature. PAHs have been used in test mixtures as model compounds to introduce a plethora of EKC approaches. MEKC separations include diverse surfactant types (SDS,<sup>69,125</sup> tetradecylsulfate,<sup>126</sup> dodecylbenzenesulfonate,<sup>127</sup> cationic surfactants,<sup>128</sup> bile salts<sup>129</sup>) as well as commonly used additives (urea,<sup>125,130</sup> organic solvents,<sup>125–130</sup> and neutral CDs).<sup>69,125</sup> Other strategies invoke solvophobic association with ThxAP, THpAP,<sup>131</sup> or DOSS<sup>130</sup> in buffered electrolytes as well as charge-transfer interactions with pyrylium salts in nonaqueous media.<sup>132</sup> The use of mixed CD systems (CDCD-EKC), containing both noncharged and negatively charged CDs (SB- $\beta$ -CD and carboxymethyl- $\beta$ -CD), has also been demonstrated.<sup>133</sup> The applicability of more elaborate secondary phases such as SUA<sup>134</sup> and SUS<sup>135</sup> oligomers, in combination with neutral CDs,<sup>136</sup> polymeric surfactants (11-acrylamidoundecanoate,<sup>137</sup> sulfated siloxanes<sup>138</sup>), starburst dendrimers,<sup>139</sup> fullerenes,<sup>140</sup> and silica-based particle suspensions<sup>141</sup> have all been demonstrated by PAH test mixtures.

Polychlorinated biphenyl (PCB) mixtures were used extensively in the past as coolant fluids in power transformers and capacitors. PCBs were widely used because of their higher stability, but are persistent environmental contaminants due to careless disposal practices, leakage, or accidents. Similar to PAHs, PCBs are neutral, highly hydrophobic, and present a large number of congeners, thus demanding EKC methodologies.

The separation of PCB congeners has been addressed by SDS/neutral CD containing electrolytes,<sup>142,143</sup> modified by organic solvents<sup>144</sup> or urea<sup>142,143</sup> and mixtures of bile salts.<sup>145</sup> CD-EKC and CDCD-EKC modes with a large assortment of ionic CDs and modifiers are often employed for the chiral discrimination of PCB racemates.<sup>42,146</sup> The use of polymeric surfactants such as polysodium undecyl sulfate (poly-SUS), in acetonitrile<sup>147</sup> and its valinate form (poly-*D*-SUV) in combination with hydroxypropyl- $\gamma$ -CD, methanol, and urea<sup>148</sup> has also been reported.

The term “dioxin” comprises a group of 75 polychlorinated dibenzo-*p*-dioxin (PCDD), and 135 polychlorinated dibenzofuran (PCDF), whose effects on human health and the environment include dermal toxicity, immunotoxicity, reproductive effects and teratogenicity, endocrine disrupting effects, and carcinogenicity. PCDD and PCDF are produced as byproducts of a myriad of processes, including bleaching of pulp, incineration of garbage, recycling of metals, and in the production of common solvents. Fires of many kinds, including forest fires and those in incinerators, also release dioxins into the environment. PCDD congeners have been successfully separated by MEKC in SDS buffers,<sup>149</sup> modified by urea and CDs.<sup>150,151</sup>

Table 31.2 compiles a few applications of EKC methodologies to PAH in real samples. For example, soil,<sup>15,38,43</sup> water,<sup>52,152</sup> air,<sup>27</sup> and other matrices.<sup>125</sup> Figure 31.2 illustrates the electromigration separation of PAH homologs. To date, no environmental applications of electromigration methods for PCBs and PCDDs have been reported.

### 31.4.3 PHENOLS

Several phenols and their derivatives (chloro- and nitrophenols) are priority polluting substances that are widespread in the environmental aquatic compartments. They originate as byproducts from the coal and oil industry and also due to pesticide and drug decay.

Phenols are UV-absorbing compounds with weakly acidic OH groups ( $pK_a \approx 9$ ), which, upon dissociation at high pH electrolytes, generate anionic species, making them suitable for CZE analysis. However, when a large number of phenolic compounds and derivatives must be assessed

**FIGURE 31.2** EKC separation of PAHs. Electrolyte:  $10 \text{ mmol L}^{-1} \text{ H}_3\text{PO}_4$  and  $70 \text{ mmol L}^{-1}$  sodium *n*-tetradecylsulfate in 75:25 methanol:H<sub>2</sub>O. Other conditions:  $-20 \text{ kV}$ , direct UV-detection at 254 nm. Peak labels: benzo[*a*]perylene (1), perylene (2), benzo[*a*]anthracene (3), pyrene (4), 9-methylanthracene (5), anthracene (6), fluorene (7), naphthalene (8), and benzophenone (9). (Modified from J. Li and J.S. Fritz, *Electrophoresis*, 20, 84–91, 1999. With permission.)

simultaneously (chlorophenol congeners, for instance), EKC methodologies should be selected as a means to increasing selectivity. Nevertheless, CZE has, by far, received more attention for real sample applications.

Literature proposed CZE methods for phenols and derivatives using test mixtures based on aqueous buffered systems (phosphate–borate<sup>153</sup> and borate<sup>154</sup>), volatile electrolytes (ammonium hydrogencarbonate,<sup>155</sup> diethylmalonic acid/dimethylamine in isopropanol<sup>156</sup> and *L*-cysteic acid, 3-amino-1-propanesulfonic acid, aminomethanesulfonic acid, and diethylmalonic acid<sup>157</sup>), and non-aqueous media (ammonium acetate in ACN/acetic acid in MeOH;<sup>158</sup> acetate, bromide, chloride, and malonate in ACN; and diprotic acids/tetrabutylammonium hydroxide<sup>159</sup> and maleate in MeOH<sup>160</sup>).

Environmental assessment using CZE methodologies includes pressurized hot water extraction of phenols from sea sand and soil,<sup>161</sup> chlorophenols<sup>162</sup> and priority phenols<sup>11</sup> in wastewater, nitrophenols<sup>163</sup> and iodophenol<sup>164</sup> in river waters, and methoxyphenols in biomass burning.<sup>86</sup> Details of these methodologies are compiled in Table 31.3.

The impact of different surfactants (SDS,<sup>22</sup> DOSS,<sup>165</sup> CTAB<sup>166</sup> and hexadimethrine bromide, HDB,<sup>167</sup> bile salts<sup>29,30</sup>), nonionic<sup>168</sup> and mixed micelles,<sup>22,169</sup> and additives (neutral<sup>170</sup> and anionic CDs,<sup>44</sup> tetraalkylammonium salts,<sup>171</sup> organic solvents<sup>29,165</sup>) in EKC separations has been demonstrated with phenol test mixtures. In addition, phenols have been chosen to introduce the applicability of more exotic EKC secondary phases such as SDS modified by bovine serum albumin,<sup>172</sup> water-soluble calixarene,<sup>173</sup> starburst dendrimers,<sup>174</sup> cationic replaceable polymeric phases,<sup>175</sup> ionenes,<sup>176</sup> amphiphilic block copolymers,<sup>177</sup> polyelectrolyte complexes,<sup>178</sup> and liposome-coated capillaries.<sup>179</sup>

The separation of phenols of environmental interest<sup>180</sup> as well as the sources and transformations of chlorophenols in the natural environment<sup>181</sup> have been revised. Examples of the investigation of phenols by EKC methodologies in aquatic systems,<sup>39,41,81</sup> soil,<sup>44</sup> and gas phase<sup>182</sup> are compiled in Table 31.3. Figure 31.3 illustrates the electromigration separation of phenols by both CZE and EKC modes.

#### 31.4.4 AMINES

Amines are organic bases that are usually present in biological materials (biogenic amines), processed foods and beverages (of concern are the nitrosamines in fried bacon, smoked/cured meat and fish,

canned sausage, etc.), as well as environmental samples. Several amines are strongly toxic and suspected carcinogens. Major sources of amines in the environment include effluents or byproducts of several chemical industry sectors such as oil refining, synthetic polymers, adhesives, rubber tyre manufacturing, leather tanning, pharmaceuticals, pesticide production, and explosives.

#### 31.4.4.1 Aliphatic Amines

The analysis of small aliphatic amines by electromigration methods faces a few challenges. Although readily protonated at low pH electrolytes, the lack of chromophore precludes direct UV-detection in both CZE and EKC mode unless derivatizing schemes are devised or alternative detectors are selected. A further complication of the EKC mode derives from the hydrophilicity and polar characteristic of aliphatic amines, which usually impair strong interaction with commonly used micellized surfactants, demanding alternative secondary phases or more elaborate electrolytes.

Indirect UV-detection is a feasible option and particularly interesting for the CZE determination of primary to quarternary amines without derivatization. Imidazole, *N*-ethylbenzylamine, and benzyltriethylammonium chloride have been proposed as electrolyte chromophoric constituents.<sup>183</sup> The indirect UV-detection of aliphatic amines in ambient air has been performed by CZE in imidazole-based buffer modified by ethanol and EDTA.<sup>184</sup> By replacing imidazole with ammonium, the electrolyte became applicable to MS detection (these details and other CZE methodologies are reported in Table 31.4).

EKC separations of aliphatic amines include electrolyte systems composed of several surfactants (SDS,<sup>185</sup> cholate,<sup>186</sup> Brij 35<sup>72</sup>) modified by certain additives (urea,<sup>185</sup> neutral CDs,<sup>185</sup> organic solvents<sup>75,186</sup>), mixed CDs,<sup>187</sup> and more unusual secondary phases [resorcarene-octacarboxylic acid,<sup>188</sup> calixarene,<sup>47</sup> poly(sodium 4-styrenesulfonate), PSSS<sup>189</sup>]. Derivatization is performed when UV (*o*-phthaldialdehyde, OPA,<sup>185,187</sup> as derivatizing agents) or LIF detection [3-(2-furoyl)quinoline-2-carboxaldehyde,<sup>186</sup> 5-(4,6-dichloro-*s*-triazin-2-ylamino)fluorescein (DTAF)<sup>72</sup> as labeling agents] is designed.

Examples of the EKC determination of aliphatic amines in water compartments<sup>75</sup> and atmospheric aerosol samples<sup>71</sup> are compiled in Table 31.4.

#### 31.4.4.2 Aromatic Amines

Direct UV spectrophotometric detection of aromatic amines from azo dye reduction in textile industry wastewaters<sup>190</sup> and electrophoretic methods for biogenic and aromatic amines<sup>191</sup> have been the subject of recent reviews. In addition, environmental applications of mutagenic heterocyclic amines have recently been revised.<sup>192</sup>

CZE analysis of aromatic amines include the use of simple buffers at varying pH (acetate,<sup>80</sup> phosphate,<sup>10,193</sup> and borate<sup>70</sup>) with direct UV,<sup>10</sup> electrochemical,<sup>80</sup> or fluorescence<sup>70,80,193</sup> detection.

EKC methodologies for aromatic amines are based on electrolytes containing SDS,<sup>64,91,194,195</sup> mixtures of SDS and nonionic surfactants,<sup>196</sup> and bile salts<sup>29</sup> as well as modifiers (tetraalkylammonium salts,<sup>195</sup> urea,<sup>64</sup> organic solvents,<sup>29,64,91,194,196</sup> and CDs<sup>197</sup>). Combinations of anionic soluble polymers<sup>198</sup> or crown ether<sup>199</sup> and CDs have also been reported. Despite being chromophoric, alternative detectors for aromatic amines have been proposed (CE-ESI-MS,<sup>91</sup> electrochemical,<sup>80</sup> and fluorescence<sup>80</sup> detection).

Examples of EKC methodologies for aromatic amines in water<sup>21,35,37,80</sup> are compiled in Table 31.4. Figure 31.4 illustrates the electromigration separation of aliphatic and aromatic amines.

#### 31.4.5 CARBONYLS

Low-molecular mass carbonyls are among the most abundant and ubiquitous volatile organic compounds in the atmosphere. They are produced from industrial activity and incomplete combustion of fossil fuels and biomass. Many aldehydes are also emitted indoors (plastic, foam insulation, lacquers, etc.). As a source of free radicals, aldehydes play an important role in the ozone formation, in urban smog events, as well as in the photochemistry of the unpolluted troposphere. Aldehydes are recognized irritants of the eye and respiratory tract, and often, carcinogenic and mutagenic characteristics are also attributed to them.

To implement CZE and EKC methodologies for the determination of carbonyl compounds, structure-related issues must be addressed. Aldehydes and ketones of environmental importance are essentially neutral molecules, interact poorly with micellar phases, and present no chromophoric moieties. Two methodological approaches have been presented: either generation of charged adducts or generation of large UV-absorbing or fluorescence derivatives. In the former, the charged adducts can be detected directly (if aromatic) or indirectly (if aliphatic). The separation of anionic aldehyde-bisulfite adducts is a fine example of the first approach.<sup>25</sup> The second approach comprises the derivatization of the molecules to generate either neutral or charged UV-absorbing or fluorescent

(Modified from (a) E.A. Pereira et al., *J. AOAC Int.*, 82, 1562–1570, 1999 and (b) E.A. Pereira et al., *J. Chromatogr. A*, 979, 409–416, 2002. With permission.)

and key articles. A comprehensive review on applications of CE to the analysis of inorganic species including organometallic compounds in diverse environmental matrices (drinking, mineral, surface, and ground waters; rainwater; snow; seawater; brine and waste waters; aerosol; and others) has been compiled.<sup>205</sup> The determination of inorganic ions in environmental aquatic samples of high salinity, particularly seawater, has been revised.<sup>206</sup>

### 31.4.6.1 Inorganic Cations

The CZE determination of alkali, alkaline earth, and transition metal cations may be conducted under indirect UV-detection in electrolytes composed of cationic chromophores (protonated imidazole, aromatic amines, pyridine derivatives at moderately low pH electrolytes) and weak complexing agents ( $\alpha$ -hydroxyisobutyric acid, HIBA, or other mono- and dicarboxylic acids), eventually modified by solvents. The simultaneous separation of 16 metal ions for inspection of river samples is an example of this approach.<sup>207</sup> Direct UV-detection at low wavelengths ( $190 \text{ nm}$ ) using nonabsorbing electrolytes (pH 10 borate buffer) is a possibility for absorbing cations such as ammonium, as determined in river and sewage samples.<sup>208</sup> Alternatively, UV-absorbing chelating (EDTA)<sup>62</sup> or ion-pair forming agents (*o*-phenanthroline)<sup>209–211</sup> can be selected for the determination of alkaline earth and transition metal ions. Figure 31.6 illustrates the electromigration separation of small cations.

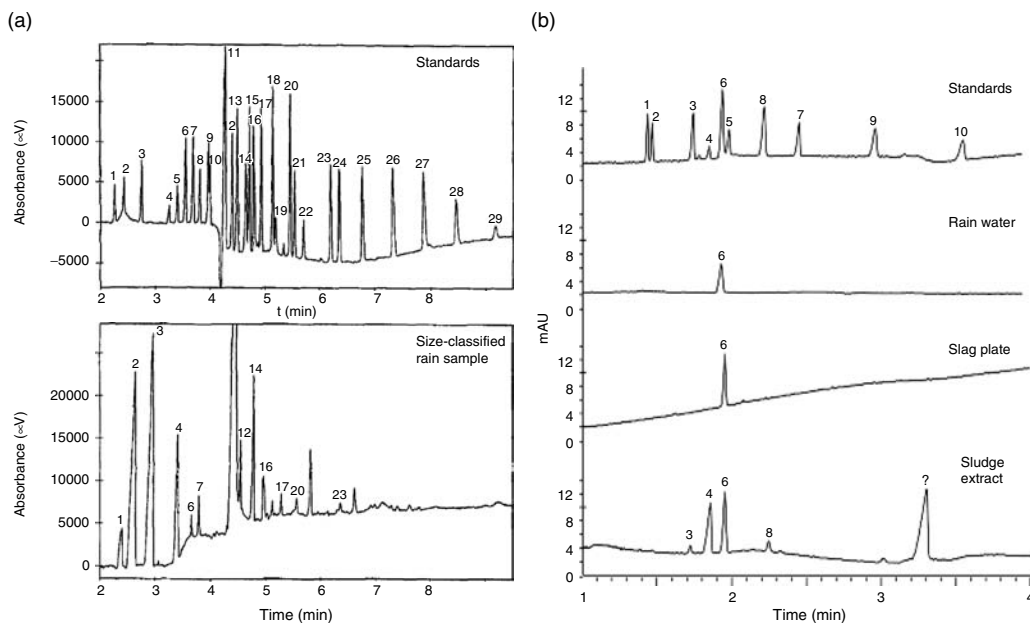

**FIGURE 31.6** Separation of metal ions. Electrolytes: (a)  $10 \text{ mmol L}^{-1}$  4-aminopyridine and  $6.5 \text{ mmol L}^{-1}$  HIBA at pH 4.5; (b)  $200 \text{ mmol L}^{-1}$  ammonium acetate at pH 5.5,  $0.5 \text{ mmol L}^{-1}$  1,10-phenanthroline,  $10 \text{ mmol L}^{-1}$  hydroxylamine, and 20% acetone. Other conditions: (a) +25 kV; indirect UV detection at 214 nm; (b) +14 kV applied voltage; direct UV-detection at 226 nm. Peak labels: (a): potassium (1), sodium (2), barium (3), strontium (4), calcium (5), magnesium (6), manganese (7), lithium (8), iron (9), cobalt (10), cadmium (11), nickel (12), zinc (13), lead (14), chromium (15), and copper (16). (Modified from (a) N. Shakulashvili et al., *J. Chromatogr. A*, 895, 205–212, 2000 and (b) E. Dabek-Zlotorzynska et al., *Anal. Bioanal. Chem.*, 372, 467–472, 2002. With permission.)

### 31.4.6.2 Inorganic Anions

Similar to the inorganic cations, the determination of inorganic anions and those derived from low-molecular mass carboxylic acids are commonly approached by indirect UV-detection. However, here the electrolyte chromophore must be anionic (chromate,<sup>212,213</sup> benzoate derivatives,<sup>214</sup> naphthalene derivatives<sup>215,216</sup> among others<sup>217,218</sup>) and an EOF reverser (long-chain tetraalkylammonium quaternary salts) is usually employed. It is worth mentioning that many methodologies for inorganic anions and even metal and nonmetal elements determined as oxoanions or anionic complexes that are reported in the literature as CZE separations are, in fact, EKC separations. This is due to the electrolyte ionic strength that forces micellization of the cationic surfactant used as flow reverser.<sup>219</sup> Direct UV-detection at low wavelengths using nonabsorbing electrolytes (phosphate, borate, chloride, formate/chloride buffers modified by solvents, and cationic surfactants) is also a possibility for UV-absorbing anions such as iodide,<sup>56,220,221</sup> iodate,<sup>222</sup> bromide,<sup>223</sup> bromate,<sup>224</sup> nitrate,<sup>225</sup> and nitrite<sup>226</sup> as well as mixtures of anions<sup>9,66,227</sup> and aromatic acids.<sup>228</sup> Figure 31.7 illustrates the electromigration separation of small anions.

### 31.4.6.3 Simultaneous Detection of Cations and Anions

An interesting strategy based on dual-opposite end sample injection that accomplishes the simultaneous separation of small cations and anions within a single run was demonstrated in the analysis

**FIGURE 31.7** Separation of inorganic and organic anions. Electrolytes: (a) 7.5 mmol L<sup>-1</sup> salicylic acid, 15 mmol L<sup>-1</sup> Tris, 400 μmol L<sup>-1</sup> DoTAH, 1050 μmol L<sup>-1</sup> Ca<sup>2+</sup>, and 600 μmol L<sup>-1</sup> Ba<sup>2+</sup>; (b) 50 mmol L<sup>-1</sup> tetraborate at pH 9.3, containing 5% methanol. Other conditions: (a) -28 kV; indirect UV-detection at 232 nm; (b) -23 kV applied voltage; direct UV-detection at 200 nm. Peak labels: (a): chloride (1), nitrate (2), sulfate (3), formate (4), fumarate (5), malonate (6), succinate (7), maleate (8), glutarate (9), methanesulfonate (10), carbonate/adipate (11), malate (12), pimelate (13), acetate (14), suberate (15), oxalate (16), azelate (17), sebacate (18), glyoxylate (19), propionate (20), methacrylate (21), lactate (22), butyrate (23), hydroxy-*iso*-butyrate (24), valerate (25), capronate (26), enanthate (27), caprylate (28), and pelargate (29); (b): bromide (1), iodide (2), nitrite (3), thiosulfate (4), chromate (5), nitrate (6), Fe(CN)<sub>6</sub><sup>4-</sup> (7), SCN<sup>-</sup> (8), MoO<sub>4</sub><sup>2-</sup> (9), and WO<sub>4</sub><sup>2-</sup> (10). (Modified from (a) A. Mainka et al., *Chromatographia*, 45, 158–162, 1997 and (b) M.I. Turnes-Carou et al., *J. Chromatogr. A*, 918, 411–421, 2001. With permission.)

of environmental water samples with indirect fluorescence<sup>73</sup> and contactless conductometric<sup>78</sup> detection.

#### 31.4.6.4 Speciation and Organometallic Compounds

Speciation of chromium (histidine/acetic acid;<sup>229</sup> acetate buffer/EDTA<sup>230</sup>), mercury (borate/MeOH),<sup>8</sup> tin (pyridine/CTAB),<sup>231</sup> lead (SDS/ $\beta$ -CD),<sup>232</sup> arsenic (borate,<sup>233</sup> phosphate or phosphate/borate,<sup>54</sup> phosphate/TTAB,<sup>234</sup> phosphate and phosphate/TTAB<sup>235</sup>), sulfur (phosphate/TTAB/ACN),<sup>236</sup> and selenium (histidine/acetic acid,<sup>237</sup> SDS/ $\beta$ -CD<sup>232</sup>) by CE methods have been reported. Other examples include the analysis of beryllium (as an acetylacetonate complex) in digested airborne dust<sup>238</sup> and the determination of Fe(II)-, Cu(I)-, Ni(II)-, Pd(II)-, and Pt(II)-cyano complexes and nitrate from leaching solutions of automobile catalytic converters.<sup>239</sup>

Metals including As, Co, Fe, Mn, Ni, and V are found at concentrations of 1–1000 ppm in crude oils. About 27–100% of the total metals in crude oil occur as organometallic porphyrin complexes. These petroporphyrins, derived from heme or chlorophyll, usually contain Ni(II) or V(IV)O and are distinguished by various ring types (Etio, DPEP, Rhodo analogs) and different substituents (H, *n*-alkyl). Petroporphyrin separations are of interest in geochemical sciences, environmental monitoring, and process control. Separation of petroporphyrin models [Ni(II) and V(II)O Etio I and Octaethyl type porphyrins] was approached by MEKC in electrolytes of varied composition: 15.8–22.5 mmol L<sup>-1</sup> borate buffer containing 15–42 mmol L<sup>-1</sup> SDS and 0–30% acetone, methylethylketone, acetonitrile, or methanol in a 6–30 min window.<sup>240</sup>

Several examples of the aforementioned methodologies and their application in environment compartments are compiled in Table 31.6.

### 31.4.7 EXPLOSIVES AND WARFARE RESIDUES

#### 31.4.7.1 Explosives

A SB- $\beta$ -CD-assisted EKC method for the determination of cyclic nitramine explosives and related degradation intermediates and the 14 EPA listed explosives (borate/SDS electrolyte) has been described.<sup>241</sup> A volatile electrolyte composed of SB- $\beta$ -CD modified ammonium acetate buffer was selected for the EKC-MS detection of nitroaromatic and cyclic nitramine compounds in soil and marine sediment,<sup>83</sup> as detailed in Table 31.7. The use of phosphate/SDS electrolytes was reported in the separation of the 14 listed nitramine and nitroaromatic explosives for the analysis of extracts of high explosives such as C-4, tetrytol, and detonating cord.<sup>242</sup>

The simultaneous detection of small cations (ammonium, sodium, potassium, calcium, magnesium, and strontium) and anions (bromide, chloride, nitrite, nitrate, sulfate, perchlorate, thiocyanate, and chlorate) from low explosives in postblast residue using an elaborate electrolyte composed of a cationic chromophore and modifiers (imidazole/HIBA/18-crown-6 ether/ACN), an anionic chromophore (1,3,6-naphthalenesulfonic acid) and flow reversal agent (tetramethylammonium hydroxide) has been presented.<sup>243</sup>

#### 31.4.7.2 Warfare Residues

A CZE method (borate buffer at pH 9.5) with LIF detection (He-Cd laser, 325 nm excitation; 450 nm emission) that simultaneously examines thiols (OPA derivatives) and cyanide (derivatized by OPAtaurine) aiming at monitoring for the potential contamination of drinking water supplies by chemical warfare (CW) nerve agents was described.<sup>244</sup> Detection limits of 9.3  $\mu\text{g L}^{-1}$  for cyanide and from 1.8 to 89  $\mu\text{g L}^{-1}$  for the thiols were obtained.

Table 31.7 compiles the details of CZE<sup>245,247</sup> and EKC<sup>247,248</sup> methodologies for inspection of contaminated water and soil for alkylphosphonic acids, the breakdown products of organophosphorus

nerve agents. The unusual detection system for CE (flame photometric detector)<sup>245</sup> with an ability to detect alkylphosphonic acids a fold below the required 1 μg mL<sup>-1</sup> level is worth mentioning here.

Figure 31.8 illustrates the electromigration separation of EPA explosives and warfare residues.

### 31.4.8 AROMATIC SULFONATES

Aromatic sulfonates and their amino- and hydroxy-derivatives are produced on a large scale in the chemical industry. Although the acute toxicity and the risk of bioaccumulation appear to be small, they became persistent and widespread environmental pollutants due to their high mobility in the aquatic compartments and limited biodegradability.

The anionic charge of sulfonates within the entire practical pH range of electromigration separations and the UV-absorbing capability of the aromatic moiety make CZE-based methodologies of aromatic sulfonates feasible. However, improved selectivity and resolution of positional isomers have been sought by means of interactions with CDs,<sup>249</sup> nonionic,<sup>250</sup> and cationic<sup>250</sup> surfactants as well as mixed micelles.<sup>251</sup> An overview of the electrophoretic methods for the determination of benzene- and naphthalenesulfonates in water samples has been presented in the literature.<sup>252</sup>

Details of a CZE methodology for the separation of 14 aromatic sulfonates in river water<sup>253</sup> and a CZE-MS evaluation of 22 compounds in influent and effluent samples of a wastewater treatment plant<sup>254</sup> are organized in Table 31.8. With the idea that phytoremediation could be used as an alternative means of wastewater treatment of recalcitrant compounds, a simple borate buffer-based

CZE methodology was used to monitor sulfonated anthraquinones uptake in hydroponic media, in which plants, bacteria, and algae had grown for 6 weeks.<sup>255</sup>

EKC methodologies for aromatic sulfonates in industrial effluents,<sup>19</sup> mono- and dinaphthalenesulfonates as well as hydroxy- and amino-derivatives in river water,<sup>17</sup> and phenoxyacetic acids in spiked water and soils<sup>28</sup> are compiled in Table 31.8. Figure 31.9 illustrates the electromigration separation of aromatic sulfonates.

### 31.4.9 SURFACTANTS

Anionic surfactants such as alkanesulfonates, alkyl sulfates, and LAS are water-soluble, surface-active materials that are consumed in large quantities in industrial and commercial formulations. Thus, their disposal may impact water reservoirs. LAS surfactants, which are used commercially, are quite complex mixtures containing several homologs and positional isomers. The degradation rates and toxicity of LAS depend on the alkyl chain length and the position of the phenyl ring.

Since LAS are chromophoric-charged compounds, they are amenable to CZE<sup>18,87</sup> determination. EKC mode is preferred when homologue discrimination or isomeric distribution is requested<sup>31,32</sup> or mixture of surfactant classes are screened.<sup>33,34</sup>

LAS were determined in influent and effluent samples of wastewater treatment plants and coastal waters receiving untreated domestic effluents using a volatile buffer-based CZE method (UV and

**FIGURE 31.10** Separation of LAS surfactants. Electrolyte:  $10 \text{ mmolL}^{-1}$  sodium phosphate at pH 6.8,  $40 \text{ mmolL}^{-1}$  SDS and 30% acetonitrile. Other conditions: +15 kV applied voltage. Peak legend: positional isomers: 5-C10 (1), 4-C10 (2), 3-C10 (3), 2-C10 (4), 6-C11 (5), 5-C11 (6), 4-C11 (7), 3-C11 (8), 2-C11 (9), 6-C12 (10), 5-C12 (11), 4-C12 (12), 3-C12 (13), 2-C12 (14), 7-C13 (15), 6-C13 (16), 5-C13 (17), 4-C13 (18), 3-C13 (19), and 2-C13 (20); first number represents the attachment point of the phenyl ring to the carbon chain. (From J.M. Herrero-Martínez et al., *Electrophoresis*, 24, 681–686, 2003. With permission.)

MS detection).<sup>87</sup> Phosphate and borate buffers containing acetonitrile were used to discriminate LAS homologues in sewage sludge, whereas unmodified buffers were applied to wastewater samples.<sup>18</sup> Isomeric separation was only possible using electrolytes with high contents of SDS and acetonitrile as organic modifier. Table 31.8 compiles the details of the aforementioned methodologies. Figure 31.10 illustrates the electromigration separation of LAS surfactants.

### 31.4.10 DYES

Synthetic dyes, including azo compounds, are widely used as coloring agents in a variety of products such as textiles, paper, leather, gasoline, and foodstuffs. Synthetic dyes persist even after conventional water treatment procedures due to their hydrophilic character and high solubility (they usually bear carboxylic or sulfonic acid groups in their structure) and, therefore, can be distributed in the environment from urban and industrial wastewater.

CZE separation of synthetic dyes has been approached by simple (borate and citrate)<sup>256</sup> and volatile buffers (ammonium acetate)<sup>257</sup> modified by solvents as well as nonaqueous systems (ammonium acetate/acetic acid in MeOH).<sup>258</sup> Environmental applications of CZE methodologies include the analysis of spent dyebaths and wastewater samples<sup>257</sup> and the monitoring of groundwater migration, where eosin was used as a fluorescent tracer (details in Table 31.8).<sup>259</sup>

EKC separations of synthetic dyes include buffered SDS systems<sup>260</sup> and polymeric electrolytes,<sup>261</sup> modified by organic solvents.<sup>260</sup> Examples of the determination of azo dyes, mono- and disulfonated compounds in water samples,<sup>20</sup> as well as synthetic dyes in spiked water and soil

matrices<sup>29</sup> have been compiled in Table 31.8. Figure 31.11 illustrates the electromigration separations of synthetic dyes.

### 31.4.11 ENDOCRINE DISRUPTORS AND PHARMACEUTICALS

Recently, it has been established that certain synthetic organic chemicals affect the reproductive health of higher organisms by contributing to infertility in various ways and even increasing the rate of cancer in reproductive organs. These chemicals have been termed “environmental estrogens” due to their disrupting effects on the endocrine system of hormone production and transmission. In addition to organochlorine insecticides, PCBs and dioxins (covered in Section 31.4.2), phenolic compounds such as bisphenol A—a widely used substance that is polymerized industrially into polycarbonate and nonylphenol—a product of the breakdown of large surfactants used in spermicides, some plastics and plasticizers such as phthalic acid esters, as well as pharmaceuticals such as synthetic estrogens belong to the list of chemicals suspected to have endocrine-disrupting effects.

#### 31.4.11.1 Phenolic Compounds

The CZE separation of halogenated phenolic and bisphenolic compounds from 25 potentially interfering phenolic derivatives for inspection in water, sludge, and sediments has been attempted<sup>262–264</sup> using aqueous (borate buffer at pH 9.4) and nonaqueous (borate buffer in MeOH) systems (details in Table 31.9).

MEKC separation and online concentration of bisphenol A and alkyl phenols has been approached in a series of experiments using SDS and other alkyl chain anionic surfactants, bile salts, and TTAB in organic solvent and CD-modified buffers.<sup>59,265,266</sup>

The EKC determination of several target endocrine disruptors in water<sup>267,268</sup> and biosolids (sewage sludge and treated sludge)<sup>269</sup> has been detailed in Table 31.9. The potential of MEEKC for the separation of priority endocrine-disrupting compounds in wastewater samples has been investigated.<sup>45</sup>

#### 31.4.11.2 Phthalate Esters

Excessive use of phthalate esters in industrial applications, mainly as plasticizers, is the main cause of their persistent presence in consumer goods and in the environment. The economic and social interest in the control of phthalate esters and the availability of analytical methodologies for areas such as environmental and food analyses have been discussed.<sup>270</sup>

#### 31.4.11.3 Pharmaceutical Residues

The occurrence and fate of pharmaceuticals from various prescription classes and related metabolites and medicinal products for veterinary use in aquatic environments as well as their removal is one of the emerging issues in environmental chemistry.<sup>271</sup> More than 80 different prescribed pharmaceuticals, metabolites, and veterinary drugs have been detected in aquatic environment (e.g., sewage influent and effluent samples, surface and groundwater, and even drinking water), as reported by studies carried out in several European countries, United States, Canada, and Brazil.<sup>271</sup>

Tetracyclines,<sup>272</sup> nonsteroidal anti-inflammatory,<sup>58,273</sup> antidepressants,<sup>274</sup> and mixtures of acidic drugs<sup>82,275</sup> as well as veterinary drug<sup>276</sup> residues have been determined by CZE (citric acid/citrate, borate, borate in MeOH, phosphate/MeOH, ammonium formate/formic acid/ACN, ammonium acetate, ammonium acetate/acetic acid/MeOH) and EKC (SDS/pH 2.5 phosphate buffer/ACN) methodologies in water samples from influent and effluent of sewage treatment plants as well as wastewater, river, surface and groundwater as compiled in Table 31.9. Estrogens have been receiving increased attention due to the already mentioned possible interference with the reproductive

### 31.4.12 MISCELLANEOUS

#### 31.4.12.1 Humic Substances

CZE of natural organic matter<sup>279</sup> and separation methods for humic substances<sup>280</sup> have been subjects of recent reviews. CZE and EKC separations (borate/TRIS/EDTA modified by CDs/SDS) and

**FIGURE 31.12** Separation of (a) endocrine disruptors and (b) veterinary drug residues. characterization (TOF-MS) of humic acids isolated from Antarctica soil<sup>281</sup> as well as interactions of organic matter and environmental pollutants<sup>282,283</sup> were reported (details in Table 31.9).

### 31.4.12.2 Algal Toxins

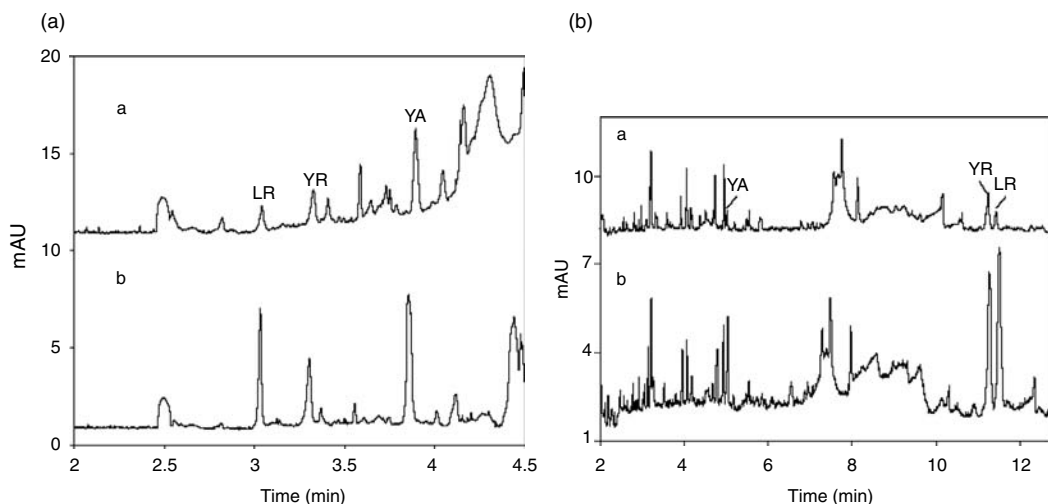

Methods for determining microcystins and microcystin-producing cyanobacteria have been reviewed.<sup>284</sup> Details of CZE and EKC analyses of cyanobacterial toxins in environmental samples<sup>285–287</sup> are compiled in Table 31.9. Figure 31.13 presents the separation of cyanobacterial toxins.

### 31.4.12.3 Other Applications

CZE and MEKC methods were used to monitor extraction procedures involving pollen allergens and organic pollutants from dust samples collected before, during, and after pollen seasons at different locations (car-traffic tunnel in Prague and a metro station in Paris) using air-filtration devices.<sup>288</sup> Water and acetic acid extracts were analyzed by CZE using acetic acid as background electrolyte whereas water and alkaline water–SDS–buffer extracts were analyzed by MEKC in Tris–phosphate–SDS electrolytes. Significant differences were found in the profiles of dust extracts from different origins.

Drinking water and humidity condensate samples collected from U.S. Space Shuttle and the Russian Mir Space Stations are analyzed routinely at the NASA–Johnson Space Center as a means of verifying water quality and monitoring the environment of the spacecraft.<sup>289</sup> Anions and cations were determined by ion chromatography whereas carboxylates and amines were determined by CE (phthalate/TTAB for carboxylates and imidazole/HIBA for amines). Results showed that Shuttle water is of distilled quality whereas Mir-recovered water contains various levels of minerals. Organic ions were rarely detected in potable water samples but were present in humidity condensates.

Table 31.9 compiles the details of the previously cited methodologies.

### 31.5 A METHOD DEVELOPMENT GUIDE FOR ENVIRONMENTAL ANALYSIS

Figure 31.14 depicts a simplified diagram that can be useful during the first stages of method development for environmental analysis. In CE, method development relies strongly on the knowledge of the analyte structural features. For neutral compounds (for instance, many classes of pesticides, PAH, PCB, dioxins, derivatized carbonyls, etc.), the obvious choice is the selection of an EKC protocol. As a first attempt, MEKC in borate/SDS electrolytes is usually recommended. Depending on the result of the exploratory run, several additives can be further tested as a means to modulating the solute–micelle interaction. Other EKC modes are also feasible options, especially when SDS fails in promoting separation, which is the case of either highly hydrophilic or highly hydrophobic compounds. Occasionally, EKC has been the technique of choice for certain classes of ionizable pollutants, such as phenol derivatives and amines, simply because the separation of a large number of positional isomers and conformers is attempted and extra selectivity is required.

Method development procedures for charged compounds, either organic pollutants with ionizable functional groups within the CE operational pH range (phenols, amines, carboxylic acids, many dyes, pharmaceuticals, etc.) or explicitly ionic compounds such as small ions, sulfonates, LAS surfactants, and so forth, will follow two distinct routes in the diagram of Figure 31.14, depending on the compound's UV-absorbing characteristics (only UV-absorbance detectors were considered here because they are practically a part of all commercially available CE equipments).

If the pollutant is charged and exhibits UV-absorbing properties, the CZE mode is readily recommended. For basic pollutants, moderately low to low pH buffers are indicated and the analyte migrates coelectroosmotically as a cation (protonated species) whereas for acidic pollutants, high pH buffers will promote the analyte dissociation and it migrates counterelectroosmotically as an anion. In both cases, buffer pH and concentration are the variables to optimize before the addition of any modifiers is considered.

If the pollutant is charged but does not present a chromophoric group, either a cationic (separation of cation) or an anionic (separation of anions) chromophore must be added to the electrolyte and

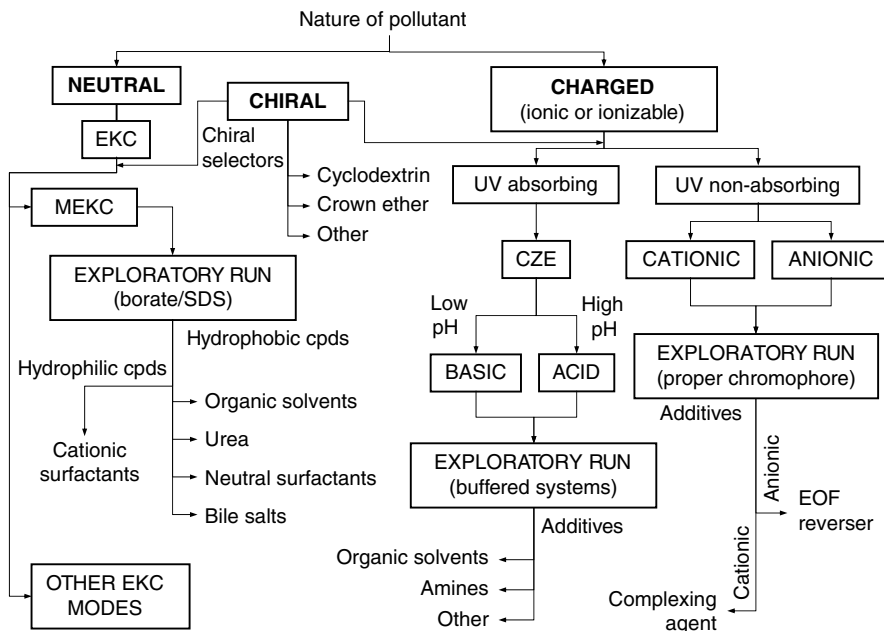

FIGURE 31.14 A method development guide for environmental analysis.

indirect detection is performed. For the cations, complexing agents will further improve resolution of similar mobility species. In the case of nonabsorbing anions, a judicious choice of both co- and counterions is recommended, the co-ion due to peak symmetry considerations while the counterion for signal enhancement. Furthermore, an EOF modifier (alkyl quaternary ammonium salt) is usually selected to expedite the separation.

Finally, in the electrolyte design during chiral pollutants method development, a chiral selector must always be considered. Cyclodextrins are among the most commonly used chiral additives and can be employed in both EKC and CZE methodologies, depending on the nature of the pollutant.

### 31.6 CONCLUDING REMARKS

On the basis of the diversity of applications presented in this chapter, it becomes clear that CE has found a niche among separation techniques for environmental analysis. Future directions will likely include refinement of preconcentration strategies and further detector improvements to achieve the desirable low-concentration limits of detection. In addition, with the consolidation of CE-MS technology, more robust methods are likely to emerge with enhanced sensitivity and superior selectivity, improving further the acceptance of CE in the routine determination of pollutants in real samples.

## 32.1 INTRODUCTION

The advent of microfabrication technology and its more recent application to the field of biology has greatly enhanced our ability to engineer *in vitro* cell culture environments. Cells and their sensing elements are several hundred nanometers to tens of micrometers (microns) in size, and thus interact within a microscale environment, or “microenvironment.” Unlike conventional cell culture methods, microfabrication-based methods allow manipulation of the physical, chemical, and electrical properties of the cellular microenvironment at the microscale. As a result of this enhanced functionality, microengineered culture environments are becoming more widely used in the biological research community for a variety of applications, including investigating fundamental questions in biology, enriching specific cell types from mixed populations, and examining the response of cells to novel chemical compounds. Microengineered culture environments impose unique requirements on analysis tools for detecting and characterizing changes in cell behavior or physiology in response to specific environmental perturbations. Optimizing existing analysis tools for use with microengineered culture environments would greatly enhance the utility of microfabrication-based methods for biological studies. In this chapter, we provide a broad overview of the most common and recent microfabrication-based methods for controlling the position of cells within a culture environment, and the properties of the cellular microenvironment.

**FIGURE 32.1** Photolithography and soft lithography. Photolithography selectively polymerizes a photoactive polymer coating using UV light filtered by a patterned mask to create microscale features of defined dimensions. Soft lithography utilizes the photolithographically defined substrates to mold polymer replicas of the microscale features. (Reprinted and adapted from Li, N., et al., *Crit Rev Biomed Eng*, 31, 423. Copyright 2003. With permission from Begell House, Inc.)

## 32.2 MICROFABRICATION TOOLS

Many microfabrication tools have been developed over the past 50 years to create more intricate and advanced microelectronics. The ability of these tools to precisely control the size and shape of polymers, metals, and other materials at scales as small as 1  $\mu\text{m}$ , make them extremely adept at creating unique cell culture microenvironments. Two processes called “photolithography” and “soft lithography” are the most commonly used for biological studies.<sup>1,2</sup> Photolithography begins by coating a substrate with a thin layer of photosensitive polymer called a “photoresist” (Figure 32.1). The thickness of the photoresist layer is controlled by spinning the substrate at a defined speed and length of time. Thinner layers are produced by spinning the wafer faster and longer. The coated substrate is then placed in contact with a thin sheet of glass or plastic that has user-defined opaque and transparent regions, called a “mask.” Ultraviolet (UV) light is then shone through the mask onto the coated substrate causing exposed regions to degrade (positive photoresist) or polymerize (negative photoresist). The exposed substrate is then placed in a chemical solution called “developer,” which removes the degraded or unpolymerized photoresist leaving user-defined features patterned on the substrate. Soft lithography uses these patterned substrates, called “masters,” to mold elastomeric polymer replicas. The most commonly used elastomer is poly(dimethyl siloxane) (PDMS), due to its biocompatibility, transparency, and high-fidelity replica molding properties.

## 32.3 CONTROLLING CELL POSITION IN 3D CULTURES

The ability to control where a cell is positioned relative to its physical environment, other cells, or regions with particular chemical identities is useful for studying cell exploration and migration in the presence of various physical and chemical cues, investigating specific cell–cell or cell–substrate interactions, characterizing autocrine or paracrine signaling, or for automating cell analysis. There is an extensive body of literature describing methods to control the position of cells on two-dimensional (2D) substrates.<sup>1,3,4</sup> For some applications 2D culture systems are ideal; however, for many others they are not. Although invaluable in developing our current understanding of many biological phenomena, 2D culture systems are artificial environments not representative of *in vivo* culture

**FIGURE 32.2** Comparison of 2D vs. 3D culture architectures. (a) 2D cultures consist of patterned or random cells (shaded spheres) on a rigid or semirigid substrate. 2D cultures can offer cells a richer environment with cell organization in three dimensions and incorporation of extracellular matrix components (black lines) with entrained growth factors and signaling molecules. (b) Scanning electron micrograph (SEM) of the deep-sea gulper shark retina. (Photo courtesy of Jill Olin, Hofstra University. With permission.)

environments except in a few distinct cases (e.g., endothelial or epithelial cells). Nearly all cells found *in vivo* are completely surrounded by an intricate and highly organized arrangement of extracellular matrix proteins, other cells, and a rich milieu of soluble biomolecules distributed throughout the extracellular fluid. Cell–cell contact and the juxtaposition of different cells or cell types relative to one another are essential components of normal biological function. Cells communicate in a variety of ways including integrin and gap junction signaling, or by secreting signaling proteins into the extracellular environment that act on the cell itself (i.e., autocrine signaling) or on neighboring cells (i.e., paracrine signaling). Two-dimensional cell cultures cannot fully replicate these intricate and complex environments (Figure 32.2) and as a result may be limited in the insight and information they can provide about normal and abnormal cell physiology. Three-dimensional (3D) culture architectures better simulate complex *in vivo* environments and may be able to provide more comprehensive and relevant information about cell responses to specific environmental factors. Because of the thorough description of 2D patterning methods in existing literature and the advantages of 3D culture systems, we will focus our discussion on efforts to control cell position in 3D culture architectures.

### 32.3.1 PHYSICAL ENTRAPMENT

The simplest method of patterning cells in a 3D culture system is to create voids on the surface of a biocompatible gel (Figure 32.3). Voids can be created by degrading select regions of the gel,<sup>5</sup> embossing the gel with patterns defined by a microfabricated stamp,<sup>6</sup> or by molding the gel on a microfabricated surface.<sup>7,8</sup> Cell patterning is achieved by seeding cells at random and rinsing away those that have not fallen into the voids created in the gel. The voids can subsequently be refilled with new gel to provide full encapsulation. Physical entrapment methods can be used with virtually any soft or moldable polymer; however, its reliance on conventional photolithography allows cell patterning in only two dimensions.

### 32.3.2 PHOTOPATTERNING

Cells can also be patterned in 3D culture constructs using a process called “photopatterning.” Photopatterning (Figure 32.4) utilizes photoactive hydrogels that become cross-linked or polymerized when exposed to light.<sup>9</sup> Cells are mixed with prepolymerized gel solution and exposed to UV light through a mask, similar to photolithography. Regions exposed to UV light polymerize and trap the cells contained within. The unpolymerized solution can be rinsed away, replaced with acellular gel solution, and flood exposed with UV light to provide a blank background. Alternatively, solutions containing other cell types can be photopatterned relative to the first pattern to create a wide variety of coculture architectures. Photopatterning is a very effective means of patterning cells in 3D cultures,

**FIGURE 32.3** Physical entrapment cell patterning. Cells can be patterned in 3D hydrogel cultures by creating voids using laser (L) degradation, embossing, and molding. Cells are seeded in the voids and those that do not can be rinsed away. Addition of more hydrogel allows full 3D encapsulation.

even though cell position can only be controlled in two dimensions. However, its use of UV light to initiate polymerization may have adverse effects on cell viability and function. UV light can damage deoxyribonucleic acid (DNA) and creates polymer or cross linker radicals that may directly damage cells.

### 32.3.3 DIELECTROPHORESIS

A phenomenon called *dielectrophoresis* has been used to pattern a variety of cell types on 2D substrates<sup>10,11</sup> and more recently in 3D culture constructs.<sup>9</sup> Unlike electrophoresis where charged species move in an applied electric field due to Coulombic forces ( $F = qE$ ), dielectrophoresis capitalizes on the ability of a cell to become *polarized* when placed in an electric field. Dielectrophoresis is most often used in conjunction with alternating current (AC) electric fields since AC fields eliminate electrophoretic movement, and have less physiological impact on cells than direct current (DC) fields.<sup>11</sup> When a cell is placed in an AC field, the magnitude and polarity of the induced dipole depend on the frequency of the applied field and the conductivities of the cell and the surrounding medium, described by the equation

$$\underline{p}(r) = 4\pi \varepsilon_m R^3 \left( \frac{\varepsilon_c - \varepsilon_m}{\varepsilon_c + 2\varepsilon_m} \right), \quad (32.1)$$

**FIGURE 32.4** Photopatterning. (a) Cells mixed with prepolymerized hydrogel solutions can be selectively illuminated with UV light through the use of an applied photomask (shown in black). (b) Regions exposed to UV become polymerized and entrap the cells. (c) The unpolymerized hydrogel can be rinsed away, replaced with acellular prepolymerized hydrogel solution, and flood exposed with UV to provide a blank background. (d) Photopatterning has been used to pattern 3T3 fibroblasts in PEG hydrogels against a blank background. (e) Aligned with other photopatterned cell types for coculture experiments. (Adapted from Albrecht, D. R., et al., *Lab Chip*, 5, 111, 2005. With permission from The Royal Society of Chemistry.)

where  $p(r)$  is the induced dipole,  $R$  is the radius of the cell,  $\underline{\epsilon}$  is the complex permittivity ( $\underline{\epsilon} = \epsilon + \sigma/(j\omega)$ ) of the cell (c) or medium (m),  $\sigma$  is the conductivity of the cell or medium,  $j = \sqrt{-1}$ ,  $\omega$  is the angular frequency of the applied electric field, and  $E(r)$  is the applied electric field.

If cells are placed in a nonuniform AC field, the spatial field gradient imparts different amounts of force on each half of the cell dipole (Figure 32.5a). When the complex permittivity of the cell is greater than that of the surrounding medium, the cell forms a positive dipole that causes it to move toward the electrode with higher field strength in what is known as “positive dielectrophoresis” (pDEP). If cell permittivity is less than that of the surrounding medium, a negative dipole is formed resulting in repulsion away from the electrode of higher field strength, or “negative dielectrophoresis” (nDEP). By engineering the shape and position of the electrodes, spatial field gradients can be created that localize cells to precise, user-defined locations (Figure 32.5b). The magnitude and direction of cell movement can be tuned by adjusting the conductivity of the surrounding medium or the frequency of the applied AC field.

Since dielectrophoresis relies on the geometry of the electrodes to create the nonuniform electric fields, the method has been limited to the creation of 2D cell patterns within 3D culture constructs (Figure 32.5c).<sup>9</sup> True 3D cell patterning would require more complex electrode geometries than those employed to date. Although dielectrophoresis has been used to levitate cells<sup>12–14</sup> and could be used for 3D patterning, the method has not been utilized solely or in combination with any other methods to pattern cells in all three dimensions within a 3D culture construct.

Because many biological hydrogels (e.g., collagen, fibrin, Matrigel™) have conductivities similar enough to cells to make dielectrophoretic cell patterning difficult, synthetic hydrogels such as poly(ethylene glycol) (PEG) are most commonly used.<sup>9</sup> PEG hydrogels are biocompatible, but are devoid of the numerous ligands and other supportive signals that cells normally receive from the extracellular environment. Although there are numerous chemistries that can be incorporated into PEG

**FIGURE 32.5** Dielectrophoresis. (a) Nonuniform magnetic fields place different amounts of force on cells with induced dipoles, causing them to move toward (pDEP) or away from (nDEP) high field densities. (b) Dielectrophoresis has been used to pattern 3T3 fibroblasts by controlling the shape and position of the electrodes. (c) Dielectrophoresis has also been used to pattern 3T3 fibroblasts in 3D PEG hydrogels. (Adapted from Albrecht, D. R., et al., *Lab Chip*, 5, 111, 2005. With permission from The Royal Society of Chemistry.)

hydrogels,<sup>15</sup> the inability to fully recapitulate the natural environment may confound experimental observations. Other confounding variables may be contributed by localized heating from the applied electric field, which could damage cells or activate intracellular signaling cascades. The electric field can also perturb the electrical state of the cell membrane and the function of membrane-embedded ion channels.

### 32.3.4 INKJET PRINTING

Inkjet printing of biological solutions has been used to pattern a variety of biological molecules on 2D substrates<sup>16</sup> and could prove to be an efficient method for patterning cells in engineered 3D culture architectures. Biological inkjet printers are adapted conventional inkjet printers<sup>17,18</sup> that deposit one or more biological solutions in user-defined patterns under the control of a computer. The computer controls the location of fluid ejection by rastering the printer head over the substrate or by moving the substrate relative to a stationary printer head. The solutions are ejected from the microfluidic channels and nozzles that constitute the inkjet printer heads using either heat-based or piezoelectric fluid displacement. Heat-based fluid displacement, also known as “bubble jet” printing, utilizes a heating element to vaporize a portion of the ink and create a bubble that ejects fluid from the nozzle and onto the substrate (Figure 32.6a). When the bubble collapses it creates a vacuum that pulls more ink into the printer head. Piezoelectric fluid displacement uses a piezoelectric transducer to physically displace the fluid within the microchannel when a voltage is applied, and eject the fluid out of the nozzle and onto the substrate (Figure 32.6b). Addition of a  $z$ -stepper motor allows 3D

**FIGURE 32.6** Inkjet printing. (a) Bubble jet printer heads use resistive heating elements to vaporize the ink and create a gas bubble that displaces fluid out of the nozzle. (b) Piezoelectric printer heads use a piezoelectric transducer to mechanically displace fluid out of the nozzle. (c) Bovine aortic endothelial cells were inkjet printed on an alginate-coated scaffold to create tubes 4 mm in diameter. (Reprinted from Varghese, D., et al., *J Thorac Cardiovasc Surg*, 129, 2, 470. Copyright 2005. With permission from American Association for Thoracic Surgery.)

cell culture constructs to be created using a layer-by-layer process. This method has been shown to effectively create 3D cultures of neuronal cell lines in fibrin gels<sup>19</sup> and a variety of cells in alginate gels<sup>18</sup> (Figure 32.6c). Because of the use of microfluidic channels in inkjet printer heads, care must be taken to choose microchannel dimensions that do not shear damage cells or other biological molecules within the printing solution. Minimization of shear effects often comes at the expense of drop size resolution, which limits how close regions of different composition can be placed relative to one another. In addition, the heating of biological ink when using bubble jet biological inkjet printers may damage cells or cause denaturation of proteins.

## 32.4 ENGINEERING THE CELLULAR MICROENVIRONMENT

The ability to control the physical, chemical, and electrical properties of the *in vitro* cell culture environment will perhaps be the single greatest contribution of microfabrication methods to the field of biology. Engineering the cellular microenvironment can be used to create more physiologically relevant culture conditions, study biological phenomena (e.g., growth, development, response to damage, death), or to direct the behavior of cells toward specific industrial outcomes (e.g., tissue engineering, chemical manufacturing). There are three ways in which the cellular microenvironment can be altered—mechanically, chemically, or electromagnetically. Although most methods intend to alter the cellular microenvironment in only one of these ways, it is often difficult to avoid secondary perturbations to the cellular environment via one or both of the other modalities. Here, we review the major methods for altering the microenvironment using microfabrication technology.

## 32.4.1 MECHANICAL MICROENVIRONMENT

### 32.4.1.1 Static Manipulations

Mechanical manipulations of the cell microenvironment can be either static or dynamic. Static manipulations consist of modifications to the physical environment with which the cell interacts. Altering the topography of the cell culture substrate is useful for understanding how cell growth and proliferation is influenced by topographical or morphological cues, and how cells explore or migrate in specific physical environments. Many studies have shown that topographical cues alone can alter cell behavior.<sup>20–22</sup> The recent development of nanofabrication methods<sup>23–27</sup> has enabled the creation of substrate topographies similar in size to those cells encounter *in vivo*, such as the protein fibers that comprise the extracellular matrix (Figure 32.7).

A variety of different microfabrication methods have been used to create complex topographies on cell culture substrates. Many of these studies<sup>20</sup> require expensive fabrication tools and complex methods and will not be discussed further here. The most common method of adding topography to cell culture substrates is by using photolithography to either add features to the substrate or mask the substrate for selective chemical or plasma etching. Alternatively, cell culture substrates can be molded<sup>28–30</sup> or embossed<sup>31</sup> directly from photolithographically defined substrates. Photolithography and soft lithography have been used to generate a wide range of cell culture substrate topographies<sup>28,32</sup> including replicas of cells<sup>33</sup> (Figure 32.8).

More complex 3D topographies can be generated using 3D patterning techniques.<sup>34</sup> The simplest method of generating 3D topographies is employing multiple iterations of photolithography (Figure 32.9a). Unfortunately, multilayer photolithography requires precise alignment of each subsequent layer and may result in poor feature resolution and fidelity. Generating multiple level features in a single photolithography step can be accomplished using gray-scale photolithography (Figure 32.9b). Gray-scale photolithography uses positive photoresists and masks printed with different gray levels<sup>35</sup> (i.e., transparency) or masks made of microfluidic channels filled with dye.<sup>36</sup> Although gray-scale photolithography is effective at making features of different heights, it cannot make more complex features such as overhangs, closed loops, or hollow objects. These types of complex 3D structures require methods such as multiphoton polymerization.<sup>37–39</sup> Multiphoton polymerization uses long wavelength lasers, where each photon has half the energy necessary to activate the photoinitiator in a photoactive polymer. When two beams are timed so that two long wavelength photons arrive at a single photoinitiator molecule at the same time, the photoinitiator absorbs both photons and is excited to its active state causing localized polymerization. By moving the focal point of the two incident laser beams, complex 3D structures can be constructed (Figure 32.9c). These features can subsequently be combined with soft lithography to form more intricate 3D structures than those that can be produced with standard photolithography (Figure 32.9d–e).<sup>39</sup>

### 32.4.1.2 Dynamic Manipulations

Dynamic manipulations of the mechanical microenvironment consist of active elements that impose mechanical force on cells. Many cell types experience mechanical forces *in vivo*. Chondrocytes and osteoblasts within skeletal and load bearing connective tissues endure large compressive forces

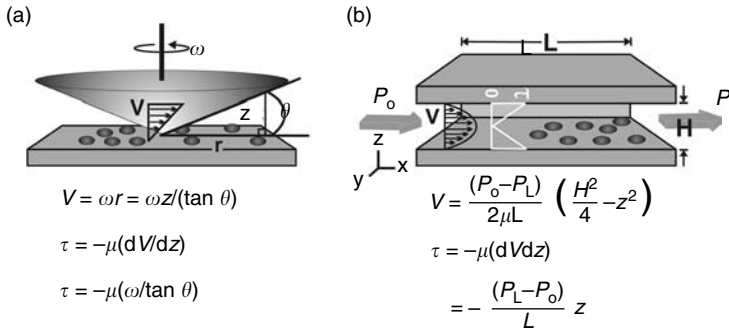

**FIGURE 32.10** Deformable substrates. (a) Force (black arrows) can be used to bend the cell culture substrate and mechanically strain attached cells. (b) The cell culture substrate can also be stretched, but due to the Poisson effect this results in accessory stresses and strains perpendicular to the direction of applied force (gray arrows), preventing mechanical loads from being truly uniaxial. (c–d) Microfabrication technology enhances the ways in which cells can be mechanically strained. Cells could be cultured on thin PDMS membranes that are patterned with a variety of unique topographies, and then mechanically strained when the membrane is deflected by pressurizing underlying microfluidic channels. (Adapted from Hoffman, J. M., et al., *Adv Mater*, 16, 23, 2201, 2004. With permission.)

during locomotion. Osteoblasts and endothelial cells experience large shear forces generated by fluid flow within the osteon and vasculature, respectively. The ability to culture cells in environments where different forms of mechanical loadings can be imposed provides invaluable insight into cell physiology.

A variety of methods have been developed to apply mechanical forces to cells.<sup>40</sup> One very common method is to culture cells on a deformable substrate that can be bent (Figure 32.10a) or stretched (Figure 32.10b). Transducers provide controlled loading with user-defined strains and strain rates, or cyclic loading with user-controlled frequency and amplitude. A recent advance in microfabrication technology now allows cells to be grown on microtopographies while being dynamically loaded. The method developed by Folch and coworkers<sup>41</sup> employs thin PDMS membranes less than 20  $\mu\text{m}$  thick that are patterned with complex substrate topographies (Figure 32.10c–d). The membranes are bonded to microfluidic channels connected to pressure or vacuum sources, allowing the membranes to be deflected dynamically. The resulting concave or convex surfaces mechanically strain cells interacting with the unique substrate topography.

Fluidic shear forces are commonly generated *in vitro* using cone and plate viscometers.<sup>42</sup> A cone and plate viscometer (Figure 32.11a) consists of a cone that rotates in close proximity to a flat substrate. Constant shear stress is created in the region between the cone and the substrate by engineering the taper of the cone to offset the influence of the increasing tangential velocity that

**FIGURE 32.11** Generating shear forces. (a) Cone and plate viscometers create constant shear stress throughout the volume between the cone and substrate. The shear stress ( $\tau$ ) is independent of the radius ( $r$ ) or distance from the cell culture surface ( $z$ ), and dependent on the angular velocity ( $\omega$ ) of the cone and the angle of the taper ( $\theta$ ). (b) Microfluidic channels have at least one dimension less than 1 mm creating a laminar flow regime restriction that creates steady velocity profiles and shear stresses along the direction of fluid flow. The well-characterized flow regime allows mathematical calculation of both the velocity profile ( $V$ ) and the shear stress distribution across the channel (white graph perpendicular to fluid flow direction) using only the microchannel dimensions ( $L$  and  $H$ ) and the applied pressure gradient ( $P_0$  and  $P_L$ ). The negative sign convention indicates that shear forces push down on the cells.

accompanies increasing radius on the shear rate. Cells cultured on the flat substrate are exposed to constant shear forces and can be examined for behavioral or physiological effects.

Microfabrication technology provides a complementary method to expose cells to specific shear stress environments. Straight microfluidic channels (Figure 32.11b) with highly precise dimensions and controlled fluid flow rates have been used to study the effects of shear stress on cells.<sup>43,44</sup> Microfluidic channels have one or more dimensions less than 1 mm, which forces flowing liquids to be confined to laminar flow regimes.<sup>45</sup> Laminar fluid flow is characterized by a parabolic velocity profile that does not change downstream of a short flow stabilization region near the entrance of the microchannel. The steady-state parabolic velocity profile produces constant shear stresses in the direction of fluid flow. The velocity profile can be calculated from the fluid channel dimensions and the applied pressure gradient, and be used to calculate the shear stress throughout the microchannel. Because the velocity profiles near the junction of two microchannel walls can be more complex to predict, cells are usually cultured near the middle of microchannels that are much wider than they are tall.

### 32.4.2 CHEMICAL MICROENVIRONMENT

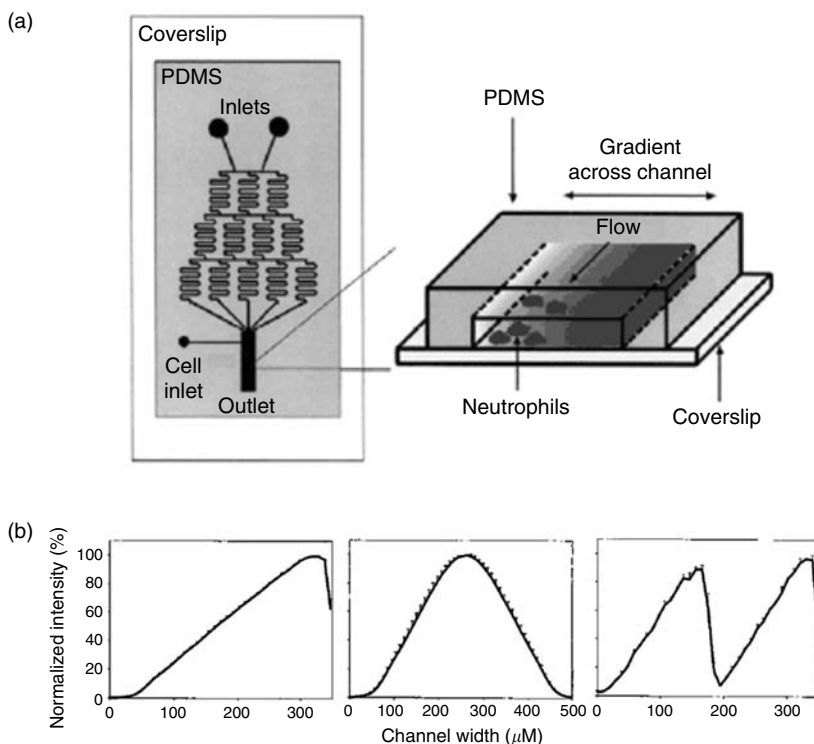

Chemical manipulation of the cellular microenvironment encompasses chemical modification of the physical components with which the cell comes into contact (i.e., substrate, extracellular matrix, etc.), and the distribution of soluble chemical species in the culture medium in which the cells are grown. Numerous methods have been developed to modify the chemistry of cell culture substrates.<sup>1,46</sup> Here we focus our discussion on different microfluidic methods for controlling the distribution of soluble chemical species in the cellular microenvironment. For this application, microfluidic devices offer unique advantages due to their restriction to laminar fluid flow.<sup>45</sup> In addition to having a constant, parabolic velocity profile, laminar fluid flow is also characterized by more linear streamlines that follow the contours of the microchannel. The fluid does not flow in circuitous, disorganized paths as it does in turbulent flow. The lack of eddies and convective mixing results in a system where chemical species can only mix via diffusion. This limitation allows creation of predictable chemical gradients, which is not possible in conventional cell culture systems. The lack of convective mixing also allows tight control over the location of different flowing streams within the microchannel,

which has proven useful for exposing specific regions of cells to defined chemical environments. Here, we will discuss both gradient generators and subcellular fluidic compartmentalization using microfluidic channels.

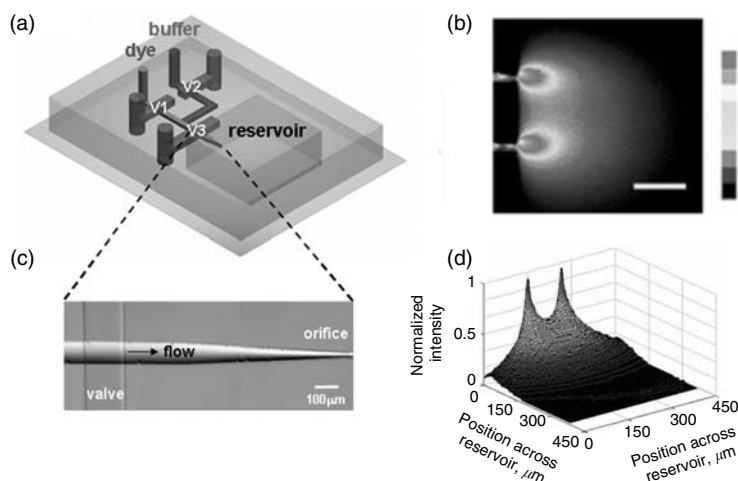

### 32.4.2.1 Gradient Generators

Gradients of diffusible biological molecules play critical roles in many biological phenomena including development, cancer, inflammation, and wound healing. A wide variety of methods have been developed to expose cells to soluble chemical gradients.<sup>47–52</sup> Unfortunately, all of these methods offer little temporal or spatial control over the gradient, and in many cases provide no way to quantify the gradient that each cell perceives.

A device we will refer to as the “Premixer Device” (Figure 32.12a)<sup>53</sup> has been used to expose a variety of cells to biochemical gradients.<sup>54–56</sup> The device generates steady-state, user-controlled gradients using constant fluid flow. The device splits and recombines inlet fluids in an upstream microfluidic mixer to generate a variety of different gradient shapes (Figure 32.12b). The use of transparent PDMS to fabricate the device and the closed channel geometry allows direct quantification of the gradient to which cells are exposed using a conventional wide field fluorescence microscope. The only disadvantage of the device is that it exposes cells to fluid flow and shear forces that can destroy autocrine or paracrine signaling, activate intracellular signaling cascades, and alter cell migration.<sup>57</sup>

**FIGURE 32.12** Premixer device. (a) An upstream microfluidic mixer splits and recombines fluids to expose cells to user-defined gradients under constant fluid flow. (b) The premixer can be designed to generate a wide variety of gradient shapes. (Adapted from Jeon, N. L., et al., *Nat Biotechnol*, 20, 8, 826. Copyright 2002. With permission from Macmillan Publishers Ltd.)

**FIGURE 32.13** Microfluidic multi-injector. (a) 3D schematic representation of the device shows two small-diameter channels under the control of microfluidic valves that pneumatically eject fluid into a cell culture reservoir to form soluble molecule gradients. (b) Top view of the device in operation forming gradients of fluorescein isothiocyanate (FITC)-conjugated dextran. (c) 3D plot of the fluorescence intensity within the cell culture reservoir. (Adapted from Chung, B. G., et al., *Lab Chip*, 6, 6, 764, 2006. Reproduced with permission from The Royal Society of Chemistry.)

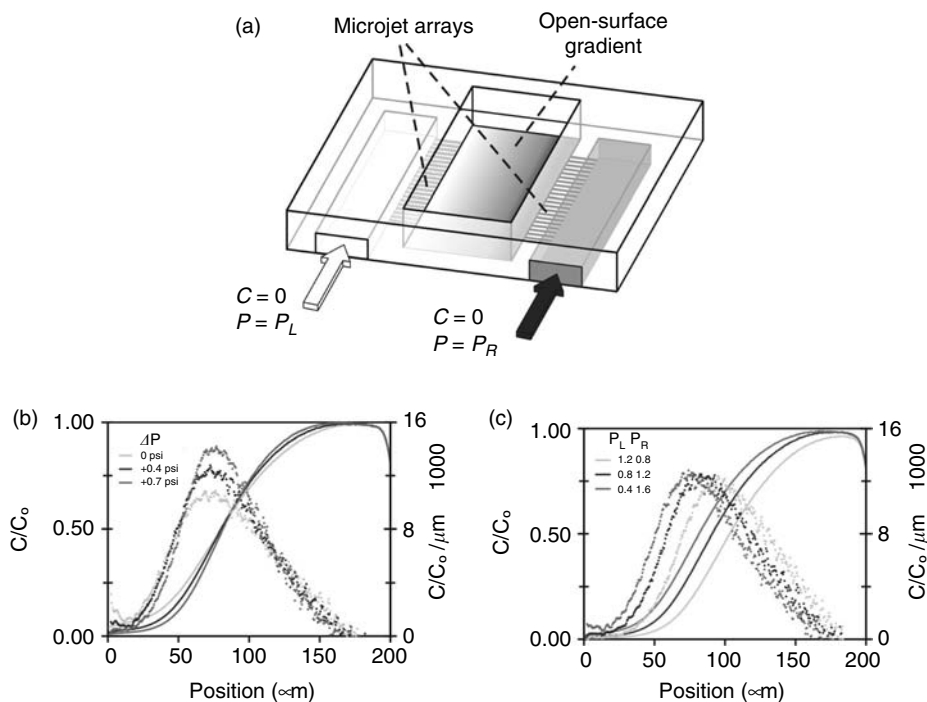

Another recently developed microfluidic device replicates a method developed by Gunderson and Barrett<sup>49</sup> in a microfluidic platform. In the Microfluidic Multi-injector<sup>58</sup> (Figure 32.13a), fluids are ejected pneumatically out of a pair of small orifices into a larger cell culture reservoir, under the control of independent microfluidic valves. Once the fluid is ejected into the reservoir, it forms a diffusive gradient (Figure 32.13b–c). Although the device generates gradients without appreciable fluid flow in the cell culture reservoir, as evidenced by a symmetric gradient, it cannot generate steady-state gradients or the complex gradients of the Premixer Device.

A microfluidic generator called the “Microjets Device” (Figure 32.14a) generates stable gradients on open surfaces without exposing cells to appreciable fluid flow.<sup>59</sup> The open architecture allows efficient nutrient and gas exchange, and the lack of flow minimizes shear forces and facilitates autocrine and paracrine signaling. Like the previously described device, the Microjets Device generates gradients by pneumatically ejecting fluids out of small orifices, which minimize convective flow and allow a diffusive gradient to form in the cell culture area. However, the Microjets Device uses two opposed arrays of small orifices delivering different concentrations of biochemical factor to generate steady-state chemical gradients. In addition, dynamic changes to the slope and position of the gradient can be accomplished by adjusting the air pressures driving the fluid out of each orifice array (Figure 32.14b–c). The Microjets Device is not capable of generating the complex gradients possible with the Premixer Device nor can the gradient be visualized with a conventional wide field fluorescence microscope. The architecture of the device requires confocal microscopy to evaluate the gradient to which the cells are exposed.

### 32.4.2.2 Subcellular Chemical Compartmentalization

The laminar flow restriction and small dimensions of microfluidic devices have been exploited to expose different portions of a single cell to different chemical environments. A method developed by Whitesides and coworkers<sup>60,61</sup> utilized hydrodynamic focusing<sup>62</sup> on a microfluidic platform to selectively label portions of a cell with different dyes (Figure 32.15). Laminar fluid flow confined the dye solution to particular regions of the channel despite being in contact with streams containing

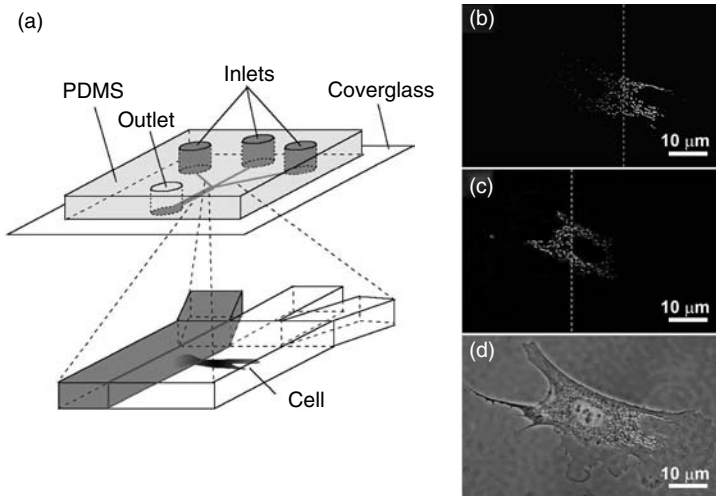

**FIGURE 32.14** Microjets device. (a) 3D schematic representation of the device showing opposed arrays of small orifices (i.e., small microfluidic channels) creating gradients in an open cell culture area. (b) Plot of the concentration profile (solid lines, left axis) and profile derivatives (dots, right axis) for three different pressure conditions illustrating how increasing the driving pressure delivered to the respective orifice arrays by the same magnitude causes an increase in gradient slope with little change in the gradient position. (c) Equal magnitude driving pressure offsets cause the gradient to shift position within the cell culture reservoir but does not affect the gradient shape. (Reprinted from Thomas M., et al., *Appl Phys Lett*, 89, 114103, 2006. Copyright 2006. With permission from American Institute of Physics.)

no dye. Cells within the microchannel were thus labeled only in the specific subcellular regions exposed to a particular dye. Microfluidic hydrodynamic focusing has since been used to examine the dynamics of epidermal growth factor (EGF) receptor signaling<sup>63</sup> and the effects of focal application of agrin in stimulating *in vitro* neuromuscular junction formation.<sup>64,65</sup>

Microfluidic channels can also be used to physically compartmentalize portions of a cell. Jeon and coworkers<sup>66</sup> replicated a Campenot<sup>67</sup> chamber using microfluidic channels to provide subcellular isolation of central nervous system growth cones from their cell bodies. Neurons seeded in a central microchannel were allowed to extend axons through narrow restrictions to another large microchannel (Figure 32.16). The restrictions prevent appreciable fluid connections from being established between the two microchannels allowing the growth cones to be exposed to a different chemical environment than the cell bodies.

### 32.4.3 ELECTRICAL MICROENVIRONMENT

Several important cell types are sensitive to the electrical characteristics of the cellular microenvironment. Neurons, cardiac myocytes, and retinal cells all generate and can be stimulated with electrical impulses. Because of the importance of these cell types, various methods have been devised to record or stimulate electrical activity within cells cultured *in vitro*. Traditionally, the electrical activity of cells has been recorded or stimulated by simply placing electrodes in the

**FIGURE 32.15** Hydrodynamic focusing. (a) A 3D schematic representation of the device shows how a fluid stream containing dye was confined by adjacent flow streams to expose only certain subcellular regions of the cell to the dye. (b) A bovine capillary endothelial cell labeled on one side with Mitotracker Green, and (c) on the other side with FM Mitotracker Red CM-H<sub>2</sub>XRos. **FIGURE 32.16** Physical compartmentalization. (a) 3D schematic representation and 2D cross section of the device shows how neurons loaded in the somal side of the device (black) are unable to cross through the narrow constriction, unlike their axons, which can extend into the axonal side (white). (b) Texas red dextran injected in the axonal side (right) does not cross into the somal side showing fluidic isolation between the compartments. (c) When green cell tracker dye is loaded into the axonal side it retrograde labels the axons and somas of the neurons. (Adapted from Taylor, A. M., et al., *Nat Methods*, 2, 8, 599. Copyright 2005. With permission from Macmillan Publishers Ltd.)

culture medium, or alternatively, using a process known as “patch clamping” (Figure 32.17a). Patch clamping uses glass capillaries that are heated and then pulled at a defined speed to form a drawn tip approximately 1 μm in diameter. The drawn capillary, or micropipette, is then filled with a conductive electrolyte solution and a metal electrode, and brought to the surface of a cell using a micromanipulator. In this configuration the micropipette can be used to record the extracellular electrical activity or stimulate cells. To measure single cell transmembrane ion currents, a small hole is ripped in the cell membrane by placing the micropipette tip in contact with the cell membrane and

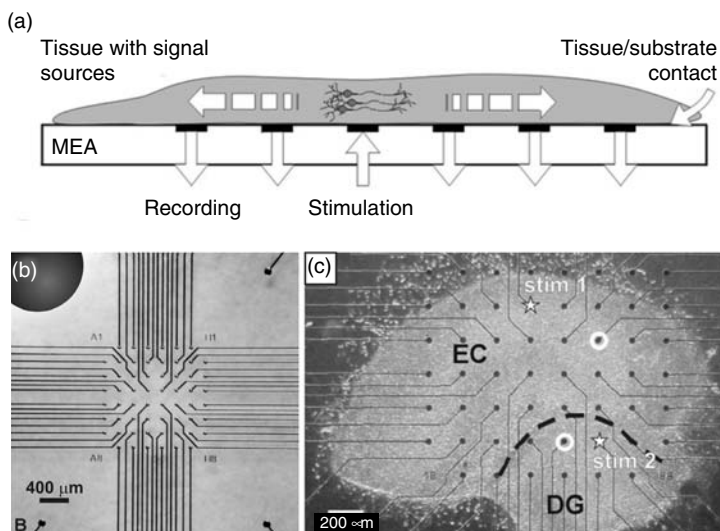

**FIGURE 32.17** Micropipette electrical recording/stimulation. (a) Pulled glass pipettes are used to measure the electrical activity of cells across the cell membrane ( $V_1$ ) by accessing the intracellular fluidic environment, or extracellularly ( $V_2$ ) by simply placing the micropipette near the cell. (b) A major limitation of micropipette-based electrical recording/stimulation is the inability to record from more than a few cells at a time due to space limitations of the micropipette set up. (Adapted Fitzsimonds, R. M., et al., *Nature*, 388, 439. Copyright 1997. With permission from Macmillan Publishers Ltd.)

gently pulling suction in the capillary. The cell membrane is pulled into the micropipette forming a high-resistance seal, and ruptured within the micropipette to provide fluidic, and thus electrical, access to the intracellular environment.

Although the quality of the recordings or stimulations is excellent using micropipettes, the method suffers significantly from its lack of scalability. It is very difficult to record or stimulate electrical activity in more than just a few cells due to space limitations (Figure 32.17b). Trying to comprehensively characterize the electrical activity of cells within a tissue section or large dissociated culture is not possible using individually placed micropipettes. It is also difficult to record from or stimulate cells for more than a few hours due to biofouling or clogging of the micropipette tip by proteins and cell components, and the instability of any seal formed between the micropipette and the cell membrane.

Microelectrode arrays (MEA) offer a solution to both the scalability and long-term recording limitations of micropipette electrodes. MEAs (Figure 32.18) are made by depositing a conductive metal on a cell culture substrate, patterning the surface with photolithography, and using the photoresist pattern as a mask for subsequent metal etching. After selective metal etching, the photoresist is stripped and the resulting metal electrodes are connected to a multichannel recorder or stimulator. Dissociated cells or tissue sections are then seeded on the MEA and can be recorded from or stimulated electrically. Micron-scale control over the size, shape, and position of the metal electrodes allows many electrodes to be placed on the cell culture substrate in a variety of configurations. Because MEAs are integrated into the cell culture substrate, they offer the ability to record from cell cultures for long periods of time.

MEAs have been used primarily to record electrical activity in tissues and cultured cells,<sup>68</sup> although they can also be used to electrically stimulate cells<sup>69,70</sup> or other functions such as electroporate dissociated cell cultures with precise spatiotemporal control.<sup>71</sup> MEAs are extremely useful for providing a comprehensive electrical profile of an entire cell culture, or for increasing experimental throughput by simultaneously recording from or stimulating multiple cells.<sup>68</sup> Although the quality of the electrical recordings of MEAs is not as good as patch clamping, it is comparable with or better than other extracellular recording methods. Effective recording or stimulation of electrically active cells using MEAs requires close contact between the cell and the electrode. Large cell-electrode distances will make action potentials difficult to detect and electrical activity difficult to stimulate due to decreasing field strength with distance from the cell or electrode, respectively. To

**FIGURE 32.18** Microelectrode arrays. (a) MEAs can be used to record or stimulate electrical activity in dissociated cell cultures, engineered 3D cultures, or whole tissue explants. (b) MEAs are constructed using metal deposition and photolithography resulting in intricate, user-defined electrode configurations. (c) Brain tissue explant cultured on a MEA after 7 days *in vitro*. (Adapted from Stett, A., et al., *Anal Bioanal Chem*, 377, 486, 2003. Copyright 2003. With permission from Springer Science and Business Media.)

encourage close contact between cells and electrodes, MEAs are often patterned with adhesive proteins such as poly(lysine) and/or extracellular matrix proteins, or adhesion-promoting self-assembled monolayers using microstamping or other patterning techniques.<sup>1</sup>

MEAs have an added advantage in that they are compatible with and can be incorporated into many other methods discussed in this chapter to address more complex questions. For example, microfluidic channels constructed around an MEA<sup>72</sup> would allow the electrical activity of cells or whole tissue sections to be recorded or stimulated while the cells are exposed to unique chemical, mechanical, or thermal<sup>73</sup> environments. Cells could be exposed to chemical gradients, regulated shear forces, or disparate fluidic environments for many days while under constant electrical monitoring or stimulation.

## 32.5 SUMMARY

Microfabrication technology has provided a plethora of tools and methods to engineer the position and microenvironment of cells *in vitro*. The unprecedented level of control over the mechanical, chemical, and electrical nature of the cellular microenvironment allows investigation of questions not addressable with conventional tools and methods. The unique insight into normal and abnormal cell behavior afforded by microfabricated tools and methods may one day lead to cures for injuries and diseases, and the ability to direct cell growth and behavior for tissue engineering or industrial applications.

Although microfabrication technology has greatly enhanced the type of complex environments in which cells can be grown and studied, there is a large need for the development of complementary analysis methods to detect and characterize changes in cell response. Existing analysis methods, some of which are covered in the other chapters of this book, are often not adaptable to or optimized for use with microfabricated cell culture tools or environments. The development of novel methods that integrate engineered cell culture environments with complementary analysis tools would greatly accelerate our understanding of normal and abnormal cell behavior.

## 33.1 INTRODUCTION

Since the concept of micro total analysis systems ( $\mu$ TAS) was first proposed,<sup>1</sup> the field has advanced rapidly, with ongoing developments promising to profoundly revolutionize modern bioanalytical platforms and methodologies. Whether termed  $\mu$ TAS, lab-on-a-chip, or microfluidics, the technologies that define the field offer important innovations capable of transforming the ways in which bioanalytical techniques are performed. For example, reduced size and power requirements can enable improved portability and higher levels of integration, with lower per-unit cost for disposable applications. Low volume fluid control enabled by microfluidics allows smaller dead volumes and reduced sample consumption, while many pumping methods including capillary action and electroosmotic flow scale favorably in these systems, enabling precise and valveless flow control at the microscale. Similarly, thermal time constants tend to be extremely small due to large surface area to volume ratios inherent in these systems, reducing the onset of significant Joule heating during electrokinetic separations and thus allowing higher separation voltages and shorter analysis times with equivalent or better separation resolution for complex mixtures in an integrated format.

A significant advantage of microfluidics is that lithographic and replication-based fabrication techniques readily lend themselves to the formation of complex systems, providing a path for effective manufacturing of highly parallel analytical tools. Specifically, we consider here the promise that microfluidics technology holds for realizing robust multidimensional separations of proteins and peptides in an integrated platform. Assuming the separation techniques used in a given two-dimensional

(2-D) system are fully orthogonal, that is, the two separation techniques are based on independent physicochemical properties of analytes, the overall peak capacity is the product of the peak capacities of the individual one-dimensional (1-D) methods.<sup>2</sup> As a result, multidimensional systems are of great interest for the analysis of complex mixtures.<sup>3</sup> Nowhere is the demand for effective analysis of complex matrices greater than in the field of proteomics. A major challenge faced in proteomics analysis is the vast number of proteins present in a typical biological sample, together with the large variation of protein relative abundances (typically greater than 6 orders of magnitude,<sup>4</sup> and higher than 10 orders of magnitude for the case of blood plasma<sup>5</sup>), which ultimately dictate the need for high resolution separations to be performed on protein or peptide samples before detection by mass spectrometry (MS). Thus, multidimensional separation technologies capable of reducing dynamic range and enhancing detection sensitivity without substantially sacrificing analytical throughput are highly desirable for many proteomic applications.

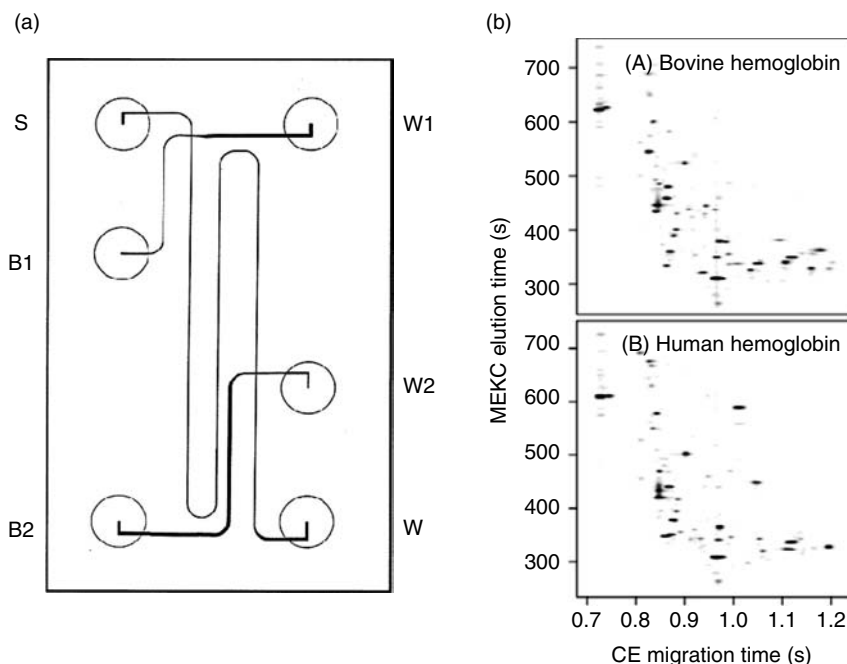

While intact protein analysis via 2-D polyacrylamide gel electrophoresis (2-D PAGE)<sup>6</sup> and bottom-up peptide analysis combining multidimensional chromatography with tandem MS analysis<sup>7,8</sup> remain the workhorse technologies for most modern proteomic studies, ongoing improvements in microfluidics for sample preparation and separations in proteomics are beginning to reveal their potential impact on the field. In this chapter, microfluidic platforms for protein and peptide analysis employing multidimensional electrophoretic separations and combined electrophoretic and chromatographic separations are discussed.

## 33.2 MICROFLUIDIC PLATFORMS FOR MULTIDIMENSIONAL SEPARATIONS

### 33.2.1 TIME-MULTIPLEXED SEPARATIONS

The majority of reported multidimensional microfluidic systems employ serial separations that are time multiplexed. In this approach, fractions from the first separation dimension are sampled sequentially, with each fraction separated in series within the second dimension while the first-dimension separation continues. In one of the first demonstrations of this approach, Rocklin et al.<sup>9</sup> performed 2-D separations of peptide mixtures in a microfluidic device using micellar electrokinetic chromatography (MEKC) and capillary zone electrophoresis (CZE) as the first and second dimensions, respectively. A schematic representation of their platform, fabricated in a glass substrate, is shown in Figure 33.1a. The MEKC separation was performed within a 65-mm-long serpentine channel located between the upper and lower channel intersection points shown in the figure, with a 10-mm-long CZE separation performed past the lower channel intersection. With a time scale for CZE on the order of a few seconds, substantially faster than the MEKC separation, large numbers of fractions could be sampled from the first dimension and separated by CZE with an overall analysis time under 10 min. Because MEKC is a transient electrokinetic separation, only a small portion (~10%) of the analyte in the first dimension could be sampled into the CZE microchannel, since no fractions could be sampled while the second dimension separation was being performed. Despite this sample loss issue, a revised chip design was later reported for peptide separations with a peak capacity greater than 4000, such as the comparative separation of tryptic digest from bovine and human hemoglobin shown in Figure 33.1b revealing distinct peptide variations between these samples.<sup>10</sup>

Similar approaches based on time multiplexing have been employed by a number of researchers. For example, Gottschlich et al.<sup>11</sup> used a spiral shaped glass channel coated with a C<sub>18</sub> stationary phase for performing chromatographic separation of trypsin-digested peptides. By providing a cross interface, peptides eluted from an MEKC<sup>9</sup> or reversed-phase<sup>11</sup> chromatography channel were sampled and rapidly separated by CZE in a short glass microchannel. Herr et al.<sup>12</sup> similarly coupled isoelectric focusing (IEF) with serial CZE for 2-D separations of model proteins, a concept that

**FIGURE 33.1** Time-multiplexed MEKC/CZE peptide separation chip schematic (From Rocklin, R. D. et al., *Anal. Chem.*, 2000, 72, 5244–5249.) and (b) pseudo-gel views for chip-based separations of human and bovine hemoglobin. (From Ramsey, J. D. et al., *Anal. Chem.*, 2003, 75, 3758–3764.)

was later implemented in a poly(dimethylsiloxane) (PDMS)-based microfluidic system using elastomeric valving to isolate the separation dimensions.<sup>13</sup> In addition, Shadpour and Soper<sup>14</sup> developed a microfluidic chip combining sodium dodecyl sulfate (SDS) gel electrophoresis with MEKC, again with multiple fractions sampled serially from the gel electrophoresis separation for time-multiplexed fractionation by MEKC in the second dimension.

In each of the preceding examples, the separations were time multiplexed, with rapid second dimension separations chosen to enable repeated sampling of analyte eluted from a slower first dimension separation. Such time-multiplexed separations have also been employed in multidimensional capillary separations, for example, through the combination of a first dimension chromatographic separation together with a second dimension separation based on CZE,<sup>15</sup> with low dead-volume switching valves used to couple the separation dimensions. For many applications, multidimensional microfluidic systems employing time-multiplexed separations may not offer compelling advantages over their capillary analogs, but rather introduce additional complexities, costs, and performance limitations, which may be avoided through the use of more traditional capillary technologies. On the other hand, unique benefits exist for applications that can leverage the small footprints and integrated nature of these microfluidic platforms, particularly when coupled with on-chip sample preparation.

### 33.2.2 SPATIALLY MULTIPLEXED SEPARATIONS

In contrast to time multiplexing, high-throughput multidimensional separations may also be performed using spatial multiplexing, with an array of second dimension microchannels used to simultaneously separate analyte sampled as multiple fractions from the entirety of a first dimension separation channel. Using this approach relaxes the requirement for the second dimension separation to be substantially faster than the first dimension, opening the door to a wider range of potential separation modes. Furthermore, spatial multiplexing enables complete sampling of the first

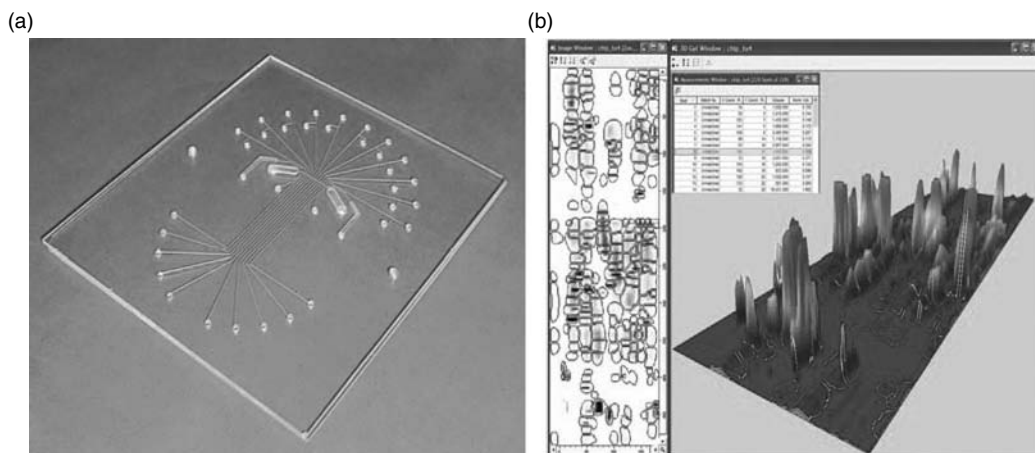

dimension separation, even for transient separation modes, thereby preventing sample loss due to a duty cycle mismatch between the dimensions. The use of spatial multiplexing also leverages a significant advantages of microfluidics, namely the ability to combine large numbers of channels in a single chip without the need for complex fluidic interconnects between the channels.

The concept of spatially-multiplexed microfluidic separations was first embodied in a micro-fabricated quartz device proposed by Becker et al.<sup>16</sup> which contained a single channel for a first dimension and an array of 500 parallel channels with submicron dimensions positioned orthogonally to the first dimension. While no separations were actually performed in this device, the concept was later extended and validated by several groups. For example, Chen et al.<sup>17</sup> described a microfluidic 2-D capillary electrophoresis platform based on a reconfigurable system of six individual PDMS layers. The chip consisted of a 2.5-cm-long microchannel for performing IEF, with an intersecting array of parallel 6-cm-long microchannels for SDS-PAGE. This six-layer PDMS microfluidic device required the alignment, bonding, removal, realignment, and rebonding of various combinations of the six layers to perform a full 2-D protein separation.

A fully integrated system developed by Li et al.<sup>18</sup> combined IEF with SDS gel electrophoresis of intact proteins in a single polycarbonate chip containing 10 parallel second dimension microchannels (Figure 33.2). By combining both separation dimensions in a single rigid polymer chip, dispersion of analyte during the transfer between the dimensions was minimized. Furthermore, different separation media were employed in each of the dimensions, allowing sample mobility to be independently tailored for rapid free-solution IEF separations and high resolution SDS-capillary gel electrophoresis (CGE) separations. By using a replaceable polyethylene oxide (PEO) gel in the SDS-CGE channels, the interface between the separation media also provided for sample stacking during the transfer of focused proteins bands into the second dimension. Using this system, a comprehensive 2-D protein separation was completed in less than 10 min, with the majority of time consumed in the required SDS-protein complexation reaction. A peak capacity of  $\sim 170$  in the second dimension of size-based separation was estimated from a measured bandwidth of  $150\ \mu\text{m}$  over a 2.5 cm channel length. Because the separation mechanisms in IEF and SDS-CGE were completely orthogonal, the overall peak capacity was estimated to be 1700 (10 fractions from IEF  $\times$  170 from SDS-CGE). Improvements in peak capacity were proposed through the use of longer channels during the size-based separation, and by increasing the density of microchannels in the array to increasing the number of IEF fractions analyzed during the size-based separation. Owing to the use of parallel

**FIGURE 33.2** Schematic representation and photograph of a 2-D IEF/SDS-CGE microfluidic chip containing 10 spatially-multiplexed channels for SDS-CGE separation. (From Li, Y. et al., *Anal. Chem.*, 2004, 76, 742–748.)

**FIGURE 33.3** (See color insert following page 810.) (a) Microfluidic PMMA chip for 2-D IEF/SDS-CGE protein separations and (b) pseudo-gel image resulting from a yeast cell lysate separation.

separations in the second dimension, there is no accompanying increase in the analysis time. Further improvements in separation resolution were later achieved through the use of individual reservoirs for the injection of PEO gel and SDS solutions into the chip, and through electrical isolation of each second dimension channel. A revised chip design is shown in Figure 33.3a, with an example separation of intact proteins from yeast cell lysate depicted in Figure 33.3b.

Ivory and coworkers<sup>19</sup> demonstrated a multistage separation platform based solely on multiple IEF separations, with an initial separation performed in a straight channel using broad-range ampholytes, followed by a second separation using a set of orthogonal microchannels that terminated in reservoirs containing ampholytes covering more narrow pI ranges for higher focusing resolution. By providing multiple sets of the orthogonal channels, progressively narrower pI ranges were established within the main separation channel. Alternately, multiple parallel narrow-range IEF separations could be performed using the apparatus. A three-stage transient IEF separation was demonstrated in this system, and additional stages were proposed. Multidimensional microfluidic separation platforms with even higher dimensionality have been proposed, such as a concept for a four-dimensional (4-D) platform combining IEF, isotachopheresis (ITP), SDS-PAGE, and reversed-phase liquid chromatography (RPLC)<sup>20</sup> (Figure 33.4). It is not yet clear whether significant advantages can be realized by such high-dimensional fractionation, since analyte loss, dispersion, and dilution may ultimately prevent effective downstream detection (e.g., by MS), in particular given the relatively low loading capacities typical of many microfluidic systems. Regardless, this 4-D concept suggests an intriguing direction for new platforms and multidimensional separation modalities that can be enabled by the unique advantages offered by integrated microfluidics technology.

### 33.2.3 INTERFACING MULTIDIMENSIONAL SEPARATIONS WITH MS

Mass spectrometry is an essential tool for the characterization of biomolecules, revealing the charge-to-mass ratio of analyte molecules following ionization. There is a strong need for effective MS in the analysis of proteins and peptides, where MS coupling is required to provide sufficient mass resolution and sequence information for modern proteomic analyses. Unlike deoxyribonucleic acid (DNA), no techniques exists for the direct amplification of proteins, and thus detection sensitivity is paramount for the identification of low abundance species from limited samples. The matter is further complicated by the enormous dynamic range of protein abundance in complex samples. For

**FIGURE 33.4** Conceptual layout of a spatially-multiplexed 4-D microfluidic system combining IEF, ITP, SDS-PAGE, and RPLC. (From Ivory, C. F., *Electrophoresis*, 2007, 28, 15–25.)

multidimensional microfluidic technologies to substantially impact the field of proteomics, effective methods for MS interfacing are a necessity.

The integration of microfluidic systems and MS received substantial attention following demonstration of the first microfluidic electrospray ionization (ESI)–MS interfaces in 1997 by the groups of Karger and coworkers,<sup>21</sup> Ramsey and Ramsey,<sup>22</sup> and Aebersold and coworkers.<sup>23</sup> Extensive studies on ESI–MS interfacing for coupling microfluidics to MS have been reported, with online ESI–MS offering a simple approach for directly interfacing microfluidic analyses with MS, while providing good sensitivity and mass accuracy, and reproducible signals for effective analyte quantification. A number of reviews have appeared in recent years, which illuminate this topic. Oleschuk and Harrison<sup>24</sup> offer an early summary of microfluidic ESI–MS interfacing, and Sung et al.<sup>25</sup> provide a more recent review addressing this area. A further review by Limbach and Meng<sup>26</sup> in 2002 updates the developments in microfluidics for ESI–MS, and reviews by Figeys and Pinto,<sup>27</sup> Lion et al.,<sup>28</sup> and Marko-Varga et al.<sup>29</sup> focus on microfabricated systems in proteomics, including summaries of relevant microfluidic-to-MS interfaces. A more detailed discussion of microfluidic ESI–MS interfacing is provided in Chapter 53 by Lazar.

While ESI–MS is well suited as an interface between serial time-multiplexed microfluidic systems and MS, as reviewed by Foret and Kusý,<sup>30</sup> interfaces based on matrix-assisted laser desorption/ionization (MALDI) offer several important advantages for spatially-multiplexed (i.e., parallel analysis) microfluidics. Unlike online ESI–MS, MALDI–MS is an offline soft ionization method, which is typically applied to the analysis of solid phase analyte co-crystallized with an energy-absorbing matrix material on the surface of a supporting target plate. In comparison with ESI–MS, MALDI–MS tends to be more tolerant of salts and other sample contaminants, offers excellent detection limits, and produces mass spectra which are relatively simple to interpret due to the absence of multiple charge states. Although generally limited to the analysis of higher molecular weight species due to interference from matrix components below ~500 Da, MALDI–MS can be applied to a wide range of sample mass, with good sensitivity above 300 kDa, compared with less than 100 kDa for ESI–MS.

From the point of view of multidimensional microfluidic systems, the off-line nature of MALDI–MS analysis represents a key advantage. First, MALDI–MS allows on-chip sample processing steps to be decoupled from back-end MS analysis. This is necessary when, for example, the time scales for biomolecular separations and online MS data acquisition are incompatible. More importantly for the present discussion, off-line MALDI–MS analysis provides a method for coupling simultaneous parallel on-chip analyses with MS detection, where ESI–MS from multiple microchannels is simply

not practical or even feasible. It should be noted that although MALDI–MS is a serial process once the sample plate has been prepared, its high duty cycle enables high throughput for large numbers of deposited samples. For reviews of work in this area, Foret and Preisler<sup>31</sup> presented an early summary of microfabricated systems for MALDI–MS interfacing, and DeVoe and Lee<sup>32</sup> recently reviewed the current state of microfluidic interfacing with MALDI–MS. Additional discussion of microfluidic MALDI–MS interfacing may be found in Chapter 49 by Laurell.

For microfluidic systems that employ parallel chromatography channels, MALDI–MS interfacing is particularly straightforward. The concept of interfacing multiplexed capillary chromatography separations with MALDI–MS for high-throughput proteome analysis was first described by Aebersold and coworkers<sup>33</sup> using a system comprising four parallel capillary chromatography columns coupled with MALDI–MS/MS. In their system, a network of capillaries connected together with microjunctions was used to interface a single gradient pump to four parallel separation columns, with eluent from each column deposited by direct mechanical spotting onto a MALDI target at a flow rate of 1  $\mu\text{L}/\text{min}$  using a commercial fraction collector. Flow rate variations of  $\pm 5\text{--}6\%$  were observed between the columns, presumably due to variations in hydrodynamic flow resistance resulting from inhomogeneity of the packed silica beads. In a recent demonstration by Knapp and coworkers,<sup>34</sup> a multichannel cyclic olefin copolymer (COC) chip was developed for parallel nanoflow RPLC analysis. Chip effluent was deposited onto a MALDI target through an electrically mediated deposition technique,<sup>35</sup> which was shown to be robust for the case of a two-channel chromatography chip.

While electrospray<sup>36</sup> and pulsed electric field<sup>35</sup> deposition has been demonstrated from multichannel chips, there are several disadvantages associated with the use of electric fields to assist sample deposition. In addition to increased system complexity, the reliability and repeatability of droplet deposition degrade as the number of parallel channels is increased. In contrast, the direct mechanical spotting strategy described by Aebersold and coworkers<sup>33</sup> in a capillary format is well suited for multichannel microfluidic chips employing a chromatographic separation in the second dimension. For example, the eight-channel COC chip shown in Figure 33.5 contains 100- $\mu\text{m}$  wide and 60- $\mu\text{m}$  deep channels, with a single fluid port connected to all eight channels through a symmetric on-chip splitter. The end of the chip was cut with a high-speed semiconductor dicing saw to expose the channel exits. Using a syringe pump, a panel of nine model peptides were deposited onto 64 target spots (8 channels  $\times$  8 spotting events) on a custom MALDI target, with a target deposition volume of 150 nL per spot corresponding to sample amounts ranging from 25 to 75 fmol for each peptide. Using a Kratos Amixa MALDI-time-of-flight (TOF) instrument, the resulting spectra showed good uniformity, with an average relative standard deviation (RSD) of 44% across all peptides.

**FIGURE 33.5** (a) Photo of an eight-channel COC chip aligned to a MALDI target mounted on a three-axis robotic positioner and (b) close up of chip exit showing droplet formation.

This compares well with an RSD of 50% in MALDI signal intensities reported for multiple peptide spots deposited from a single capillary using an optimized matrix seed layer technique.<sup>37</sup> Further improvements in deposition volume uniformity were realized for an eight-channel chip containing a methacrylate monolith developed for reversed-phase chromatography in the second separation dimension, with negligible variations at flow rates down to 200 nL/min per channel.

### 33.3 METHODS DEVELOPMENT GUIDELINES

#### 33.3.1 FABRICATION OF SPATIALLY MULTIPLEXED MICROFLUIDIC CHIPS

There are a number of practical issues that must be addressed to realize functional multidimensional microfluidic separation platforms. For devices based on spatially-multiplexed microfluidics, challenges exist even at the fabrication level, since producing microfluidic substrates with large numbers of parallel channels can be difficult. For example, when rapid prototyping methods based on hot embossing of thermoplastics such as polymethyl methacrylate (PMMA) or COC are used for substrate patterning, high frictional forces imposed during demolding of the plastic from dense microchannel arrays can lead to distortion of channel geometry, substrate warping, template damage, and in extreme cases prevent demolding from occurring entirely. It can also be difficult to achieve sufficient adhesion strength when bonding chips containing closely-spaced microchannels due to the reduced bond surface area. While these problems can be alleviated by employing low aspect ratio and tapered channel geometries, limiting the overall chip real estate occupied by the channels, and by keeping “reasonable” spacing between adjacent channels, such solutions can often be in conflict with desired performance goals for the system. The appropriate channel spacing must be evaluated on the basis of the particular fabrication methods, materials, and channel dimensions being employed, and weighed against potential performance losses resulting from a compromised design.

#### 33.3.2 ELECTRICAL AND HYDRODYNAMIC CROSSTALK

Another fundamental challenge results from electrical and hydrodynamic crosstalk between multiple interconnected channels that are inherent in spatially-multiplexed systems. To illustrate this point, consider the schematic representation of the 2-D IEF/SDS–CGE protein separation chip previously depicted in Figure 33.2a. This chip contains 11 parallel channels above the horizontal IEF channel, and 10 parallel channels below. As shown in the figure, each of these channels terminate in one of two common reservoirs, which connect the distal ends of the upper and lower channel arrays. In practice, this configuration results in a resistive network that shunts electrical current through the reservoirs during IEF separation, thereby producing an uneven electric field distribution within the IEF channel. More significantly, both analytes and ampholytes (for the creation of pH gradient in the IEF channel) can be unintentionally injected into the upper and lower channel networks by electrophoresis, resulting in potentially severe sample loss, and preventing establishment of the desired pH gradient for the present example of IEF as the first separation dimension. Issues with crosstalk can also manifest during hydrodynamic sample injection, since the resistive network introduced by the interconnected SDS–CGE channels applies equally to hydrodynamic and electrical current shunts.

One approach to solve this problem would be to integrate flow control elements such as elastomeric valves into the system, but the additional complexity and inherent fabrication constraints make this solution less than ideal for real-world applications. Another obvious approach for eliminating crosstalk would be to provide individual reservoirs for all channels within the second dimension array, thereby isolating each channel both electrically and fluidically. As an example, this approach was chosen for the IEF/SDS–CGE device shown in Figure 33.3. However, there are practical limitations to this solution. As the number of reservoirs increases, so does the challenge of achieving efficient interfacing between off-chip plumbing and on-chip channels. For applications requiring

**FIGURE 33.6** (a) Manifold interface for providing fluidic interconnects between on-chip microchannels and off-chip pumps, valves, and electrodes and (b) manifold with integrated valves positioned above an IEF/SDS–CGE chip during testing.

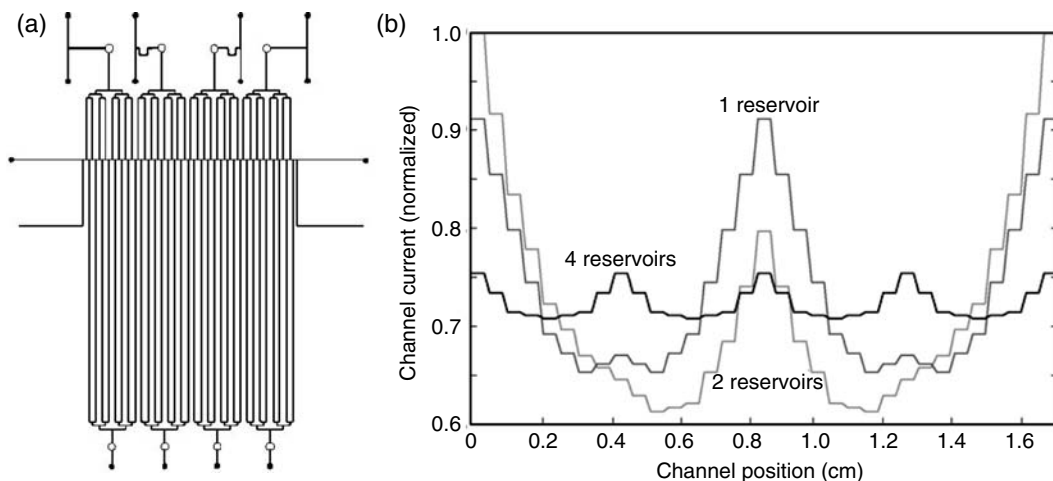

pressure injection of sample, buffer, or other solutions into the device, on-chip connections are generally required at each reservoir (with the potential exception of waste reservoirs) to provide interfacing to pumps, valves, and/or electrodes, leading to a complex overall interface. For applications in which simple open reservoirs are suitable, for example, when electrokinetic sample injection is favored over pressure injection, the need for large numbers of interconnects to off-chip components may be alleviated, but additional challenges are introduced by bulk flow induced by hydrodynamic pressure gradients resulting from uneven fluid heights among large numbers of reservoirs in the chip. Furthermore, each added reservoir represents an additional point for bubble formation and entrapment, reducing the robustness of the microfluidic system.

There are several solutions that may be used to address this interface challenge. For the case of the relatively simple IEF/SDS–CGE chip previously described in Figure 33.3a, 38 individual reservoirs were ultimately required for effective operation of the system, with a manifold interface used to simplify the fluidic and electrical interface. The manifold consisted of a machined PMMA block as shown in Figure 33.6, with O-ring compression seals and integrated valves, which provided leak-free hydrodynamic pressure control for chip preparation and sample introduction, and electrodes for electrokinetic control. The use of manifolds for microfluidic interfacing can substantially reduce the time and effort required for chip preparation and testing by eliminating the need for discrete fluidic or electrical ports to be added to each on-chip reservoir. Another solution is to reduce the required number of reservoirs by connecting limited numbers of channels to common fluid ports for off-chip access. Consider the example of a chip design comprising 32 second dimension channels shown in Figure 33.7a. Each set of eight adjacent channels within the upper and lower arrays are connected to a single reservoir, substantially reducing the total number of required ports. Although channels within each group remain subject to crosstalk during the first dimension separation, the overall current uniformity is greatly improved by segregating each group from the others as revealed in Figure 33.7b.

### 33.3.3 SAMPLE DISPERSION AND LOSS AT CHANNEL INTERSECTIONS

When spatial or time multiplexing is employed as a multidimensional separation strategy with a first dimension based on an electrokinetic separation mode, an inherent difficulty arises from the need for the first dimension separation channel to be intersected by one or more second dimension channels. Regardless of whether the first dimension separation is operated in a transient (e.g., CZE) or steady-state (e.g., IEF) mode, electric field lines extending into the intersecting channels result in dispersion of sample out of the first dimension channel, and ultimately to sample loss as diffusion

**FIGURE 33.7** (a) Schematic representation of 2-D separation chip containing 32 second dimension microchannels, with groups of 8 second microchannels terminating at one of four common reservoirs and (b) model results showing relative current uniformity within the first dimension channel when using 1, 2, and 4 reservoirs.

allows sample to travel beyond the influence of the radiating electric field lines. This is of particular concern when analyte passing the intersections is in a concentrated band, since a substantial portion of the analyte may be lost into the interconnecting channel, while the remaining portion suffers from broadening after passing the intersection.

Li et al.<sup>18</sup> addressed this issue by integrating multiple separation media, with relatively low resistivity ampholyte and buffer in the first separation dimension for IEF and higher resistivity PEO gel used for the second dimension for CGE. As a result, the electric field remained largely constrained within the first dimension microchannel during IEF, and minimal sample dispersion was observed. In addition to constraining the electric field, low diffusion in the gel allowed dispersed analyte to be mobilized back into the first dimension channel without suffering a high degree of loss. As discussed previously, another benefit of this approach is that the multiple separation media further enabled effective sample stacking as focused analyte was electrokinetically transferred to the second separation dimension. Cui et al.<sup>38</sup> proposed a solution based on the integration of addressable electrodes near each channel intersection to control the local current streamlines and thereby limit sample dispersion and loss. This is a more general approach that may be applied to a range of multidimensional systems. A potential disadvantage is that additional current is injected by each electrode, leading to current and electric field gradients within the first dimension separation channel, which can affect separation performance.

### 33.3.4 INHIBITING BULK FLOW IN MULTIDIMENSIONAL MICROCHANNEL NETWORKS

An important practical issue that affects many microfluidic systems, and multidimensional microfluidics in particular, is unwanted hydrodynamic flow induced by on-chip pressure gradients. Owing to the complexity of the microchannel networks and relatively large numbers of reservoirs or other off-chip interconnects required to operate multidimensional separation chips, there is a large potential for pressure gradients to be induced by sources such as gravity (due to uneven fluid heights in the reservoirs), variations in capillary forces at the reservoirs, or trapped air bubbles within the reservoirs or microchannel networks. In the authors' experience, fully eliminating these pressure

gradient sources in complex microfluidic devices is rarely feasible, even when employing automated manifold interfaces, taking great care in chip preparation, and allowing pressure gradients to equilibrate over long periods of time. A more effective approach is to minimize hydrodynamic flow through the use of media, which inhibit bulk fluid motion, either by increasing the effective viscosity of fluids or by generating a physical barrier to flow. For example, Cui et al.<sup>19</sup> added a 2.5% solution of methylcellulose to all reservoirs in a multidimensional IEF chip to limit the intrusion of reservoir solutions into the separation channels, while the replaceable PEO gel used as a second dimension separation medium by Li et al.<sup>18</sup> served a similar purpose. In general, multidimensional systems employing gel-based separations are likely to suffer from less bulk flow than those using free solutions, as are systems employing chromatographic media that require high-pressure gradients to generate bulk flow.

### 33.4 CONCLUDING REMARKS

The development of novel platforms for multidimensional separations of proteins and peptides remains an area of great interest throughout the analytical community. Microfluidic technologies offer real advantages over capillary-based systems in this area, particularly for the analysis of limited samples. Despite the promise and numerous examples of multidimensional microfluidic platforms for proteomic analysis, a number of challenges remain before these systems can become competitive with modern capillary systems such as 2-D liquid chromatography system for the analysis of complex substrates. The authors believe that as multidimensional microfluidic systems continue to evolve, the benefits of the technology will become increasingly evident. Specific areas that require attention include improved methods for fluidic interfacing and on-chip valving, which do not substantially impact system complexity or cost. Another important area of research currently being addressed by a number of groups is the development microfluidic systems with novel coupled separation dimensions that may offer improvements in separation efficiency. Interfacing spatially-multiplexed systems with MS also remains a significant challenge, and although a variety of solutions have been proposed and explored more efforts are needed to achieve parity with serial capillary ESI-MS.

New development efforts in the area of time-multiplexed multidimensional separations may also provide real-world benefits for proteomic analysis. One of the difficulties with time multiplexing relates to sample loss resulting from the inability to fully sample all separated analyte bands within the first dimension microchannel. When a transient separation is employed in the first dimension, sample loss is inherent in this configuration due to the inability to collect fractions while the second dimension separation is proceeding. The difficulties with sample loss imposed by the serial nature of the second separation dimension could potentially be alleviated through the use of on-chip trap columns to store fractions before injection into the second dimension channel, providing parity between the desired rate of fraction acquisition and the duty cycle of the second dimension separation. Alternately, a combined time- and spatial-multiplexing scheme could be envisioned, wherein multiple second dimension separation channels sequentially sample the first dimension.

Clearly, there are research issues that remain to be addressed before multidimensional microfluidics is commercially competitive against more traditional multidimensional capillary systems. However, with the demand for higher analytical throughput and smaller sample quantities in proteomics continuing to increase, there is an open opportunity for novel multidimensional platforms based on microfluidics to meet this demand. Beyond the concepts described in this chapter such as rapid and parallel separations, zero dead-volume flow control, and effective multichannel MS interfacing, further functionalities are also of great interest, for example, the combination of cell lysis, protein preconcentration, and digestion before multidimensional separation. Such technologies, already demonstrated for related lab-on-a-chip applications, offer an intriguing glimpse of what could ultimately be possible in a fully integrated system for protein or peptide analysis.

## 34.1 INTRODUCTION

It is predicted that an enormous number of analyses will be required in the future in our daily lives, especially in the clinical and biochemical fields. Rapid progress in molecular biology and biochemistry has brought about a deluge of useful and important information. From these achievements, a significant number of genetic mutations have been elucidated, and a number of biomarkers concordant with disease have been established. These are not only useful for revealing the presence and, potentially, staging the disease but also for the a priori prediction of patient predisposition to diseases. By simple calculation, the number of required diagnostic analyses is thought to be the product of the population size and the number of indices. To perform all of these analyses, it is clear that significant investment of funds, time, and resources will be required, which is very difficult to realize with conventional analytical methods. One form of evolving technology, microfluidic devices or microchips can be a powerful solution to this problem.

Microchip devices for chemical and biochemical analyses have been greatly advanced owing to the progress of microfabrication techniques. Microchemical systems using these devices have attracted much attention, not only from scientists and engineers but also from the clinical, forensic, and biomedical research communities. Thus far, most studies describing microchip-based analytical systems have focused on deoxyribonucleic acid (DNA) analysis by microchip electrophoresis with laser-induced fluorescence detection. These microchip-based electrophoretic systems have great advantages in some applications, especially in the clinical diagnostics and molecular biological fields. Other analytical methods must also be performed for select applications, which involve several distinct biochemical processes. To realize process functionality in these complicated systems, it is necessary to utilize the chemical properties and potential of molecules involved in an effective way.

Immunoassay, founded by Rosalyn Yalow [1] in the late 1950s in the form of the “radioimmunoassay,” is still today one of the most powerful and important analytical methods used in clinical diagnoses and biochemical studies, primarily because of its extremely high selectivity and sensitivity. The antibody-based method used today has two generic classifications: homogeneous and heterogeneous. In heterogeneous immunoassays, the antibody is immobilized on a solid surface, while homogeneous assays take place in a solution phase. Integration of both types of immunoassay into microchips has been accomplished with reasonable success by numerous research groups. Most of the homogeneous immunoassays carried out in the microchip format have been based on a microchip electrophoresis [2,3], where the benefit of the chip-based integration was primarily the

reduction in separation time. In heterogeneous microchip immunoassay, however, a number of other advantages exist—and this represents the focus of this chapter.

Enzyme-linked immunosorbent assay (ELISA) or other immunosorbent assay systems, in which antigen or antibodies are fixed on a solid surface, are applicable to many analytes with high sensitivity. These are used practically in many fields including clinical diagnoses and life science researches. The conventional heterogeneous immunoassay, however, requires a relatively long assay time and involves troublesome liquid-handling procedures and large quantities of expensive antibody reagents. Moreover, realization of point-of-care (POC) testing is difficult with the conventional immunoassay, since rather large devices are necessary for automated practical diagnosis systems. To overcome these drawbacks, a microchip-based system is effective. The integration of analytical systems into a microchip should bring about enhanced reaction efficiency, a reduced assay time, simplified procedures, and a lowered consumption of samples, reagents, and energy.

The main reason of the long assay time in the conventional heterogeneous assay is that the reaction efficiency is very poor. This is because the reactions occur only on the solid surface. Moreover, it takes long time to complete the reaction due to the long molecular diffusion time. In a microchip, since it is easy to reduce the diffusion distance and increase the surface area-to-volume ratio, the reaction time can be reduced to several minutes rather than hours or days.

A major source of the loss of reproducibility in the conventional assay is human error, because the assay procedure contains many troublesome manual operations. In the microchip format, all procedures can be controlled by pumps and valves that are regulated by a computer. Automation is very favorable without the need for any large-scale robotic equipment.

Antibodies, enzymes, and other reagents used for immunoassay are expensive, hence, when used in the conventional method causes a large problem. Moreover, in many cases, samples are very precious or only a very small amount of samples can be obtained. Therefore, any reduction of the consumption in the microchip systems is welcomed.

## 34.2 BASICS OF IMMUNOASSAY MICROCHIPS

Microfluidic devices for heterogeneous immunoassays consist of microchannels for transporting solutions, reaction solid phase, and detection area. There are several important factors to develop a high performance system.

Microchip substrate is open to a variety of materials. Silicon wafer is a good material to build up microstructures if fabrication facilities are available. Glass has good chemical and optical properties, and some polymers are cost effective for mass production. The surface treatment of the microchannel is critically important for all materials. This is because of the nonspecific adsorption of the analytes and antibodies to the channel wall that will result in considerable analytical error. It is very important to modify the surface with some blocking reagents or other materials to prevent protein adsorption before experiments. Therefore, we must choose a material of which, surface chemistry is well understood.

Reaction solid phase is the core of the immunoassay microchip where the primary antibody (capture antibody) is immobilized on the surface. There are some formats for the immobilization (Figure 34.1). The simplest method is a fixation of the antibody to the channel wall [4]. Several strategies have been used to adsorb or fix antibodies on the surface (e.g., direct adsorption), covalent bonding to react with function groups on the surface, and microcontact printing. While direct adsorption is common on hydrophobic polymer surfaces, covalent bonding by silanization reagents is used for silicon and glass surface. Since the amount and activity of the immobilized antibody is strongly dependent on the immobilization method, study of the fixation method is important [5].

Another type of solid support for capture antibody is microbeads. Beads coated with antibodies are packed in the microchannel with a dam or cage structure. Bead format is considerably superior to

**FIGURE 34.1** Formats of the reaction solid phase for microchip immunoassay. (a) channel wall, (b) packed microbeads, (c) monolithic structure, and (d) magnetic beads.

**FIGURE 34.2** Schematic illustrations of the antigen–antibody reaction. (a) Microtiter plate and (b) microchip.

the wall surface immobilization methods. Microbeads bring extremely large surface area-to-volume ratio and decrease the size of the liquid phase (i.e., decreasing the diffusion distance). These effects are useful to reduce the assay time dramatically. An example is shown in Figure 34.2.

The surface area-to-volume ratio of a 50- $\mu\text{L}$  solution in a microtiter plate well (0.65 mm in diameter) was estimated to be  $13\text{ cm}^{-1}$ , whereas that of the microchannel (11 beads in  $100\text{ }\mu\text{m} \times 100\text{ }\mu\text{m} \times 200\text{ }\mu\text{m}$  channel space) was  $480\text{ cm}^{-1}$ . Therefore, the surface area-to-volume ratio the microchannel was 37 times larger than that of the microtiter plate, and the reaction rate may be increased because of this larger reaction field.

In the case of the conventional microtiter plate assay, a 1.5-mm movement would be necessary for the most distant located antibody molecule to react with an antigen fixed on the surface of the well, since the liquid depth was 1.5 mm. On the other hand, the liquid phase of the microchannel filled with polystyrene beads was much smaller. The maximum distance from an antibody molecule to the reaction-solid surface will not exceed  $20\text{ }\mu\text{m}$ . Because the diffusion time is proportional to the squares of the diffusion distance, the diffusion time of the antibody molecule to the antigen in the microchip would be more than 5600 times shorter than in the conventional method [6].

The monolithic porous structure has also the same properties and suitable for the reaction solid phase. However, it is difficult to remove the monolith from the chip after an assay so the chip is then disposed. Hence, this happens even though the change of the beads is very easy. Therefore, the monolithic format is not favorable unless the cost of the chip is very low.

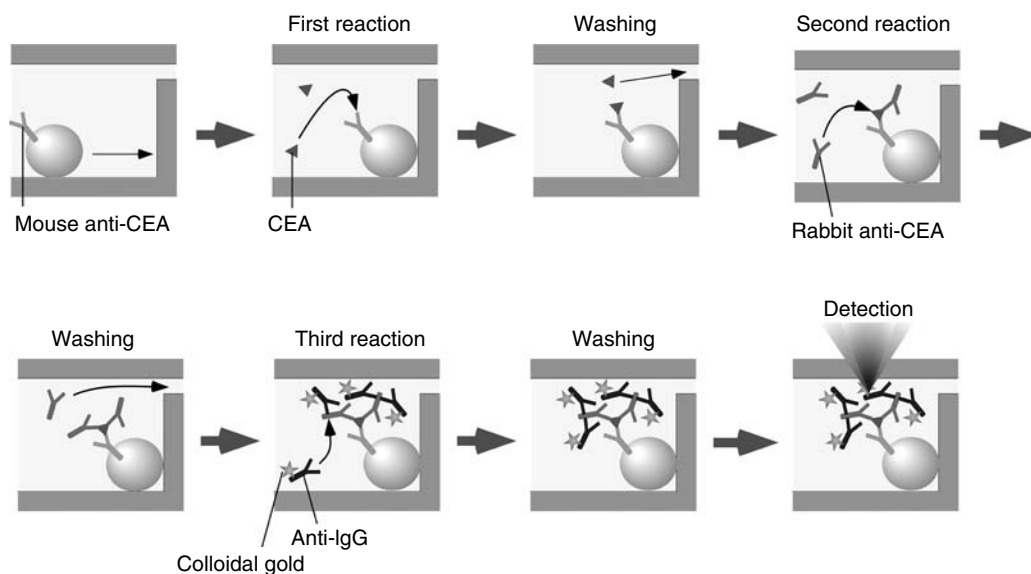

Magnetic fine particles are another choice for the solid support. These particles can be captured in the channel easily with a magnet without any microstructures inside. In many cases, however, the particles are gathered very tightly and reagents are unable to go through them. That limits the number of particles contributed to the reaction.

There are several kinds of detection methods for microchip-based heterogeneous immunoassays. The most popular technique is a fluorescent detection. Fluorescent molecules are used as a labeling material and detection is done at the reaction solid phase. A combination of a laser-induced fluorescence microscope, a highly sensitive detector, and a good labeling material may bring very sensitive determination, while the beads may scatter light. Nonfluorescent material, colloidal gold nanoparticle, is also useful for detection with a laser-induced thermal lens microscope (TLM).

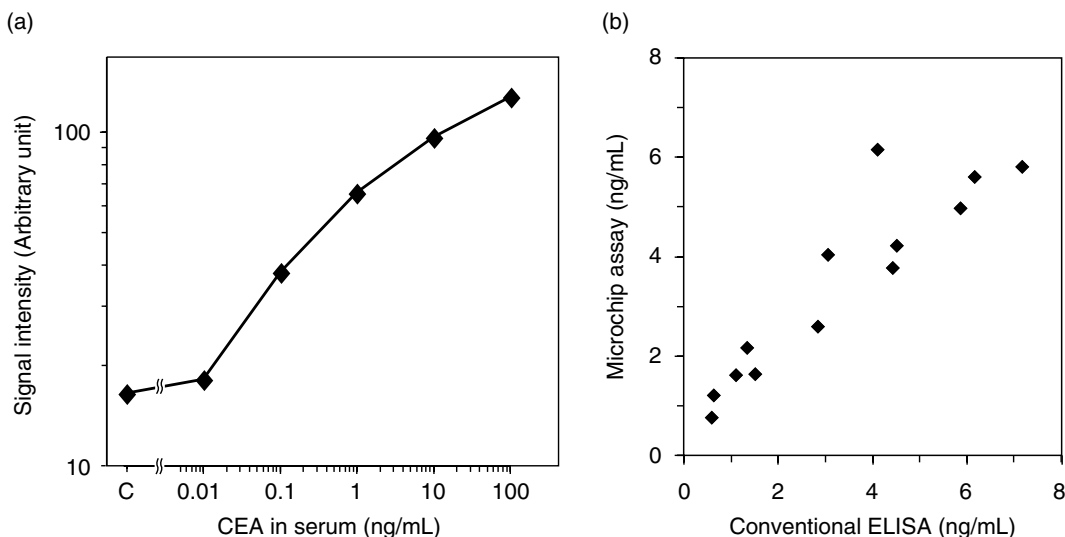

Instead of the optical labels, enzymes are also used as a labeling material [7]. ELISA is one of the most popular techniques in the conventional immunoassay and suitable in the microchip format. By using a fluorogenic reaction, the fluorescent signal can be taken at the downstream microchannel without interruption by microbeads. In the case of chromogenic reaction, a TLM is useful [8].

### 34.3 APPLICATIONS

An example of the application of the microchip-based immunosorbent assay is shown below. The human carcinoembryonic antigen (CEA), one of the most widely used tumor markers for serodiagnosis of colon cancer, was assayed with a microchip-based system [9]. An ultratrace amount of CEA dissolved in serum samples was successfully determined within a short time. Polystyrene beads pre-coated with anti-CEA antibody were introduced into a microchannel. Then a serum sample containing CEA, the first antibody, and the second antibody conjugated with colloidal gold,

**FIGURE 34.3** Schematic illustrations of the microchip-based immunosorbent assay using microbeads.

**FIGURE 34.4** Determination of a tumor marker, human CEA. (a) Calibration curve for CEA in human sera. (b) Correlation between the conventional ELISA and the microchip-based immunoassay.

were reacted successively (Figure 34.3). The resulting antigen–antibody complex, fixed on the bead surface, was detected using a TLM. A highly selective and sensitive determination of an ultratrace amount of CEA in human sera was made possible by a sandwich immunoassay system that requires three antibodies for an assay. A detection limit in the orders of magnitude lower than the conventional ELISA was achieved (Figure 34.4). Moreover and pertinent to the clinical application of this technology, the analysis of serum samples from 13 patients showed a high correlation ( $r = .917$ ) with the conventional ELISA. This integration reduced the time necessary for the antigen–antibody reaction to  $\sim 1\%$ , thus shortening the overall analysis time from 45 h to 35 min. This microchip-based diagnostic system might be the first micrototal analysis system ( $\mu$ TAS) to show a practical usefulness for clinical diagnoses with short analysis times, high sensitivity, and easy procedures.

In numerous microchip systems, researchers have shown that multiplexed analysis can be achieved by increasing the number of channels available for parallel processing of numerous samples simultaneously for protein crystallization [10] and genetic [11] analysis. This type of higher integration has been achieved for multiplexed immunoassay analysis capable of processing several samples simultaneously [12]. In this integrated system, the chip had branching multichannels connected to four reaction and detection regions; thus, the system could process four samples at a time with only a single fluid pumping unit (Figure 34.5). To show utility, interferon gamma was assayed by a three-step sandwich immunoassay with the system coupled to a TLM as a detector. The biases of the signal intensities obtained from each channel were within 10%, with percent coefficient of variance (CVs) were almost the same level as the single straight channel assay. The total assay time for all four samples was 50 min when compared with 35 min for one sample in the single channel assay; hence, a higher throughput was realized with the branching structure chip. The simultaneous assay of many samples may also be achieved by simply arraying many channels in parallel on a chip. This approach, however, requires many pumps and capillary connections, and high integration seems to be difficult. On the other hand, a microchip with branching microchannels seems to be suitable for carrying out the simultaneous assay, since the numbers of pumps and capillary connections required for the system can be minimized.

### 34.4 FUTURE DIRECTIONS

It is clear that much research has been done in this area, with the general sense that the microfluidic immunoassay can be superior to conventional immunoassay systems. It is interesting that, despite the large potential market size, microchip-based immunoassay systems have not yet been commercialized. One of the main reasons is the difficulty associated with creating a truly high-throughput assay without interfacing with automated fluidic control systems. While one microchip immunoassay can be completed in 30 min with manual operation, 96 assays can be completed within several hours in the conventional format. Therefore, it is clear that parallelization and automation will be required to realize the full potential. However, this will require the development and perfection of compact, cheap, precise, and automatic fluidic controller systems (including pumps, valves, and mixers). Precise control of submicroliter solutions without dead volume is a technical challenge and it is difficult to realize it only with inexpensive devices—however, such developments are underway in numerous labs. In addition, assay cost presents a problem, largely due to the cost of a 96-well microtiter plate at less than \$2 dollars, while microchip costs could approach \$100 dollars. Clearly, developing a cost-effective mass production approach will be a necessity. A candidate design for the automated and compact system might be a compact disk (CD) format. It is very easy to array more than 96 microchannels radially on a CD and all solutions/reagents can be controlled by centrifugal force without any pumping. The structured portable CD player or CD drive in a laptop PC might be a good analyzer as it can control the rotation speed precisely and has optical readout and could accommodate fluorescent detection. Ultimately, development of a functional, easy-to-use, and cost-effective system is a key to the acceptance and dissemination of such technology.

## 35.1 INTRODUCTION

Solvent extraction is a method capable of separating compounds based on their solution preferences for two different immiscible liquids. In other words, it is the extraction of a substance from one liquid phase into another liquid phase. Solvent extraction is a fundamental technique in chemical/biological laboratories and chemical industries, where it is carried out in the macroscale using separatory funnels. The advantage of doing a solvent extraction in the microspace on a chip is the scale merit of using small dimensions, that is, a large specific interface area (the interface-to-volume ratio) and a short diffusion distance, which together results in a short diffusion time. High speed and high performance solvent extraction systems are possible on chips, without the need for mechanical stirring, mixing, or shaking, all of which are necessary for the conventional method.

This chapter focuses on the analytical aspects of solvent extraction on microchips. Although there are several reports in the literature on the application of chemical reactions,<sup>1–7</sup> the topics dealt with here are limited only to application using parallel (side-by-side) flow schemes inside microchannels. Other examples, such as using a porous membrane,<sup>8</sup> metal mesh,<sup>9</sup> or droplets<sup>10</sup> lie outside the scope of this chapter.

## 35.2 COCURRENT SOLVENT EXTRACTION

### 35.2.1 SIMPLE APPROACHES

In order to perform an on-chip solvent extraction, a chip with at least two inlets for two immiscible liquids is required. However, the difficulty associated with its use, and the resultant extraction efficiency depends on the shape and dimensions of the channel, as well as other variables. Glass is the substrate usually used when performing solvent extraction using chips due to its chemical inertness toward organic solvents. If a polymer is to be used as the substrate, chemical modification of the channel is typically required.

The first solvent extraction carried out using a two-phase parallel flow in a microchannel was demonstrated by Tokeshi et al.<sup>11</sup> using the typical extraction set up shown in Figure 35.1. An aqueous solution of Fe-bathophenanthrolinedisulfonic acid complex and a chloroform solution of capriquat were introduced into the microchannel, using syringe pumps at a constant flow rate to establish a parallel two-phase flow in the microchannel (Figure 35.2). In the case of ordinary solvent extraction using a separatory funnel, the two solutions in the separatory funnel are separated vertically by the difference in their specific gravities. Generally, in a microchannel, the liquid–liquid interface does not have this vertical arrangement, instead the flows are positioned parallel to the sidewalls

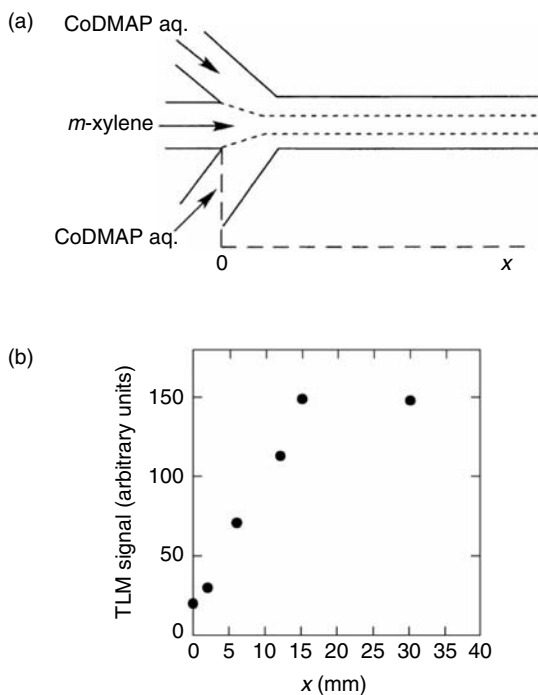

**FIGURE 35.1** Schematic illustration of experimental setup. (From Tokeshi, M. et al., *Anal. Chem.*, 72, 1711, 2000.)

**FIGURE 35.2** Schematic illustration of microextraction system. (From Tokeshi, M. et al., *Anal. Chem.*, 72, 1711, 2000.)

of the microchannel. This is due to the fact that the interfacial tension and friction force are much stronger than the force of gravity in the microspace provided by the microchannel.<sup>12</sup> However, this also depends on the microchannel geometry—for example, the properties of the wall surface (hydrophobicity, hydrophilicity, wettability), the properties of liquids (viscosity, interfacial tension), and so forth.<sup>13</sup> The time taken for the extraction in the  $250\ \mu\text{m}$  (w)  $\times$   $100\ \mu\text{m}$  (d) microchannel of Figure 35.2 was determined to be 45 s—this roughly coincides with the molecular diffusion time. The extraction time was also at least one order of magnitude shorter when compared with the conventional extraction time using a separatory funnel and mechanical mixing (shaking). In a similar manner, the Ni-dimethylglyoxime complex,<sup>14</sup> Co-2-nitroso-5-dimethylaminophenol (DMAP) complex,<sup>15</sup> and Al-2,2'-dihydroxyazobenzene (DHAB) complex<sup>16</sup> were all analyzed by performing an extraction at a two-phase interface, water/chloroform, water/toluene, and water/1-butanol, respectively. The determination of radioactive nuclides, such as uranium, was carried out by the extraction of U(IV) from an  $\text{HNO}_3$  aqueous solution to 30% (70% *n*-dodecane) and 100% tri-*n*-butyl phosphate phase (TBP).<sup>17</sup> In the conventional method, 100% TBP was not used as an extraction solvent because it is impossible to get a separation between these two phases due to the fact that the specific gravity of the two liquids is almost identical. Alternatively, with the chip, the extraction of U(IV) can be achieved by using a two-phase aqueous/100% TBP flow because specific gravity is not a dominant variable. Moreover, using a three-phase flow, it is possible to obtain a rapid solvent extraction as illustrated in the following example, in which the extraction solvent *m*-xylene, was sandwiched by two aqueous solutions of Co-2-nitroso-DMAP complex to form a microchannel-based three-phase flow (Figure 35.3).<sup>12</sup> The concentration of Co-2-nitroso-DMAP complex in the *m*-xylene phase was determined by using thermal lens microscopy (TLM)<sup>18</sup> and corresponded well with the time taken for the extraction process. The dependence of the TLM signal on the distance  $x$  from the junction is shown in the graph of Figure 35.3. The extraction process reached equilibrium after only a distance of 1.5 cm, indicating that the extraction equilibrium was attained within 3 s of contact. The extraction efficiency can, however, be improved by using specially designed microchannels, for example, an asymmetrical zigzag-side-walled microchannel<sup>19</sup> or a microchannel, which has intermittent partition walls in the center of the confluent part.<sup>20</sup>

Uniquely, Minagawa et al.<sup>21</sup> demonstrated the integration of two chemical processes on a chip: a chelating reaction and solvent extraction. The layout of the microchannels fabricated on the glass plates is shown in Figure 35.4 and a schematic illustration of the molecular behavior demonstrated

**FIGURE 35.3** (a) Schematic illustration of multilayer extraction system. (b) Position dependence of thermal lens signal intensity on distance  $x$ . (From Hibara, A. et al., *Anal. Sci.*, 17, 89, 2001.)

**FIGURE 35.4** Layout and dimensions of microchip. Microchannel was 100- $\mu\text{m}$  deep and 250- $\mu\text{m}$  wide. (From Minagawa, T. et al., *Lab Chip*, 1, 72, 2001.)

in the microchannels is given in Figure 35.5. First, the *m*-xylene and the 2-nitroso-1-naphthol (NN) aqueous solutions were introduced into the two inlets of the first Y-shaped microchannel by the first syringe pump at a constant flow rate. These two liquids met at the intersection point, and a parallel two-phase flow, that is, an organic/aqueous interface, was formed in the microchannel. In this region, the NN in the aqueous phase could not be extracted into the *m*-xylene, whether or not the liquids were flowing. Next, the sample solution of cobalt ion [Co(II)] was introduced into the third inlet of the second Y-shaped microchannel using a second syringe pump at the same constant flow rate. Therefore, a three-phase parallel flow was formed upstream of the intersection point of the second Y-shaped structure. There was almost no interdiffusion in the three fluids under the flow condition, although the lack of interdiffusion depended on the flow rate. However, under these experimental conditions, interdiffusion can never occur. Thus, the chelating

**FIGURE 35.5** Schematic illustration of the chelating reaction and solvent extraction in microchannel. (From Minagawa, T. et al., *Lab Chip*, 1, 72, 2001.)

reaction of Co(II) with the NN and the extraction of Co chelates did not occur under flow. When the flow was stopped, the NN solution and the Co(II) sample solution promptly mixed, and Co(II) reacted with NN. Then, the reaction product, Co chelate in the aqueous phase was extracted into the organic phase. By using on-chip detection with a thermal lens microscope, troublesome operations such as the phase separation necessary for the conventional system can be avoided.

### 35.2.2 ION SENSING

The liquid microspace provides a short diffusion distance, and large specific interfacial area, of the liquid–liquid interface. As a result several novel and attractive analytical features arise including extremely fast ion sensing, and a need for only an ultra small volume of reagent solution. In contrast to the slow response time of a standard ion-selective optode, where the response time is basically governed by the slow diffusion of ionic species in the viscous polymer membrane, that of the on-chip ion-sensing system is clearly faster due to the short diffusion distance and low viscosity of organic solution. The ion-pair extraction scheme is an established methodology employed for ion-selective optodes, which provide highly selective optical ion determination for various kinds of ions, using a single lipophilic pH indicator dye and a highly selective neutral ionophore. However, exploitation of an ion-pair extraction reaction and chip technology provide attractive advantages that would not be achieved by conventional ion sensors. The advantages of on-chip ion-sensing systems are as follows:

1. Reaction time (response time) can be dramatically reduced by the fast molecular transport achievable in a microspace.
2. Since the required reagent solution volume is extremely small ( $\sim 100$  nL), a fresh organic phase can be used in every measurement. Subsequently, response degradation caused by the leaching of ion-sensing components, a typical problem of ion-selective optodes, would not need to be taken into consideration. This merit is directly reflected in the excellent reproducibility of the response during continuous measurements and the effective reduction of the amount of expensive reagents consumed in one measurement.
3. Ion determination can essentially be carried out by detection of the protonation/deprotonation process of a single lipophilic anionic dye in the organic phase. Therefore, no special color-responsive chelating reagents are required for the measurement of another kind of analyte ion. One only need to alter the neutral ionophore for different ion-selective ionophores. From the viewpoint of optical instrumentation, this merit is

quite important; there is no need to change the excitation source to match the excitation wavelength of the different chelating reagents.

4. Highly selective ionophores or carriers, for various kinds of ions developed for application to ion-selective electrodes, are commercially available and can be used without any chemical modification.

Figure 35.6 shows a schematic illustration of the experimental setup and ion-pair extraction scheme.<sup>22</sup> The organic solution containing a neutral ionophore, a lipophilic pH indicator dye, and an aqueous solution containing sample ion ( $K^+$  or  $Na^+$ ) were independently introduced into the microchannel to form an organic/aqueous interface. Then determination of the ion was done using a thermal lens microscope positioned downstream, where the ion-pair extraction occurred in the organic phase under continuous-flow conditions. The response time and minimal required volume of reagent for the on-chip ion-sensing system were about 8 s and 125 nL, respectively.

In other work, a sequential multi-ion-sensing system using a single chip was successfully identified by expanding the concept of on-chip ion sensing.<sup>23</sup> Figure 35.7 shows the basic concept for this chip-based multi-ion sensor. Different organic phases containing the same lipophilic pH indicator dyes, but different ionophores were introduced sequentially into the microchannel by the on-off switching of syringe pumps. In this case, having each organic phase contain different ionophores avoids contamination. The aqueous sample solution containing the different ions is introduced from the other inlet, to form a parallel two-phase flow with the intermittently pumped

**FIGURE 35.6** Schematic illustration of experimental setup and ion-pair extraction in microchannel. (From Hisamoto, H. et al., *Anal. Chem.*, 73, 1382, 2001.)

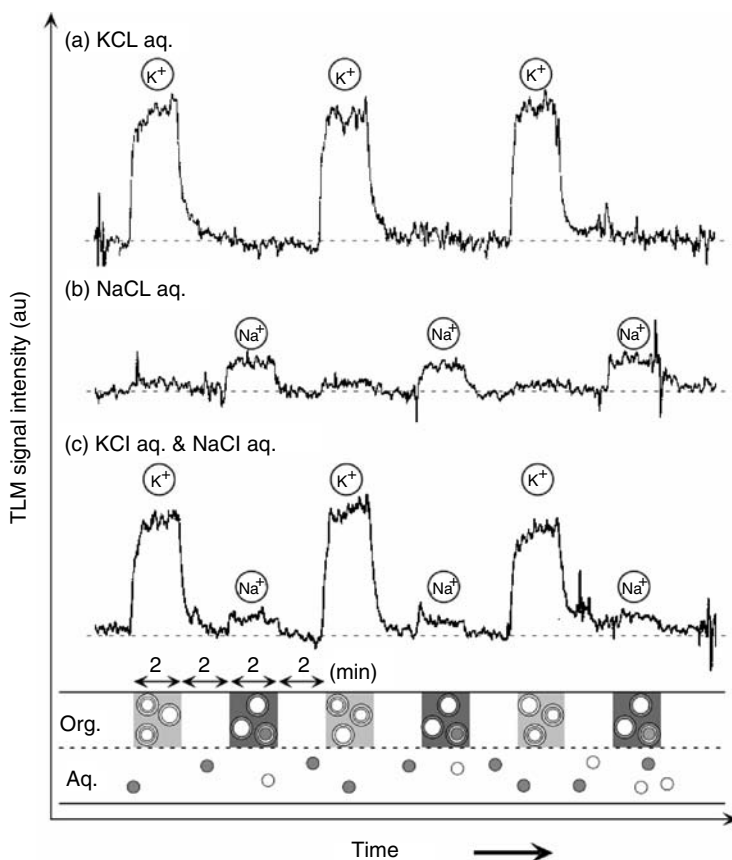

**FIGURE 35.7** Concept of sequential ion-sensing system using single microchip. (From Hisamoto, H. et al., *Anal. Chem.*, 73, 5551, 2001.)

organic phases. The selective ion-pair extraction reaction proceeds during flow; thus, different ions can be selectively extracted into different organic phases, depending on the selectivity of the neutral ionophores contained in the respective organic phases. Downstream in the flow, the ion-pair extraction reaction becomes equilibrated; thus, downstream detection of the color change of the organic phase, allowed for sequential and selective multi-ion sensing in the single aqueous sample solution containing multiple ions. In this case, valinomycin and 2,6,13,16,19-pentaoxapentacyclo-[18.4.4.4.<sup>7,12</sup>0.<sup>1,20</sup>0<sup>7,12</sup>]dotriacontane (DD16C5)—known to exhibit high selectivity when used in conventional ion sensors—were used as highly selective potassium and sodium ionophores, respectively. Three types of aqueous sample solutions were analyzed with the system: a buffer solution containing  $10^{-2}$  M  $K^+$ ,  $10^{-2}$  M  $Na^+$ , or both ions. When the aqueous phases containing a single type of ion were used, selective extractions occurred in each case; that is, potassium ions were extracted only for an organic phase segment containing valinomycin, and sodium ions were extracted only for that containing DD16C5. When the aqueous phase containing both ions was examined, both ions were independently extracted into different organic phases, depending on the nature of the ionophores in the respective organic phase (Figure 35.8). The minimum volume of single organic phase needed to obtain an equilibrium response without dilution by cross dispersion of two organic phases was  $\sim 500$  nL in the system, indicating that the required amounts of expensive reagents in one measurement could be reduced to a few nanograms.

### 35.2.3 LIQUID MEMBRANE

A liquid membrane, composed of an organic phase with two aqueous phases, has a wide variety of industrial and analytical applications, including separation, concentration, and removal of

**FIGURE 35.8** Response profiles for different aqueous solutions obtained by intermittent pumping of organic phase: (a) Aqueous solution containing  $10^{-2}$  M KCl, (b) aqueous solution containing  $10^{-2}$  M NaCl, and (c) aqueous solution containing both  $10^{-2}$  M KCl and  $10^{-2}$  M NaCl. (From Hisamoto, H. et al., *Anal. Chem.*, 73, 5551, 2001.)

analytes from wastewater, environmental, and biomedical samples. Surmeian et al.<sup>24</sup> demonstrated molecular transport on a chip using a stable three-layer flow membrane system, water/organic and solvent/water. Under continuous-flow conditions, the analyte (methyl red) was rapidly extracted across the microchannel from the donor to the acceptor phase through the organic phase (cyclohexene). The thickness of the organic phase, sandwiched by the two aqueous phases, was  $\sim 64 \mu\text{m}$ , and it was considered a thin liquid organic membrane. Permeability studies identified the effects of molecular diffusion, layer thickness, and organic solvent-water partition coefficient on the molecular transport. In the chip, complete equilibration was achieved in several seconds, in contrast to a conventional apparatus, where it would require tens of minutes for the comparable extraction. Maruyama et al.<sup>25</sup> showed another selective separation by using a three-layer flow membrane, water/*n*-heptane/water, to separate yttrium ions within a few seconds. In studies such as these, the formation of a stable liquid/liquid interface inside the microchannel under flow conditions is very important. The use of the microchannel structures and surface modification are particularly effective for stabilization of the liquid/liquid interface inside the microchannel.<sup>7,20,24–28</sup>

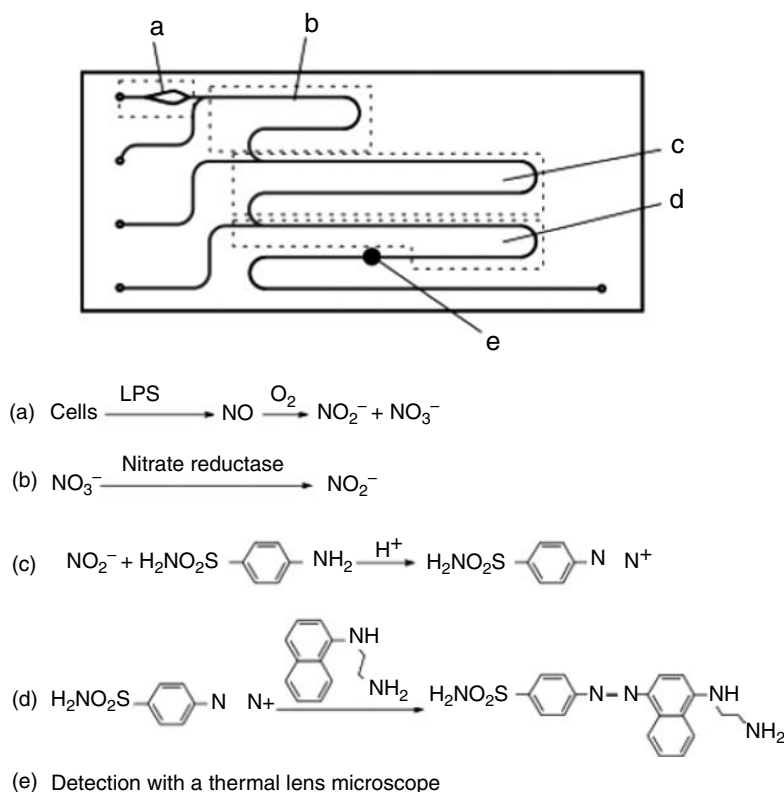

### 35.2.4 CONTINUOUS FLOW CHEMICAL PROCESSING

The integration of chemical processes on a chip by using continuous-flow chemical processing (CFCP) in combination with microunit operations, such as solvent extraction, phase separation, and

**FIGURE 35.9** Schematic illustration of Co(II) determination by using CFCP.

so forth, under continuous flow conditions is a strategy used for the construction of real micro-total analysis systems.<sup>27–30</sup> The integration of a Co(II) wet analysis provides a good example of CFCP,<sup>27</sup> and Figure 35.9 schematically illustrates this analysis. The microchip consists of two different areas: the former is the reaction and extraction area, and the latter is the washing, that is, decomposition and removal, area. In the former area, a sample solution containing Co(II) ions, a NN solution and *m*-xylene, are introduced at a constant flow rate through three inlets using syringe pumps. The three liquids meet at the intersection point, and a parallel two-phase flow, consisting of an organic/aqueous interface, forms in the microchannel. The chelating reaction of Co(II) and NN and extraction of the resulting Co(II) chelate proceed as the reacting mixture flows along the microchannel. Since the NN reacts with the coexisting metal ions [such as Cu(II), Ni(II), and Fe(II)], these coexisting metal chelates are also extracted into *m*-xylene. Therefore, a postextraction washing process is necessary for the decomposition and removal of the undesired coexisting metal chelates. The coexisting metal chelates decompose when they make contact with hydrochloric acid, and the metal ions are moved into an HCl solution (back extraction). The decomposed chelating reagent, NN, is dissolved in a sodium hydroxide solution. In contrast to the coexisting metal chelates, the Co chelate is stable in HCl and NaOH solutions, and remains. In the latter (washing) area, the *m*-xylene phase containing Co chelates and the coexisting metal chelates from the former (reaction and extraction) area is interposed between the other two inlets at a constant flow rate. Then, the three-phase flow, HCl/*m*-xylene/NaOH, forms in the microchannel. The decomposition and removal of the coexisting metal chelates proceed along the microchannel in the same manner as described above. Finally, the target chelates in *m*-xylene are detected downstream. Cobalt in an admixture sample was successfully determined with a rapid analysis time of less than 1 min. The advantages of this approach, compared with a conventional method, are the simplified nature of the procedure and avoiding troublesome operations. In the conventional method, the acid and alkali solutions cannot be used simultaneously, and alternative washing procedures must be repeated several times. The same effect can be obtained by using three-phase flow in the microchannel. In a subsequent paper, Kikutani et al.<sup>31</sup> expanded the concept of CFCP to integrate four parallel analyses of Co(II) and Fe(II) on a chip in a three-dimensional microchannel network.

**FIGURE 35.10** Chemical processes carried out in microchip for bioassay of macrophage-stimulating agent. (From Tokeshi, M. et al., *Anal. Chem.*, 74, 1565, 2002.)

Goto et al.<sup>32</sup> demonstrated the integration of a bioassay system that illustrated all processes required for a bioassay, that is, cell culture, chemical stimulation of cells, chemical and enzymatic reactions, and detection, on a chip using CFCP (Figure 35.10). By using the temperature control device, spatial temperature control of the system was possible, with areas on the chip maintained at different temperatures. Nitric oxide released from macrophage-like cells stimulated by lipopolysaccharide was successfully monitored by this system. The total assay time was reduced from 24 to 4 h, and the detection limit for nitric oxide was improved from  $1 \times 10^{-6}$  M to  $7 \times 10^{-8}$  M compared with the conventional batch methods. Moreover, the system could monitor a time course of the release, which is difficult to measure by conventional methods.

Smirnova et al.<sup>33</sup> demonstrated the determination of the insecticide, carbaryl, using a two-chip system. The first chip (for the hydrolysis of carbaryl) had a simple Y-shaped channel while the second chip (for the diazo coupling reaction between hydrolyzed products and 2,4,6-trimethylaniline)—the extraction required special channel shapes with a partial surface—modification obtained by using capillary-restricted modification (CARM) (Figure 35.11).<sup>34</sup> Determination of carbaryl pesticide in water with sufficient sensitivity was carried out with an analysis time of 8 min. In a similar manner, Honda et al.<sup>35</sup> developed a combination of a tube-type enzyme-immobilized microreactor and a microextractor with partial surface modification to produce optically pure amino acids.

### 35.2.5 SAMPLE PREPARATION FOR GAS CHROMATOGRAPHY AND MASS SPECTROSCOPY

As the successful applications of a commercially available liquid chromatography (LC) chip for mass spectroscopy (MS) have been made apparent, the development of sample preparation chips for other

**FIGURE 35.11** Concept of integration of carbaryl determination onto microchips. Target carbaryl was hydrolyzed in chip 1 to the product 1-naphthol. In chip 2, 1-naphthol was coupled with diazonium ion and was extracted into the organic phase. (From Smirnova, A. et al., *Anal. Chim. Acta*, 558, 69, 2006.)

**FIGURE 35.12** Schematic illustration of synthesis microchip-extraction microchip-ESI-MS. (From Takahashi, Y. et al., *J. Mass Spectrom. Soc. Jpn.*, 54, 19, 2006.)

conventional analytical systems, such as gas chromatography (GC), are also strongly desirable. As described above, microfluidic chips have great potential to integrate chemical processing such as sample preparation (see Chapter 44 by Biemvenue). Recently, several groups have developed the sample preparation chips for GC and GC-MS, and MS analyses.

Miyaguchi et al.<sup>36</sup> developed a solvent extraction chip for the off-chip GC analysis of amphetamine-type stimulants (a class of illegal drugs) in urine. Microchannels, partially fluoroalkylated by the CARM method,<sup>34</sup> were employed for stabilizing the 1-chlorobutane/alkalize urine interface and obtaining a GC-amenable fraction. As a practical demonstration, methoxyphenamine hydrochloride was administered to three healthy volunteers, and the concentration of methoxyphenamine in their urine determined. This showed the potential of chip-based sample preparation to contribute to the rapid automated analysis in forensic toxicology. Similarly, Xiao et al.<sup>37</sup> carried out solvent extraction of ephedrine using a polydimethylsiloxane (PDMS)/glass chip that had been obtained by surface modification of half of the glass wall, with octadecyltrichlorosilane. On-chip extraction of hydrocarbons from a North Sea oil for GC-MS analysis was also reported.<sup>38</sup>

Figure 35.12 shows a schematic diagram of an online high-throughput detection system for a reaction product synthesized by a microreactor.<sup>39</sup> The system has a synthesis chip that a microreactor for the synthesis of 2,2,2-trifluoro-*N*-phenetyl acetamide (TPA), an extraction chip for the purification of TPA from the reaction mixture, and an electrospray ionization mass spectrometer (ESI-MS) for

detection. In this system, the extraction chip is placed between the microreactor and the ESI-MS to reduce the ionization hindrances for the reaction products. This placement makes the detection of the reaction product possible under any reaction conditions. The system as described here may be useful for the optimization of reaction conditions and the screening of valuable chemicals such as precursors of pharmaceuticals.

### 35.3 COUNTER-CURRENT SOLVENT EXTRACTION

From the viewpoint of recovery efficiency, cocurrent solvent extraction as described above, can reach a theoretical plate number of only unity. In contrast to cocurrent solvent extraction, a higher theoretical plate number is expected using counter-current solvent extraction. However, counter-current flow in a microchannel cannot be easily formed because of interfacial tension and viscous force of both (aqueous and organic) phases. In an ordinary microchannel, counter-current flow cannot occur because the two phases collide, and high shear stress at the liquid/liquid interface causes breakup. To form counter-current flow, the aqueous solution must flow along one side of the channel, and the organic solution flow along the other, without breakup. Aota et al.<sup>40</sup> successfully developed a counter-current flow system, which was obtained by selectively modifying the lower half of a microchannel with a hydrophobic group (Figure 35.13). Using this system, they realized that a theoretical plate number of 4.6 was needed for the extraction of a Co(II)-2-nitroso-dimethylaminopyridine (DMAP) complex in an aqueous-toluene counter-current flow. Counter-current flow is expected to be applicable to enrichment processes for various environmental analyses and biomolecular separations.

**FIGURE 35.13** (a) Photograph of microchip and (b) schematic illustration of counter-current extraction system. (From Aota, A. et al., *Angew. Chem. Int. Ed.*, 46, 878, 2007.)

## 35.4 FUTURE DIRECTIONS

The development and application of chip-based solvent extraction is gradually expanding as shown in this chapter. With methods for surface modification, the liquid–liquid interface in a microchannel can be stabilized, and so special techniques for solvent extraction are not required. Therefore, since solvent extraction is one of the basic chemical processes, it is expected that it will be used more often in the future.

In the next 5 years, from a practical viewpoint, the combination of solvent extraction chips with conventional analytical apparatuses, such as GC, LC, MS, and so forth, and the integration of solvent extraction and other chemical processes will become more and more important. From the viewpoint of the basic science of two-phase and multi-phase flows, the flow itself near the liquid–liquid interface is very interesting. In fact, chaotic vortices and transient vortex-like flows have been observed around the liquid–liquid interface in the counter-current flow.<sup>41</sup>

## 36.1 INTRODUCTION

Microfluidic devices are changing the way analytical procedures are performed. The speed that they bring to an analysis, the small sample size and limited reagent use, integration of multiple processing steps into a single unit, as well as the possibility for on-site analysis, all point to changes in the way analytical methods are to be used in the relatively near future. Nowhere is this going to be more important than in the field of clinical analysis. Microfluidic devices in the doctor's office, at the patient's bedside, or at any point-of-care will be as common and easy to use as the blood glucose and home pregnancy testing devices currently available. In the operating room, where rapid analysis while a patient is still in surgery can provide information to the surgeon regarding the extent of damage, to the emergency room, where rapid feedback could identify agents that might cause an epidemic, or are the result of a terrorist attack, the clinical analysis methods provided by microchips will be invaluable. Developments in microfluidics methods directed toward the clinical laboratory have been progressing over the past few years, and fully integrated devices are now being reported. This chapter will review what has been achieved, and look to what is still needed to move this technology into the mainstream of clinical diagnostics.

## 36.2 BACKGROUND

Not long after the early development of microchips for electrophoretic separations of DNA, the potential of these devices for clinical applications was realized.<sup>1–3</sup> While microchip electrophoresis remains a major area in clinical analysis to which microchip processing is applied, implementation of additional processing and analysis steps on microchips over the past few years is also providing new devices designed to replace existing methods utilized in the clinical laboratory.<sup>4–6</sup> The goal of many of these efforts is to eliminate the need for sample transportation to and processing in a central laboratory, by bringing the microfluidic technology directly to the point of care.<sup>7</sup> A report sponsored by the National Cancer Institute discusses the development of point-of-care systems for cancer diagnosis and prognosis, in which integrated microfluidic systems play an essential role.<sup>8</sup>

The purpose of this chapter is to explore clinical analyses that have been transferred to an electrophoretic microchip, along with some of the microchip preparatory methods that are now being integrated with an electrophoretic analysis step to provide lab-on-a-chip type devices. There are a vast number of clinical analyses that are now being transferred to microdevices, but the scope of this chapter is limited to only those that have an electrophoretic component in accord with the nature of this volume. A number of clinical analysis methods simply take advantage of the microfluidic architecture in microchips to decrease sample size and reaction times without requiring a separation step. The most common example of these is microarrays, recently reviewed by Situma et al.,<sup>9</sup> that utilize oligonucleotide to detect the presence of specific DNA sequences.<sup>10–14</sup> Similar types of immunoassays for clinical detection of specific proteins have also been developed on microfluidic devices by immobilizing antibodies within microchannels,<sup>15,16</sup> while these are not included in this chapter, a number of reviews<sup>17,18</sup> as well as an earlier Chapter 34 in this book by Sato and Kitamori cover these types of microchip immunoassays with applications to clinical analyses in more detail. Protein immunoassays on microchips that incorporate a separation step are included in this chapter along with analyses for specific ions,<sup>19</sup> glucose,<sup>20</sup> pH,<sup>21</sup> enzymatic activity,<sup>21,22</sup> and other types of bioaffinity interactions.<sup>23</sup>

The use of mass spectroscopy in clinical analysis is increasing, but is not yet widely employed, thus electrophoretic microchips designed for interfacing with MS detection are also not included here; these devices are covered in Chapter 49 by Laurell for coupling with matrix-assisted laser desorption/ionization-mass spectrometry (MALDI-MS) detection, and Chapter 53 by Lazar for electrospray-MS. A number of microchip applications also relate to the trapping, growth, and analysis of cells on microdevices, but these are not methods utilized in clinical analysis and thus are not included. The reader is directed to a recent review of these techniques by El-Ali et al.<sup>24</sup> as well as in Chapter 32 by Keenan and Beebe. Even with these limitations, the number of clinical methods that have been transferred to microchips is impressive and a comprehensive review is not possible. A number of reviews on microchip separations for clinical analyses have been written,<sup>25–29</sup> the most recent of which reported on microchip separations utilized for detection of cancer, cardiovascular disease, renal disease, neurological disease, immune disorders, diabetes, hereditary disorders, thyroid functioning, and infectious agents in body fluids.<sup>29</sup>

## 36.3 THEORETICAL ASPECTS

Microchip electrophoretic separations themselves and the theory behind them have been covered in Chapters 33 by DeVoe and Lee and 55 by Mahmoudian et al. This is also true of sample processing methods on microdevices, which have been covered in Chapter 43 by Bienvenue and Landers, Chapter 50 by van Midwoud and Verpoorte. The theory and engineering behind integration of multiple processes on a single device, in which both sample pretreatment and analysis steps are performed without removal of the sample from the device, are also explored in Chapter 43 by Bienvenue and Landers, as well as Chapter 40 by Easley and Landers describing valves to control flow within and between processes. This chapter seeks to show how the methods and theory discussed

in these other chapters are being applied to real problems in clinical analysis. In addition, some of the issues involved in developing microdevices for utilization in the clinical laboratory not covered elsewhere will be described.

## 36.4 PRACTICAL APPLICATIONS

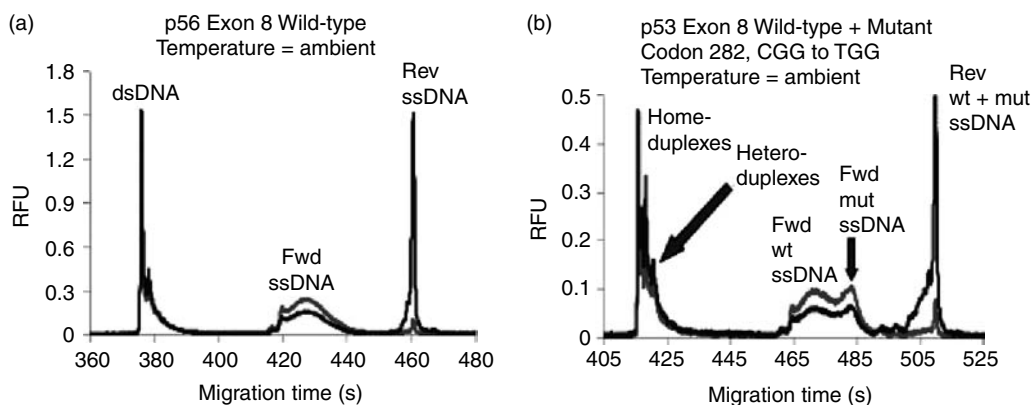

### 36.4.1 DNA ANALYSES

The ability to use laser-induced fluorescence (LIF) for detection allowed DNA separations on microchips to advance more rapidly than separations of other types of clinically relevant compounds. Chapter 6 by Szántai and Guttman reviewed the use of capillary electrophoresis of DNA for clinical diagnostic purposes, and any of those methods can easily be transferred to the microchip platform. Most often, clinical microchip DNA diagnostic devices utilize separations of specific fragments of DNA amplified using the polymerase chain reaction (PCR). Nucleic acid targets of clinical interest for amplification include mutations associated with particular diseases, the presence of exogenous DNA or RNA from pathogens, or over expressed DNA indicating the presence of a single clonal variation. In the coming genetic medicine revolution, where treatment options are also based on particular DNA sequences within a patient's genome, the use of microchip DNA separations will expand even further in the clinical laboratory.

#### 36.4.1.1 Genotyping and Mutation Detection

One of the most common methods for detection of mutations in PCR-amplified DNA fragments is single-stranded conformational polymorphism (SSCP) analysis. Tian et al.<sup>30</sup> reported microchip separations for the detection of common mutations in *BRCA1* and *BRCA2*, two breast cancer susceptibility genes specific for the Ashkenazi Jewish population. Separations were performed in 140 s, fourfold faster than the CE-based assay, with profiles from the wild-type and mutant alleles easily distinguishable. As was important in the development of all of these clinical microchip methods, no loss of diagnostic ability was seen in moving to the microfluidic analysis method. This method was further pursued by Kang et al.<sup>31</sup> for rapid detection of a point mutation in the obesity gene. In addition to the SSCP technique, heteroduplex analysis (HDA) is a second method utilized for mutation analysis that has been transferred to microchips. Hestekin et al.<sup>32</sup> used a combination of SSCP and HDA separations on a microchip to evaluate mutations in specific exons in the *p53* gene, a gene for a transcription factor important in regulating the cell cycle and preventing tumor growth. Figure 36.1 shows microchip separations of fragments generated from samples of a wild type and an exon 8 mutant of the *p53* gene. Tian et al.<sup>33</sup> also utilized HDA on a microchip, combining it with allele-specific PCR to identify additional mutations in the *BRCA* genes as well as the *PTEN* tumor suppressor gene. The clinical potential for all of these electrophoretic methods based on migration differences due to the presence of mutations was recently reviewed by Hestekin and Barron.<sup>34</sup>

The mutations for which the above methods are most applicable are simple deletion and insertion mutations affecting only a few bases. Substitution mutations are difficult to monitor in this way,<sup>30</sup> but represent a significant class of DNA mutations called single nucleotide polymorphisms (SNP), which will play a significant role in the area of personalized medicine. Woolley et al.<sup>35</sup> performed SNP detection in *HLA-H*, a marker gene for hemochromatosis, on a 12-channel microchip using selective restriction digestion of a PCR-amplified product followed by traditional DNA sizing electrophoresis. Shi et al.<sup>36</sup> utilized this same method on a 96-channel radial array microchip for SNP detection in the gene for methylenetetrahydrofolate reductase, the protein product of which regulates folate and methionine metabolism. This same 96-channel microchip design was used by Medintz et al.<sup>37</sup> to evaluate a polymorphism in the *HFE* gene resulting in hereditary hemochromatosis using

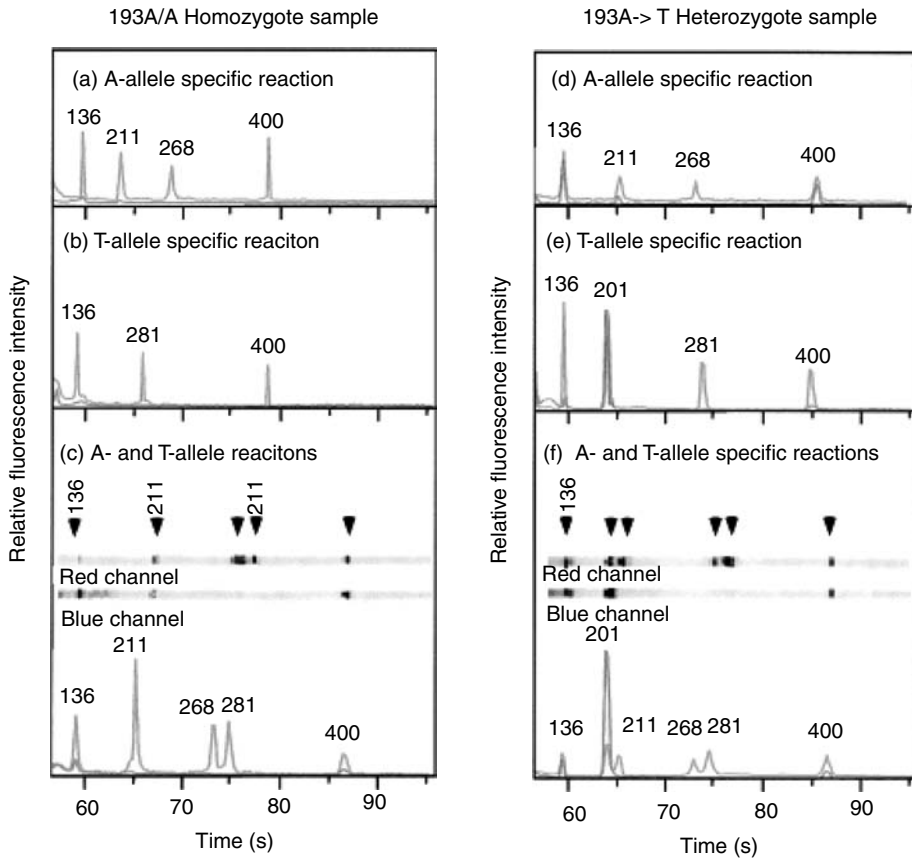

**FIGURE 36.1** Electropherograms showing analysis of *p53* exon 8 amplicons for mutation detection by tandem SSCP/HA. dsDNA peaks are identified by the overlap of the FAM (forward strand) and JOE (reverse strand) dyes. ssDNA peaks are identified by the predominance of one fluorescent dye. Peaks due to the mutation are indicated by the arrows. Separation conditions: ambient temperature, 0.1% PHEA dynamically coated channel, 350–450 V/cm applied electric field strengths. (Reprinted from Hestekin, C. N., et al., *Electrophoresis*, 27, 3823, 2006. With permission.)

allele-specific primers to generate different sized products. Figure 36.2 shows the separation and detection of both homozygote and heterozygote mutations in the S62C variants of the *HFE* gene on a microchip. The authors extended this work to simultaneously detect three SNP mutations within this same gene based on the sizes of the DNA fragments produced.<sup>38</sup>

Simple size-based electrophoretic separations in microchips can also be employed for insertion and deletion mutations, which modify the size of the PCR-amplified DNA fragments. Sung et al.<sup>39</sup> utilized this method on a plastic microchip to evaluate fragile X alleles that have multiple repeat units of a trimeric CGG repeat. A tetranucleotide repeat in microsatellite alleles, related to hypercholesterolemia in families, was investigated by Cantafora et al.<sup>40</sup> using the Agilent 2100 Bioanalyzer, a commercially available microchip electrophoresis instrument capable of analyzing up to 12 samples in 30 min. This same instrumentation was used in the evaluation of deletion and duplication mutations associated with Duchenne muscular dystrophy in two papers by Ferrance et al.,<sup>41,42</sup> which looked at a total of 13 loci in the dystrophin gene using two PCR amplifications and electrophoretic separations. A total of 50 samples were evaluated in the initial work, with all 35 samples with mutations being identified.<sup>41</sup> Figure 36.3 shows the traditional Southern blot analysis versus the microchip separation for the detection of a particular deletion. The subsequent work went on to establish normal ranges for each exon product using 40 control samples, which were then used to correctly evaluate patient samples for the presence of mutations.<sup>42</sup>

The Bioanalyzer was also used in two studies by Sohni et al.<sup>43,44</sup> that looked at both variable number of tandem repeat and deletion mutations in genes of clinical interest. The first study investigated polymorphisms in the cytokine genes *IL-1RN* and *CCR5*, both of which are important in immune system functioning.<sup>43</sup> The second study investigated nucleotide repeats in the promoter region of the inducible NO<sub>2</sub> synthase gene and the endothelial NO<sub>2</sub> gene, both associated with complications in diabetes, and a deletion/insertion mutation in the angiotensin-converting enzyme gene associated with NO<sub>2</sub> activity.<sup>44</sup> In addition to the Agilent instrument, Hitachi also developed a commercial microchip electrophoresis instrument (SV 1210) both of which were utilized by Zhang et al.<sup>45</sup> to evaluate gene fragments generated from 3  $\mu$ L of blood in less than 20 min using a DNA extraction disk and a capillary PCR instrument.

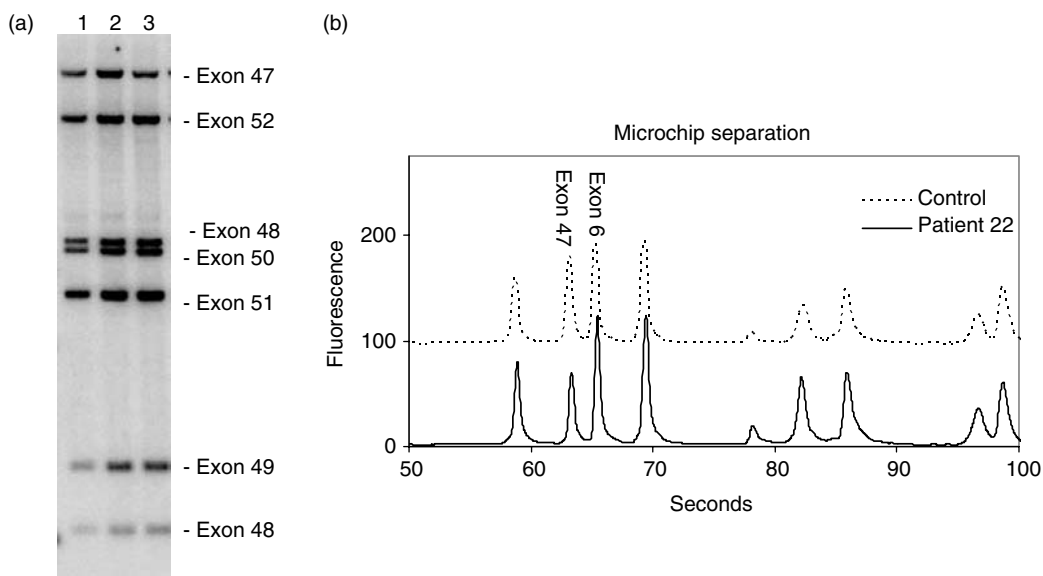

**FIGURE 36.2** Detection of a heterozygous mutation (right panel) in the *HFE* gene using allele-specific PCR with two-color (red/blue) detection. (a and d) Separation of the A-allele specific amplicon (211 bp) from the 136 bp and 400 bp internal standards (red channel); (b and e) separation of T-allele specific amplicon (201 bp) from the same samples (blue channel); (c and f) separation of both amplicons showing only the A-allele fragment in the homozygous sample but both fragments in the heterozygous mutant sample. Numbers above the peaks indicate fragment length (bp). (Reprinted from Medintz, I., et al., *Electrophoresis*, 21, 2352, 2000. With permission.)

### 36.4.1.2 Other Nucleic Acid Analyses

Mutation detection and genotyping represent a significant portion of clinical DNA analyses, but other DNA separations of clinical interest have also been transferred to microchips. In lymphoproliferative disorders, a single clonal variation is often overexpressed in T- or B-cells resulting in a loss of heterogeneity in the immune system. Munro et al.<sup>46</sup> translated slab gel separations of PCR-amplified fragments, traditionally used to detect these disorders, to a microchip, effectively detecting clonal populations in the variable region of the T-cell receptor- $\gamma$  gene and the immunoglobulin heavy chain gene. Again, no loss of diagnostic information was seen in the transition to the microchip separation system, in fact, a patient diagnosed as not having a lymphoma using the gel-based method was re-evaluated based on the microchip results and found to be in an early stage of the disease. Quantification of mRNA species has also been proposed as a clinical method, and reverse transcriptase-PCR (RT-PCR) products from renal biopsies have also been separated on microchips as a diagnostic method.<sup>47</sup>

**FIGURE 36.3** (a) Southern blot results obtained using DNA digested with HindIII and probed with cDMD 8. Lane 1: normal male control; lane 2: normal female control; lane 3: female patient with a deletion in exon 47. (b) Microchip electropherograms of a multiplex amplification for a control and a female patient with a deletion in exon 47.

The presence of exogenous DNA or RNA in a patient is also of clinical interest, as this can be used to indicate the presence of a bacterial or viral pathogen. Höfgartner et al.<sup>48</sup> used a single-channel glass microchip for the detection of herpes simplex virus (HSV) in cerebrospinal fluid (CSF) through separation of PCR-amplified products. The microchip-based electrophoresis method allowed for rapid diagnosis of herpes simplex encephalitis (HSE), in less than 100 s, compared to 18 h for identical results obtained by hybridization. Chen et al.<sup>49</sup> were able to detect viral RNA from the hepatitis C virus through RT-PCR amplification with product identification performed using an electrophoretic separation on a plastic microdevice. This group went on to further quantify the amount of viral DNA present using a competitive PCR procedure, with product analysis again on the plastic microchips.<sup>50</sup> The Agilent Bioanalyzer also provides an efficient method for the separation of PCR products generated from exogenous DNA in CSF to show the presence of viral infections. Separations showing the presence of infections from a number of viral pathogens are shown in Figure 36.4. The Agilent instrument was also used to evaluate repetitive sequence PCR products from *Mycobacterium* species by Goldberg and coworkers.<sup>51</sup> This kind of genotypic analysis can be used to identify particular strains, track tuberculosis transmission in outbreaks, and identify cross contamination in the laboratory.

### 36.4.2 PROTEIN ANALYSIS

Electrophoretic analysis of proteins was one of the first methods transitioned to capillaries in clinical laboratories—this is highlighted in Chapter 2 by Hempe. Unfortunately, protein analysis has not made the same transition to microchips. This is due to the difficulties in implementing a ultraviolet (UV) absorbance method on microchips, the method normally utilized for proteins detection on CE. A number of fluorescent methods have been employed both for standard separations as well as for immunoassay analyses that utilize separations. Two-dimensional separations have also been performed on microchips,<sup>52</sup> as reviewed in Chapter 33 by Lee, and these might have clinical significance at some point in the future.

**FIGURE 36.4** Electropherograms of PCR-amplified cerebral spinal fluid samples from patients with suspected infectious agents. (a) Samples from patients possibly infected with HSV; clinical diagnosis by traditional means: patient 2—infected HSV type 1, patient 6—negative. (b) Samples from patients possibly infected with cytomegalovirus; clinical diagnosis by traditional means: patient 9—infected, patient 20—negative.

### 36.4.2.1 Protein Separations

Human serum protein quantification is an important method for determining the relative abundances of albumin, IgG, and other important serum proteins. Colyer et al.<sup>53</sup> investigated serum proteins through microchip separations of fluorescently labeled proteins, showing that quantification was possible even after labeling. Real samples, however, could not be evaluated because of poor sensitivity. Callewaert et al.<sup>54</sup> also utilized a fluorescent labeling scheme to tag N-glycan components in serum, but was able to separate these real clinical samples on a microchip; a typical separation is shown in Figure 36.5, in which the difference between serum from a patient with cirrhosis and one with chronic hepatitis is illustrated. Separation of lipoproteins in serum on a microchip was reported by Weiller et al.<sup>55</sup> who utilized NBD as a fluorescent label to allow detection of both high- and low-density lipoproteins, important risk factors for cardiac disease. This group further refined the work to allow analysis of the low-density lipoprotein (LDL) components to show the presence of different forms of LDL in serum samples.<sup>56</sup>

A number of other covalent and dynamic fluorescent labeling schemes have now been proposed for the detection of proteins on microchips, all of which could be applied for clinical protein analysis.<sup>57–60</sup> Bio-Rad has adopted an on-column dynamic labeling scheme in their commercial microchip electrophoresis instrument, which Chan and Herold<sup>61</sup> utilized to evaluate microalbuminuria, a marker for cardiovascular disease and nephropathy in diabetic patients. Through the use of an SDS-based separation, these experiments can provide quantitative and qualitative information about the proteins. However, the use of covalent and dynamic labeling of native proteins must be evaluated for each system studied as fluorescent tags are not incorporated homogeneously across proteins, and are known to be influenced by the hydrophobicity and secondary structure of the proteins. This heterogeneity affects both the electrophoretic mobility and fluorescence response of each protein differently, and thus must be accounted for in the results obtained from any clinical protein separation. Giordano et al.<sup>60</sup> developed a partially denaturing technique for fluorescent labeling, to minimize preferential binding, in which SDS was added to the sample, but no heat denaturation step was employed. Figure 36.6 shows the microchip protein profiling of human sera, using this method for the detection of gammopathies. The separations show clear spikes in the protein profiles of severely affected patient sera, but detection of more subtle changes was not evaluated.

UV detection on microchips has not been completely bypassed, but it does require quartz microdevices, as the normal glass and plastic microchips absorb too much UV radiation in the wavelengths of interest. Zhuang et al.<sup>62</sup> have developed quartz microchips for protein detection, and

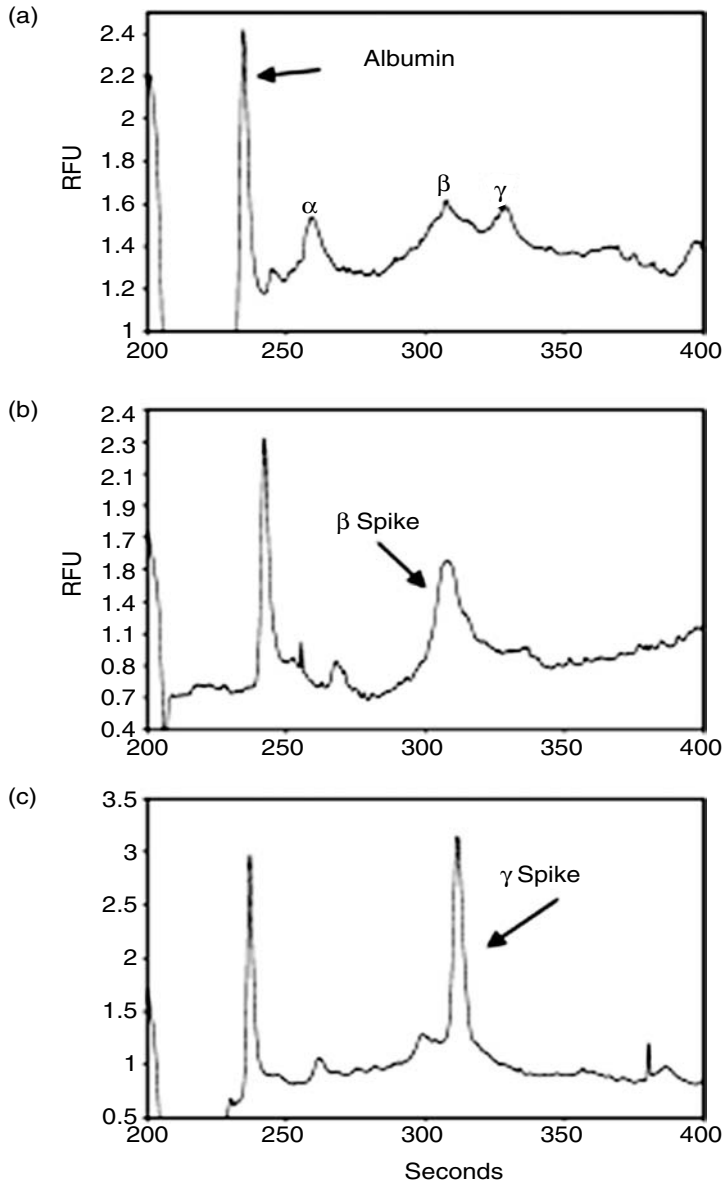

**FIGURE 36.5** Profiling of two serum samples: one from a noncirrhotic chronic hepatitis patient and one from a patient with cirrhosis. Log (peak 7/peak 8) is diagnostic for liver cirrhosis, and these two peaks are well resolved in the microfluidics profiles. (Reprinted from Callewaert, N., et al., *Electrophoresis*, 25, 3128, 2004. With permission.)

have utilized them for electrophoretic analysis of urinary proteins of clinical interest.<sup>63</sup> This group has also now applied quartz microchips to the analysis of serum lipoproteins<sup>64</sup> without the need for fluorescent tagging as discussed above.<sup>55</sup> UV detection is also covered in a review by Wang et al.<sup>65</sup> who detail the use of electrophoretic microchips for the clinical analysis of hemoglobin, with various detection methods.

### 36.4.2.2 Microchip Immunoassays

A number of microchip immunoassays have been developed that utilize an on-chip reaction followed by a separation component to separate free antigen from that bound to the antibody—if a labeled antigen is used—or to separate free antibody from the antigen/antibody complex—if labeled antibodies are used. Schmalzing et al.<sup>66</sup> utilized the latter method to demonstrate an immunoassay for T4 in serum for clinical evaluation of thyroid function on fused-silica microchips. The immunoassay used a competitive format with labeled antigens competing against antigens in the serum for antibody-binding sites; the amount of free labeled antigen was used to quantify the amount of T4 in the samples. The same group also reported a microchip electrophoretic immunoassay for cortisol in serum using a similar method,<sup>67</sup> which could quantify cortisol in serum within the clinical range without extraction from the sample or other preparation steps. Qiu and Harrison<sup>68</sup> were able to incorporate a calibration step into their immunoassay microchip that will be important for eventual implementation in clinical analyses. Using a microchip with multiple inlets, they could control the amount of antibody mixed with labeled antigen, in this case bovine serum albumin (BSA). While this antigen is not clinically relevant, the ability to calibrate the microchip response, as shown in Figure 36.7, will be important for protein quantification.

In addition to fluorescent-based assays, electrochemical detection has also been utilized for microchip immunoassays. Wang et al.<sup>69</sup> initially utilized an alkaline phosphatase-labeled antibody,

**FIGURE 36.6** Comparison of CZE analysis of partially denatured human sera using run buffer containing 0.04% NanoOrange dye. Sera were diluted 1:500 in 0.5% SDS, with 1% dye included in the sample buffer. Separation conditions: 100 mM borate, 3 mM diaminobutane, pH 8.5. (Reprinted from Giordano, B. C., et al., *Anal. Chem.*, 76, 4705, 2004. With permission.)

which was mixed with the antigen (mouse IgG), then separated on-chip to resolve the free antibody from the complex. Using a post column reaction of the alkaline phosphatase to produce 4-aminophenol, they were able to monitor the products using electrochemical detection. This same group also used ferrocene tagged antibodies, simply measuring the reduction of the ferrocene in the free antibody and the complex using amperometric detection.<sup>70</sup> Measurement of both IgG and T3 antigens were shown in this format. More recently, Herr et al.<sup>71</sup> showed fluorescent microchip immunoassays for both tetanus antibody and tetanus toxin, utilizing fluorescently labeled tetanus toxin C-fragment and a fluorescent marker as an internal standard for quantification. The microchip separation provided a direct immunoassay for the presence of tetanus antibody, and a competitive

**FIGURE 36.7** Traces from an on-chip calibration series. Intensity changes as a function of the amount of anti-BSA delivered to the reaction, the complex peak increases in intensity while the labeled BSA peak decreases. At the highest antibody concentration impurities can be seen in the BSA peak region. (Reprinted from Qiu, C. X., and Harrison, D. J., *Electrophoresis*, 22, 3949, 2001. With permission.)

assay for the presence of tetanus toxin could be used to generate a dose-response curve as shown in Figure 36.8; the microchip design, however, did not include an integrated incubation step.

### 36.4.3 ADDITIONAL CLINICALLY RELEVANT ANALYSES

In addition to DNA and proteins, a number of other important clinical markers have been evaluated using electrophoretic separations on microchips. Fanguy and Henry<sup>72</sup> quantified uric acid in urine using a microchip electrophoretic separation with electrochemical detection. This work was extended to include three markers of renal function normally measured in clinical assays: uric acid, creatinine, and creatine.<sup>73</sup> Detection of glucose has also been performed directly from human plasma on a microchip, with no need for sample pretreatment. Du et al.<sup>74</sup> utilized a poly(dimethylsiloxane) (PDMS) microchip containing a copper electrode for electrocatalytic oxidation of the glucose as the detection method. Additional investigations involving the analysis of carbohydrates by microchip electrophoresis, a few of which are of interest for clinical analyses, are covered in a review by Suzuki and Honda.<sup>75</sup> This review covers not only electrochemical detection methods but also reports on the use of fluorescent and UV absorbing tags; the authors suggest, however, that the need for a derivatization step eliminates the rapid separation advantage provided by the microchip analysis.

A number of small molecules of interest in clinical analyses have also been analyzed using microchip-based separations. Zhao et al.<sup>76</sup> utilized a microchip separation for detection on the antibiotic lincomycin directly from urine samples. This method, also employing electrochemical detection, allowed lincomycin analysis in under 40 s. Crevillen et al.<sup>77</sup> utilized a similar method for

**FIGURE 36.8** Dose–response curve for the tetanus toxin C-fragment using a microchip competitive immunoassay. Symbols show the normalized response (peak height of complex/peak height of free dye) with error bars indicating the standard error in the measurements ( $n = 3\text{--}5$ ). A correlation coefficient of .95 was obtained for the linear fit through the points indicated. The inset shows electropherograms with TTC concentrations of (a) 2.0, (b) 7.8, and (c) 15.6 nM, with a labeled TTC\* concentrations of 13.0 nM and 6.0 nM anti-TTC. Peaks 1 and 2 are due to free dye with peak 2 used for normalization; peak 3 is free TTC\*, and peak 4 is the complex. Separation conditions: 300 V/cm, total length 6.1 cm, and length to detector 6 mm. (Reprinted from Herr, A. E., et al., *Anal. Chem.*, 77, 585, 2005. With permission.)

separation and detection of hydroquinone and hydroquinone glycoside, important in clinical analyses because of their presence in pharmaceuticals and natural remedies. They were able to separate and detect these components using different injection methods, and also applied the microchip method to the analysis of urine samples. Figure 36.9 shows application of this method to a variety of sample types. Electrochemical detection was also utilized on microchips for the separation of six organic acids (fumaric, citric, succinic, pyruvic, acetic, and lactic acids) and three cations ( $K^+$ ,  $Na^+$ , and  $Li^+$ ).<sup>78</sup> This microchip used a four-electrode system with no direct contact between the electrodes and the separation channel, but was not tested with real samples.

Munro et al.<sup>79</sup> showed separation and detection of amino acids on microchips using an indirect fluorescence detection method. Figure 36.10 shows application of this method to urine samples with no pretreatment other than dilution in the appropriate separation buffer. Abnormal amounts of amino acids can easily be detected in the two patient samples compared to the healthy control sample. An absorbance detection based approach was utilized for the clinical analysis of calcium ion in serum, which is important in the regulation of a number of physiological processes.<sup>80</sup> Beads with an immobilized calcium reactive dye were placed into the detection region, and the samples mobilized past the beads using electrophoretic flow. While a true separation was not intended, the interference of magnesium ions was significantly less than seen in pressure flow devices,<sup>19</sup> since  $Mg^{2+}$  moves through the channel faster than  $Ca^{2+}$  allowing less interaction time with the beads.

#### 36.4.4 SAMPLE PREPARATION

There are a large number of biological sample processing steps that have now been translated to microchip methods and been shown to provide the same results, while utilizing smaller amounts of sample and less reagents, thus reducing both cost and waste generated. At the same time, the miniaturization of these processes has often produced a significant reduction in the time required,

**FIGURE 36.9** Electropherograms of (a) the nutraceutical HMP, (b) urine, (c) a cosmetic formulation, and (d) a wine sample. Peak labels correspond to (1) hydroquinone and (2) arbutin. The (a) traces are unspiked sample (b and d) or spiked with 150 ppm of (a) hydroquinone and (c) arbutin. The (b) traces are spiked with 150 ppm of hydroquinone and 125 ppm of arbutin. by reducing diffusional lengths, thermocycling times, and column volumes. This chapter will not address all of these processes, but again will be limited to those processes directly related to clinical analysis and those that would be utilized in conjunction with a subsequent electrophoretic separation for analysis. Chapter 43 by Bienvenue and Landers, Chapter 50 by van Midwoud and Verpoorte in this volume address additional methods and provide more in-depth coverage of the microchip sample preparation literature. In addition, early work on sample preparation methods utilized for clinical molecular diagnostics that have been translated to microfluidic formats is covered in a review by Huang et al.<sup>81</sup> These methods include cell sorting/selection, which can be used for clinical diagnostics but are not covered here, as well as nucleic acid purifications, and nucleic acid amplifications methods.

#### 36.4.4.1 Enzymatic Reactions

Enzymatic amplification of specific fragments of a nucleic acid template, particularly through the use of the PCR, is one of the most widely translated methods to microchips associated with a subsequent electrophoretic analysis. A number of microdevices and thermocycling methods have been described and are summarized in a recent review by Zhang et al.<sup>82</sup> covering the basic designs and practical applications of microchip PCR. Not all of the microchip PCR developments showed direct clinical utility, and thus are not included here, but most of the methods could theoretically be utilized for clinical analysis. In addition to the traditional PCR-based DNA amplification, amplifications from RNA using RT to first generate a cDNA are also of clinical interest, as well as other enzymatic methods, which are not as widely utilized.

Most clinically relevant microchip PCR amplifications have been utilized for the detection of infectious agents. Mikhailovich et al.<sup>83</sup> showed allele-specific amplifications of mycobacterium tuberculosis to evaluate rifampicin resistance as a method for monitoring the use of this drug for treatment. They compared this method to a hybridization method, providing similar results but greatly decreasing the analysis time. Yang et al.<sup>84</sup> utilized a plastic microchip to test the sensitivity and specificity of detection of a K12-specific fragment from *Escherichia coli*. They were able to detect as low as 10 *E. coli* cells with this method in the presence of 2% blood, and could do multiplex PCR to show specificity. For the detection of hepatitis B, a common infectious disease and blood borne pathogen, Cho et al.<sup>85</sup> conducted a large-scale study of a microchip PCR method for the virus in real clinical samples. The authors utilized a real-time detection method, employing a miniature fluorescence detection system using light emitting diodes and photodiode detectors, to monitor amplification of sequences specific for the hepatitis B virus, thus a separation was not needed. The study, however, evaluated specificity, sensitivity, cross reactivity, reproducibility, and limits of detection in a large-scale clinical evaluation of the method ( $n = 563$ ) to show the applicability of microchip methods for routine clinical analysis.

Real-time detection was also used for an isothermal amplification procedure termed nucleic acid sequence-based amplification, for the detection of artificial human papilloma virus sequences in SiHa cells.<sup>86</sup> This method was not applied to real samples, but demonstrates the clinical applicability of additional microchip enzymatic amplification methods. Not all clinical microchip PCR amplifications looked for infectious agents, however. Cheng et al.<sup>87</sup> showed a microchip PCR method for multiplex amplifications of dystrophin gene fragments for the detection of mutations associated with muscular dystrophy.

Other types of enzymatic reactions have also been implemented on microchips. Using PCR-amplified DNA as the template, Lou et al.<sup>88</sup> utilized ligase chain reaction to identify a mutation in the *NOD2/CARD15* gene, a marker for inflammatory bowel disease, using DNA from blood of healthy volunteers. The reaction used the ligase enzyme to join short oligonucleotides sequences when the corresponding complementary wild-type or mutant DNA template was present. Digestion of DNA on a microchip using restriction enzymes has also been reported, but at this time, this has not yet been utilized for analyses relevant to clinical work.<sup>89</sup> Likewise, digestions of proteins have been shown on microchips, but have not been applied for clinical analyses.<sup>90,91</sup> A number of

these enzymatic reactions and others have been transferred to microchips, but are covered within Section 36.4.5 below since they have been directly coupled to the subsequent electrophoretic separation on the same microchip.

#### 36.4.4.2 Purification and/or Concentration

A number of diverse methods fall under this category with respect to clinical analysis. One important process in clinical analyses is the isolation of plasma from whole blood, which has been performed on a microchip using a transverse flow microfilter design.<sup>92</sup> Utilizing capillary action for the separation, both the plasma and the cell components of the blood were available on-chip for additional processing. Processing of blood to separate the leukocytes from other components has also been shown on a microchip for clinical applications requiring removal of erythrocytes.<sup>93</sup> This microchip was designed to mimic intrinsic blood flow processes, such as leukocyte margination, to separate the two cell types and allow collection of the white cells. Another interesting technique applied to serum and urine samples is laminar flow diffusion, which takes advantage of the laminar flow and short diffusion lengths provided by microchips.<sup>94</sup> By flowing the sample in parallel with a water stream, low molecular weight components are extracted into the water phase, which can then be collected in a separate stream from the original sample. While used only for spectroscopic detection in the original work, this could be implemented for the removal of small molecular weight components for analysis, such as urea and creatine from urine. Additional details on this process can be found in Chapter 35 on liquid/liquid extraction by Tokeshi and Kitamori.

One of the most widely investigated purification methods on microchips is DNA extraction, which has been shown using a number of different phases and microchip designs, but only those methods that have been shown to deal with real samples such as whole blood are of clinical interest. Breadmore et al.<sup>95</sup> capture DNA directly from blood utilizing silica beads immobilized in place with a silica sol-gel matrix, showing that it was possible to perform PCR amplification on the eluted genomic DNA. Chung et al.<sup>96</sup> used beads with organic surface groups for capture of DNA on a poly(methyl methacrylate) (PMMA) microchip. The beads were immobilized to the surface of the PMMA through the organic surface groups, and the DNA containing solution passed back and forth over the immobilized beads. DNA from *E. coli* cells could be extracted and amplified from serum and whole blood, with the immobilized beads providing significantly better extraction efficiency than free beads as the number of *E. coli* in the blood sample decreased.

Rather than packing beads into a microchannel, Wu et al.<sup>97</sup> utilized the liquid precursor of the silica sol-gel to form a monolithic matrix in a microchannel for DNA extraction. This solid phase provided extraction efficiency with good reproducibility using standards, but extraction efficiency fell off quickly with whole blood when the devices were used repeatedly. This is not necessarily a problem, in that these devices for clinical applications would be designed for only a single use to prevent cross contamination of samples. Figure 36.11 shows the protein and DNA profiles generated on the sol-gel microchip during purification of DNA directly from lysed blood. While the sol-gel matrix was easier to generate in the channel, the liquid precursor filled all of the channels. Wen et al.<sup>98</sup> solved this problem through the use of a photopolymerizable matrix, which they coated with a sol-gel precursor to increase the DNA-binding capacity. For whole blood application, they found that the proteins competed for binding sites, and significantly decreased the capacity of the monolith for DNA. A dual phase microchip was developed using an initial C18 phase to capture the proteins from the lysed blood as the DNA passed through for capture on the monolith. Volumes as large as 10  $\mu\text{L}$  of blood could be processed on this device with good extraction efficiencies.

In addition to proteins competing for binding sites in the DNA extraction process, removal of proteins from the solid phase is normally performed using an alcohol-based wash step to prevent protein coelution with the DNA and possible interference with the subsequent processing steps. As reported by Legendre et al.<sup>99</sup> this wash step causes its own problems in that isopropanol inhibits PCR, which is often the next process on an integrated device. Wen et al.<sup>98</sup> were able to eliminate this

**FIGURE 36.11** Protein and DNA extraction profiles from a lysed human blood sample loaded onto a sol-gel filled microchip. Protein (closed squares) is removed in the wash step and DNA (open circles) is released during the elution step.

step using the dual phase method, but other approaches have also been investigated. Witek et al.<sup>100</sup> utilized a photoactivated polycarbonate (PPC) microfluidic device for DNA extraction from *E. coli*, which incorporated an ethanol wash step, but the device could be dried before elution of the DNA to eliminate inhibition from the wash buffer. Larger elution volumes were required, however, and this work did not address DNA purification from human whole blood. An amine-coated microchip that had lower protein binding was used in work by Nakagawa et al.<sup>101</sup> to extract DNA from whole blood. No wash step was required, avoiding the use of PCR-inhibiting reagents, but the amine phase showed only moderate efficiency. A competing approach was developed by Cao et al.<sup>102</sup> using the protonated amine groups on chitosan at a low pH to capture the negatively charged DNA. The DNA was easily released at a high pH at which the amine groups became neutral. Very little protein was found to bind to the chitosan phase, thus a wash step was also not required in this method. Using the chitosan technology, a microchip capture device could be constructed simply by immobilizing the chitosan directly on the surface of a bifurcated channel structure within a microchip.

While DNA represents a major focus of purification on microchips, capture of RNA has also been explored. Kokoris et al.<sup>103</sup> utilized a silica membrane immobilized in a microchip for RNA purification. The “lab card” device provided RNA suitable for reverse transcriptase amplification with a yield and quality better than that obtained using traditional RNA extraction methods. A number of protein preconcentration or extraction microchip devices have also been developed, using either a general hydrophobic capture phase to capture all proteins, or an antibody or ligand-based phase for specific capture of a protein of interest. Most of these are designed for use with MS analysis of the collected products, however, and are covered in Chapter 53 by Lazar. One exception is the use of a phosphocholine ligand capture phase for selective capture of C-reactive protein (CRP), of interest as a cardiac and inflammation marker.<sup>104</sup> This work required subsequent electrophoretic separation to quantify the CRP because of capture of additional phosphocholine-binding proteins in the extraction; quantitative results generated from the microchip extraction process agreed well with current CRP analysis method results.

### 36.4.5 CHIP-BASED INTEGRATION OF SAMPLE PREPARATION STEPS

The ultimate motivation for transfer of electrophoretic separations from a capillary to a microchip was the ability to perform these additional processing steps in the microchip format, which was not as easily achieved in a capillary system. This provides the microchip the advantage of sequential integration of a number of processing steps directly with the electrophoretic analysis, and many

of the integrated devices that resulted are of interest in clinical analyses.<sup>105</sup> As with microchip electrophoresis itself, much of this work has focused on DNA for genetic analysis<sup>106</sup> (see Chapter 43 by Bienvenue and Landers), but a number of integrated protein microchips have also been reported, along with multiprocess assays for small molecules.

### 36.4.5.1 DNA Amplification

A significant number of groups have reported on integration of the PCR process directly with the subsequent electrophoretic separation on the same microchip.<sup>87,107–115</sup> As with the microchip PCR for clinical applications, most of the integrated microchip work focused on detection of infectious agents, starting in 1996 with Woolley et al.<sup>107</sup> who showed amplification and electrophoresis of a fragment of salmonella DNA. Figure 36.12 shows the microchip separation of the amplified salmonella fragment along with a co-injection of the amplified product with a size standard for peak identification. Waters et al.<sup>108,109</sup> incorporated cell lysis, and amplified and separated fragments from multiple regions of the *E. coli* genome in their integrated device. Bacterial detection of both *E. coli* 0157 and salmonella was performed by Koh et al.<sup>113</sup> in a plastic integrated device fabricated in cyclic olefin copolymer (COC). Limits of detection as low as six copies were possible. Lagally et al.<sup>114</sup> also evaluated an integrated microchip for pathogen detection, amplifying genes from both *E. coli* and *Staphylococcus aureus*. Limits of detection in this system were as low as two to three bacterial cells. Easley et al.<sup>115</sup> developed an integrated microchip that utilized valves for pressure-based injections from the PCR chamber into the separation channel for the detection of salmonella DNA. This allowed dilution

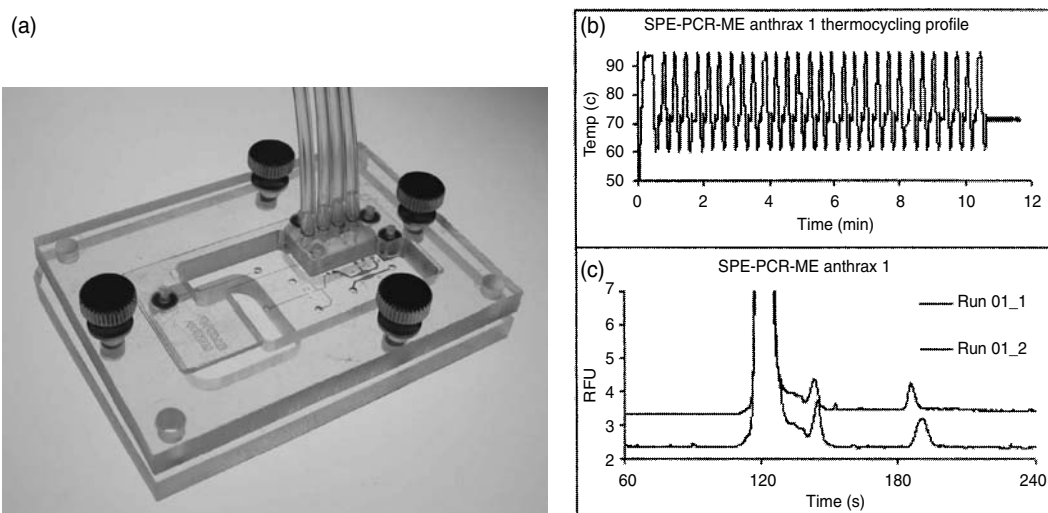

**FIGURE 36.12** Integrated PCR-electrophoresis microdevice assay for the detection of salmonella DNA. (a) Microchip separation of the PCR product was performed immediately following a 39-min amplification in the integrated microdevice. Primer-dimer (light gray peak) appears at 51 s and the PCR product (dark gray peak) appears at 61 s. (b) Sizing of the *Salmonella* product (1:100 dilution) in a separate microchip using a  $\Phi$ X174 HaeIII digest DNA standard (1 ng/ $\mu$ L). Total analysis time for the salmonella sample using the integrated microdevice was less than 45 min. (Reprinted from Woolley, A. T., et al., *Anal. Chem.*, 68, 4081, 1996. With permission.)

of the PCR product with water to provide a stacking effect as it was co-injected with a DNA size standard for accurate sizing.

For the detection of a severe acute respiratory syndrome coronavirus, Zhou et al.<sup>116</sup> used an integrated microchip to perform RT-PCR along with electrophoretic sizing. Nasopharyngeal swab samples were utilized in the analysis with the microchip method showing infection in 17 of 18 patient samples; this was better than the conventional RT-PCR method that identified only 12 infected patients. Pal et al.<sup>117</sup> incorporated an additional reaction step in their integrated microchip for the identification of hemagglutinin A subtypes of influenza virus. Identification was based on restriction fragments, thus an on-chip enzymatic digestion was performed after the PCR. Separation of the digested products allowed successful discrimination of two influenza strains. In more recent work, Kaigala et al.<sup>118</sup> used a PCR electrophoresis microchip to assess the risk of nephropathy in renal transplant patients. The analysis could distinguish between low, medium, and high BK viral loads, indicating patients at risk for complications; detection of as low as two viral copies was possible. Easley et al.<sup>119</sup> went further, incorporating a DNA extraction step with the PCR and separation steps to show a fully-integrated analysis following off-chip cell lysis. They reported on analysis of mouse blood for the detection of *Bacillus anthracis* infections showing detection in asymptomatic mice from less than 1  $\mu\text{L}$  of blood samples. A similar sized sample of nasal aspirate was used to show the presence of *Bordetella pertussis* in a patient confirmed to have whooping cough. Figure 36.13a shows a picture of the integrated microchip utilized in this work, Figure 36.13b shows the IR-mediated thermocycling profile on the device, and Figure 36.13c shows consecutive injections and separations of the amplified product for the *B. anthracis* analysis.

For detection of mutations, Cheng et al.<sup>87</sup> used an integrated PCR-microchip electrophoresis device for a multiplex amplification to identify deletions in the dystrophin gene, with successful amplification and resolution of all of the products. Taylor et al.<sup>120</sup> detected mutations in mitochondrial DNA, which are indicated in a wide range of human disease states, utilizing a different set of on-chip processes. DNA was digested using a restriction enzyme, then denatured and reannealed to perform a HDA in the separation step for the identification of mutations.

**FIGURE 36.13** (a) Integrated microchip used for the detection of *B. anthracis* infection in murine blood. The right channels are the solid phase extraction region; the dark filled chambers are the PCR area; the left channel is the separation channel, with the cross-t injection region covered by the pneumatic actuation lines used for an on-chip pumped injection. (b) Thermocycling profile for the microchip using IR-mediated PCR. (c) Electrophoretic analysis of the amplified product showing sequential pressure injections and separations on the integrated device to confirm the presence of the amplified fragment.

### 36.4.5.2 Onboard Sample Preparation for Other Analytes

Integrated microdevices have also been developed for protein analysis, most often using MS detection, as in the discovery of new biomarkers useful for clinical analysis.<sup>121</sup> Gottschlich et al.<sup>122</sup> showed early integration on a microchip, combining a protein digestion step directly with an electrophoretic separation of the products, but often only a preconcentration step is integrated with the on-chip separation. Membranes have been formed in a cross channel for concentrating proteins during the injection step using both laser patterning<sup>123</sup> and photopolymerization.<sup>124</sup> While these methods might be applicable to clinical analysis, no clinical sample was evaluated. Both concentration and selective protein removal was shown on a microchip that integrated two electrophoretic channels with built-in electrochemical detection.<sup>125</sup> The first channel was used for sample preconcentration utilizing an isotachopheresis method, followed by a normal CZE separation; a myoglobin sample could be concentrated by greater than 60-fold in this system. Selective removal of proteins from a peptide sample was also shown in conjunction with desalting of the sample for subsequent analysis of the peptides.

In addition to proteins, small molecules have also been analyzed on integrated microchips. Analyses of three markers of renal function, uric acid, creatinine, and creatine, along with *p*-aminohippuric acid were investigated using integrated microchips by Wang and Chatrathi.<sup>126</sup> This work utilized fluid control to mix in creatinase and creatininase enzymes with the samples for on-chip enzymatic reactions before the electrophoresis. The unreacted acid species were separated from the neutral hydrogen peroxide, generated in the two enzymatic reactions, with detection using an amperometric method. To individually quantify the creatine and creatinine concentrations in a sample, the creatininase was simply eliminated from the reaction. A similar method was employed by Wang et al.<sup>127</sup> for the measurement of uric acid integrated with measurements of ascorbic acid, glucose, and acetaminophen on a single device. This work utilized the integrated microchip to mix the sample with glucose oxidase for generating hydrogen peroxide from the glucose present. Again, electrophoretic separation from the acidic species was possible with amperometric detection used for quantification. Acetaminophen, another neutral species, which migrated with the hydrogen peroxide, was detected by analyzing the sample with and without glucose oxidase to determine the difference in detector response when the neutral components passed the detector.

## 36.5 METHOD DEVELOPMENT GUIDELINES

Implementation of microchip methods for clinical analysis has thus far been almost exclusively confined to the research laboratory. This is changing with the availability and ease of use of the commercially available microchip electrophoresis instrumentation. These instruments provide both quantification and size determination of DNA or protein samples, thus could be immediately implemented into any clinical laboratory. Microdevices for sample preparation steps, at least for DNA processing, are currently under commercial development, but have not yet been introduced. Sample extractions and concentrations on microdevices are easily implemented in any laboratory, simply by placing the appropriate solid phase matrix into a microchip rather than using a suspension or large column, or centrifugal tube format. The only issue is fabrication or purchase of the microchips that have the appropriate sized channel and a constriction or frit for retention of the solid phase within the channel. Interfaces for the connection of syringe pumps to flow material through the microchip column have been described in the literature,<sup>95</sup> and microchip reservoirs/connectors are also commercially available from IDEX<sup>®</sup> Corporation.

In-house development of a microchip PCR amplification system is a bit more challenging than the DNA extraction system, but a noncontact IR heating design has been described in the literature.<sup>128</sup> As an easier approach, simply putting the microfluidic device into a conventional thermocycler also works, and Legendre et al.<sup>99</sup> showed that it was possible to integrate microchip DNA extraction with the PCR amplification using this technique. Integration of capture and separations, or enzymatic

or labeling reactions with the electrophoretic separation, are also possible in many laboratories, again obtaining or fabricating the specifically designed microchips will be a significant part of the processes. Development of fully-integrated devices, however, is at this point beyond the realm of most laboratories that do not have experience with microfluidic design and utilization.

In addition to simply designing and fabricating the devices and instrumentation to use microchip methods, a number of issues also have to be dealt with that are more specific for clinical application of these devices. The use of microfluidic devices with biological samples provides some important differences relative to the use of these devices for standards or “real samples” that have been cleaned up or spiked to greatly increase the concentration of the compound of interest. The proteins, lipids, and DNA mixture found in any biological sample have numerous charged species, as well as both hydrophobic and hydrophilic compounds. Thus, surfaces in microchips formed from almost any substrate will attract or interact with some component in the sample. In addition, there are issues with the sheer mass of material, such as proteins that can compete nonspecifically with an assay, the particulate matter left by cell lysis that can clog the microstructures, and the viscosity of biological samples that make it hard to pump material through the microdevice. The development of microchips for clinical applications then must look beyond the initial testing of the microchip assays using standards, and show that the assay, method, and microchip are rugged and reliable enough for use with real samples at the required concentrations, which is not always the case.<sup>2</sup>

Often, the primary issue when implementing on-chip clinical analyses is biofouling, where proteins or lipids bind to the microchip surface interfering with the assay being performed on the device; this is particularly an issue in microchips because of the large surface-to-volume ratio presented by these devices. One of the biggest clinical applications in which this is important is PCR amplification of DNA, in which binding of *Taq* polymerase and  $Mg^{2+}$  to the microchip surface can inhibit the reaction.<sup>129,130</sup> A review by Kricka and Wilding<sup>131</sup> detailed the various methods that had been utilized for passivating microchip surfaces to prevent PCR inhibition, and this group has shown increased efficiency for PCR through coating selection.<sup>132</sup> Preventing reaction components from binding to the surface can also be accomplished by preventing the components in the aqueous solutions from reaching the surfaces by surrounding the aqueous phase with an organic phase such as a fluorocarbon oil, as reported by Roach et al.<sup>133</sup>

Of more interest is some recent work that looks at the modification of the microchip surfaces to resist nonspecific adsorption in polymeric devices, since these represent the future of inexpensive, disposable microchips that will be needed for clinical analyses. Bi et al.<sup>134</sup> utilized an acrylate copolymer to modify the surface of PMMA devices to exhibit poly(ethylene glycol) (PEG) on the surface. PEG is known to prevent protein adsorption, and these microdevices were utilized in electrophoretic separations of proteins, with good theoretical efficiencies. Application of these devices directly to serum or plasma should be possible with no biofouling of the separation channel surface. This same group was also able to generate a phospholipid coating on the surface of PMMA microchip channels as a biomimetic surface to prevent protein binding.<sup>135</sup> This coating was also evaluated for the electrophoretic separation of proteins, showing stable electrophoretic mobility, with little nonspecific adhesion of proteins or platelets when serum or plasma was utilized in the device. For PDMS devices, Wu et al.<sup>136</sup> grafted hydrophilic polymers onto the surface to create a surface with a strongly suppressed electroosmotic flow (EOF), and significantly decreased adsorption of BSA and lysozyme than the native PDMS surface. These microchips were also utilized for electrophoretic separations of protein, both native and denatured, as well as peptides.

In addition to adsorption, issues to be addressed for the routine use of microchips for clinical analysis include the development of lower cost, compact instrumentation for detection on microchips. Shrinivasan et al.<sup>137</sup> detailed the development of a miniaturized LIF detector applicable for fluorescent detection of DNA on microchips, which could also be applied to proteins with the necessary fluorescent tags. By replacing the argon-ion laser with a diode laser, the cost and power requirements were significantly decreased, with only a small loss in sensitivity. Integration of fluid flow and mixing

components into the microchips must also be addressed. Kim et al.<sup>138</sup> describe a microchip for blood typing that incorporates flow splitting designs, micromixers, and microfilters directly fabricated into an injection molded COC device.<sup>139</sup> This group also developed a COC microchip for partial oxygen, glucose, and lactate levels in blood that incorporates an on-chip power source for fluid manipulation. Vestad et al.<sup>140</sup> addressed the need to reduce the associated hardware for flow control through microchips through the use of capillary pumping, allowing surface tension to pull fluid through their devices. Flow path can be controlled through the use of elastomeric valves, similar to those utilized in the integrated devices. Again, the goal is to eliminate the need for external power sources in the instrumentation for fluid flow control, to simplify the instrumentation and make it cost effective and compact enough for use in point-of-care applications.

### 36.6 CONCLUDING REMARKS

There are a number of clinical areas in which microchip devices will be implemented over the next decade. For DNA, the switch will actually be away from the devices described here to a large extent as real time-PCR analysis becomes the predominant method for detecting and quantifying specific DNA sequences. Real-time PCR takes advantage of the amplification method while eliminating the separation step to reduce the complexity of the analysis and the microchip design. These devices will be implemented both for mutation detection and infectious agent analysis. For proteins, the separation will remain an integral part of the analysis, thus microchip separations will expand to form a larger part of the clinical diagnostic arena. Most of these devices will utilize MS detection, however, unless new breakthroughs in protein labeling or UV detection on microchips are seen. Electrophoretic microchips for small molecule detection will play some part in clinical analysis, but individualized instrumentation specific for a particular analyte or group of analytes may be the final format.

For this to become reality, reductions in the costs of both the microdevices and the instrumentation will be needed to move these methods into routine clinical laboratory use. On the instrumentation side, replacing research designs with commercial grade instruments, with simple user interfaces and integrated components for sample and reagent loading, alignment, and thermal processing must be completed. Initial commercial microchip electrophoresis instruments show that this is possible, but more demand from the clinical community may be needed to show the potential for additional microchip instrumentation to commercial entities. The microchips themselves must also be cost effective for the analyses being performed, with disposable devices required to prevent contamination or false positive and false negative results. The cost of a PCR microchip, even a plastic and disposable one, will never be as inexpensive as a PCR tube, thus additional advantages must be provided by the microchip methods to justify their implementation. These can include reduced reagent consumption in the microchip, or incorporation of additional processing steps such as the DNA extraction, but some added benefit must be present in the microchips if they are to be accepted and used by the clinical community.

In terms of integrating additional steps onto a microdevice, issues related to fluid flow control, either through on-chip or off-chip valving or flow metering, still need to be more fully addressed. Handling of the nanoliter volumes utilized in microchips presents additional challenges for instrumentation development, particularly with reagent addition and mixing with components already on a microdevice. Further work is also needed in the area of on-chip storage of reagents, possibly already lyophilized in the necessary compartments, or sealed off for storage but easily available on-chip when needed. Development of integrated microchips will continue, however, and these will begin to focus more on the actual end applications now that the concepts have been shown using standards and simulants. More specific clinical analyses will be translated to microchips over the next few years, and the complexity of the designs and instrumentation will determine how quickly they will be transitioned into the clinical laboratory.

# 37 Advances in Microfluidics: Development of a Forensic Integrated DNA Microchip (IDChip)

*Katie M. Horsman and James P. Landers*

## CONTENTS

37.1 Introduction .....	1065
37.2 Differential Extraction .....	1066
37.3 DNA Extraction .....	1068
37.4 DNA Quantification .....	1069
37.5 DNA Amplification .....	1070
37.6 Separation of PCR Products .....	1074
37.7 Impact .....	1078
37.8 Concluding Remarks .....	1081
References .....	1081

## 37.1 INTRODUCTION

The past half decade has seen deoxyribonucleic acid (DNA) analysis performed on microdevices become more accepted and much more routine. Only recently, however, have analytical chemists addressed the specific needs of forensic science to allow the forensics community to harness these advances in microfluidics. The research focus of a number of groups has led to the development of microfluidic systems specifically tailored to forensic applications. As a result, we are beginning to witness the validation of microfluidic devices in forensic laboratories, and their widespread adoption in the coming years can be anticipated. Microfluidics has the potential to advance forensic DNA analysis in ways that were unforeseen at the time that restriction fragment length polymorphisms (RFLPs) were adopted. It will introduce a rapid, automatable technology that will enable our severely backlogged crime laboratories to process casework more efficiently.

In many respects, the forensics community has been awaiting the advent of microdevices. Microfluidic chips have been proven to carry out processes more efficiently than their macroscale counterparts (e.g., polymerase chain reaction or PCR and electrophoretic separations), thus, considerably decreasing sample processing time.<sup>1,2</sup> The current advances in integration of multiple processes on a single device serve to further enhance the processing speed.<sup>3-5</sup> Single-process devices, such as those for DNA purification as well as multiprocess devices, will significantly reduce the opportunity for laboratory sources of sample contamination by completing the sample preparation in a closed system and, thus, eliminating the multiple tube transfers and additional handling. Forensics, perhaps more than any other field, stands to benefit from this inherently closed-system design. The ease

of automation of the microchip methods is advantageous to the forensics community in the same way it will benefit the clinical community—by decreasing technician time and, thus, dramatically decreasing costs associated with DNA analysis. This decrease in sample processing time and costs could, in turn, have a dramatic impact on the DNA analysis backlog in crime laboratories. Although yet to be fully realized, it is reasonable to expect a concomitant improvement in limit of detection by the transfer to the microscale format from the macroscale counterpart. Therefore, we can expect to see successful DNA typing in cases where limited or no profile was previously obtained with conventional methods.

Conventional forensic DNA analysis involves DNA extraction and purification, quantification, and amplification, followed by separation of PCR products, detection, and data analysis. In sexual assault casework, differential extraction, a cell sorting process by which DNA is differentially extracted from sperm and vaginal epithelial cells (or other nonsperm cell types), must be utilized to obtain enriched fractions of male and female DNA. In this chapter, we will discuss the specific development of these techniques on the microscale for application to forensic human DNA analysis.

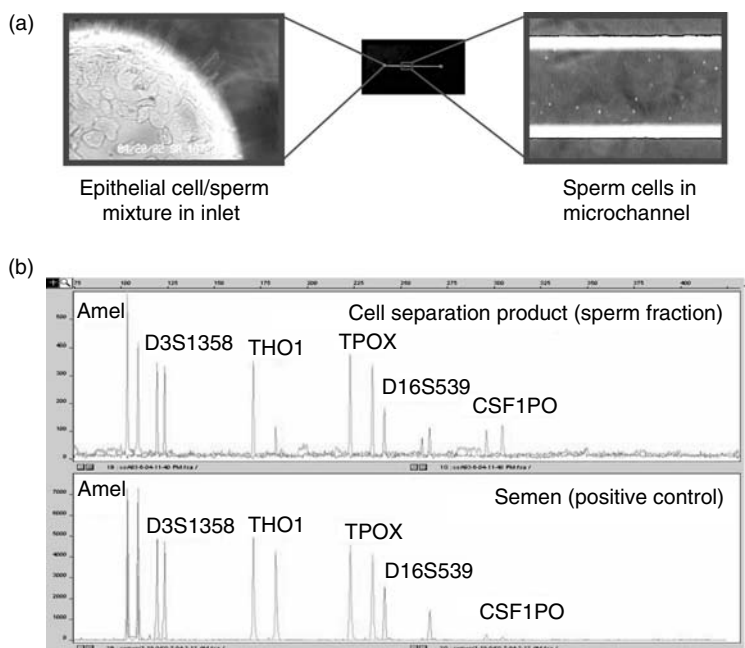

## 37.2 DIFFERENTIAL EXTRACTION

Differential extraction is employed by forensic DNA analysts to obtain enriched fractions of male and female DNA from sexual assault evidence. This evidence, typically obtained from a vaginal swab during evidence collection at the emergency room, contains sperm cells from the perpetrator often in an overwhelming number of vaginal epithelial cells from the victim. Although the victim's DNA profile can often be obtained by other means, a "clean" profile of the perpetrator is sought for prosecution. As a result, Gill<sup>6</sup> developed differential extraction, which exploits the differential stability of the nuclei of sperm and vaginal epithelial cells to obtain enriched male and female DNA fractions. The mixed cell sample is first extracted using mild conditions (Gill Buffer [10 mM Trizma, pH 8, 10 mM EDTA, 0.1 M NaCl, and 2% SDS] and 20  $\mu\text{g}/\text{mL}$  proteinase K, incubate for 2+ h at 56°C), the swab removed, and sample centrifuged. The supernatant contains female DNA (from lysed vaginal epithelial cells) while the pellet contains unlysed nuclei from sperm heads. After extensive washing of the sperm cell pellet, incubation under harsh extraction conditions [Gill buffer containing 40 mM dithiothreitol (DTT) and 20  $\mu\text{g}/\text{mL}$  proteinase K] results in the lysis of the sperm cell nuclei.

In the translation of this process to the microscale, several approaches have been developed. The conventional method has not been directly translated to the chip, most likely due to the inherent need for centrifugation. While centrifugation has been demonstrated on microdevices,<sup>7</sup> it is not in widespread use, requires specialized chip design, and the development of methods for washing the sperm cell pellet in order to obtain results comparable to the macroscale method.

One microscale method developed for differential extraction involves a filter-based system and lysis using acoustic energy.<sup>8</sup> The sample is first infused over a filter (size and material not indicated) in which the sperm cells ( $\sim 4\text{--}6\ \mu\text{m}$  diameter) pass through unimpeded and the much larger epithelial cells ( $\sim 50\ \mu\text{m}$  diameter) are retained. The DNA is then extracted using ultrasonic disruption of the cells. Although it is too early to gauge the success of this method, filtration has been explored on the macroscale for this application without widespread success.

Another method for the analysis of sexual assault evidence exploits the differential physical and chemical properties of sperm and epithelial cells to result in a cell separation, from which DNA can be extracted from each population independently.<sup>9</sup> In this simple method, the epithelial cells settle to the bottom of the microchip inlet reservoir more rapidly than the sperm cells (as a result of their size and density). By subsequently invoking flow in the microchannel, sperm cells are swept from the inlet to the outlet reservoir, where they can be either collected for subsequent analysis or packed up against a silica bead/sol-gel bed for DNA extraction (Figure 37.1a). Efficient separation of a mixture of sperm and epithelial cells has been demonstrated via short tandem repeat

**FIGURE 37.1** Separation of sperm and vaginal epithelial cells on a glass microdevice. (a) Photographs of the straight-channel microdevice (center), the inlet reservoir (containing a mixture of sperm and vaginal epithelial cells), and the microchannel (containing sperm cells) during cell separation. In this method, the cells were separated based on their physicochemical differences, resulting in differential sedimentation of the cell types. Upon application of a negative pressure at the outlet reservoir, sperm cells were swept into the microchannel, whereas the epithelial cells adsorbed to the glass substrate of the inlet reservoir. (b) Forensic STR profile obtained from the material in the outlet reservoir following cell separation. This compares favorably with the semen donor's profile and indicates an efficient separation from the vaginal epithelial cell DNA. (Adapted and reproduced from Horsman et al., *Anal Chem* 2005, 77, 742–749. Copyright 2005. With permission from American Chemical Society.)

(STR) profiling (Figure 37.1b), and, in addition, cell separation with integrated DNA extraction has also been demonstrated.<sup>10</sup> A drawback associated with this method is the sample volume that can be loaded into the chip. The proof-of-principle work demonstrated a sample load that was in the 10–50  $\mu\text{L}$  range, where biological material from vaginal swabs are typically eluted in 500  $\mu\text{L}$  or more. Because the number of sperm cells on a given swab is unknown (and, thus, the amount of DNA available for subsequent processing), the device must be capable of accepting the entire volume from the evidentiary sample. In addition, this method represents a divergence from the conventional macroscale method, assuming that both cell types exist on and are eluted from the swab intact. Any epithelial cells that have lysed in storage (due to dehydration) will yield free female DNA that co-migrates to the outlet reservoir with the sperm cells, thus contaminating the male fraction. While this method has shown promise for use in forensic DNA analysis, it did not meet the requirements for accommodating larger sample volumes.

An interesting approach reported for obtaining purified male and female fractions on microdevices involves acoustic differential extraction (ADE)<sup>11</sup> and exploits microacoustic transducer developments (see Chapter 44 by Laurell for details). This method involves the elution of biological material from the vaginal swab under mild lysis conditions, resulting in a mixture of sperm cells and epithelial cell lysate. The sample is then infused in the microdevice, and sperm cells trapped in a monolayer above an ultrasonic transducer while free DNA (from the lysed epithelial cells) flows through the system unretained. Flow of the epithelial cell lysate is directed to the outlet reservoir

using laminar flow valving<sup>12</sup> while the sperm cells are retained by the transducer. Upon deactivation of the ultrasound, the sperm cells are released and directed to the sperm cell outlet. Highly enriched fractions of male and female DNA have been shown to be obtained using this method. In addition, this approach addresses the shortcoming of the aforementioned cell sorting method, in that it is capable of readily processing large volume samples, although cell sorting integrated with DNA extraction is under development but has not yet been demonstrated.

All of these methods are amenable to eventual integration with downstream sample preparation steps, such as the solid-phase extraction of DNA, for automated processing of samples in a format that is a closed, fully contained system, thereby diminishing contamination by outside sources. However, none of the methods described here identify sperm cells specifically. Before DNA analysis, analysts conduct a time-consuming “sperm search” using light microscopy to identify sperm morphologically and gauge the relative abundance. While the “sperm search” is currently considered a separate entity, any method that *could* incorporate the positive identification of sperm cells, would be attractive to the forensic laboratories and eliminate another time-consuming analysis step. Although not on a microchip, one method that has been detailed for this is laser microdissection, which has recently been used to identify and capture sperm cells from a membrane-coated microscope slide.<sup>13,14</sup> While effective, particularly for evidence containing low cell numbers, this method is not likely to be used for high-throughput casework.

While several microscale alternatives to differential extraction have been proposed and demonstrated, one school of thought is that none are likely to significantly impact the forensic community without direct integration with DNA extraction.

### 37.3 DNA EXTRACTION

DNA extraction and purification on microdevices has gained widespread use for clinical and forensic applications, and has been reviewed in detail in Chapter 43 by Bienvenue. On the macroscale, DNA purification is completed using organic extraction (historically), or, more commonly, solid phases such as QIAamp and DNA IQ. The development of DNA extraction methods on the microscale has largely focused on the use of silica-based solid phases,<sup>15–19</sup> although purification has also been recently demonstrated using an ion-exchange resin in a microdevice.<sup>20</sup> Any microscale DNA extraction method must demonstrate high efficiency of extraction comparable to or better than the currently available methods (e.g., ~46% for whole blood<sup>21</sup> using QIAamp). In addition, the extraction bed must be of relatively high capacity to enable binding of sufficient DNA for downstream processing, and the extraction must be capable of accepting large volumes (e.g., up to 500  $\mu$ L) in a timely manner.

Most solid-phase DNA extraction techniques involve loading the DNA onto the solid phase using a chaotropic salt (e.g., Guanidine HCl), washing with ethanol to remove proteins, and eluting the DNA with water or other solvent. A more detailed explanation of these methods can be found in Chapter 43, entitled “Integrating Sample Preparation Into Multifluidic Devices.”

Christel et al.<sup>16</sup> reported the first microdevice-based solid-phase extraction of DNA in 1999 using an etched silica solid phase consisting of silicon pillars. This work reported extraction efficiencies of approximately 50% from prepurified DNA. As a result, the extension of this method to forensic samples, which are often low-copy number samples, seems unlikely. Higher extraction efficiencies have been demonstrated using silica bead and sol-gel-based solid phases. These phases are added to the microchannel as liquid suspensions, thus, circumventing the complex etching required for the pillar design described previously. Silica beads and sol-gel have been demonstrated individually<sup>3,22</sup> and in tandem<sup>17</sup> where the sol-gel acts as a glue holding the beads in place. In both methods, DNA purification has been demonstrated using blood and other biological fluids common to forensic analyses with high extraction efficiencies (up to 60%) and high capacities (~20 ng, 1.5 cm extraction bed) comparable to the macroscale counterpart such as the QIAamp kit. In a clear demonstration

of the application of this work to forensic analyses, on-chip sperm cell lysis and DNA extraction using a silica bead solid phase was reported by the addition of 40 mM DTT to the 6 M guanidine lysis solution.<sup>18</sup> The purified DNA was shown to be amenable to downstream (off-chip) processing including STR amplification and separation of PCR products.

DNA purification on microdevices, as currently performed, appears to meet the needs of the forensics community. That is, extraction efficiencies and capacities comparable to the conventional methods have been demonstrated. Most notably, these methods typically result in elution volumes on the order of 10  $\mu$ L or less, negating the need for an additional concentration step (e.g., Microcon) and, thus, further diminishing DNA loss and additional processing time. Because the commercially available kits accept limited volumes of DNA, concentration of the eluted DNA is commonly required in forensic samples in order to maximize the amount of template DNA added to the STR amplification. In addition, because the target amount of template DNA added to an STR reaction is important in order to minimize possible PCR artifacts such as allelic dropout, off-scale alleles, and so forth, DNA quantification following extraction is necessary.

### 37.4 DNA QUANTIFICATION

Unlike DNA diagnostics with clinical samples, where the amount of DNA in a volume of blood or other biological fluid can be estimated with little consequence, postpurification DNA quantification is of the utmost importance in forensic sample analysis. The target mass of DNA required for effective use of the commercially available STR kits is  $\sim$ 1 ng. When a reduced mass of DNA is added to the PCR, stochastic effects that could include “allelic dropout,” may make interpretation difficult. Alternatively, an excess of DNA in the PCR ( $>$ 5 ng) can result in off-scale peaks, “pull-up” (color bleeding usually due to off-scale peaks), increased levels of stutter (small peaks typically one repeat unit shorter than the STR allele, believed to be due to slippage of the primer or template during replication) or other artifacts in the subsequent electrophoretic separation.

Until recently, DNA quantification in forensic analyses has most commonly involved the use of slot-blot methods. In the past few years, the forensics community has shifted focus to the use of quantitative PCR as the preferred method for quantification. Both methods allow for human-specific DNA quantification, although qPCR has significantly lower limits of detection and gives an indication of the PCR-amplifiability of the DNA as well. Recently, multiplex qPCR assays have been developed to simultaneously determine the total amount of genomic and mitochondrial DNA,<sup>23–25</sup> total genomic and male DNA,<sup>26,27</sup> or assess the extent of DNA degradation for specific forensic applications.<sup>28,29</sup> Because of the utility of qPCR to the forensic community, we focus on the development of qPCR on microdevices here.

Although real-time PCR has been demonstrated on microdevices, no qPCR has been reported to date. That is, fluorescence detection during the accumulation of PCR products throughout cycling has been demonstrated. However, no standard curve was simultaneously amplified to allow for DNA quantification based on the signal generated. Real-time PCR has been demonstrated by Lin et al.<sup>30</sup> in 25  $\mu$ L reactions using fluorogenic probes and the SYBR Green I intercalating dye, respectively. In both cases, multiplex PCRs that include generation of a standard curve for quantification have not been described. In 2003, Quake and coworkers<sup>31</sup> reported the development of picoliter volume PCR chambers on a microfluidic device for parallel real-time PCR assays. Although not demonstrated, the authors indicate that the eight flow channels can be used for the generation of a standard curve and, thus, the chip can be used for quantitative PCR.

While DNA quantification remains the least-developed sample processing step on microchip for forensic DNA analysis, it is anticipated that extension of the reported methods to qPCR will be forthcoming. Any such qPCR method should be directly applicable to forensic DNA quantification by use of the appropriate primers and probes described in the literature for the macroscale counterpart. Following successful demonstration of qPCR on-chip, integration of this

method with DNA extraction and DNA amplification would be the next microfluidic challenge; however, recent advances in this arena suggest this is possible.<sup>32–34</sup> In addition, development of valving or other means of metering the appropriate volume of purified DNA into the amplification reaction must be carried out. This then results in the need for a storage mechanism on chip or off chip for the unused extracted DNA, which is derived from the original evidence sample. This material must be saved for subsequent reprocessing, permanent storage, or use by opposing legal council.

### 37.5 DNA AMPLIFICATION

DNA amplification on microdevices has been demonstrated routinely, and Roper et al.<sup>35</sup> have not only provided an extensive review of the literature on this topic (also see Chapter 43 by Bienvenue) but also provided a scoring method for device comparison. However, it is noteworthy that few examples of the complex PCR associated with forensic DNA typing have been demonstrated on chip. Forensic DNA typing most commonly involves the amplification of STRs via PCR using multiplex PCRs involving up to 16 primer pairs for coamplification of STRs from multiple loci. Primers are tagged with fluorescent tags (typically one of three or four fluorophores) for discrimination of loci. Commercially available kits have been developed, are the industry standard, and are used by every forensic DNA laboratory in the United States. Of primary interest to the forensics community in the development of a microfluidic device for PCR is the limit of detection for the amplification fragments (low-copy number amplifications), unbiased amplification, limiting the DNA template required for effective amplification, total reaction time, the ability to perform multiplex amplifications (as in the commercially available kits), and multiple chamber amplification (to amplify >1 sample at a time). Of course, any microdevice method must show that the PCR amplification product is comparable to that obtained on the macroscale, permitting any future results to be related to those previously obtained and are contained in the national DNA database.

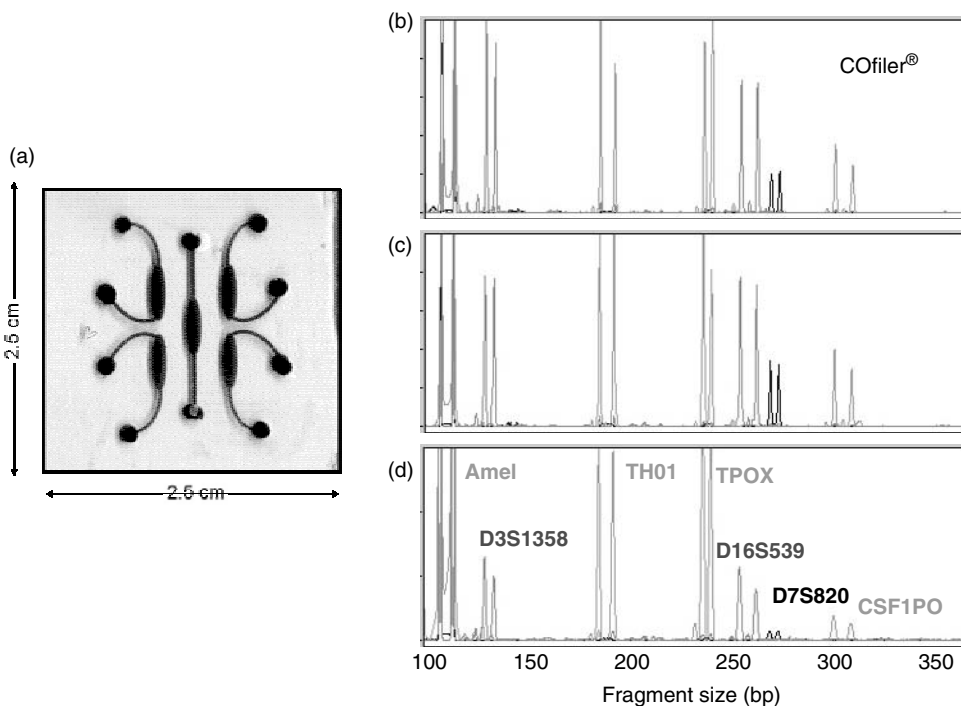

Microchip DNA amplification, to date, has already demonstrated the potential for low limits of detection, with amplification demonstrated from single-copy sources.<sup>36</sup> The useful limit of detection (so as to prevent stochastic effects in forensic analyses) with microchip PCR is yet to be determined. However, the reduced reaction volume inherent to the microchip supports the expectation of lower limits of detection. Fast thermocycling has been demonstrated by a number of microchip PCR designs and methods with amplification rates approaching the biological limit of the processivity of *Taq* polymerase, that is, with 20–25 cycles in under 5 min.<sup>1,2</sup> This fast thermocycling has not yet been applied to STR amplifications, although preliminary data have shown a reduction in total amplification time by almost half.<sup>37</sup> Therefore, it is not unreasonable to anticipate that the approximately 3-h conventional thermocycling protocol will be reduced to 45 min or less. There are a few demonstrations of STR amplifications in microdevices. Liu et al.<sup>4</sup> have demonstrated the amplification of a mini Y-STR multiplex, Bienvenue et al.<sup>5</sup> and Legendre et al.<sup>37</sup> have demonstrated amplification using the AmpFISTR COfiler and Profiler Plus kits, and Schmidt et al.<sup>40</sup> demonstrated microchip amplification using the PowerPlex 16 STR kit. Recently, amplification of mitochondrial DNA has been reported on a glass microchip.<sup>41</sup> Following amplification, a subsequent mitochondrial sequencing reaction was performed. These data indicated amplification with template amounts as low as 1 pg, where product was not detected by the conventional method. Large masses of mitochondrial DNA (500 pg–1 ng) resulted in some nonspecific product formation when amplified in the low volume reaction. Table 37.1 summarizes the characteristics of these reported microchip forensic DNA amplifications. In addition to multiproduct amplification in each chamber (corresponding to the multiple loci), simultaneous amplification in multiple chambers will likely be needed to compete with the conventional thermocyclers. This has been shown by Waters et al.<sup>42</sup> (four chambers), Legendre et al.<sup>37</sup> (three reactions performed—although four chambers are fabricated in the device) (Figure 37.2), Lutz-Bonengel et al.<sup>41</sup> (60 reaction spots), and Schmidt et al.<sup>40</sup> (23 reactions

**TABLE 37.1**

<sup>a</sup>This reaction time is reported for the PCR amplification and the DNA extraction in total.

<sup>b</sup>This reaction time is reported for the PCR amplification only, not the sequencing step, which requires approximately an additional 220 min.

**FIGURE 37.2** Multiple simultaneous STR amplifications on a single glass microdevice. (a) Photograph of the microdevice for multiple chamber PCR microdevice. The chip contains five chambers: one for temperature control (center) and four surrounding PCR chambers for parallel amplification. Amplification of the COfiler multiplex STR loci was performed simultaneously in three of the four reaction chambers on this microdevice using less than 1 ng template DNA. (Adapted and reproduced from Legendre, L. et al. Multiplex microchip PCR for STR Analysis. Poster presented at The 15th International Symposium on Human Identification, 2004. With permission.) The resulting STR profiles (following conventional DNA separation) are shown in panels B–D, indicating amplification in each chamber with no apparent PCR artifacts that would complicate analysis of the DNA profile. (Figures 37.2B through 37.2D are courtesy of L. Legendre.)

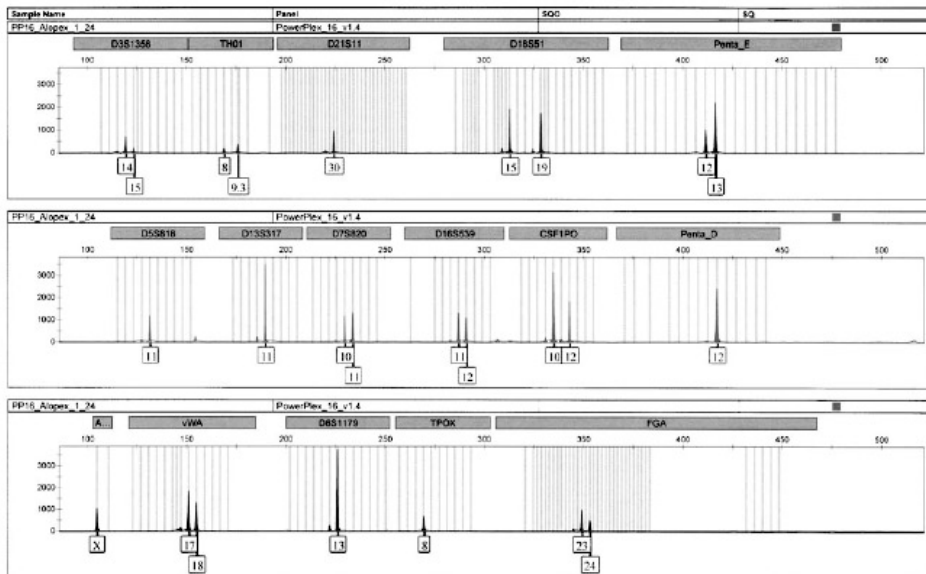

performed—although the chip contains 60 reaction spots) (Figure 37.3). Multiple PCR chambers per device will enable high-throughput processing but also allow analysts to simultaneously process the necessary controls (reagent blanks, positives, negatives).

The application of microfabricated devices to the amplification of STR fragments in forensic DNA typing provides numerous advantages over the conventional methodology—specifically, lower limits of detection,<sup>36</sup> less reagent and sample consumption, enhanced processing speed,<sup>1</sup> and so forth. However, it also brings along issues that are not currently encountered with conventional methodology. For example, the STR amplifications on microchip discussed above involve total reaction volumes that range from 160 nL to 1.2  $\mu$ L. Thus, the DNA added to the reaction must be contained in a fraction of a microliter, rather than the common 10–200  $\mu$ L obtained from a Qiagen purification and then used for a conventional 25  $\mu$ L amplification reaction. Consequently, the DNA must be concentrated to a greater extent than needed for conventional amplification. As a result, for microchip PCR to be utilized in forensic laboratories it will most likely require direct integration with microchip DNA extraction, where the DNA is routinely eluted in microliter volumes. This need to amplify the entire mass of DNA and, thus, concentrate the purified DNA to a high degree, is most critical in cases where low starting copies of DNA template are available. Bienvenue et al.<sup>5</sup> have demonstrated DNA purification and PCR amplification on the same microdevice, carrying out microliter-scale DNA extraction as reported previously in a glass

(a)

(b)

**FIGURE 37.3** (a) Photograph of a glass microchip containing 60 reaction spots, each with a hydrophilic surface surrounded by a hydrophobic ring. Each spot is loaded with 0.5  $\mu\text{L}$  PCR mix and 0.5  $\mu\text{L}$  of DNA template and covered with 5  $\mu\text{L}$  oil to decrease evaporation and contamination. Thus, the total reaction volume on this device is 1  $\mu\text{L}$ . The chip was thermocycled on conventional instrumentation using an *in situ* adapter. (Photo courtesy of Schmidt, U.) (b) A complete STR profile generated by PowerPlex 16 amplification of 32 pg genomic DNA on the chip shown in (a). Allele names are identified in the gray boxes above each set of peaks. Repeat numbers for the corresponding alleles are indicated below each peak. (Adapted and reproduced from Schmidt, U. et al., *Int J Legal Med* 2006, 120, 42–48. Copyright 2005. microdevice.<sup>17,22,43</sup> However, in a unique approach, the DNA was eluted from the solid phase using PCR master mix and retained in a chamber. Subsequent placement of the device into a conventional (block) thermocycler allowed for amplification of the STR fragments in the Cofiler and Profiler Plus kits. These results are significant as they represent the first work demonstrating the potential for interfacing microfluidic DNA extraction technology with conventional PCR instrumentation. Of course, for application to forensic casework, the integration of a DNA quantification step will also be necessary.

### 37.6 SEPARATION OF PCR PRODUCTS

As described in detail in Chapter 25 by McCord, forensic DNA profiling is routinely accomplished by capillary electrophoresis (CE) in forensic laboratories. Recently, microchip electrophoresis is being evaluated for use in casework by the *Virginia Department of Forensic Science* and the *Forensic Science Service* (U.K.). While DNA separations on microdevices are becoming more commonplace, separations for forensic DNA analysis have been less-frequently demonstrated. DNA separations for forensic analyses, like DNA sequencing, require single base pair resolution and multicolor fluorescence detection (see Chapters 6, 27, and 44). In addition, the STR separation must be rapid (less than 30 min) to compete with the current capillary-based method. For nondisposable, single-process devices, the sieving matrix must be of relatively low viscosity to enable loading and replacement of the matrix after each separation (as in the capillary) to prevent carryover.

Table 37.2 provides some of the pertinent details associated with the STR separations carried out on microdevices to date. All of these STR separations have utilized long-read polyacrylamide (LPA) or polydimethylacrylamide (PDMA) [the main component of the commercially available polyolefin plastomer polymers, known as “POP” polymers]; POP-4 (where the number dictates the %PDMA) is the polymer used for capillary STR separations on ABI instruments. Acceptable polymers for these separations must be capable of single base pair resolution at low temperatures (preferably, room temperature) with short effective separation length ( $L_{\text{eff}}$  – distance from injection point to detection point) and of relatively low viscosity to enable replacement and ease of filling the microchannel. Overall, it appears that LPA is capable of providing the requisite resolution with microchannels having an  $L_{\text{eff}}$  of 11.5 cm,<sup>44</sup> although shorter distances are unlikely to be adequate with the current methodology.<sup>45</sup> In general, the separations require 25 or more minutes,<sup>46–48</sup> which is comparable to that obtained on the conventional capillary instrumentation. One embodiment<sup>46,48</sup>, however, utilizes a 96-microchannel device (Figure 37.4) and can accomplish 96 simultaneous separations, resulting in greater throughput capabilities than the commonly encountered 4- and 16-capillary conventional CE instruments. An example of data obtained on this microdevice is shown in Figure 37.5. POP-4 has also been used for the separation of STR fragments on microdevices, where the separation of an Identifiler allelic ladder was accomplished with an  $L_{\text{eff}}$  of only 8 cm and in under 12 min.<sup>49</sup> This separation is distinct in that the optical requirements for the detection system are relatively simple—containing only a laser and a single photomultiplier tube (PMT), because of the electronic filtering capabilities of an inline acousto-optic tunable filter (AOTF) to select the desired emission wavelengths sequentially (see Chapter 45 by Karlinsey). The value of the AOTF stems from the ease with which four-color detection can be expanded to five or more colors, which may be optimal for portable systems. One of the benefits of microchip electrophoresis reported by Goedecke et al.<sup>47</sup> (Figure 37.6) was the improved data quality and stability when compared to the commercially available capillary array instruments. This advantage arises from the enhanced thermal and mechanical stability of the separation channel, as well as the improved heat-sinking inherent to glass microchips.

As mentioned earlier, devices similar to those described in Schmalzing et al.<sup>50</sup> and Yeung et al.<sup>48</sup> are currently undergoing evaluation in the United States and the United Kingdom. It is anticipated

<sup>a</sup> The separation channels are not straight and, therefore, the field strength is not uniform. Voltage was applied as follows: +1300 V at the anode reservoir, +200 V at the cathode reservoir, +325 V at the sample reservoir, and +325 V at the waste reservoir.

<sup>b</sup> The separation channels are not straight and, therefore, the field strength is not uniform. Voltage was applied as follows: +2500 V at the anode reservoir, +0 V at the cathode reservoir, +180 V at the sample reservoir, and +200 V at the waste reservoir.

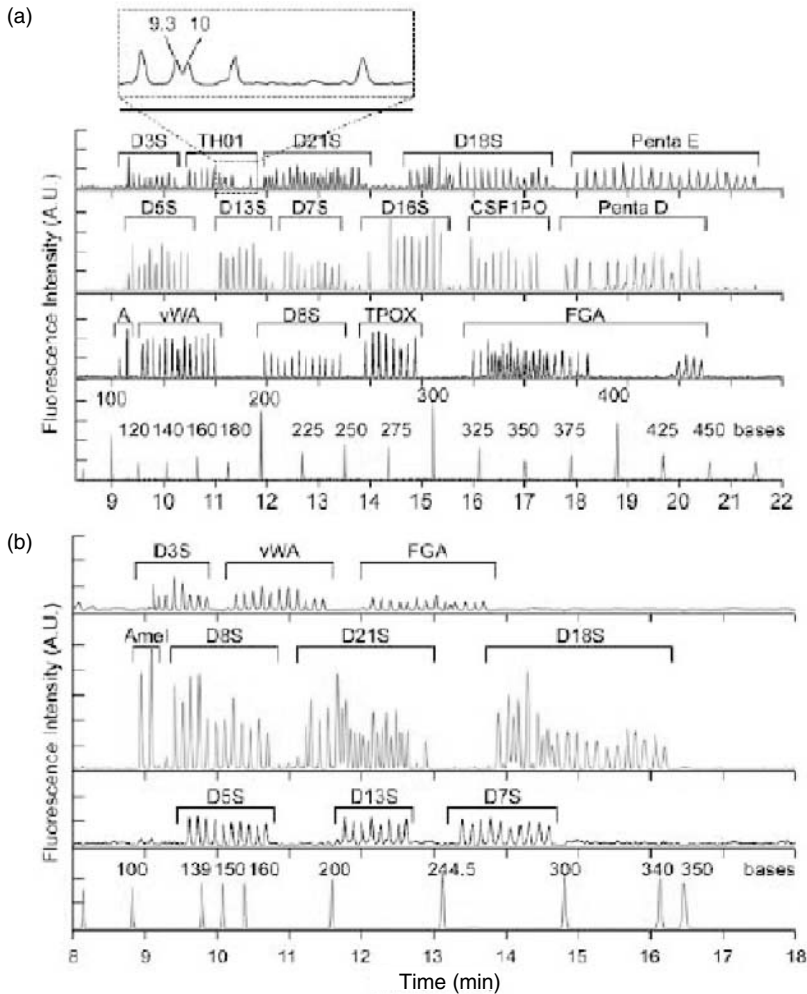

**FIGURE 37.4** (a) Design for the 96-channel  $\mu$ CAE microdevice by Mathies and coworkers. The glass microdevice is approximately the dimensions of a compact disk. The microchannel structure consists of 48 doublet structures, each containing two electrophoresis lanes that share common cathode and waste reservoirs. (b) Magnified view of the doublet structure, highlighting the “hyperturn,” which prevents band-broadening dispersion as the DNA molecules traverse the turn, thereby enabling high-resolution DNA separations in a compact device. (Adapted and reproduced from Yeung, S. H. et al., *J Forensic Sci* 2006, 51, 740–747. Copyright 2006. With permission from Blackwell Publishing, Inc.)

that microdevices for the separation of STR products will appear in casework soon. Because little advantage has been gained in processing time with these devices, as compared to the conventional multiple-capillary CE instrumentation, there is little impetus for the forensic community to implement this separation-only microdevice. While not used in forensic laboratories, there are commercial 96-capillary CE instruments capable of the same throughput as the 96-microchannel microcapillary array electrophoresis ( $\mu$ CAE) device in a similar time frame. One would anticipate more widespread adoption by forensic laboratories either following a reduction in the separation time or, better still, when the integration of  $\mu$ PCR and DNA separation has been achieved in an effective and robust manner. Liu et al.<sup>4</sup> have demonstrated an instrument capable of  $\mu$ PCR of a mini-Y STR multiplex and separation of the PCR product in under 64 min.

### 37.7 IMPACT

Advancements in forensic DNA analysis methodology have, historically, focused on alterations in the basic science permitting individualization of biological material. In its origins, RFLP was used to generate the DNA profile. However, the focus then shifted to the use of variable number of tandem repeats (VNTRs) and, eventually, to STRs. It is the STRs that are currently being used to build the national and international DNA databases (containing DNA of convicted offenders and from unsolved cases) and are, therefore, unlikely to be supplanted in the near future. Microdevices do not represent a shift in the basic science, but rather the technology platform on which the STR profiles

**FIGURE 37.5** Electropherograms of (a) Promega PowerPlex 16 allelic ladder and (b) Applied Biosystems AmpFISTR Profiler Plus allelic ladder obtained on the  $\mu$ CAE microdevice shown in Figure 37.4. are obtained much like the witnessed transitions from slab gels to the capillary format for the DNA separations. While the effectiveness of this technology platform and its inherent ability to enhance throughput might be considered revolutionary, it will not likely be viewed as a “paradigm shift” in the same way that the introduction of PCR was to forensic DNA analysis. Instead, it may be viewed as a necessary overhaul of the technology which, ultimately, will lead to better, more efficient processing of DNA evidence. Because the underlying principles of the DNA analysis have not been changed, merely the technological platform, its introduction, and acceptance by the courts should be relatively straightforward. With similar validation studies as those completed when shifting from slab gels to CE, their acceptance is not anticipated to be threatened.

As a result of the shift from the conventional methodology and technology to the microchip format, it is possible that DNA testing in criminal laboratories will undergo a “make-over,” giving it a very different look than it has today. While the criminalistics on the *front-end* (e.g., determining which samples should be tested) will remain largely unchanged, there will be dramatically less analyst

**FIGURE 37.6** Microdevice for STR separations, capable of 16 simultaneous separations. The device is constructed of two glass layers with interface boards at each end. The left interface board contains the anode buffer reservoir (2 mL). The right interface board contains the cathode buffer reservoir (2 mL), 16 sample inlets (70  $\mu$ L), and 16 sample waste reservoirs (70  $\mu$ L). The entire device measures approximately 5-cm wide and 25-cm long, and the separation channels have an effective length of 20 cm. (Adapted and reproduced from Goedecke, N. et al., *J Chromatogr A* 2006, 1111, 206–213. Copyright 2006. With permission Elsevier.)

intervention in the analysis during the sample processing due to the automation. Thus, the job of the analyst will necessarily shift from carrying out the entire analysis to only the criminalistics on the *front-end* and the interpretation of the STR profile results produced by the instrument. While this will increase the throughput of forensic DNA laboratories, it will, in most laboratories, not decrease the number of analysts employed. Instead, the number of samples submitted to and processed by laboratories is expected to increase. In this way, DNA testing in cases where it is not currently routine (e.g., robbery) in all jurisdictions may become more commonplace. While a major advantage of microfluidic devices in forensic analyses is the concomitant automation anticipated, automation alone is not the only advantage of the microdevice, as robotic methods are also able to achieve more automated analyses. Microdevices allow the distinct advantage of integrating multiple sample processes (such as DNA extraction, quantification, PCR, and separation) on a single platform. This allows for DNA analysis in a closed system and, therefore, less opportunity for contamination by the analyst with tube transfers and sample handling. In addition, many microfluidic processes have been shown to be more efficient than their macroscale counterparts such as DNA amplification, which typically requires 2–3 h conventionally, but can be completed in an order-of-magnitude less time on the microscale with concomitant decreases in sample and reagent consumption. Decreased sample consumption in forensic casework, where there is often not abundant sample at the outset, is highly valued. This might be expected to lead to the ability to obtain an STR profile where one cannot be obtained with conventional methodology and will, likely, be a major driving force for the transition to microfabricated technology in forensic laboratories.

In recent years, we have witnessed the incorporation of microdevices into the U.S. and U.K. crime laboratories. Currently, only separation of PCR products is completed on these instruments, with limited advantage over the current conventional methodology, CE. However, the major advantage of microdevice technology is in the ability to incorporate multiple sample processing steps on a single platform. Thus, the true value of the microchip in forensic laboratories will be realized when multiple processes are integrated onto a single automated device, thus, decreasing analyst time as well as total processing time and reagent consumption. Since microchip electrophoresis is the most mature of the microchip processes described above, it is of no surprise that this would be the first process to be introduced into the forensic laboratory. The more unseasoned microchip processes such as PCR and

DNA extraction are expected to follow suit in due time. The significant advantages of incorporating these devices will, undoubtedly, drive their introduction into forensic laboratories.

### 37.8 CONCLUDING REMARKS

The microfluidics community has successfully demonstrated microscale methods for cell sorting/differential extraction, DNA extraction, PCR amplification, and electrophoretic separation of STR products. Most of these individual microscale processes meet needs and desires of the forensics community by demonstrating efficient extraction of DNA, rapid thermocycling, and single base pair resolution (with multicolor detection) of STR fragments. However, quantitative PCR has yet to be demonstrated on chip. Several examples of cell sorting (for use in sexual assault evidence) have been demonstrated, although much work remains to show that efficiency and sensitivity of these methods are comparable to the conventional differential extraction and, thus, merit implementation. Most notably, many of these methods fall short addressing the macro-to-micro volume connection where the macroscale sample size (mL) must be interfaced with the small volumes (nL to  $\mu$ L) of the microscale environment. With forensic samples involving large volumes of solution that need to be processed, volume reduction need to be invoked on chip in order to obtain sufficient DNA for STR typing. Therefore, the *front-end* processes, such as cell sorting and DNA extraction, must be capable of processing large sample volumes in order to compete with their macroscale counterparts. Developments like the ADE offer the potential to address this issue.<sup>51</sup> In addition, with the maturity of the microfluidics field, as with any other analytical development, one can anticipate further advances in the automation of these processes. This automation, although not yet demonstrated for all processes, provides a significant advantage over the conventional processes used in the financially strapped forensic laboratories.

Also, the concept of single-process versus integrated (multiprocess) microdevices has been discussed. Single-process devices are designed with higher-throughput capabilities to process multiple samples simultaneously. However, these devices are capable of only one step of the analysis process. Integrated devices are typically lower-throughput but feature a totally integrated analysis in a “sample-in-answer-out” fashion. For example, a microliter of blood could be introduced to the inlet of the device and all sample processing steps occur on the device, resulting in a DNA profile detected at the outlet. While both of these designs have promise in forensic DNA analysis, their adoption may be highly dependent on the intricacies of the sample type and the application. For samples such as those of convicted felons to be added to the national DNA databank, high-throughput single-process devices may be the microchip of choice. These devices can be easily designed with throughput in mind, such as the 96-channel microdevice for STR separations. Alternatively, casework samples may be better suited for an integrated device that is all inclusive and would not require sample handling after introduction of the sample to the inlet reservoir. Ultimately, the choice of microchip format most appropriate in forensic laboratories will need to be driven by the forensics community, as many caveats to DNA typing are not intuitive to the analytical chemists and engineers developing microfluidic devices.

## 38.1 INTRODUCTION

Sample preconcentration methods, including stacking and focusing techniques, enable high-sensitivity detection by increasing analyte ion concentration. Sample preconcentration also leads to a decrease in the axial dimension of sample plugs (i.e., peak widths) and this can improve resolution in electrophoretic separations. In this chapter, we describe the basic principles and limitations of electrokinetic sample stacking and focusing techniques. We highlight the importance of Taylor dispersion in determining the efficiency of preconcentration methods. Sample preconcentration techniques can be broadly classified into two types:

1. In an increase in sample ion concentration occurs due to a local decrease in the magnitude of the drift velocity of an ion. For drift velocity vector field  $\bar{v}_d$ , stacking occurs when

locally  $\nabla \cdot \bar{v}_d < 0$ . These gradients are typically limited to a small region relative to the length of a separation channel. Ions enter the region, are stacked, leave the region, and subsequently disperse and decrease in concentration. After stacking, peak (spatial) variance tends to grow linearly in time. Stacking includes field-amplified sample stacking (FASS) and its derivative techniques.

2. In focusing, the condition  $\nabla \cdot \bar{v}_d < 0$  is typically satisfied throughout a large extent of the channel and there is, additionally, a focal point,  $\bar{x}_{\text{foc}}$  (or focal region), for the solute. There is a reference frame where the continuous vector field  $\bar{v}_d$  changes sign at  $\bar{x}_{\text{foc}}$ . In this frame, the opposing signs of  $\bar{v}_d$  drive the initially widely distributed sample to  $\bar{x}_{\text{foc}}$ , where sample ions accumulate. For a finite amount of sample, sample peak width reaches a steady-state value determined by the opposing effects of the  $\bar{v}_d$  gradient and dispersion. Focusing includes isoelectric focusing (IEF) and thermal gradient focusing (TGF) where  $\bar{x}_{\text{foc}}$  is fixed in space; and also includes isotachopheresis (ITP) where  $\bar{x}_{\text{foc}}$  propagates at a wave speed set by the bulk flow and the ion mobilities in the system.

Leveraging heterogeneous buffer systems to effect changes in sample drift velocity is a common feature of electrophoretic preconcentration techniques. The sample and background electrolyte (BGE) can differ in ionic strength and ionic makeup (e.g., ion mobility or valence). The theoretical concentration enhancement of most of these techniques has been well known for many decades. For example, the maximum concentration enhancement in FASS is predicted to be equal to the ratio of the (relatively high) conductivity of the BGE to the (relatively low) conductivity of the sample solution. This ratio determines the low-to-high analyte drift velocity ratio. In ITP, the theoretical drift velocity ratio and associated prediction of concentration enhancement is a function of the leading ion concentration and various ionic mobilities. Several numerical simulation tools that can predict the concentration enhancement in various electrophoretic preconcentration techniques are available. One fairly comprehensive and useful simulation tool is Simul, which is available free download on the Web [1]. Simul solves one-dimensional multispecies electromigration–diffusion phenomena (e.g., for electromigration in long thin tubes of constant area). The code includes ionization equilibria of weak electrolytes, calculation of local pH fields, and the dependence of ionic mobilities on ionic strength and pH. Given initial conditions and ion information (e.g., fully ionized mobility,  $pK_a$  values, diffusivity), the code predicts the evolution of ionic species in the presence of an electric field. Simul is, however, limited to one dimension and does not include flow-induced dispersion caused by nonuniform electroosmosis or body forces due to conductivity gradients.

In practice, both molecular diffusion and advective dispersion (i.e., Taylor dispersion [2]) limit the achievable concentration enhancement of preconcentration techniques. In some techniques, such as TGF, an external-pressure-driven velocity field is integral to the focusing effect and dispersive effects are inherent in the system. In other techniques such as FASS, external-pressure-driven flows are minimal (e.g., due to unwanted hydrostatic pressure heads in end-channel reservoirs). However, despite efforts to suppress electroosmotic flow (EOF), electrophoresis in capillaries is typically accompanied by at least trace EOF. The heterogeneous nature of buffers creates gradients in EOF mobility. These heterogeneities include ion density and ion mobilities and may also include temperature gradients, valence (via chemical reactions), and perhaps permittivity and viscosity. More importantly, variations in local ionic conductivity (and local permittivity) affect strong variations in local electric field. Both these effects (gradients in EOF mobility and gradients in field) create nonuniform EOF that leads to the generation of internal pressure gradients. Secondary flows generated by these pressure gradients tend to disperse analyte plugs and reduce the preconcentration effect.

In this chapter, we will identify the role and the scaling of dispersive effects in determining the ultimate limits of sample preconcentration techniques. Where possible, we will offer simple quantitative theory for estimating the effects of dispersion, and in all cases we will provide scaling arguments that can help guide empirical optimization of preconcentration techniques. First, we will

explain the basic physics of Taylor dispersion and provide reduced order models to qualitatively and quantitatively describe it. Second, we will present simple relations to estimate the importance of Taylor dispersion in relation to other peak broadening mechanisms in capillary electrophoresis (CE) systems. These relations are useful in, for example, empirically identifying optima in applied field and conductivity ratios. Finally, we will briefly describe three examples of preconcentration techniques as instructive “case studies” in which dispersion plays an important role in determining concentration enhancement.

## 38.2 BACKGROUND

Dispersion, the tendency for ordered molecules to decrease gradients and local concentration, is caused by both molecular diffusion and nonuniform bulk liquid motion. High dispersion rates may be advantageous for mixing and chemical reactions, but are undesirable in separation and purification applications. For separations, minimizing dispersion improves resolution and sensitivity [3] and yields improved dynamics for concentration and purification [4]. As a consequence, the physical processes that lead to dispersion have been a subject of intense interest for more than a century. In recent years, the development of the concept of the micro-total analysis system ( $\mu$ TAS) or “labs on a chip” has motivated further exploration of dispersion in microchannel flows.

In the field of CE, researchers are most familiar with dispersion caused by molecular diffusion and Taylor dispersion [2]. In 1953, G. I. Taylor demonstrated that, under certain conditions, the cross-sectional average of the unsteady, three-dimensional concentration field within a channel evolves as a one-dimensional convective–diffusion equation with a coefficient analogous to a modified diffusivity. Here, the advective dispersion in the axial direction is balanced by spanwise and depthwise (e.g., radial in a cylindrical tube) diffusion, causing peak variance to increase linearly in time, with the characteristic slope determined by an effective dispersion coefficient. Taylor further demonstrated that given enough time, theoretically, all solute plugs flowing within a channel ultimately reach this limit. Subsequently, Aris [5] proved that the (now named) Taylor regime could be unified with the pure diffusive regime by using an effective dispersion coefficient, which was the sum of the molecular diffusivity and the Taylor dispersion coefficient. The effective dispersion concept has proved to be extremely useful and has been extended to other geometries [6], generalized using alternative analyses [7,8], and extended to apply to EOF [9] and electrophoresis in nanochannels [10,11].

## 38.3 THEORETICAL ASPECTS

The nonuniform velocity distribution over the cross section of a capillary or a microchannel leads to distortion of the sample plug. This velocity-induced distortion generates a radial concentration gradient of the analyte. Molecular diffusion acts to reduce this radial concentration gradient. The two effects in tandem determine the effective dispersion rate of the sample plug. The increase in variance can be quantified in terms of an effective dispersion coefficient,  $D_{\text{eff}}$ . In this section, we will describe the details of calculating this effective diffusion coefficient for a sample velocity profile. This section is targeted at readers who may want to understand the mathematical details behind calculation of  $D_{\text{eff}}$ . Practitioners who are not interested in these details may skip to the next section without loss of continuity. The next section describes simple relations to estimate the role of dispersion in peak broadening in CE.

### 38.3.1 TAYLOR DISPERSION ANALYSIS VIA AREA AVERAGING

We derive the Taylor dispersion equation using an area averaging approach as described by Stone and Brenner [8]. We consider axisymmetric flow in a cylindrical capillary of radius “ $a$ ,” but will later discuss the application of these principles to other cross sections (such as typical wet etched

“ $D$ ” profiles). We consider a nonuniform (in  $x$ ) drift velocity to account for electrophoresis, and the scaling of streamwise coordinates by a characteristic length  $U_p t_c$ , where  $U_p$  is the magnitude of the deviation of axial velocity from the area-averaged velocity and  $t_c$  is the characteristic time for stacking or focusing. This approach can be applied to stacking and focusing. The following equations describe the convective dispersion of a charged species in a parabolic velocity field:

$$\begin{aligned} \frac{\partial C_i}{\partial t} + \frac{\partial}{\partial x} (u_{ii}(x, r) C_i) &= D_i \left( \frac{1}{r} \frac{\partial}{\partial r} \left( r \frac{\partial C_i}{\partial r} \right) + \frac{\partial^2 C_i}{\partial x^2} \right); \quad i = 1 : N, \\ \frac{\partial C_i}{\partial r} &= 0 \quad \text{at } r = a, 0, \end{aligned} \quad (38.1)$$

where  $C_i$  is the concentration of a dilute and, in general, charged solute of interest. In general electrokinetic flow physics, applied electric fields couple with conductivity gradients and lead to the generation of net charge in the bulk liquid. However, this charge density is negligible compared to the total background ion concentration. We can, therefore, assume that the solution is approximately electrically neutral everywhere outside of the electrical double layer, so that  $\sum_{i=1}^N z_i C_i \approx 0$ , where  $z_i$  is the valence. This approximation is discussed in detail elsewhere [12–14].

In Equation 38.1, we have made the typical “nearly parallel flow” approximation common in lubrication analysis that the flow is nearly parallel to the axis in this long thin tube [15]. This approximation holds as long as axial gradients in electroosmotic mobility and conductivity scale is  $1/\sigma$ , where the characteristic plug width of the solute,  $\sigma$ , is such that  $\sigma \gg a$ . This condition is commonly met in sample stacking and focusing techniques, although it may not be met in, for example, high field regimes of ITP in the so-called peak mode. This and other limitations are discussed later.

We consider the velocity field bounded by a cylindrical slip surface, which excludes a thin electric double layer (EDL) [16]. The velocity scale  $u_i$  includes the effects of local pressure gradients, electroosmosis, and electrophoresis and can be expressed as follows:

$$u_{ii}(x, r, t) \cong u_p(x, r, t) + U_{\text{eph},i}(x, t) + U_{\text{eof}}(x, t), \quad (38.2)$$

where  $u_p(x, r, t)$  is the axial velocity component due to a local pressure gradient,  $\partial p(x, t)/\partial x$ , and equal to  $-a^2(\partial p/\partial x)(1 - r^2/a^2)/4\eta$ , where  $\eta$  is dynamic viscosity.

$U_{\text{eph},i}(x, t)$  is an axial electrophoretic drift due to an approximately purely axial electric field,  $E(x, t)$ , and can be written as  $z_i F \mu_{\text{eph},i} E(x, t)$ , where  $z_i$ ,  $\mu_{\text{eph},i}$ , and  $F$  are the valence, electrophoretic mobility, and Faraday’s constant [12].  $U_{\text{eof}}(x, t)$  is the (exactly axial) velocity component due to electroosmosis, which can be expressed as  $zF \mu_{\text{eof}} E(x, t)$ , where  $\mu_{\text{eof}}$  is electroosmotic mobility and  $E(x, t)$  is the axial field component at the slip plane (near the wall). We also consider changes slow enough such that fluid inertia and charge relaxation are negligible. See Storey et al. [17] and Lin et al. [18] for more detailed discussion of quasi-steady electromigration, electroosmosis, and pressure-driven flow in long thin channels.

We define  $U_e(x, t) = U_{\text{eph},i}(x, t) + U_{\text{eof}}(x, t)$  as the sum of the electroosmotic and approximately parallel electrophoretic velocities. Note that  $\nabla \cdot (U_{\text{eof}} + u_p) = \partial(U_{\text{eof}} + u_p)/\partial x = 0$ . The convective diffusion equation then becomes

$$\frac{\partial C_i}{\partial t} + (U_{e,i} + u_p) \frac{\partial C_i}{\partial x} + \frac{\partial U_{\text{eph},i}}{\partial x} C_i = D_i \left( \frac{1}{r} \frac{\partial}{\partial r} \left( r \frac{\partial C_i}{\partial r} \right) + \frac{\partial^2 C_i}{\partial x^2} \right). \quad (38.3)$$

The dependent variables are expressed in terms of cross-sectional averages and deviations:

$$\begin{aligned} C_i(x, r, t) &= \langle C_i \rangle(x, t) + C'_i(x, r, t), \\ u(x, r, t) &= \langle u_p \rangle(x, t) + \langle U_{e,i} \rangle(x, t) + u'_p(x, r, t) = U_p + U_{e,i} + u_p. \end{aligned} \quad (38.4)$$

The cross-sectional average is defined as  $\langle \dots \rangle = 1/\pi a^2 \int_0^a 2\pi r(\dots) dr$ . Note  $u'_p$  is  $U_p(1 - 2r^2/a^2)$ , where  $U_p = -\pi a^4(\partial p/\partial x)/8\eta$  is the bulk (area-averaged) velocity due to pressure gradients. We can interpret primed quantities as describing the concentration field in a frame moving with the area-averaged velocity of the solute. Substituting these definitions into Equation 38.1:

$$\begin{aligned} \frac{\partial \langle C_i \rangle}{\partial t} + \frac{\partial C'_i}{\partial t} + (U_{e,i} + \langle u_p \rangle) \frac{\partial \langle C_i \rangle}{\partial x} + (U_{e,i} + \langle u_p \rangle) \frac{\partial C'_i}{\partial x} + u'_p \frac{\partial \langle C_i \rangle}{\partial x} + u'_p \frac{\partial C'_i}{\partial x} \\ + \frac{\partial U_{\text{eph},i}}{\partial x} \langle C_i \rangle + \frac{\partial U_{\text{eph},i}}{\partial x} C'_i = D_i \left( \frac{1}{r} \frac{\partial}{\partial r} \left( r \frac{\partial C'_i}{\partial r} \right) + \frac{\partial^2 \langle C_i \rangle}{\partial x^2} + \frac{\partial^2 C'_i}{\partial x^2} \right). \end{aligned} \quad (38.5)$$

Subject to

$$\frac{\partial C'_i}{\partial r} = 0 \quad \text{at } r = a, 0.$$

Note that  $\langle U_{\text{eph},i} \rangle = U_{\text{eph},i}$  and  $U'_{\text{eph},i} = 0$ . The boundary conditions (BC) reduce to this since  $\partial \langle C_i \rangle / \partial r$  is exactly zero by definition,  $\langle C_i \rangle$  being only a function of  $x$ . Next, we take a cross-sectional average of Equation 38.5:

$$\begin{aligned} \frac{\partial \langle C_i \rangle}{\partial t} + \underbrace{\left\langle \frac{\partial C'_i}{\partial t} \right\rangle}_{=0 \text{ by def}} + (U_{e,i} + \langle u_p \rangle) \frac{\partial \langle C_i \rangle}{\partial x} + \underbrace{(U_{e,i} + \langle u_p \rangle) \left\langle \frac{\partial C'_i}{\partial x} \right\rangle}_{=0 \text{ by def}} + \underbrace{\langle u'_p \rangle \frac{\partial \langle C_i \rangle}{\partial x}}_{=0 \text{ by def}} \\ + \underbrace{\left\langle u'_p \frac{\partial C'_i}{\partial x} \right\rangle}_{=0 \text{ by def}} + \frac{\partial U_{\text{eph},i}}{\partial x} \langle C_i \rangle + \underbrace{\left\langle \frac{\partial U_{\text{eph},i}}{\partial x} C'_i \right\rangle}_{=0 \text{ by def}} = D_i \left( \underbrace{\left\langle \frac{1}{r} \frac{\partial}{\partial r} \left( r \frac{\partial C'_i}{\partial r} \right) \right\rangle}_{\text{evaluate using BC}} + \frac{\partial^2 \langle C_i \rangle}{\partial x^2} + \underbrace{\left\langle \frac{\partial^2 C'_i}{\partial x^2} \right\rangle}_{=0 \text{ by def}} \right), \end{aligned} \quad (38.6)$$

where the notes “= 0 by def” and “evaluate using BC” denote a quantity zero by definition and a term that can be evaluated with the BCs. Evaluating the first term on the right-hand side:

$$\left\langle \frac{1}{r} \frac{\partial}{\partial r} \left( r \frac{\partial C'_i}{\partial r} \right) \right\rangle = \frac{1}{\pi a^2} \int_0^a 2\pi \frac{\partial}{\partial r} \left( r \frac{\partial C'_i}{\partial r} \right) dr = \frac{2}{a^2} \int_0^a d \left( r \frac{\partial C'_i}{\partial r} \right) = r \frac{\partial C'_i}{\partial r} \Big|_a - r \frac{\partial C'_i}{\partial r} \Big|_0 = 0.$$

(From BC,  $\partial C'_i/\partial r$  is zero at both  $r = 0$  and  $r = a$ .) Collecting nonzero terms in Equation 38.6:

$$\frac{\partial \langle C_i \rangle}{\partial t} + (U_{e,i} + \langle u_p \rangle) \frac{\partial \langle C_i \rangle}{\partial x} + \frac{\partial U_{\text{eph},i}}{\partial x} \langle C_i \rangle = D_i \left( \frac{\partial^2 \langle C_i \rangle}{\partial x^2} \right) - \left\langle u'_p \frac{\partial C'_i}{\partial x} \right\rangle. \quad (38.7)$$

The cross-correlation term is placed on the right-hand side as it acts as a source of dispersion (as does diffusion). We now derive an expression for  $C'_i$ . To do so, subtract Equation 38.7 from Equation 38.5:

$$\begin{aligned} \frac{\partial C'_i}{\partial t} + u'_p \frac{\partial \langle C_i \rangle}{\partial x} + (U_{e,i} + \langle u_p \rangle) \frac{\partial C'_i}{\partial x} + u'_p \frac{\partial C'_i}{\partial x} + \frac{\partial U_{\text{eph},i}}{\partial x} C'_i \\ = D_i \left( \frac{1}{r} \frac{\partial}{\partial r} \left( r \frac{\partial C'_i}{\partial r} \right) + \frac{\partial^2 C'_i}{\partial x^2} \right) + \left\langle u'_p \frac{\partial C'_i}{\partial x} \right\rangle. \end{aligned} \quad (38.8)$$

Scale the variables as follows:  $r^* = r/a$ ,  $x^* = x/\sigma$ ,  $C_i'^* = C_i'/C_{io}'$ ,  $\langle C_i \rangle^* = \langle C_i \rangle/C_{io}$ ,  $t^* = t/t_c$ , and  $\langle u_p \rangle^* = \langle u_p \rangle/U_p = 1$ ,  $u_p'^* = u_p'/U_p$ , and  $\langle U_{e,i} \rangle^* = \langle U_{e,i} \rangle/(U_{eph,i}(x, t) + U_{eof}(x, t)) = 1$ . We choose both  $C_{io}'$  and  $C_{io}$  as we will use the ratio  $C_{io}'/C_{io}$  as a smallness parameter in our scaling arguments.

We scale axial gradients using the characteristic width of dispersion  $\sigma$ . For techniques where variance width of the sample plug increases approximately linearly in time, we can interpret  $\sigma$  as the characteristic length scale of advective dispersion,  $U_p t_c$ . Here,  $t_c$  is the time of observation or time between injection and detection. In focusing techniques where solute dispersion length scales reach a steady value,  $\sigma$  is an inherent length scale associated with the focusing stacking dynamics. For example, in ITP stacking or TGF of finite injection volumes, sample widths eventually reach a steady-state value. In these techniques, the axial concentration and velocity gradients of the peak are determined by the interplay between electromigration (which provides the focusing fluxes) and diffusion and dispersion (which limit the amount of stacking). The inherent length scale of dispersion,  $\sigma$ , is then an internal length scale (i.e., determined by the specific condition). For such cases, we will assume  $\sigma \gg a$  with the understanding that the analysis is checked for self consistency and is only valid if it indeed predicts long thin solute plugs.

Equation 38.8 can then be written as

$$\begin{aligned} & \left( \frac{C_{o,i}'}{t_c} \right) \frac{\partial C_i'^*}{\partial t^*} + \left( \frac{U_p C_{o,i}'}{\sigma} \right) u_p'^* \frac{\partial \langle C_i \rangle^*}{\partial x^*} + \left( \frac{C_{o,i}'}{\sigma} \right) (U_p + U_{e,i} + U_p u_p'^*) \frac{\partial C_i'^*}{\partial x^*} + \left( \frac{U_p C_{o,i}'}{\sigma} \right) \frac{\partial U_{eph,i} C_i'}{\partial x^*} \\ & = \left( \frac{D_i C_{o,i}'}{a^2} \right) \left( \frac{1}{r^*} \frac{\partial}{\partial r^*} \left( r^* \frac{\partial C_i'^*}{\partial r^*} \right) \right) + \left( \frac{D_i C_{o,i}'}{\sigma^2} \right) \frac{\partial^2 C_i'^*}{\partial x^{*2}} + \left( \frac{U_p C_{o,i}'}{\sigma} \right) \left\langle u_p'^* \frac{\partial C_i'^*}{\partial x^*} \right\rangle. \end{aligned} \tag{38.9}$$

Next, multiply this equation by  $a^2/(D_i C_{o,i}')$ .

$$\begin{aligned} & \underbrace{\left( \frac{a^2 C_{o,i}'}{D_i t_c C_{o,i}'} \right)}_{\text{order } \varepsilon^2} \frac{\partial C_i'^*}{\partial t^*} + \underbrace{\left( \frac{a^2 U_p}{\sigma D_i} \right)}_{\text{order } \varepsilon} u_p'^* \frac{\partial \langle C_i \rangle^*}{\partial x^*} + \underbrace{\left( \frac{a^2 U_p C_{o,i}'}{\sigma D_i C_{o,i}'} \right)}_{\text{order } \varepsilon^2} \left( 1 + \frac{U_{e,i}}{U_p} + u_p'^* \right) \frac{\partial C_i'^*}{\partial x^*} + \underbrace{\left( \frac{a^2 U_p C_{o,i}'}{\sigma D_i C_{o,i}'} \right)}_{\text{order } \varepsilon^2} \\ & \times \frac{\partial U_{eph,i} C_i'}{\partial x} = \underbrace{\left( \frac{C_{o,i}'}{C_{o,i}'} \right)}_{\text{order } \varepsilon} \left( \frac{1}{r^*} \frac{\partial}{\partial r^*} \left( r^* \frac{\partial C_i'^*}{\partial r^*} \right) \right) + \underbrace{\left( \frac{a^2 C_{o,i}'}{\sigma D_i C_{o,i}'} \right)}_{\text{order } \varepsilon^2} \frac{\partial^2 C_i'^*}{\partial x^{*2}} + \underbrace{\left( \frac{a^2 U_p C_{o,i}'}{\sigma D_i C_{o,i}'} \right)}_{\text{order } \varepsilon^2} \left\langle u_p'^* \frac{\partial C_i'^*}{\partial x^*} \right\rangle. \end{aligned} \tag{38.10}$$

The notes below the various terms denote the order of magnitude. Of interest are the long times relative to streamwise transport so that  $t_c \gg a^2/D_i$ . In other words, the plug is long compared to the radius of the capillary such that  $\sigma \gg a$  and the smallness parameter,  $\varepsilon$ , is

$$\varepsilon \sim \left( \frac{a}{\sigma} \right)^2 \sim \frac{a^2}{D_i t_c} \ll 1.$$

For the third term on the left-hand side, we assume that the displacement time,  $\sigma/(U_p + U_{e,i}(x))$ , is much longer than the radial diffusion time,  $a^2/D_i$ . For TGF,  $U_p + U_{e,i}(x) = 0$  and the term in question is zero. For FASS and ITP, the solute plug velocity,  $U_p + U_{e,i}$ , is finite and this assumption implies the diffusion time,  $a^2/D_i$ , must be smaller than the time required for the plug to move a characteristic distance  $\sigma$ . This condition should hold for FASS where typically  $\sigma$  is significantly larger than  $a$ . For ITP, we will restrict our analysis to the cases where this third term is negligible. In comparing the second and third terms on the left-hand side, we see this assumption allows  $[U_p + U_{e,i}]/U_p$  to be somewhat larger than unity (or smaller), but not so large that  $[U_p + U_{e,i}]C_{o,i}'/(U_p C_{o,i}')$  is order

unity. This seems reasonable for ITP plugs with interface axial lengths,  $\sigma$ , of order  $a$  and larger. (The challenges of analyzing Taylor dispersion in ITP are discussed further below.) The current assumptions lead to the following:

$$\left(\frac{a^2 U_p}{\sigma D_i}\right) u_p^* \frac{\partial \langle C_i \rangle^*}{\partial x^*} \approx \left(\frac{C'_{o,i}}{C_{o,i}}\right) \left(\frac{1}{r^*} \frac{\partial}{\partial r^*} \left(r^* \frac{\partial C'_{i,*}}{\partial r^*}\right)\right). \quad (38.11)$$

Or, in dimensional form:

$$u_p' \frac{\partial \langle C_i \rangle}{\partial x} \approx D_i \left(\frac{1}{r} \frac{\partial}{\partial r} \left(r \frac{\partial C'_i}{\partial r}\right)\right). \quad (38.12)$$

Perturbations in the axial velocity must be balanced by radial diffusion. Substituting for  $u_p'$

$$U_p \left(1 - \frac{2r^2}{a^2}\right) \frac{\partial \langle C_i \rangle}{\partial x} \approx D_i \left(\frac{1}{r} \frac{\partial}{\partial r} \left(r \frac{\partial C'_i}{\partial r}\right)\right).$$

Multiply both sides by  $r$  and integrate in  $r$

$$U_p \frac{\partial \langle C_i \rangle}{\partial x} \left(\frac{r^2}{2} - \frac{r^4}{2a^2}\right) \approx D_i \left(r \frac{\partial C'_i}{\partial r}\right) + C_1.$$

Apply BC at  $r = a$ :  $C_1 = 0$ . Divide both sides by  $r$  (and  $D$ ) and integrate again:

$$C'_i(r, x, t) = C'_i(0, x, t) + \frac{U_p(x, t) a^2}{4D_i} \frac{\partial \langle C_i \rangle}{\partial x} \left[\frac{r^2}{a^2} - \frac{r^4}{2a^4}\right]. \quad (38.13)$$

where  $C'_i(0, x, t)$  is the constant of integration obtained from the BC at  $r = 0$ . Now, we can evaluate the cross term in Equation 38.7. Take the  $x$ -derivative of Equation 38.13,

$$\frac{\partial C'_i(r, x, t)}{\partial x} = \frac{\partial C'_i(0, x, t)}{\partial x} + \frac{\partial}{\partial x} \left(U_p \frac{\partial \langle C_i \rangle}{\partial x}\right) \frac{a^2}{4D_i} \left[\frac{r^2}{a^2} - \frac{r^4}{2a^4}\right].$$

multiply this by  $u'$  (from Equation 38.4), and integrate over the cross section:

$$\left\langle u' \frac{\partial C'_i}{\partial x} \right\rangle = -\frac{\partial}{\partial x} \left(\frac{a^2 U_p^2}{48D_i} \frac{\partial \langle C_i \rangle}{\partial x}\right). \quad (38.14)$$

Substitute this into Equation 38.7, which was the area average of the originally decomposed convective diffusion equation, to yield

$$\frac{\partial \langle C_i \rangle}{\partial t} + (U_{e,i} + \langle u_p \rangle) \frac{\partial \langle C_i \rangle}{\partial x} + \frac{\partial U_{\text{eph},i}}{\partial x} \langle C_i \rangle = D_i \left(\frac{\partial^2 \langle C_i \rangle}{\partial x^2}\right) + \frac{\partial}{\partial x} \left(\frac{a^2 U_p^2}{48D_i} \frac{\partial \langle C_i \rangle}{\partial x}\right). \quad (38.15)$$

To review, the main assumptions are that the velocity and electric fields are nearly parallel and that  $a^2/(D_i t_{\text{obs}}) \ll 1$  and  $a/\sigma \ll 1$ .

We rewrite Equation 38.15 as

$$\frac{\partial \langle C_i \rangle}{\partial t} + (U_{\text{eph},i} + U_{\text{eof}} + U_p) \frac{\partial \langle C_i \rangle}{\partial x} + \frac{\partial U_{\text{eph},i}}{\partial x} \langle C_i \rangle = \frac{\partial}{\partial x} \left(D_{\text{eff},i} \frac{\partial \langle C_i \rangle}{\partial x}\right), \quad (38.16)$$

where  $D_{\text{eff},i}(x, t) = D_i + a^2 U_p(x, t)^2 / (48 D_i) = D_i(1 + Pe_i^2/48)$ . Here  $Pe_i$  is a Peclet number defined as  $U_p a / D_i$ . We do not know of analytical solutions to the nontrivial cases where  $U_{\text{eph},i}$ ,  $U_{\text{eof}}$ , and  $U_p$  indeed vary in  $x$  (as in the case of nonuniform EOF velocities), and so this requires numerical solutions. However, we argue that significant insight can be gleaned from this equation, and this insight is valuable in optimizing sample preconcentration processes.

The previously mentioned equation shows that the area-averaged solute plugs will travel along the capillary with a nonuniform wave velocity of the form  $U_{\text{eph},i} + U_{\text{eof}} + U_p$ , as expected. The local dispersion coefficient,  $D_{\text{eff},i}$ , is strictly a function of the pressure-driven flow component, which has nonzero radial gradients, and has the same form as the well-known Taylor–Aris solution [5], but with axial and temporal variations in the dispersion coefficient. The focusing effect of electrophoresis is captured by the electrophoresis term  $\langle C_i \rangle \partial U_{\text{eph},i} / \partial x$ . This analysis captures the interplay between dispersion and preconcentration forces in electrophoretic stacking methods.  $D_{\text{eff},i}$  acts to increase sample plug variance (in the absence of stacking fluxes, variance scales as  $D_{\text{eff},i} t$ , where  $t$  is time). This dispersion is countered by gradients of ion drift velocity that generate a negative value of  $\langle C_i \rangle \partial U_{\text{eph},i} / \partial x$ . For a positive  $x$ -direction electric field, preconcentration (local increase in  $\langle C_i \rangle$ ) occurs for a cation when  $U_{\text{eff},i}$  has negative axial gradient,  $\partial U_{\text{eph},i} / \partial x < 0$  (and where  $\partial U_{\text{eph},i} / \partial x > 0$  for an anion). Opposite signs for  $\partial U_{\text{eph},i} / \partial x$  cause so-called electromigration dispersion and associated reductions in  $\langle C_i \rangle$  [19]. As described earlier, focusing occurs when we have a frame of reference in which  $\partial U_{\text{eph},i} / \partial x$  is accompanied by a change in sign of the electrophoretic velocity, and solute is driven toward this focal point from large regions of the channel. [ $U_{\text{eof}}$  and  $U_p$  cannot cause preconcentration since  $\nabla \cdot (U_{\text{eof}} + U_p)$  is identically zero.] The relative strength of stacking and focusing versus dispersion is determined by the relative strength of  $\partial U_{\text{eph},i} / \partial x$  and  $D_{\text{eff},i}$ ; more simply,  $\partial U_{\text{eph},i} / \partial x$  acts to reduce  $\sigma$  while  $D_{\text{eff},i}$  acts to increase it. This balance determines the maximum achievable concentration increase, and can determine the resolution of simultaneous preconcentration and separation. This concept is further developed in the next section.

As mentioned earlier, Taylor-type dispersion analyses have been extended to other geometries including flow in rectangular channels of varying aspect ratio and channels with the characteristic “D” shape of isotropic chemical etching [6,20]. In general, these analyses lead to an effective dispersion coefficient of the form  $D(1 + \kappa Pe^2)$ , where  $\kappa$  takes into account geometric dependences. Table 38.1 list sample  $\kappa$  values for several flow geometries. This elegant and general form of the dispersion coefficient implies that the insights gained by the area-averaging are generally applicable to dispersion in a wide range of geometries.

Often, microchannels are etched with finite (and sometimes high) width-to-depth aspect ratios,  $w/h$ , with typical values ranging from 2 to 20. For such channels, the time scale for diffusion across

---

---

the channel depth,  $\tau_h \sim h^2/D_i$  is short compared to across the channel width  $\tau_w \sim w^2/D_i$ . Ajdari et al. [20] points out that dispersion in shallow-channels with smooth spanwise height distributions is controlled by the product  $\kappa Pe_w^2$ , where  $Pe_w = wU/D_i$ . In wide, shallow channels dispersion, owing to spanwise (width direction) velocity gradients, occurs at rates that are not negligible compared to spanwise diffusion. Statistical sampling of solute molecules along the spanwise direction is, therefore, less efficient and leads to increased dispersion over that of an idealized, infinitely wide channel with the same depth. A key consequence of the analysis is that the largest cross-section dimension controls the time scale to reach the Taylor dispersion limit. For arbitrarily shaped channels, the criteria for achieving Taylor dispersion are then modified to  $t_c \gg w^2/D_i$  (where  $w$  is the largest cross section scale) and  $\sigma \gg a$ , where again  $\sigma$  is the characteristic axial dimension of the solute (or interface region) of interest.

### 38.3.2 SCALING RELATIONS TO ESTIMATE DISPERSION EFFECTS

In the presence of axial gradients in ionic strength (and conductivity) or pH, both electric field and electroosmotic mobility will vary along the axis of the capillary or microchannel [21]. As discussed earlier, this leads to the generation of internal pressure gradients to satisfy the continuity equation (i.e., mass conservation). In the absence of an external, applied pressure difference,  $u_p$  is generated strictly by gradients in EOF mobility  $U_{\text{eof}} = \mu_{\text{eof}}(x)E(x)$ . For this case, we can estimate the relative importance of Taylor dispersion to molecular diffusion by performing a simple scaling analysis. This exercise highlights the importance of judicious choices of system parameters to minimize dispersion. These choices include separation voltage, EOF suppression strategy, and channel shape and dimensions.

We present an example scaling analysis for dispersion and optimum electric field in a single-interface FASS problem. (The scaling of pressure velocity magnitudes versus local electric field and electroosmotic mobility will also hold for other single-interface preconcentration methods such as the ITP method demonstrated by Jung et al. [22]). This simple case yields approximations as with closed-form analytical expressions. Obtaining estimates for the electroosmotic velocity is the first step. This can be achieved in at least two ways: direct experimental measurement (e.g., in calibration experiments) and theoretical estimates. EOF velocities can be measured under various conditions using the current monitoring method [23], micron-resolution particle image velocimetry measurements [24], or neutral marker tracking [25]. If these measurements are difficult to obtain, EOF velocity can be estimated using various models for the electrical double layer. For thin EDLs, the Helmholtz–Smoluchowski model yields a simple relation [26]:

$$u_{\text{EOF}} = -\frac{\varepsilon \zeta E}{\eta}, \quad (38.17)$$

where  $\varepsilon$  is the permittivity constant and  $\zeta$  is the zeta potential [27]. The zeta potential is a function of ionic strength and pH of the electrolyte. Various models and correlations are available in the literature to estimate the zeta potential for various substrates [28–30]. In the presence of axial gradients in conductivity, electric field will also vary along the axis of the channel. Electric field variation can be estimated by invoking conservation of current and Gauss's law. For example, consider the two-zone preconcentration problem in a cylindrical tube as depicted in Figure 38.1. After negligible charge relaxation time scales [13], the following relations hold true [31]:

$$\begin{aligned} \sigma_{e1}E_1 &\cong \sigma_{e2}E_2, \\ E_1xL + E_2(1-x)L &= V, \end{aligned} \quad (38.18)$$

where  $\sigma_e$  refers to electrical conductivity and  $x$  is the fraction of channel filled with  $\sigma_{e1}$ . These equations can be solved simultaneously to obtain  $E_1$  and  $E_2$ . Upon deriving the estimates for the

**FIGURE 38.1** Schematic representation of a capillary with axial gradient in conductivity, zeta potential, and electric field. The interface is located at distance  $x/L$  from the end of the channel (i.e., the applied potential), where  $x$  is the fraction of the length  $L$  occupied by the liquid 1. The potential drop across the capillary is  $V$ .

local electric fields and zeta potentials, the EOF mismatch-induced pressure-driven component of the velocity field can be obtained. To do so, we invoke the continuity equation:

$$U_{\text{EOF},1} + U_{p1} = U_{\text{EOF},2} + U_{p2}, \quad (38.19)$$

where  $U_{p1}$  and  $U_{p2}$  are related by following:

$$\frac{U_{p1}}{U_{p2}} = -\frac{(1-x)}{x}. \quad (38.20)$$

Finally, the maximum pressure-driven component of the velocity field is (assuming  $x < 0.5$ ):

$$U_{p1} = (U_{\text{EOF},2} - U_{\text{EOF},1})(1-x). \quad (38.21)$$

Burgi and Chien [31] have derived similar relations for estimating internal pressure gradients and for predicting optimum conductivity ratio for FASS. Now, the dispersion coefficient is estimated:

$$D_{\text{eff}} = D + \frac{a^2 U_{p1}^2}{48D} = D + \frac{a^2}{48D} (U_{\text{EOF},2} - U_{\text{EOF},1})^2 (1-x)^2. \quad (38.22)$$

Furthermore,

$$U_{\text{EOF},2} - U_{\text{EOF},1} = \varepsilon \frac{(\zeta_1 - \gamma \zeta_2)}{\eta} E_1, \quad (38.23)$$

where  $\gamma = \sigma_1/\sigma_2$ . Noting  $E_1 = E_0/(x + \gamma(1-x))$ , where  $E_0 = V/L$  is the nominal electric field, we have

$$D_{\text{eff}} = D + \frac{a^2 \varepsilon^2 E_0^2}{48D\eta^2} (\zeta_1 - \gamma \zeta_2) \frac{(1-x)^2}{x + \gamma(1-x)}. \quad (38.24)$$

We now assume that we are concerned with a stacking technique such as FASS where variance increases in time. For such a technique, the peak variance due to molecular diffusion and Taylor dispersion scales is

$$\sigma_{\text{total}}^2 \sim 2D_{\text{eff}} \tau_{\text{obs}}. \quad (38.25)$$

Note that  $D_{\text{eff}}$  varies in space and time as per equation (38.24). However, for scaling purposes the maximum dispersion coefficient can be used. The observation time,  $\tau_{\text{obs}}$ , is a complex quantity to determine, depending on the electrophoretic, electroosmotic, and induced pressure-driven velocities.

A closed form solution may be found in some simple scenarios, but in all cases the time scales linearly with  $E_0$ , such that  $\tau_{\text{obs}} \sim L/\mu_{\text{eff}}E_0$ , where  $\mu_{\text{eff}}$  is an effective species mobility. Thus,

$$\sigma_{\text{total}}^2 \sim \left[ \frac{a^2 \varepsilon^2}{24D\eta^2} (\zeta_1 - \gamma \zeta_2)^2 \frac{(1-x)^2}{x + \gamma(1-x)} \frac{L}{\mu_{\text{eff}}} \right] E_0 + \left[ \frac{2D}{\mu_{\text{eff}}} \right] \frac{1}{E_0}. \quad (38.26)$$

In this relation, the first term on the right-hand side is the contribution of Taylor dispersion to the overall band broadening. The second is due to molecular diffusion. A key point is that the contribution to the variance due to Taylor dispersion increases with nominal electric field,  $E_0$ , whereas variance due to molecular diffusion decreases with electric field,  $1/E_0$ . This is a consequence of the  $U_p^2$  and therefore,  $E_0^2$  scaling of  $D_{\text{eff}}$  on the one hand, and the  $L/u$  and therefore,  $1/E_0$  scaling of time. Therefore, there exists an optimum electric field that will minimize the peak broadening. This optimum electric field can be derived by minimizing the variance with respect to field to obtain

$$E_{\text{optimum}} \sim \sqrt{\frac{48D^2\eta^2(x + \gamma(1-x))}{a^2\varepsilon^2(\zeta_1 - \gamma\zeta_2)^2(1-x)^2}}. \quad (38.27)$$

As we discuss later in this chapter, techniques achieving a steady-state dispersion-limited width typically also have optimum electric fields that reduce dispersion. At negligible Taylor dispersion conditions (i.e., low electric fields), the sample axial dimension is determined by a balance between electrophoretic focusing fluxes and molecular diffusion. Plug axial dimension, therefore, scales as  $D/E_0$  (see Equations 38.40, 38.41, 38.44, and associated discussions). At higher electric fields, Taylor dispersion becomes important and axial dimensions scale as  $D_{\text{eff}}/E_0$ . At sufficiently high fields, the Taylor dispersion term, which scales as  $a^2\varepsilon^2E_0^2/(48D\eta^2)$ , dominates and then interface width again scales as  $E_0$ .

In all cases, the optimum field for minimization of Taylor dispersion is a function of sample (through  $D$ ), channel geometry, solution viscosity, and zeta potential value for a given conductivity ratio and solution permittivity. Finally, we note the earlier analysis neglects the effects of Joule heating [32,33] on dispersion. Joule heating places additional constraints on the optimum field as temperature rise is a function of both conductivity distribution and pore diameter. We, however, stress the main purpose of the analysis is to argue that all preconcentration phenomena have optimum fields and that they are often limited by the dispersion associated with even residual EOF.

## 38.4 PRACTICAL APPLICATIONS

### 38.4.1 FIELD-AMPLIFIED SAMPLE STACKING

#### 38.4.1.1 Introduction

Field-amplified sample stacking is a fairly widely applicable method of achieving increased sensitivity for capillary and on-chip assays in a scheme that is easily integrated with electrophoretic separation techniques [4,34–43]. FASS is typically used as a preconcentration step that occurs before the electrophoretic separation of analyte ions.

The transport phenomena associated with FASS (as in all preconcentration methods) are, in general, a complex coupling of convective–diffusion, electrostatics, and electrokinetics along with the unsteady effects associated with the response of the electrical double layer to varying bulk ion concentrations. The detailed understanding of the process dynamics is important for optimization of high-sensitivity systems. The effects of EOF on preconcentration and separation are very important to studies of FASS as even slight EOF couples with axial conductivity gradients to generate internal

**FIGURE 38.2** (a) Schematic diagram showing FASS of anionic species in the absence of EOF. A gradient in the BGE ion concentration is established. The sample is in a region of locally low conductivity. Upon application of an electric field, the axial gradient in conductivity results in an electric field gradient. Since area-averaged current density is uniform along the axis of the channel, the low conductivity section is a region of high electric field, and the region of high conductivity contains relatively low electric field. As sample ions exit the high field/high electrophoretic velocity region and enter the low velocity region, they locally accumulate and increase in concentration. (b) Stacking in the presence of EOF. Gradients in conductivity generate axial variation in electric field and electroosmotic mobility. The system generates internal pressure gradients, which tend to disperse the sample.

pressure gradients. These internal pressure gradients disperse the sample and thereby, limit the practically achievable concentration enhancement.

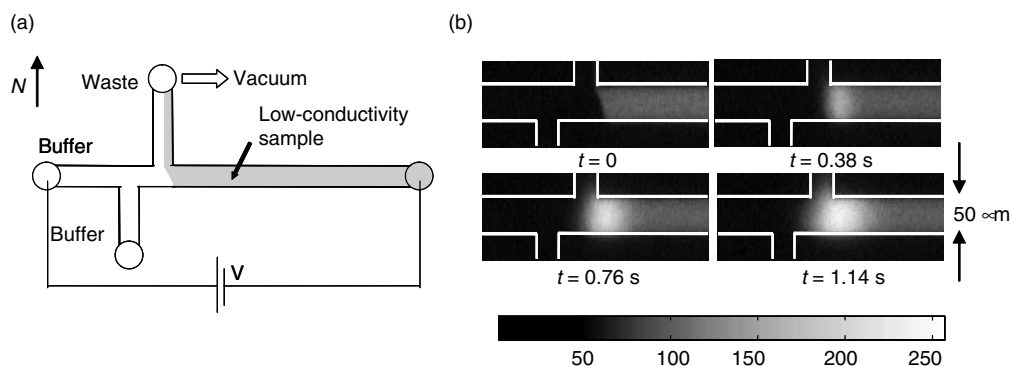

### 38.4.1.2 Basic Theory and Implementation

The principle behind FASS is shown schematically in Figure 38.2a. An axial gradient in ionic conductivity (and therefore electric field) is achieved by preparing the sample in an electrolyte solution of lower concentration than the BGE. Upon application of an axial potential gradient, the sample region acts as a high electrical resistance zone in series with the rest of the channel and a locally high electric field is generated within the sample zone. Under the influence of electric field, sample ions migrate from the high to low drift velocity region. This leads to a local accumulation or “stacking” of sample ions near the interface between high and low conductivity regions. This stacking increases sample concentration and results in an increased signal. The process depicted in Figure 38.2a is for an idealized case where diffusion and advection are neglected. The maximum concentration enhancement is given by a conservation of species at the interface

$$\frac{C_{\text{Stacked}}}{C_{\text{Initial}}} = \frac{E_S}{E_{\text{BGE}}} = \gamma, \quad (38.28)$$

where  $E_S$  and  $E_{\text{BGE}}$  are the electric field in the sample and the BGE regions, respectively. In essence, FASS relies strictly on electric field gradients generated by spatial variations in ion density. This makes FASS unlike other preconcentration techniques (such as ITP and IEF), which require more specific buffer chemistries and ion mobilities. For example, FASS can be implemented with the same type of ions in the BGE and sample zones. As such, FASS provides flexibility in the choice of BGE buffer chemistry and can nearly always be performed under well-controlled pH conditions.

Figure 38.2b shows a more realistic system where finite EOF is present. The gradient in the electrolyte concentration required for stacking leads to a gradient in electric field and electroosmotic mobility. This causes a mismatch of electroosmotic velocity and hence generation of a pressure

**FIGURE 38.3** Single interface stacking experiments. (a) Schematic diagram of a microchip. Width and centerline depth of channels were  $50\ \mu\text{m}$  and  $20\ \mu\text{m}$ , respectively. (b) Epifluorescence CCD images showing establishment of initial condition for conductivity gradient and subsequent stacking across interface. The sample was anionic  $17\ \mu\text{m}$  bodipy dye and the buffer was HEPES at  $\text{pH} = 7$ .

gradient (consistent with the continuity constraint). The pressure gradient tends to disperse the concentration fields and thereby lower the efficiency of stacking.

FASS has been applied in a variety of assay formats in both capillaries and microchips. The configurations can be broadly classified as (1) single interface configuration and (2) finite-plug configuration. The single interface configuration includes techniques such as field-amplified sample injection (FASI) [36,37,44], large volume sample stacking (LVSS) [38], and Head-Column FASS [45]. These techniques involve a single interface between the sample region and BGE. In these techniques, the volume of sample loaded into the capillary or the microchannel often exceeds the total volume of (initially low concentration) sample loaded into the capillary, or the microchannel can exceed the total volume of the capillary. In contrast, the finite-plug technique involves sample zones of fixed size. The sample zone size can be defined by duration of sample injection by either electrokinetic flows or by hydrodynamics flow. In microchannel networks, the sample size can be accurately controlled by chip geometry, for example, by using pinched-injection or staggered-T injection [46–48].

Figure 38.3 shows schematic representation of microchip-based single-interface FASS system. The interface between high and low conductivity buffer regions is generated by applying a vacuum at the north reservoir. Once a buffer–buffer interface is established, the vacuum is released and an axial electric field is applied. Upon application of an axial electric field along the west-to-east direction, sample stacks at the interface between buffer streams. Figure 38.3b shows images of the stacking process at selected times. In Figure 38.4, instantaneous images of stacking process are shown for a case where EOF was not suppressed. Since the EOF velocity in all regions is greater than the negative electrophoretic velocity of fluorescein dye, the stacked region moves in the direction of EOF. The images clearly show the favorable pressure-gradient-induced curvature of the stacked ions on the downstream (left-hand) side of the interface. As described earlier, these pressure gradients act to disperse sample and reduce the efficiency of FASS. From Figures 38.3b and 38.4, the efficacy of the EOF-suppression method is apparent as the conductivity interface is nearly stationary and there is negligible pressure-induced curvature of stacked analyte. Figure 38.5 shows the temporal development of the spatial concentration distribution of sample ions. The peak intensity increases roughly exponentially at first and then saturates at a maximum achievable concentration enhancement of  $\gamma$ .

### 38.4.1.3 Dispersion Theory

In most electrophoretic experiments, the quantity of practical interest is the cross-sectional area-averaged concentration distribution of sample ions. This quantity is, for example, proportional to the

**FIGURE 38.4** CCD images of on-chip FASS in an untreated channel with significant EOF mobility. The images clearly show the development of stacked fluorescein in the favorable pressure gradient region (i.e., the high conductivity region). The sample was 25  $\mu\text{m}$  fluorescein dye dissolved in 5 mM Borate buffer. The BGE for this particular experiment was 25 mM Borate buffer (pH = 9.2). The electric field in the sample region was 50 V/cm and  $\gamma = 4$ .

**FIGURE 38.5** Measured axial intensity profiles for sample ions. The profiles were obtained by averaging two-dimensional image intensity data along the width of the channel. The applied nominal electric field was 588 V/cm and  $\gamma = 4$ . Time between individual profiles was 0.15 s.

measured signal intensity of line-of-sight optical integrators such as pointwise fluorescence detectors, transmitted-mode absorption detectors, and width-averaged electrophoregrams from charge-coupled device (CCD) arrays. This signal determines the key detectability constraints of electrophoretic separations [3]. As described earlier, Taylor dispersion analysis allows us to develop cross-sectional area-averaged transport equations. Such models provide useful insight into the physics of the process and lead to the identification of key parameters that can be used to develop optimization strategies for FASS experiments.

The FASS model requires description of electromigration, diffusion, and advection of sample ions as well as BGE ions. The general system of equations is highly coupled and nonlinear and, therefore, difficult to solve. However, the concentration of sample ions is much smaller than the buffer ions (typically  $\mu\text{M}$  sample ions concentration or less versus order 1 mM buffer ion concentrations). Therefore, we can decouple the buffer and sample ion concentration fields. Using this approach, Bharadwaj and Santiago [4] have developed a dynamic model for FASS in a flat-plate

**FIGURE 38.6** Comparison of model predictions and measured concentration profiles.  $\gamma = 4$ ,  $E_0 = 379$  V/cm, and time-between-frames was 76 ms. The model parameters are  $Pe_e = 55$ ,  $\alpha = 0.23$ ,  $\beta = 0.28$ ,  $\delta = 1.27$ .

geometry. The analysis provides the following equation for the cross-sectional area-averaged sample ion distribution,  $C_S$ :

$$\frac{\partial C_S}{\partial t} + \alpha \langle u \rangle \frac{\partial C_S}{\partial x} = D \frac{\partial^2 C_S}{\partial x^2} \frac{1}{Pe_e} + \alpha^2 \beta^2 Pe_e \frac{8g(x,t)}{105D} \frac{\partial}{\partial x} \left( g(x,t) \frac{\partial C_S}{\partial x} \right) - z_S \mu_S \frac{\partial (C_S E)}{\partial x}. \quad (38.29)$$

The parameters governing this system of equations are

$$Pe_e = \frac{E_0 \mu_{\text{eph}} F_{SS}}{D_S}; \quad \alpha = \frac{-\varepsilon_0 \varepsilon_r \zeta / \eta}{\mu_{\text{eph}}} = \frac{\mu_{\text{eof}}}{\mu_{\text{eph}}}; \quad \beta = \frac{d}{s_S}; \quad \text{and} \quad \delta = \frac{s_B}{s_S}.$$

$Pe_e$  is the electric Peclet number, expressed as the ratio of diffusion time to electromigration time;  $\alpha$  is the ratio of electroosmosis to electrophoretic mobility;  $\beta$  is the ratio of channel width to characteristic length scale for the initial sample ion concentration distribution; and  $\delta$  is the ratio of the length scale of the initial BGE and sample ion concentration gradients. Here,  $d$  is the channel depth,  $s_S$  and  $s_B$  are the initial sample and BGE ion concentration gradients, and  $E_0$  is the nominal electric field. The function  $g(x, t)$  in the advective dispersion term accounts for the axial variation in pressure-driven velocity profile (cf. Figure 38.2).

Figure 38.6 shows comparisons between dispersion model predictions and experimentally measured concentration profiles. Experiments are shown for  $\gamma = 4$  and 9 and  $E_S$  values of 379 and 588 V/cm. There is a quantitative agreement between measured area-averaged concentration profiles and the model prediction throughout the time of observation. The model predictions were obtained by solving Equation 38.29. As shown in Figure 38.3b, for times approaching 1 s, the region of high area-averaged concentration becomes two-dimensional as it enters the staggered-T injection region of the system, which cannot be captured by one-dimensional model. The dispersion model is able to capture important features such as the development of peak width and the temporal growth of the maximum concentration. Also, the model describes convective–electromigration–diffusion dynamics in a purely two-dimensional flow in a wide, shallow channel (neglecting the influence of side walls). In reality, however, the microchannels in the experiment have a D-shape characteristic of an isotropic etch with a width to maximum depth ratio of 2.5. This assumption may be improved in future refinements of the dispersion model. For example, Dutta and Leighton [6] have investigated the effect of isotropic-etched microchannel geometries on the dispersion coefficient for simple pressure-driven flows. Their analysis shows, in the Taylor dispersion limit (ruled by the widest channel dimension), the dispersion coefficients for the D-shaped channels can be three to four times

**FIGURE 38.7** Optimum value of  $\gamma$  for fixed stacking times of 1 s. The parameters for the dispersion model are:  $\alpha = 0.5$ ,  $\beta = 2$ , and  $\delta = 1$ . For a given analysis time and fixed values of  $Pe_e$ ,  $\alpha$ ,  $\beta$ , and  $\delta$ , there is a unique value of  $\gamma$  that provides maximum concentration enhancement.

larger than those predicted by simple two-dimensional analysis. Such advective–diffusion effects would be most important in flow for large  $\gamma$  values (associated with larger internally generated pressure gradients) and the large Peclet numbers associated with high electric fields. Another possible refinement of the model would include dispersive effects due to Joule heating [49], which should also lead to reduction in the rate of concentration increase.

#### 38.4.1.4 Performance and Guidelines

In this section, we summarize some parametric and optimization results from dispersion models. First, we consider the effect of conductivity ratio,  $\gamma$ , on stacking efficiency. Figure 38.7 shows clearly that there is an optimum value of  $\gamma$  for a given set of parameters and analysis time. In these plots, the analysis time is fixed as we are interested in FASS as a preconcentration step before electrophoretic separation. These fixed-time comparisons help to determine the time needed to achieve adequate concentration enhancement and the initial condition of the subsequent uniform-conductivity separation process. These model predictions were generated with a parametric variation study using the numerical model described earlier. This result is in contrast with the ideal concentration factor described earlier, which shows that increasing  $\gamma$  always increases the concentration enhancement (Equation 38.28). This is an important feature of the dispersion analysis as it gives experimentalists a method of choosing values of  $\gamma$  to yield optimal signal detections.

The existence of an optimal value of  $\gamma$  can be better understood by considering the scaling of the parameters of interest. Equation 38.28 shows that the maximum sample concentration is proportional to  $\gamma$ :

$$C_{C,\max} \propto \gamma. \quad (38.30)$$

In contrast, the ratio of the EOF velocities in the low-conductivity region to the value in the high-conductivity region scales as

$$\frac{U_{\text{EOF},S}}{U_{\text{EOF},B}} \sim \frac{\zeta_S E_S}{\zeta_B E_B} \sim \gamma^{1+n}. \quad (38.31)$$

The parameter  $n$  refers to the ratio of the zeta potential in the sample and the BGE regions. Typical values of this parameter range between 0.2 and 0.3 [50,51], so that the advective dispersion effects of mismatched slip velocities is negligible for low  $\gamma$  but dominates at high  $\gamma$ . An analogous scaling

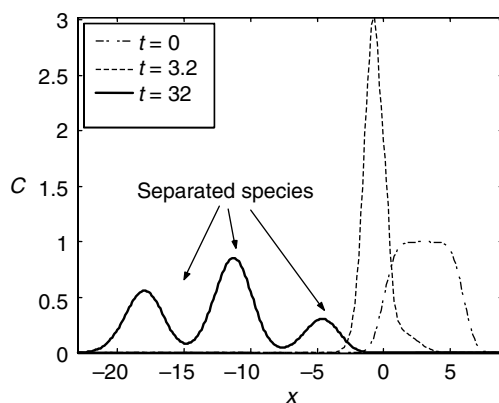

**FIGURE 38.8** Optimum value of  $Pe_e$  for a fixed stacking time of 1 s. The parameters for the dispersion model are  $\alpha = 0.5$ ,  $\beta = 2$ , and  $\delta = 1$ . At low  $Pe_e$ , diffusive dispersion dominates and concentration enhancement suffers. At high  $Pe_e$ , advective dispersion is dominant and again concentration enhancement suffers. For fixed  $\gamma$  and analysis time, there is a unique, optimal  $Pe_e$  (e.g., an optimal electric field for a given channel system) which results in maximum concentration increase.

observation was made by Burgi and Chien [31]. They discuss the existence of an optimum  $\gamma$  using simple scaling arguments. They developed an algebraic model for the long-time behavior of a finite-length sample plug variance as a function of  $\gamma$ , using a one-dimensional Taylor dispersion approximation. In contrast to their model, the dynamic model described here allows quantitative prediction of both temporal and spatial development of the sample ion, BGE ions, and electric field profiles.

Another important parameter determining the convective dispersion and hence, rate of concentration increase in FASS is  $\alpha$ , or the ratio of electroosmotic and electrophoretic mobilities. For a typical value of electrophoretic mobility (e.g.,  $3E-8 \text{ m}^2 \text{ V}^{-1} \text{ s}^{-1}$ ),  $\alpha$  is approximately equal to 2 for glass microchips. Therefore, the dispersion dynamics of untreated glass chips are well in the advection regime. However, at least an order of magnitude reduction in electroosmotic mobility is possible by dynamic surface coatings using neutral water-soluble polymers [52]. It is, therefore, interesting to experimentalist to quantify the importance of suppressing EOF in determining maximum achievable concentration increases. Bharadwaj and Santiago [4] show that, even for the case of a 10-fold decrease in electroosmotic mobility ( $\alpha = 0.2$ ), there is significant convective dispersion. The preconcentration time required to reach the maximum concentration enhancement can be as much as 50% longer for  $\alpha = 0.2$  case as compared to a case where there is no EOF. This result has important consequences in the design of microchip-based FASS systems because a slower rate of concentration increase can adversely affect both the amount of sample required per separation and the throughput of the device. To increase the rate of concentration enhancement, the electric field and Peclet number should be increased.

Figure 38.8 describes the effect of Peclet number,  $Pe_e = E_0 \mu_{\text{eph}} F s_S / D_S$ , on maximum concentration achievable for a given analysis time. Initially, increases in  $Pe_e$  are favorable for concentration enhancement. This is due to a reduced contribution of molecular diffusion, which scales as  $Pe_e^{-1}$ . However, as  $Pe_e$  is increased further, the concentration increase slows down and, past a critical  $Pe_e$ , the achievable concentration begins to decrease. The latter effect is due to the aforementioned fact that convective dispersion increases with increasing  $Pe_e$ . Equation 38.29 shows the dispersion term scales as  $\alpha^2 \beta^2 Pe_e$ . There is, therefore, an optimum value of  $Pe_e$  (e.g., an optimum electric field for a given process and geometry) for a given analysis time and fixed values of  $\gamma$ ,  $\alpha$ , and  $\beta$ . Note that the optimum value of  $Pe_e$  may be somewhat smaller in practice than that predicted by our dispersion model since we do not account for the effects of Joule heating [49]. Joule heating is proportional to the square of local electric field and is expected to be important for very high field strengths and relatively large channels.

**FIGURE 38.9** Stacking and separation dynamics of three negatively charged sample species. The model parameters are  $Pe_e = 40$ ,  $\gamma = 5$ ,  $\beta = 2$ ,  $\alpha = 0.05$ ,  $\delta = 1$ , and  $h = 6$ . The dimensionless electrophoretic mobilities of the species are 1, 2, and 3, respectively. The initial dimensionless concentrations of the sample species are  $1/6$ ,  $1/2$ , and  $1/3$ , respectively.

Finally, Figure 38.9 shows model results for sample stacking and separation dynamics of a finite injection volume (initially approximately six channel depths wide) of three anionic sample ions. Initially, there is rapid stacking (accumulation) of the sample ions as they exit the low conductivity region and enter the high conductivity region. Once sample ions enter the high conductivity region, sample stacking ends and ions are subsequently electrophoretically separated into three distinct peaks. The dispersion model can be used to optimally design FASS-based electrophoretic separation systems for the analysis of multiple sample species. For example, the model predictions can guide the location of detector and width of initial sample plug to ensure adequate signal-to-noise ratio (SNR) and resolution.

## 38.4.2 TEMPERATURE GRADIENT FOCUSING

### 38.4.2.1 Introduction

So far, we have alluded to a number of preconcentration techniques that are of interest to the CE community and, in the previous section, we examined FASS in detail. In this section, we consider dispersion as it relates to focusing techniques. The quintessential focusing technique is IEF [53–55]. In IEF, charged species migrate through a pH gradient under the influence of an electric field until they reach their isoelectric, or pI, point. At the pI, a species becomes net neutral and ceases to migrate. While this is the most common focusing technique, it is not the most general from the perspective of dispersion analysis and scaling. Consequently, we choose microfluidic temperature gradient focusing (TGF) as it represents an excellent case study in dispersion and provides a more general model. The approach and discussions presented can be extended to the analysis of Taylor dispersion in IEF.

TGF is a form of electric field gradient focusing, where a temperature-induced gradient in electric field helps produce the gradient in electrophoretic velocity required for focusing (in contrast to IEF, where the focusing effect is caused by the changing charge on an ampholyte). TGF was first described in a seminal paper by Ross and Locascio [56], where they demonstrated the successful focusing of charged fluorescent dyes, amino acids, green fluorescent protein, DNA, and polystyrene particles, illustrating the general utility of TGF. TGF has subsequently been extended to DNA hybridization assays and single nucleotide polymorphism detection [57], as well as the detection of chiral enantiomers [58]. Focusing of neutral and ionic hydrophobic analytes (e.g., coumarin)

**FIGURE 38.10** Schematic of TGF process with advective dispersion. An electrophoretic velocity is countered by an opposing liquid flow, composed of both pressure-driven and electroosmotic flow (top). A temperature gradient is applied to a microchannel, inducing a gradient in the electrophoretic velocity of an analyte. The analyte focuses where the electrophoretic and convective (“bulk”) fluxes sum to zero (middle). Both molecular diffusion and advective dispersion broaden the band about the focus point. The bottom image shows Bodipy focused in a 20 by 200  $\mu\text{m}$  wide channel with an applied electric field and temperature gradient of 60 V/mm and 10°C/mm, respectively.

has also been achieved [59,60] using TGF combined with micellar electrokinetic chromatography (MEKC). The capabilities of TGF allow it to be used in analytical (i.e., detection and separation) and preparative (i.e., concentration and purification) applications. In both applications, minimization of dispersion is an important design goal.

We have already discussed the basics of dispersion, noting how decreased dispersion improves resolution and sensitivity in separation applications [61], and also yields improved dynamics for concentration and purification applications [4]. However, there are some key differences to consider when comparing focusing techniques such as TGF with other techniques. We describe the basics of TGF theory, implementation details, and the modifications to Taylor dispersion required for TGF. Finally, we present tips for empirical optimization of TGF preconcentration factors and resolution.

### 38.4.2.2 Basic Theory and Implementation

Temperature gradient focusing focuses charged species by balancing an axially varying electrophoretic flux with a counterflow, causing species to focus at locations where their net fluxes sum to zero (Figure 38.10) [56].

$$\langle u_{\text{bulk}} \rangle + u_{\text{eph}}(x_{\text{foc}}) = 0, \quad (38.32)$$

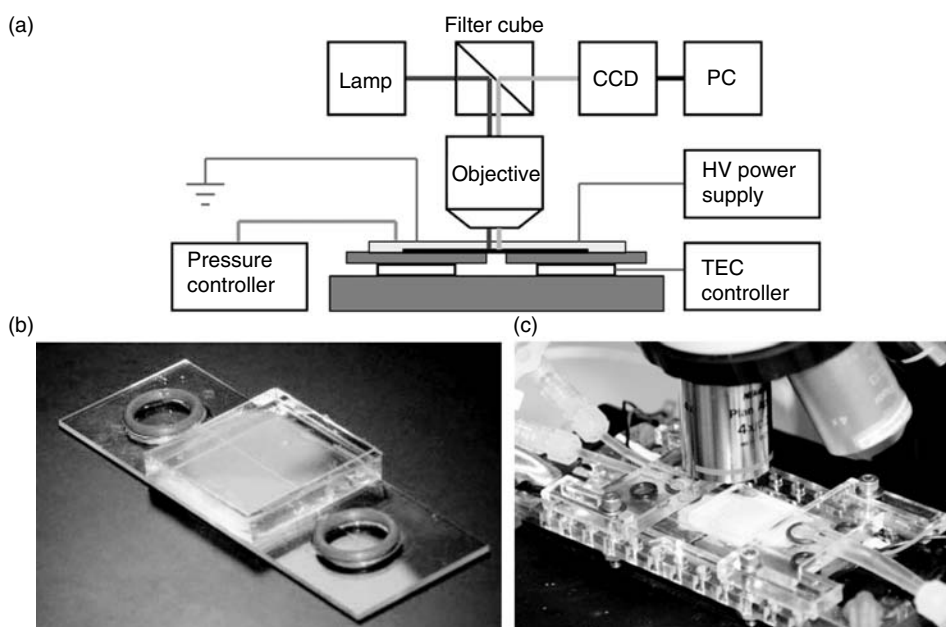

where  $x_{\text{foc}}$  is the focus location for the species in question and “bulk” refers to the net effect of both pressure-driven flow and electroosmosis. Note that, unlike IEF, the electrophoretic velocity of the charged species is always nonzero, so a counterflow, and its associated dispersive effects, is always present and significant. In practice, the counterflow is provided by a combination of flow due to electroosmosis and flow caused by an externally applied pressure difference. Variation in electrophoretic flux is accomplished by applying a temperature gradient along the axis of the microchannel and by using a buffer with a temperature-dependent ionic strength (e.g., due to temperature-dependent dissociation of a weak electrolyte).

Within the channel, local electric field is inversely proportional to conductivity, which in turn is a function of local viscosity and ion density. Using the convention of Ross et al. [56], we write the conductivity as  $\sigma(T) = \mu_0\sigma_0/(\mu f)$ , where  $\mu_0$  and  $\sigma_0$  are the buffer viscosity and conductivity at a defined reference temperature,  $\mu(T)$  is the viscosity, and  $f(T)$  is a nondimensional function incorporating any remaining conductivity dependencies (primarily the change in ionic strength). A similar decomposition is applied to the electrophoretic mobility, yielding  $v_{\text{eph}} = v_{0,\text{eph}}\mu_0/(\mu f_{\text{eph}})$ , where  $v_{0,\text{eph}}$  is the analyte's electrophoretic mobility at the reference temperature, and  $f_{\text{eph}}(T)$  accounts for any other temperature dependencies. The usefulness of this decomposition becomes apparent when we assume uniform current,  $I$ , use Ohm's law to determine the local electric field, and solve for the electrophoretic velocity:

$$u_{\text{eph}} = v_{0,\text{eph}}E_0f/f_{\text{eph}}, \quad (38.33)$$

where  $E_0 = I/A\sigma_0$  and  $A$  is the channel cross-sectional area. Most analyses assume  $f_{\text{eph}}(T)$  remains near unity, which is equivalent to assuming that the ion has a charge and drag coefficient independent of temperature. In this case, we see the electrophoretic velocity is a function only of the temperature, through  $f$ . In addition, we note the rate of (global) mass accumulation in the entire volume of a channel due to electrophoretic focusing is proportional to the difference in  $f$  on the boundaries. However, for a differential volume or for linear  $f(T(x))$ , the focusing is proportional to the gradient of  $f$ .

TGF has been implemented in a variety of microfluidic formats, including channels imprinted in polymer substrates and embedded capillaries [56,62]. In most cases, the temperature gradient is imposed by mounting the channel across temperature-regulated blocks, such that the temperature gradient is established via thermal conduction in the gap between the blocks. Figure 38.11 shows

**FIGURE 38.11** Control schematic and images of TGF fixture and capillary assembly. The TGF assembly (a) provides the thermal, fluidic, and electrical interface to the microchannel. A temperature gradient is established across a gap between two copper plates, each heated or cooled by a thermoelectric (Peltier) device. Pressure control is accomplished by adjusting the relative heights of two external reservoirs. The capillary assembly (b) consists of a 20 by 200  $\mu\text{m}$  rectangular glass borosilicate capillary that spans the distance between two O-ring reservoirs and underneath an insulating PDMS block. In the assembly photo (c), the capillary assembly is mounted on the TGF fixture. The encapsulating PDMS block is located directly below the objective, and the fluidic manifolds are to the left and right of the block [62].

one such implementation. Alternatively, Joule heating has also been used to form the temperature gradient independent of external fixtures [56,63].

### 38.4.2.3 Dispersion Theory

To analyze dispersion in TGF, we must modify our previous derivation to account for changes due to the temperature gradient. This includes an axially varying electrophoretic velocity and diffusivity. In its most general form, the transport equation becomes

$$\frac{\partial c}{\partial t} + \mathbf{u}_{\text{bulk}} \cdot \nabla c + \nabla \cdot (\mathbf{u}_{\text{eph}} c) = \nabla \cdot \nabla (Dc), \quad (38.34)$$

where  $c$  is the concentration of the sample analyte and  $D$  is the analyte's molecular diffusivity. Note the placement of the electrophoretic velocity and diffusivity within the gradient operators. In particular, the placement of the diffusivity within the second gradient operator reflects the use of the Fokker–Planck diffusivity law,  $\mathbf{J} = -\nabla(Dc)$ . Although it is common practice to use Fick's law for the diffusive flux (yielding the traditional  $\nabla \cdot D\nabla c$ ), Fick's law strictly applies only to diffusion with homogeneous  $D$  [64]. To recover the more familiar diffusion representation, we differentiate, yielding the terms,  $D\nabla c$  and  $c\nabla D$ . The latter term thus represents a flux due to a diffusivity-induced velocity,  $\nabla D$ , which is typically small in comparison to the electrophoretic velocity.

For a purely axial temperature gradient, if the cross section mean decomposition is again performed, a new mean concentration transport equation is derived

$$\frac{\partial \langle c \rangle}{\partial t} + \langle u_{\text{bulk}} \rangle \frac{\partial \langle c \rangle}{\partial x} = \frac{\partial}{\partial x} (\langle u_{\text{eph}} \rangle \langle c \rangle) = \frac{\partial}{\partial x} \left( D \frac{\partial \langle c \rangle}{\partial x} - \langle u'_{\text{bulk}} c' \rangle \right). \quad (38.35)$$

The deviation transport equation again reduces to a form analogous to Equation 38.11 following our scaling arguments, although with one exception, the characteristic time scale for TGF is no longer the observation time, but is instead the focusing time for a nondiffusive particle approaching its focal point,  $\tau_{\text{foc}}$ . (See solution for form of  $\tau_{\text{foc}}$ .) Note that if any of these assumptions are violated, then new dispersion mechanisms arise. For example, if  $\tau_{\text{foc}}$  is of order  $a^2/D$  or less, then ballistic dispersion [20] can become significant. The correlation term on the right-hand side of Equation 38.35 once again corresponds to the advective dispersion arising from transverse variations in the axial velocity. To evaluate this term, we need an expression for  $u'$ .

An analytical solution for  $u'$  was derived by Huber and Santiago [62]. Using a decomposition on the Helmholtz–Smolukowski equation similar to that performed by Ross for the electrophoretic velocity, they determined the nonuniform electroosmotic slip velocity to be

$$u_{eo} = v_{eo,0} E_0 f(T) g(T), \quad (38.36)$$

where  $v_{eo}$  is the electroosmotic mobility,  $g(T) \equiv v_{eo}(T)\mu(T)/v_{eo,0}\mu_0 = \varepsilon(T)\zeta(T)/\varepsilon_0\zeta_0$ ,  $\varepsilon$  is the permittivity,  $\zeta$  is the zeta potential, and the subscript zero indicates a value at the reference temperature [16]. By extending the lubrication flow solution of Ghosal [65] to include variable viscosity and the nonuniform electroosmotic slip velocity of Equation 38.3, Huber and Santiago derived an analytical expression for the bulk velocity, from which the deviation velocity was determined:

$$u'_{\text{bulk}} = U_p \left( \frac{1}{2} - \frac{3y^2}{2a^2} \right), \quad (38.37)$$

$$U_p = \frac{a^2}{3\{\mu\}} \frac{\Delta P}{L_{\text{ch}}} + v_{eo,0} E_0 \frac{\{\mu f g\}}{\{\mu\}} - v_{eo,0} E_0 f g, \quad (38.38)$$

where  $a$  is the channel half-height,  $L_{\text{ch}}$  is the length of the channel,  $\Delta P$  the applied pressure difference, and the curved brackets indicate an axial mean over the length of the channel. We see the flow field is a superposition of a uniform electroosmotic component and a parabolic (in  $y$ ) pressure-driven component (for flow between parallel plates). The two are linked through continuity, so as one decreases, the other must increase. Thus,  $U_p$ , the pressure-driven flow component, contains both the externally applied pressure gradient and the internally generated pressure gradient, which results from the local slip velocity deviating from the axial average. Note that the axially averaged terms are uniform and constant, and  $f$  and  $g$  are functions of  $T$ ; therefore, the velocity profile varies in  $x$  in response to axial temperature changes.

We analyze a flat-plate geometry again for simplicity and as an approximation to the full focusing problem. This implies, we are interested in characteristic focusing times much longer than that for molecular diffusion along the depth but not for spanwise diffusion along the width of the channel. This implies that our analysis is an estimate of the maximum concentrations achieved over these relatively short focusing times (along the centerline of the channel) and does not account for the finite amount of dispersion introduced by spanwise velocity gradients. Improvements on this model are discussed in the following text.

Given  $u'$  and  $c'$ , the advective dispersion term may be determined, which yields

$$\frac{\partial \langle c \rangle}{\partial t} + \langle u_{\text{bulk}} \rangle \cdot \frac{\partial \langle c \rangle}{\partial x} + \frac{\partial}{\partial x} (\langle u_{\text{eph}} \rangle \langle c \rangle) = \frac{\partial}{\partial x} \left( D_{\text{eff}} \frac{\partial \langle c \rangle}{\partial x} \right), \quad (38.39)$$

$$D_{\text{eff}} = D \left( 1 + \frac{2}{105} \frac{U_p^2 a^2}{D^2} \right). \quad (38.40)$$

This 1-D convection–diffusion equation has features of the Taylor–Aris dispersion equation. However, in contrast to Taylor–Aris, here  $D_{\text{eff}}$  is a function of temperature and the axial coordinate, as it depends on both  $D$  and  $U_p$ . When  $f$  is a linear function of the axial dimension, Equation 38.39 can be solved in closed form subject to the form of  $D_{\text{eff}}$ . If  $D_{\text{eff}}$  is uniform, the solution is a Gaussian with peak variance  $\sigma^2 = 2D_{\text{eff}} \tau_{\text{foc}}$ , where  $\tau_{\text{foc}} = 1/2E_0 v_0 |df/dx|$ . If  $D_{\text{eff}}$  is also a linear function of  $x$ , the solution is

$$c = c_0 \exp \left\{ -\frac{x/L - \ln(1 + x/L)}{\sigma^2/L^2} \right\}, \quad (38.41)$$

where  $c_0$  is the peak height and  $L = D_{\text{eff}}(0)/(dD_{\text{eff}}/dx)$  [62]. Although unusual in form, this solution produces Gaussian-like peaks with a skew that grows with the slope of  $D_{\text{eff}}$ . For more general cases, the equation can be solved numerically.

Figure 38.12 shows sample full-field fluorescence images of focused Bodipy propionic acid in an applied temperature gradient of 10°C/mm and electric fields from 1 to 215 V/mm. The two cases illustrate different dispersion regimes. The images on the left show focusing in the molecular diffusion dominated regime. Note the lack of spanwise curvature in the peaks and the near inverse square root dependence of peak width on electric field (dotted line). The images on the right-hand side show focusing experiments where the Taylor dispersion criteria are violated about  $E_0 = 40$  V/mm and there is enhanced advective (or ballistic) dispersion [20]. The solid line is a theoretical prediction for the peak width based on an heuristic ballistic dispersion model [66]. In both cases the direction of electrophoretic flux is left to right, while the bulk flow is right to left, driven by electroosmosis. The experimental and theoretical peak widths agree closely with some deviation at low fields, where the focused peak remains slightly “over-focused” as field was decreased, having had insufficient time to diffuse out to full width.

**FIGURE 38.12** Bodipy peak images and width as function of reference field. The images show focused Bodipy dye within a  $20 \times 200 \mu\text{m}$  rectangular capillary, while the bottom figures plot the peak widths versus electric field as determined by the fitting of Gaussian profiles to each peak. The applied temperature gradient was  $10^\circ\text{C}/\text{mm}$  and the applied electric fields ranged from 1 to 215 V/mm. The left hand side shows results for focusing in the molecular diffusion dominated regime. The current-normalized fields,  $E_0$ , were (a)  $-1.5$ , (b)  $-15$ , and (c)  $-30$  V/mm. The right hand gives results which violate the Taylor scaling arguments above 40 V/mm and thus feature enhanced ballistic dispersion. (Note the curvature in the images of the peaks.) The fields were (d)  $-38$ , (e)  $-81$ , and (f)  $-212$  V/mm [62,66].

#### 38.4.2.4 Performance and Guidelines

As we have described, TGF has successfully demonstrated the simultaneous concentration and separation of a wide range of species in a variety of implementations. Key figures of merit for TGF as a separation modality are the concentration factor and peak capacity. Static TGF, where the externally applied pressure remains constant, has demonstrated concentration factors in excess of 20,000 but is limited to peak capacities  $< 10$  [56]. As a result, there has been recent work to develop a dynamic form of TGF called scanning TGF [67], where the externally applied pressure is varied with time. This technique allows higher peak capacity and tunable resolution and concentration by adjusting the rate at which the procedure scans through the applied pressures.

In implementation, the complexities of TGF extend beyond that due to advective dispersion and encompass system design details such as device geometry, temperature control, and buffer selection. In static TGF, larger temperature gradients produce faster focusing and sharper peaks but reduce resolution [56]. The latter may be addressable using scanning TGF, but particular attention must be paid to the temperatures within the system because analytes of interest (e.g., enzymes) may be extremely sensitive to temperature and Joule heating may adversely influence the temperature gradients. In order to produce desired temperature profiles, designers must consider conductive and convective heat transfer within the channel, Joule heating due to the electric field, and heat transfer from the channel to its fixture and the environment. While it is possible to model these effects, in most cases, empirical studies will be required to validate models and refine optimizations.

Optimization of TGF preconcentration and (static) resolution is similar to other sample preconcentration methods. As described earlier, the contribution of molecular diffusion to the total peak variance scales as  $1/E$ , while the Taylor dispersion coefficient scales as  $U_p^2$  and therefore,  $E^2$ . Sample

peak variance, therefore, scales as  $1/E$  at low fields and as  $E$  at high fields. Thus, there will (again) be an optimal field strength that minimizes the overall peak width. Finally, we note that reducing the characteristic width of the channel simultaneously decreases the amount of Taylor dispersion and Joule heating. However, we caution that most detection techniques rely on depthwise integration of a signal (e.g., fluorescence), which then scales as the channel height,  $h$ . Thus, TGF system designers must also optimize the channel width subject to their desired detection limits.

### 38.4.3 ISOTACHOPHORESIS

#### 38.4.3.1 Introduction

Isotachopheresis [68] is an electrophoretic preconcentration and separation technique that utilizes a heterogenous buffer system of disparate electrophoretic mobilities. Typically, a plug containing sample ions to be focused and separated is introduced between the leading and trailing electrolyte (LE and TE) whose mobilities are respectively higher and lower than any of the mobilities of sample ions. Under the influence of an electric field, the sample ions separate and redistribute themselves in contiguous zones in order of reducing mobility starting from LE to TE (each is focused into its respective, mobility-dependent focal point). At steady state, these focused sample zones migrate at a same speed as the leading zone, hence the name “iso-tacho-phoresis.”

ITP, also known as displacement electrophoresis, was first performed in capillary tubes by Everaerts et al. [69] for the separation of strong anions using a thermocouple detector. Since then, ITP has been used for the analysis of various important chemical and biological species such as amino acids [70], peptides [71], nucleotides [72], proteins [73,74], heavy metal ions [75], and other organic/inorganic ions [76,77] on a variety of detection platforms such as UV absorbance, conductivity and fluorescence detection. Over the past 15 years, ITP has been used as a preconcentration technique in conjunction with CE [78]. This mode of ITP, referred to as transient isotachopheresis (tITP), has been implemented on microchip platform in the recent years to achieve improved sensitivity [22,79,80].

#### 38.4.3.2 Basic Theory and Implementation

ITP leverages differences in the mobility of sample ions to create a segregation of species on the basis of mobility. ITP separation results in a system of contiguous sample zones, sandwiched between leading and trailing electrolytes, migrating at identical speeds. The inherent preconcentration effect of ITP maintains sharp concentration boundaries between adjacent sample zones. In the absence of dispersion due to (radially) nonuniform bulk flow, the thickness of these boundaries is governed by the balance of electromigration and diffusion flux, as we shall discuss later. Away from this diffused boundary region, the sample concentration is uniform and can be obtained in each zone using species conservation equations and the electroneutrality condition [81]. Consider a simple model ITP system, shown in Figure 38.13, consisting of a plug of sample ions ( $X_i$ ) injected between the leading electrolyte (LE) and trailing electrolyte (TE), and common counterion (A) present everywhere. For now, we assume EOF is fully suppressed to negligible levels. After sufficient focusing time, the various zones in the system will develop locally uniform concentrations (concentration “plateaus” around their respective focal points) where diffusive fluxes are locally insignificant. For this long-time condition, the species conservation equations can be simplified to obtain the well-known Kohlrausch regulating function (KRF) [82] given by

$$\left( \sum_i \frac{C_i}{\mu_{\text{eph},i}} \right)_x = f(x), \quad (38.42)$$

**FIGURE 38.13** A schematic of the steps involved in a typical anionic ITP experiment is shown. (a) First, the capillary/microchannel is filled with the leading electrolyte using pressure driven flow. Sample electrolyte is introduced in well 1 and the capillary/channel is partially filled with this sample electrolyte by applying vacuum on well 2. (b) Well 1 is emptied and filled with the trailing electrolyte which is then drawn into the capillary/channel. (c) Next, high voltage is applied across the capillary and an electric field is setup inside the capillary/channel initiating separation of sample zones and achieving ITP condition. Sample ions  $X_1$  and  $X_3$  are present in high initial concentration and hence their zones form plateau shaped peaks and achieve the concentration as required by KRF.  $X_2$  appears as a peak in the diffused interface between  $X_1$  and  $X_3$  zones and has a much lower concentration than predicted by KRF. (d) Finally, well 1 is emptied and is filled with LE. The LE ions overtake the TE and sample ions and “break” the ITP mode into CE mode. The sample peaks separate in the CE mode and also disperse due to electromigration dispersion.

where  $C_i$  and  $\mu_{\text{eph},i}$  are the concentration and the mobility of species  $i$ , at axial location  $x$  in the channel. The constant (in time) function  $f(x)$  is governed by the initial condition. This relation can be stated as follows: The sum of concentration-to-mobility ratio of all species at a given location in the channel (relative to the channel wall at negligible electroosmosis conditions) remains invariant with time.

Using the KRF, we can arrive at the following expression to obtain the concentration adjustment of an ITP zone assuming no dispersions and bulk fluid velocity [83]:

$$C_X = C_L \frac{\mu_X \mu_A + |\mu_L|}{\mu_L \mu_A + |\mu_X|}, \quad (38.43)$$

where the adjusted sample concentration,  $C_X$ , is strictly a function of the LE concentration and electrophoretic mobilities in the nondiffuse one-dimensional model. Note that KRF may be used to estimate sample concentration in an ITP zone only if the species are strong ions (fully ionized). Further, the species are present in sufficiently high initial concentration to form concentrated regions with finite-width, but locally uniform concentrations (a plateau in analyte peaks, e.g., samples  $X_1$  and  $X_3$  in Figure 38.13c).

For low initial concentrations (or short preconcentration times), the ITP zone width can be on the order of the diffusion width between zones (e.g., sample  $X_2$  in Figure 38.13c). In that case, as pointed out by Svoboda [84], analyte width is a function of both initial concentration and injected plug length (see also the quantitative data of Jung et al. [22]). This regime of ITP has been called the spiked mode [85] and here, the analyte zone appears as a spike between adjacent zones rather than a plateau. One often encounters this spiked mode ITP in trace analyte detection and separation. In this regime, Taylor dispersion is a critical factor in determining the maximum concentration enhancement achieved. As a result, the sample peak widths (in spike mode) and interfaces between ITP zones can often be greater than peak widths predicted by diffusion alone. In our work, this factor is also reflected in the rate of growth of sample peaks. Despite this, there has been very little work in the analysis and modeling of Taylor dispersion in ITP.

**FIGURE 38.14** (See color insert following page 810.) CCD camera images of on-chip sample peaks of AlexaFluor 488 at the LE/TE interface in two different ITP experiments. In (a) there is finite (nonuniform) EOF and the sample peak streamwise dimension is on the order of channel width or larger. In (b) EOF is suppressed and the sample is concentrated in narrower zone ( $\sim 5 \mu\text{m}$ ) at relatively high electric field. While Taylor dispersion based analysis is probably applicable in the first case, more comprehensive modeling is required for case (b).

**FIGURE 38.15** Schematic of ITP/CE assay protocol in a microchip. Configurations of co-ions are also shown at each step. (a) The north and the south reservoirs are filled LE, and the west reservoir is filled with a mixture of TE and sample. TE/LE boundary is formed by applying vacuum at the south reservoir. White arrows show the direction of pressure-driven flows. (b) ITP pre-concentration is initiated by applying high voltage and ground at the east and west reservoirs, respectively. The black arrow denotes the direction of electric field. Sample anions electromigrate toward the anode as EOF is suppressed. The early stage of ITP pre-concentration results in a partial separation (i.e., moving boundary electrophoresis). (c) The field is switched toward the north reservoir to inject LE ions behind the sample and initiate CE. ITP pre-concentration continues until LE ions overtake the TE and sample ions. (d) Separation of samples occurs further downstream where sample ions electromigrate in nearly homogeneous LE electrolyte (remnant of TE not shown).

Example visualizations of ITP-focused sample peaks in a  $50 \mu\text{m}$  wide by  $20 \mu\text{m}$  deep (isotropically etched) microchannel are shown in Figure 38.14. The top image shows a typical ITP sample peak in a channel with finite EOF and Taylor dispersion. Interface lengths are on the order of or larger than the characteristic channel cross section dimensions. In this experiment, the ITP stacking occurs over a long duration ( $\sim 5 \text{ min}$ ) such that the peak has a substantial axial dimension compared to the channel width and has clearly dispersed edges. The area-averaging dispersion analysis and scaling presented earlier should apply here. Figure 38.14b shows early stage of an ITP plug created on-chip with high-quality EOF suppression (using poly-*N*-hydroxyethylacrylamide [PHEA] coating on a borosilicate glass wall [22]), high electric field ( $\sim 1000 \text{ V/cm}$  in the TE), and high LE concentration ( $\sim 1 \text{ M}$ ). The injection protocol used here is shown in Figure 38.15a,b. Here, the sample peak is a narrow concentration “shock wave” with extremely high electric field and concentration

gradients. Accurate prediction of the focusing dynamics of such a peak will probably require fairly comprehensive two- and three-dimensional models.

The coupling of ITP with CE is shown in Figures 38.13d and 38.15c–d. This coupling is referred to as transient ITP (tITP). tITP is typically achieved by replacing the TE ions with LE ions, which interrupts the ITP process. After sufficient sample preconcentration via ITP (as in Figure 38.13c), LE ions are introduced behind the contiguous sample zones. This is accomplished by either manually exchanging the buffer in well 1 (e.g., with a hand pipette, as shown in Figure 38.13c) or by using a side channel of a microchip to inject LE ions electrokinetically behind the train of sample zones (Figure 38.15c,d) [22,86]. The LE ions enter the sample zones faster. Sample zone concentrations reduce in order to satisfy the KRF-type regulation, and sample plug typically forms long tails as shown. This form of dispersion is termed as electromigration dispersion (EMD), and has been extensively investigated [87–89]. Once the ITP process is interrupted, the samples separate via standard mobility-based CE separation.

### 38.4.3.3 Dispersion Theory

The isotachophoretic boundary between two adjacent zones, under constant current condition and in the absence of bulk flow, assumes a constant width governed by the balance of electromigration and dispersion fluxes. For negligible electroosmosis (and negligible Taylor dispersion), the dispersion is determined by diffusion alone. Analytical solution to the concentration of the species in this diffused boundary, for a three-component fully ionized system, has been presented by Saville et al. [90]. The characteristic length-scale,  $\delta$ , of the ITP boundary in this case is given by

$$\delta = \frac{\mu_L \mu_T}{\mu_L - \mu_T} \frac{C_L}{j} \left( \frac{k_B T}{e} \right), \quad (38.44)$$

where  $\mu_L$  and  $\mu_T$  are electrophoretic mobilities of LE and TE, respectively,  $C_L$  is the concentration of leading ion,  $j$  is the current density, and  $k_B T/e$  is the thermal voltage. For negligible Taylor dispersion (e.g., low fields), peak axial dimension scales as  $D/E$  (since diffusivity is proportional to mobility by the Nernst–Einstein relation). Typical concentration profiles of LE, TE, and counterion in an ITP boundary (with molecular diffusion alone contributing to dispersion) are shown in Figure 38.16.

The case of nonsuppressed EOF conditions is much more complex. For even trace EOF mobilities, there will be a mismatch in electroosmotic mobility and electric field in the adjacent zones. This results in a mismatch in the electroosmotic velocity and hence generation of internal pressure gradients as discussed earlier. These pressure gradients result in increased width of the interface due to dispersion and have detrimental effects on preconcentration of trace samples via ITP.

**FIGURE 38.16** Schematic of the distribution of ions in the diffused interface between leading and trailing electrolyte in an ITP system.  $\delta$  is the characteristic length scale of this diffused boundary, obtained from the balance of electromigration and diffusion fluxes.

Saville [91] investigates the effect of electroosmosis on the interface between two ITP zones. To our knowledge, this is the only published Taylor dispersion analysis for ITP. Saville's analysis is for a simplified problem. He neglects the influence of electrolyte concentration and pH on electroosmotic mobility. Similar to the analyses presented earlier, a purely axial flow velocity is split into the bulk area average velocity  $\langle u \rangle$  and a deviation velocity,  $u'_p = u - \langle u \rangle$ . The pressure-driven flow velocity component due to a mismatch in electroosmotic slip velocity (alone) is  $u'_p = 2(\mu_{\text{eof}} E - \{\mu_{\text{eof}} E\})(1 - 2r^2/a^2)$ . While simplifying approximations, Saville assumes  $\mu_{\text{eof}}$  is uniform, and the local electric field governing EOF (but not the electric field governing electrophoresis) is approximately uniform in  $x$ . For example, assuming the TE voltage drop is much larger than that of the LE; and assuming solute plug is approximately halfway along the length of the channel, our expression reduces to  $\mu_{\text{eof}} E_{\text{TE}}(x)(1 - 2r^2/a^2)$ . Saville writes this as

$$u'_p = \mu_{\text{eof}} E_0(1 - 2r^2/a^2), \quad (38.45)$$

where  $E_0$  is assumed constant and uniform. Saville further expands  $\mu_{\text{eof}}$  as  $-\varepsilon\zeta E/\eta$  (where  $\varepsilon$  is the permittivity,  $\mu$  is the viscosity of the liquid, and  $\zeta$  is the zeta potential) but we shall retain the more compact form here. In a frame of reference moving at  $\langle u_{\text{bulk}} \rangle = U_{\text{EOF}} + U_p$ , the species conservation equation for any species  $i$  can be expressed as

$$\frac{\partial C_i}{\partial t} + u'_p \frac{\partial C_i}{\partial x} = \frac{\partial}{\partial x} \left[ -\mu_{\text{eph},i} C_i E_x(x, r) + D_i \frac{\partial C_i}{\partial x} \right] + \frac{1}{r} \frac{\partial}{\partial r} r \left[ -\mu_{\text{eph},i} C_i E_r(x, r) + D_i \frac{\partial C_i}{\partial r} \right], \quad (38.46)$$

where  $\mu_{\text{eph},i}$  is the electrophoretic mobility ( $\text{m}^2/\text{V}/\text{s}$ ),  $E$  is the electric field ( $\text{V}/\text{m}$ ), and  $C_i$  is the concentration of the species  $i$ . The species relations are constrained by the electroneutrality approximation expressed as

$$\sum_i z_i C_i = 0. \quad (38.47)$$

Next, the conservation equations are transformed to the frame of reference moving with the interface at the speed  $U_{\text{ITP}}$  ( $U_{\text{ITP}} = \mu_{\text{L}} E_{\text{LE}}$ , where  $E_{\text{LE}}$  is the electric field strength in the LE region) and subsequently nondimensionalized to obtain the following dimensionless equations:

$$\begin{aligned} & -C_i^* + Pe(1 - 2r^{*2}) \frac{\partial C_i^*}{\partial x^*} \\ & = \frac{\partial}{\partial x^*} \left[ -\mu_{\text{eph},i}^* C_i^* E_x^* + \mu_{\text{eph},i}^* \frac{\partial C_i^*}{\partial x^*} \right] + \lambda^2 \frac{1}{r^*} \frac{\partial}{\partial r^*} r^* \left[ -\mu_{\text{eph},i}^* C_i^* E_r^* + \mu_{\text{eph},i}^* \frac{\partial C_i^*}{\partial r^*} \right] \end{aligned} \quad (38.48)$$

and

$$\sum_i z_i C_i^* = 0. \quad (38.49)$$

In arriving at the previous equation, the following scaling has been used:

$$C_i^* = C_i/C_A, \quad \mu_{\text{eph},i}^* = \mu_{\text{eph},i}/\mu_{\text{eph},A}, \quad x^* = x/l, \quad r^* = r/a, \quad E_x^* = E_x \mu_{\text{eph},A} l/D_A$$

and

$$E_r^* = E_r \mu_{\text{eph},A} a/D_A.$$

Here, the following dimensionless parameters appear: Peclet number  $Pe = \mu_{\text{eof}} E_0 l / D_A$  and the aspect ratio  $\lambda = l^2 / a^2$ , where  $l$  is the electrical length scale obtained by balancing diffusion and electromigration flux,  $l = D_A / U_{\text{ITP}}$ .

The typical value of Peclet number is  $\sim 10$  indicating that convection plays an important role in determining the shape of the interface. By performing asymptotic expansion on the concentration and potential terms in the species conservation equation and area-averaging the equation over the cross section of the capillary, Saville obtains the following:

$$-\frac{\partial \langle C_i^* \rangle}{\partial x^*} = \frac{\partial}{\partial x^*} [-\mu_{\text{eph},i}^* \langle C_i^* \rangle \langle E_x^* \rangle] + \left( \mu_{\text{eph},i}^* + \frac{(Pe)^2}{48 \mu_{\text{eph},i}^* \lambda^2} \right) \frac{\partial^2 \langle C_i^* \rangle}{\partial x^{*2}}. \quad (38.50)$$

Reverting back to dimensional form, we write

$$-U_{\text{ITP}} \frac{\partial \langle C_i \rangle}{\partial x} = \frac{\partial}{\partial x} [-\mu_{\text{eph},i} \langle C_i \rangle \langle E_x \rangle] + \left( D_i + \frac{(\mu_{\text{eof}} E_0)^2 a^2}{48 D_i} \right) \frac{\partial^2 \langle C_i \rangle}{\partial x^2}. \quad (38.51)$$

Hence, we arrive at a expression similar to the one derived in Taylor dispersion using area-averaging section, with

$$D_{\text{eff},i} = \left( D_i + \frac{(\mu_{\text{eof}} E_0)^2 a^2}{48 D_i} \right).$$

Note that Equation 38.49 follows from our more general Equation 38.16 (e.g., transform the equation to the  $U_{\text{ITP}}$  frame of reference and assume a uniform constant value of  $D_{\text{eff}}$ ). Saville presents numerical solutions of his model for the case where  $\lambda = 1$ ,  $\mu_{\text{eph,LE}}^* = 1$ ,  $\mu_{\text{eph,TE}}^* = 0.5$ , and  $Pe = 10$ . The model shows interface width (e.g., the interface between two adjacent species) as a strong function of  $Pe$  (and  $E_0$ ). In the conditions Saville modeled, Taylor dispersion increases the effective dispersion coefficient up to  $\sim 18$ -fold over diffusion alone.

Despite the dearth of work on ITP Taylor dispersion, there is fairly clear experimental evidence that Taylor dispersion often limits maximum achievable concentration increase. Next, we present experimental studies of Taylor dispersion in ITP and present an empirical optimization of ITP that minimizes dispersion to maximize preconcentration factor. We studied the effects of Taylor dispersion on the width of single interface ITP systems shown schematically in Figure 38.15a-b, under constant (in time) current conditions. In a typical ITP experiment, the LE contains high concentration of  $\text{Cl}^-$  (100 mM to 1 M), the TE contains HEPES $^-$  (5–100 mM) and the sample ions (Alexa Fluor 488) in trace concentration (100 aM to 1 nM). We setup an interface between the LE and TE using pressure-driven flow, and ITP is initiated by applying high voltage ( $\sim 3$  kV) across this interface. Under the influence of the applied electric field, sample ions overspeed TE ions in the TE zone and stack at the LE/TE interface. Figure 38.17 shows a typical result for the width (along the axial direction) of the focused sample plug as it propagates down the channel toward the anode. Data are shown for four values of applied current in this 50  $\mu\text{m}$  wide by 20  $\mu\text{m}$  deep borosilicate glass microchannel (Mycralyne Inc.). Here, EOF was suppressed by adding polyvinyl pyrrolidone (PVP) (0.2% w/w) to the LE and TE. In the absence of Taylor dispersion (but including the effects of diffusion), we expect the sample plug width to remain constant. However, the sample width clearly grows nearly linearly in space. This behavior of sample plug width is observed even in ITP experiments with high degree of EOF suppression. We hypothesize that this type of growth is due to a mismatch in the EOF between the LE and TE region, which induces Taylor dispersion. This experimental evidence suggests that the interface dimension in ITP is often controlled by Taylor dispersion.

Analytical and even numerical computations of ITP processes including diffusion and Taylor dispersion are difficult. However, the analyses presented in this chapter can be used as a guide for

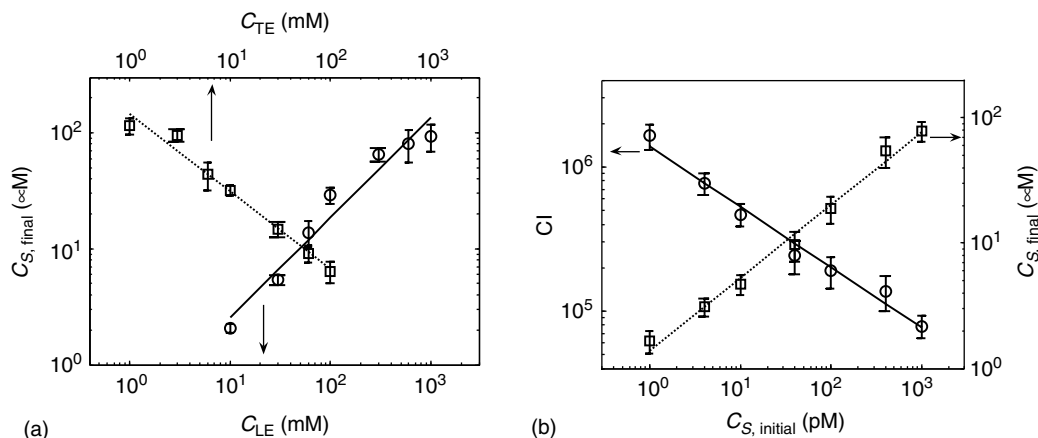

**FIGURE 38.17** Plot of the width of the sample plug (10 nM Alexa Fluor 488) focused at the interface of LE (750 mM Tris-Hcl) and TE (25 mM Tris-Hepes) at various locations downstream in a 50  $\mu\text{m}$  wide (20  $\mu\text{m}$  deep) microchannel. Each data set represents five realizations of a constant current ITP experiment.

empirical optimizations of the ITP process. Key parameters influencing the sample preconcentration achieved are the concentrations of LE, TE, and the initial sample concentration; the local applied electric field; the initial conductivity gradient of the initial condition, which partly determines time to reach steady state; and the degree to which EOF is suppressed.

Jung et al. [22] performed a systematic variation of LE, TE, and sample concentration and measured the effect of these variations on concentration increase, CI ( $CI = C_{\text{sample,final}}/C_{\text{sample}}$ ). In each case, we ensure that the ITP zones reached a fully preconcentrated state (i.e., maximum focusing) by verifying the transients of the preconcentration procedure using full-field imaging at low magnifications. In all cases, ITP zones reached a quasi-steady concentration, but we emphasize this does not imply that the KRF analysis is valid (since plateau-shaped peaks were not achieved [84]). We suppressed EOF (to minimize Taylor dispersion) by adding 0.1% (w/w) poly-*N*-hydroxyethylacrylamide (PHEA) to all electrolytes to suppress EOF. We tried several suppression strategies including poly-ethylPEO coating and PVP, but PHEA yielded the lowest electroosmotic mobility (as verified by current monitoring measurements [23]). For convenience in working with relatively high voltages (up to 3 kV), we used constant voltage control in this optimization of preconcentration.

Effects of LE (NaCl) concentration,  $C_{\text{LE}}$ , TE (HEPES) concentration,  $C_{\text{TE}}$  and initial concentration of sample (Alexa Fluor 488),  $C_{\text{S,initial}}$  on sample preconcentration are summarized in Figure 38.18.  $C_{\text{LE}}$  was varied from 10 mM to 1 M to study its effect on maximum focused sample concentration,  $C_{\text{S,final}}$  and concentration increase, CI (Figure 38.18a). The 5 mM HEPES TE solution contained 1 nM Alexa Fluor 488 as a sample. The focused sample concentration is nearly directly proportional to the concentration of LE, as expected from a one-dimensional nondispersive model (i.e., KRF theory). However, the nondispersive model drastically underpredicts the proportionality constant; the measured focused sample concentrations are 3500- to 7900-fold less than that predicted by Equation 38.43 despite all cases reaching fully-focused state. This gross difference between KRF theory and experiments is because the sample is in a “smeared” region of locally varying conductivity and electric field, as dictated by the effects of diffusion and Taylor dispersion.

Figure 38.18a also shows the effect of  $C_{\text{TE}}$  on ITP preconcentration, where  $C_{\text{TE}}$  were varied from 1 to 100 mM. The LE was fixed at 1 M NaCl, and  $C_{\text{S,initial}}$  was fixed at 1 nM. The KRF model suggests that focused sample concentration is not a function of  $C_{\text{S,initial}}$  or  $C_{\text{TE}}$ . However, the measurements show that  $C_{\text{S,final}}$  increased for lower  $C_{\text{TE}}$  (i.e., as conductivity ratio increases). High LE-to-TE conductivity ratios (associated with low TE concentrations) increase the electric fields in the TE and focused sample zones. High electric field leads to fast-focusing dynamics and high electric Peclet numbers ( $U_{\text{eph}}a/D$ , where  $a$  is the characteristic channel scale) and thereby, high  $C_{\text{S,final}}$ , as the preconcentration process is less susceptible to dispersion. Higher electric fields would

**FIGURE 38.18** Parametric variations of initial concentration profile. The nominal applied field was 220 V/cm. CCD viewing area was centered 30 mm downstream of the channel intersection. (a) Maximum focused sample concentration,  $C_{S,final}$ , versus LE concentration,  $C_{LE}$  and TE concentration,  $C_{TE}$ . For variation of  $C_{LE}$ , sample analyte and TE were respectively 1 nM alexa fluor 488 and 5 mM HEPES. The regression coefficient,  $R^2$ , is 0.95. For variation of  $C_{TE}$ , sample analyte and LE were respectively 1 nM alexa fluor 488 and 1 M NaCl.  $R^2 = 0.97$ . (b) CI and  $C_{S,final}$  versus initial sample concentration,  $C_{S,initial}$ . TE and LE were 5 mM HEPES and 1 M NaCl, respectively. The regression coefficients for CI and  $C_{S,final}$  are respectively 0.97 and 0.98.

eventually lower maximum focusing due to the effects of dispersion (e.g., due to Taylor dispersion or Joule heating or both).

Next, initial sample concentrations,  $C_{S,initial}$  were varied from 1 pM to 1 nM as shown in Figure 38.18b. The LE and TE were, respectively, fixed at 1 M NaCl and 5 mM HEPES. The LE-to-TE conductivity ratio was kept constant at  $1.3 \times 10^3$  in an effort to decouple the dependence of the TE zone electric field on this conductivity ratio. The data shows CI increases as  $C_{S,initial}$  decreases. This trend is roughly consistent with the KRF model. However, the dependence of CI on  $C_{S,initial}$  is weaker than the inversely proportional dependence predicted by the simple model (CI changes just under two orders of magnitude while  $C_{S,initial}$  changes three orders of magnitude). This discrepancy is also apparent in the measurements of the maximum concentration,  $C_{S,final}$ . The experimental data show  $C_{S,final}$  as a linear function of (although not directly proportional to)  $C_{S,initial}$ , which is not attributable to changes in local field in the TE zone. We again hypothesize that this discrepancy between the simple model and observations is due directly to the effects of dispersion. Dispersed interfaces of finite width cause a final sample concentration to be a function of initial sample concentration.

#### 38.4.3.4 Performance and Guidelines

These experimental parametric studies yield important insight into key ITP stacking parameters and suggest strategies for optimizing ITP in practice. Suppression of EOF to minimize Taylor dispersion is a key component. Also important are high LE concentration and low initial sample concentration to maximize achievable concentration increase, and the implementation of a single-column ITP configuration (where initially, there is a single interface between the LE and the TE/sample mixture) to inject a large effective sample width. As shown in Figure 38.18b, these simple strategies derived from earlier scaling arguments achieve ITP preconcentration with final-to-initial sample concentration ratios exceeding one million.

An example implementation of these strategies is shown in Figure 38.19. These are results of a tITP assay (again, ITP followed by injection of LE ions on the cathode side of the TE to interrupt ITP and initiate CE), which uses the single interface ITP configuration described schematically in Figure 38.15. The figure shows two example separations of 100 aM (100 attomolar) concentrations

**FIGURE 38.19** Two 100 aM sample electropherograms of ITP/CE separation of Alexa Fluor 488 (the peaks near 73.5 s) and Bodipy (peaks near 76.5 s). A glass microchip (microchannel cross-sectional dimensions are 50  $\mu\text{m}$  wide and 20  $\mu\text{m}$  deep) and 60 $\times$  water immersion objective (N.A. = 0.9) were used. The detector was located 30 mm downstream of the injection region.

each of Alexa Fluor 488 and Bodipy, detected 30 mm after injection with 40 s ITP preconcentration under a nominal field of 220 V/cm. LE and TE were 600 mM NaCl and 5 mM HEPES, respectively. The concentrations measured after injection, ITP preconcentration, and separation are, respectively, 21 and 16 pM for Alexa Fluor 488 and bodipy, as averaged across five realizations. This experiment achieves a concentration increase of  $2.1 \times 10^5$  fold relative to the initial sample concentration of 100 aM. This 100 aM sensitivity is, to our knowledge, the highest ever reported sensitivity for an electrophoresis experiment.

### 38.5 CONCLUDING REMARKS

Dispersion effects arising from nonuniform fluid motion have detrimental effects on CE sensitivity and resolution. Quantification and minimization of dispersion effects is especially important for sample stacking and focusing techniques. In preconcentration methods, EOF of heterogeneous buffer systems give rise to internal pressure gradients and strong dispersive forces. Generalized Taylor dispersion analysis is a powerful approach for quantifying these effects. More importantly, scaling, analytical solutions, and numerical solutions of Taylor dispersion provide unique insight. This can guide the choices of separation voltage, EOF suppression strategy, and channel shape, width, and depth for a given target analyte and buffer chemistry. The goal of such models and understanding is the optimization of preconcentration efficiency and resolution across a broad range of physical regimes and techniques.

Further improvements in the predictive capability of the stacking and focusing models presented here can be made by accounting for the 3D effects of typical D-shaped, wet-etched channel cross sections. More sophisticated dispersion analyses of the unsteady three-dimensional velocity field should also be carried out. This is particularly important for the high electric field regimes of TGF and ITP, where the sample plug widths become on the order of, or smaller than, the channel width. More comprehensive models should aid in the systematic design and optimization of CE separations under a wide range of conditions.

## 39.1 INTRODUCTION

As electrophoretic separations move beyond traditional capillary systems to include microfabricated “lab-on-a-chip” technology, researchers must consider the mechanical response of devices, as dictated by the materials and methods involved in channel fabrication. Microfluidic chips created using planar lithography (e.g., [1–4]) enable increasingly complex separations, such as multidimensional chromatography [5–9] and on-chip sample preparation [10,11]. Unfortunately, lithographic techniques generate open channels, which require a subsequent bond step to produce an enclosed capillary network suitable for electrophoretic separations. In contrast to tubular capillaries comprised of a single material piece, the bonded interface of a microchip separation channel introduces a new failure mechanism, which limits electrophoretic or chromatographic methods that rely on pressure (i.e., capillary electrokinetic chromatography (CEC) [12–15], microchip isoelectric focusing (mIEF) [16], high ionic strength buffers [17], or polymer-based separations [18]).

Relatively recent additions of external and/or integrated features that control fluid motion (e.g., valves [19–21]) further increase the need to understand and quantify the mechanics controlling interface strength. This is especially true as hybrid chips pairing different types of materials (e.g., glass and polydimethylsiloxane (PDMS)) become increasingly prevalent; the bonding of surfaces with elastic and thermal expansion mismatch can induce significant stresses, which influence the performance and reliability of the final device. This chapter is designed to provide separation scientists with an introduction to interface and film mechanics that can be used to promote successful microfluidic design and fabrication.

Interface stability affects several aspects of lab-on-chip development. Successful device fabrication requires consistent bonding between different layers, often of different materials, and this remains among the most challenging obstacles to device development. Figure 39.1 provides schematic illustrations of several features/geometries that play increasingly important roles in microfluidic separation devices. Figure 39.1a is a top view of a typical multilayer assembly; a layer with lithographically patterned channels is “sealed” by bonding additional layers. The interface formed by the layers is typically weaker than the layers themselves, such that interface failure defines device reliability. Figure 39.1b is a side view of the interface failure shown in Figure 39.1a; the corner formed by bonding a capping layer to the layer with etched channels serves as the initiation site for failure. Device performance may further include deformable elements interacting with adjacent elements (e.g., valving). Such dynamic elements may require controlled debonding (e.g., valve release [19–21]) or site-specific bonding for ideal performance (e.g., check valves [22,23]). Figures 39.1c and 39.1d illustrate the side views of two common multilayer valve assemblies; the clear layer is a deformable element that is pushed or pulled via external pressure actuation to allow (Figure 39.1c) or prevent (Figure 39.1d) fluid motion in through the channels.

Thus, device reliability for many systems is dictated by interface stability, which in turn dictates the maximum allowable conditions and pressures. The use of pressure in microfluidic chips naturally introduces a competition between pressure limitations due to interface strength and that required for operation. Consider two examples: (1) filling a microchip channel with a viscous separation polymer (e.g., for DNA sequencing [24]) and (2) creating an integrated valve that is actuated using pressure [19–21]. Both require elevated pressures, which must be balanced against the possibility of breaking the chip apart. In designing features for these diverse devices, two fundamental questions arise:

- I. What are the physical parameters that affect interface stability?
- II. How do geometry, material properties and device pressures govern performance and reliability?

The principle motivation for this chapter is to establish the framework to predict device performance and reliability *a priori*, by detailing the mechanics underlying the behavior of typical geometries.

**FIGURE 39.1** Schematic illustrations of common microfluidic features utilized in microchip separation devices: (a) top view of a multilayer assembly of microchannels formed by capping a layer with etched channels, (b) side view of micropatterned channel with capping film layer, (c) side view of a vacuum-driven three-layer negative pressure valve, (d) side view of a positive pressure valve.

To complement this, we describe basic materials characterization experiments used to determine the relevant parameters. This combination can be used to optimize proven device configurations and develop new strategies to improve fabrication, performance and reliability.

## 39.2 BACKGROUND

Microfluidic separation devices have increased in complexity beyond the original cross-t design of Manz and coworkers (e.g., [25,26]) to include a wide variety of designs with intricate intersecting channels. The bulk of these devices are fabricated in glass or PDMS. Several reviews (and previous chapters in this book) discuss the methods used in the fabrication of microfluidic devices [27,28]. Nearly all are based on planar lithography and “soft” lithographic techniques to produce channels embedded in the surface of a substrate (e.g., [29,30]). To create an enclosed microcapillary network suitable for electrophoretic separations, these channels must be bonded to a cover plate(s) as shown in Figure 39.1a. The bonding of two different layers creates an interface that is typically weaker than either layer; hence, the “seam” that runs along the edge of the channel acts as an initiation site for chip failure. This is shown schematically in Figure 39.1a (top view) and Figure 39.1b (cross-section view). Interface failure usually corresponds to device failure, as fluid from the channel is lost to the interface “crack”; with sufficient pressure (or volume injected into the channel), the entire interface may debond.

Here we will focus on two material systems common to chip based electrophoretic separations. The first, *glass-on-glass* devices, are common for “cross-t” and gated electrokinetic injections. Such devices depend on a high temperature anneal to facilitate bonding between the cover plate and substrate with etched channels [27,28]. The successful high temperature anneal of two pieces of glass requires flat, defect free surfaces and the uniform application of pressure during fabrication. In many ways, successful bonding of *glass-on-glass* devices is considered a “black art”: while

strong bonds produce robust chips that are ideal for pressurized applications, fabrication yield can be depressingly low, especially in the hands of a novice. The second class of chips, *glass-on-PDMS* hybrid devices, are widely utilized because of their ease in fabrication/assembly and to produce integrated elastomeric valves, such as those shown in Figures 39.1c and 39.1d. Depending on the application, glass-PDMS devices are either weakly bonded using reversible van der Waals forces, or more strongly bonded through oxidative modification of the material surfaces prior to bonding.

The physical demands placed on these devices can be quite different due to the rigid nature of glass–glass interfaces and extreme deformation (arising from large pressures relative to the elastic modulus) that may occur with PDMS hybrid chips. Regardless of the material(s) or fabrication techniques, the performance and reliability of all microfluidic chips designed for CE separations depend upon controlling the interface bond between neighboring substrates. Device operation (either interface failure or desired debonding) is governed by (1) the physics of interface debonding and (2) the relationship between loading (e.g., pressure and/or temperature) and chip deformation. The two are strongly interrelated, because both are essentially governed by energy stored by elastic deformation.

### 39.2.1 THE MECHANICS OF INTERFACE FAILURE

The mechanics of interface failure, while often complex, has been firmly established in the context of thin film multilayers commonly found in microelectronics and protective coatings. This large body of work serves as the foundation for the present chapter; it is succinctly summarized by the review article by Hutchinson and Suo [31] and covered in great detail in the book by Freund and Suresh [32]. We present the most basic framework needed to quantify the performance of microfluidic devices, and summarize results for geometries and materials common to such devices. The focus is on prediction of debonding initiated from sharp changes in geometry, as illustrated schematically in Figure 39.2.\* For these systems, the act of debonding or delaminating under pressure is simplified by considering the process as the formation and/or propagation of a crack at the interface.

As a first approximation for analyzing interfaces, an elementary “strength of materials” approach is to determine the maximum stress in the component and then compare its value to the strength of the material (or interface), as measured via a conventional uniaxial tension test. Unfortunately, this approach is not applicable in the presence of material discontinuities, such as an interface that is only partially bonded or a corner formed by bonding two materials (see Figure 39.2a). If one obtains a complete solution for the stress distribution, the stress field diverges to infinity as the discontinuity is approached: that is, the stress diverges to infinity as distance from the crack tip becomes smaller and smaller. This is shown schematically in Figure 39.2b (refer to log-log scale on the right-hand side). Hence, the discontinuity represents a *singularity* in the stress distribution. This nonphysical result (i.e., an infinite stress at a crack tip) is a consequence of assuming elastic behavior applies at

**FIGURE 39.2** Schematic illustration of the stress distribution at the tip of a delamination crack: the presence of a stress singularity necessitates an energy-based approach.

\* “Delamination” is commonly used to describe the debonding of thin films or bonded stacks of thin films (i.e., multilayers); hence, in the present context, debonding and delamination refer to the same phenomena.

an arbitrarily small length-scale. To get around these conceptual difficulties, *linear elastic fracture mechanics* (LEFM) theory [33] is a very successful approach to predicting crack growth without resorting to molecular simulations. That is, one can successfully predict failure using macroscopic continuum solutions. It is interesting to note that for materials with limited mechanisms for nanoscale deformation,\* continuum elasticity solutions are applicable to impressively small scales, that is, several nanometers. Hence, it is not surprising that they can serve as the basis for predicting failure in predominantly elastic systems.

With the exception of an infinitely long material interface, any mathematically sharp geometry change introduces a singularity, for example, right-angled corners, the edge of a debonded region, or material interfaces that intersect a free edge. The form of this singularity depends on the angle of the junction (e.g., the  $90^\circ$  corner junction shown in Figure 39.2a), as well as the elastic mismatch between the materials comprising the junction (e.g., [34–36]). At the moment, the mechanics of crack stability are considerably more established than that required to predict debond initiation from a bimaterial corner junction. That is, the criteria needed to predict the advance of a sharp interface delamination crack is more clearly defined than that needed to predict its initiation from a right-angled corner. Debond initiation from blunt corners is a critical problem that requires continued study.† However, as luck would have it, when the film and substrate have very large elastic mismatch—such as for PDMS-glass systems—it is reasonable to assume that the substrate is “rigid.” In this limit, the corner initiation problem reduces to that of an interface crack: the entire span shown in Figure 39.2a corresponds to the “crack,” and well-established interface fracture mechanics is applicable. This is because the substrate does not deform, such that it is immaterial whether or not the substrate geometry forms a perfect  $90^\circ$  corner or is partially debonded as shown in Figure 39.2a.

In systems where the elastic moduli of the layers are comparable—critically, glass-glass or any homogenous system—one must distinguish between the corner initiation geometry and the partially debonded region shown in Figure 39.2a. This is because the deformation of the substrate lying between the original corner and leading edge of the debond region (i.e., crack tip) may influence the stress distribution at the edge of the crack tip. When the distance between the corner and the crack tip is sufficiently large, the influence of geometry of the channel (and hence corner) can be neglected and one can again treat the entire debonded length as a crack between geometrically uniform layers. This limit is reached when the distance between the corner and debond edge is several times greater than the film thickness (or thickness of the more compliant layer) (see [37] for the related study of delamination from vertical edges of a two layer system). The fact that even short cracks (measured from the edge of the corner to the debond crack tip) might lead to undesirable behavior—such as fluid or pressure loss—highlights the need for additional mechanics analyses of the initiation and short-crack propagation problems for elastically similar materials. Such analyses are beyond the scope of this introduction, and hence, we must assume here that the debond crack tip is located at least several film thicknesses from the corner.

The stress singularity implies that stress-based failure criteria are not feasible and one must adopt energy frameworks to describe the conditions that lead to debonding.‡ The central concept that is that the crack front advances when the energy available to drive the crack reaches a critical value, often referred to as the interface toughness. The energy available to drive the crack, or energy release rate (ERR), is dictated by the potential energy of the system. This is comprised of the strain energy stored in the deformed structure and the work done by applied loads. The critical value of the ERR

---

\* Glass is a classic example: atomic bonds can stretch (elasticity) or rupture, but typically do not reform. In metals, atomic bonds can “slide” and reform, a phenomenon described by dislocation theory; this gives rise to energy dissipation, which makes it much more difficult to propagate a crack in metals.

† Significant inroads into the corner initiation problem have been established (e.g., [34–36]); these studies, however, require more extensive discussion of mechanics concepts that are beyond the scope of this work.

‡ Or, one can use equivalent stress-based frameworks that deal with the nature of the singularity rather than a “maximum stress”: these approaches use the stress intensity factor, which is essentially the amplitude of the singularity (see Section 39.3.1.)

**FIGURE 39.3** Schematic illustration of three types of film response: (a) elastic half-space behavior, dominated by bulk compression of the film, (b) plate behavior, dominated by bending deformation of the film, and (c) membrane behavior, dominated by axial stretching of the film.

(which has units of  $N/m$  or  $J/m^2$ ) is the energy per unit area needed to create new crack surface and is fundamentally dictated by the bonding at the interface. As such, it is often referred as the adhesion energy. This chapter outlines the mechanics needed to compute the ERR for various combinations of load and geometry, as well as that needed to design and interpret experiments for extracting the interface toughness.

### 39.2.2 OVERVIEW OF THE MECHANICS DESCRIBING DEFORMABLE PLATES/FILMS

The relationships between geometry, external loading (i.e., pressures) and deformation has been an area of intense study in the solid mechanics community for more than century; hence, our goal is to provide a condensed overview of the theory and solutions that apply specifically to microfluidic applications. A number of classical mechanics results are relevant to microfluidic devices and the trick is to determine which is applicable. The key consideration is the “aspect ratio” of the device that relates the pressurized span,  $L$ , to the film thickness,  $h$ , as shown in Figure 39.3. Three different types of deformation “modes” are amenable to closed-form analytical solutions. Figure 39.3a depicts small aspect ratios  $L/h$ : very thick structures respond as *half-spaces*, in that the deformation does not depend on the film thickness, which is taken to be semi-infinite. Figure 39.3b depicts moderate to large aspect ratios  $L/h$ : moderately thin structures respond as *plates*, in that bending deformation of the film dominates film stretching. Figure 39.3c depicts large aspect ratios  $L/h$ : very thin structures respond as *membranes*, in that axial stretching deformation of the film dominates the effects of bending.\*

The scaling relationships shown in Figure 39.3 apply regardless of the out-of-plane geometry (e.g., elliptical or rectangular), which only affects a constant prefactor. In this chapter, we review the relevant analytical solutions that bracket the range of behaviors, as well as numerical solutions that can be used for intermediate aspect ratios. The focus is on providing guidelines that enable chip designers to identify appropriate solutions for a given geometry and pressure magnitude.

## 39.3 THEORETICAL ASPECTS

Since a truly comprehensive treatment of the mechanics relevant to microfluidic devices is beyond the scope of a single chapter, we provide a basic introduction that adopts several simplifications. First and foremost, we assume that materials are linearly elastic; while, this is obviously objectionable for elastomers at large strains, it allows for closed-form analytical solutions that can be used to guide initial device design and broadly assess reliability. It is important to note that even when

\* It should be noted that many refer to flexible thin films (commonly elastomers) as “membranes,” regardless of their dimensions, presumably because they are easily deformed by relatively low pressures (relative to atmospheric pressure). Here, we adopt the classical mechanics definition of *membrane*, that is, a stretch-dominated structure (as opposed to bending-dominated).

deformation is large (i.e., displacements are significant compared to film thickness), strains may still be small. Moreover, the loss of accuracy due to linearization of material response is oftentimes not significant for strains less than  $\sim 30\%$  (e.g., [38]). Secondly, we assume that interface debonding occurs at an asymptotically sharp crack front, as opposed to a bimaterial corner defined by a finite angle. This approximation has no impact on glass–PDMS interfaces due to the elastic mismatch; for interfaces formed between similar materials, this approximation is valid when the debond crack tip is sufficiently far from corners, other crack tips and so on. Finally, we assume that the interface is sufficiently weak to ensure that delamination cracks propagate at the interface, that is, interface delaminations will not “kink” and turn to run in the materials on either side of the interface.

### 39.3.1 INTERFACE FRACTURE MECHANICS

Interfacial stability is predicted using the ERR, which is defined as the mechanical energy that is released during an incremental increase in crack length. Crack advance occurs when the ERR reaches a critical value, often referred to as the interface toughness, denoted here as  $\Gamma_i$ . Thus, the crack growth criterion is  $G \geq \Gamma_i$ . The ERR is defined as [33]

$$G \equiv -\frac{\partial U}{\partial A}, \quad (39.1)$$

where  $A$  is the area of the new surface formed by crack advance (dictated by the geometry of the crack front) and  $U$  is the mechanical energy of the system.  $U$  is a function of the current crack size, loads such as applied pressure or residual stress and the elastic properties of the system. When the crack propagates with a straight crack front, the ERR can be written in terms of the crack length and the associated length of the crack front. The ERR thus has units of  $N/m$ , or  $J/m^2$  and hence, the interface toughness has units of energy per unit area; for this reason, the toughness is often referred to as the critical adhesion energy, or simply the adhesion energy. The interface toughness is governed by the nature of bonding at the interface and should be considered a material property to be measured for each system and fabrication approach.

For bimaterial interfaces, the interface toughness is also a function of the *mode-mixity*, which describes the relative amounts of crack tip opening, sliding and tearing deformation [31,32]. Figure 39.4 illustrates the definitions of the three fundamental modes of crack growth. For straight crack fronts with no deformation gradients in the direction parallel to the crack front, there is no out-of-plane tearing and mode III is identically zero. The stress intensity factors  $K_I$  and  $K_{II}$  relate to the contributions of opening and sliding displacements, respectively and hence are outcomes of the solution to the crack tip elasticity problem. In essence, the stress intensity factors describe the amplitude of the stress singularity shown schematically in Figure 39.2b. As such, they are dependent on the applied load, crack geometry and elastic properties on either side of the interface. It is important to note that bending of thin films near crack tips can introduce a significant mode II component; thus, even though pressurized crack faces may seem to be “pure mode I,” the deformation that involves relative sliding of the material near the interface crack tip, which implies that mode II is present.

It has been demonstrated that any two-dimensional bimaterial problem can be uniquely described in terms of the two Dundur’s parameters, defined as

$$\alpha = \frac{\bar{E}_f - \bar{E}_s}{\bar{E}_f + \bar{E}_s}, \quad \beta = \frac{E_f(1 + \nu_s)(1 - 2\nu_s) - E_s(1 + \nu_f)(1 - 2\nu_f)}{E_f(1 + \nu_s)(1 - \nu_s) + E_s(1 + \nu_f)(1 - \nu_f)}, \quad (39.2)$$

where  $\bar{E} = E/(1 - \nu^2)$  and the subscripts  $f$  and  $s$  refer to the film and substrate, respectively. That is, the behavior of any interface crack with identical Dundur’s parameters is independent of individual elastic properties of the film and substrate. Dundur’s parameters for several material systems relevant to microfluidic systems are shown in Table 39.1.

**FIGURE 39.4** Modes of crack loading: for the scenarios considered here, mode III is assumed to be zero due to the absence of deformation gradients parallel to the crack front.

**TABLE 39.1**  
**Dundur’s Parameters for Several Interfaces Relevant to Microfluidic Devices**

Materials Forming the Interface				Dundur’s Parameters	
Material #1	$E, \nu$	Material #2	$E, \nu$	$\alpha$	$\beta$
Elastomer	1 MPa, 0.5	Glass	70 GPa, 0.2	$\sim -1$	$1.4 \times 10^{-5}$
Elastomer	1 MPa, 0.5	Polymer	3 GPa, 0.4	$\sim -1$	$1.2 \times 10^{-4}$
Polymer	3 GPa, 0.4	Glass	70, GPa, 0.2	-0.91	-0.28
Identical	—	Identical	—	0	0

*Note:* Interchanging materials #1 and #2 simply changes sign of Dundur’s parameters.

Here, we limit our attention to scenarios where  $\beta \sim 0$ , which essentially eliminates combinations of materials with comparable—but not identical—stiffness. Note that  $\beta$  is identically zero for identical materials. When  $\beta \sim 0$  the crack tip fields are analogous to those in a homogenous material (i.e., the crack tip stresses scale as  $\sigma_{ij} \sim 1/\sqrt{r}$ ) and  $K_I$  and  $K_{II}$  dictate the contributions of opening and sliding displacements, respectively (or normal and shear stresses). If  $\beta \neq 0$ , the opening and sliding modes are coupled and crack advance criteria require additional parameters [31,32].

The simplification that  $\beta = 0$  implies that crack advance can be predicted in the context of a mixed-mode interface toughness, that is,

$$\Gamma_i = f(\psi), \quad \text{where } \psi \equiv \tan^{-1}\left(\frac{K_{II}}{K_I}\right), \quad (39.3)$$

where  $K_I$  and  $K_{II}$  are computed from the elasticity solution to the given crack problem.

Since interface toughness depends strongly on the amount of mode-mixity, the ERR alone is not sufficient to predict delamination; one must also compute the phase angle from the relevant elasticity solution and have measurements that describe  $\Gamma_i = f(\psi)$ .

However, measurements on a variety of systems have illustrated that the minimum interface toughness,  $\Gamma_i^{\min}$ , is obtained for pure mode I. That is, the measured toughness for cracks dominated by mode II ( $\psi \rightarrow \pi/2$ ) is generally much higher. Hence, assuming  $\psi \sim 0$  and adopting the crack advance criterion  $G \geq \Gamma_i(\psi = 0) = \Gamma_i^{\min}$  is generally conservative, in that it underestimates crack stability. Moreover, experiments on interfaces between glassy polymers (e.g., PMMA) and glass suggest  $\Gamma_i \approx \Gamma_i(\psi = 0)$  for  $-15^\circ < \psi < 60^\circ$  [31,32].

If the interface toughness is known, the prediction of debonding thus essentially boils down to computing the potential energy of the system,  $U$  and computing its derivative with respect to crack length. The potential energy of the system is computed from the solution to the solid mechanics problem at hand; this is described in the next section. For simple geometries, this can be done in closed-form, as illustrated in Section 39.4.2. For more complex geometries, this is typically done with commercial finite element analysis (FEA) software and many codes have a built-in option for doing so.

### 39.3.2 POTENTIAL ENERGY AND PRESSURE–DEFLECTION RELATIONSHIPS

The relationship between loads, geometry and deformation is governed by the solution of partial differential equations (PDEs) that are derived using three fundamental relationships: (1) equilibrium conditions, expressed as linear PDEs involving up to six stress components, (2) strain-displacement compatibility conditions, expressed as differential equations involve up to six strain components and three displacements and (3) a constitutive description, expressed as an algebraic equation relating the six stress and six strain components. The governing equations are completely linear for linear elastic materials that experience relatively small displacements. For large deflections, the strain-displacement relationships are nonlinear, such that numerical solutions are typically needed. The deformation of linearly elastic membranes is a notable exception, in that several important nonlinear solutions (that account for large-displacements) can be derived in closed form.

The stresses and displacements at the boundaries of the deformable domain (applied or enforced) dictate the *boundary conditions*, which effectively determine the particular solution to the PDEs. If the problem is truly three-dimensional (because geometry and/or loads vary in all three directions) then numerical solutions are needed for all but the most elementary example cases. FEA is the de facto choice for such scenarios and commercial codes abound; ABAQUS and ANSYS (software programs) are arguably the most common. An example of a simple geometry that is nevertheless a truly three-dimensional problem is a film capping an elliptical hole, that is, an elliptical plate or membrane.

If the geometry and loads do not vary in the third dimension, the derivatives with respect to the third coordinate are identically zero and the problem is inherently two-dimensional. Important examples include long, straight-walled channels, or axisymmetric structures such as circular plates: one can obtain the relevant solution by analyzing a two-dimensional “slice” taken from the full structure. For simple boundary conditions, such scenarios are highly amenable to analytical solutions. This is the focus of the remainder of this section.

#### 39.3.2.1 Small Deformation Plate Behavior

Consider a film to a pressure distribution shown in Figure 39.5a. It is assumed that the variation in displacement in the  $z$ -direction is zero, that is,  $\epsilon_z = 0$ ; this is referred to as *plane-strain deformation*. (Note that this does not imply  $\sigma_z = 0$ .) First, consider platelike behavior, wherein the bending strain

**FIGURE 39.5** (a) Schematic illustration of film subjected to an arbitrary pressure distribution, (b) a differential element of the film showing the variables used for strain–displacement and equilibrium equations.

in the film dominates axial stretching. For small deformations relative to the film thickness, the only relevant strain-displacement relationship is:

$$\varepsilon_{xx}(x, y) = \delta''(x) \cdot y, \quad (39.4)$$

where  $\delta''(x)$  is the second derivative of the vertical deflection with respect to the  $x$ -coordinate (i.e., the local curvature) and  $y$  is the distance from the centerline of the film.

The net internal moment acting at any cross-section (about the  $z$ -axis) is given by

$$M(x) = \int_{-h/2}^{h/2} \sigma_{xx}(x, y) \cdot y \cdot dy = \frac{\bar{E}h^3}{12} \delta''(x), \quad (39.5)$$

where  $\sigma_{xx} = \bar{E}\varepsilon_{xx}$  is used as the constitutive law.  $\bar{E} = E/(1 - \nu^2)$  is the plane-strain modulus, where  $\nu$  is the Poisson's ratio of the film. This assumes that the in-plane stress  $\sigma_{xx}$  dominates the vertical stress  $\sigma_{yy}$  through most of the film thickness; that is, the structure translates the vertical pressure into a linear bending stress. Vertical equilibrium of the differential element shown in Figure 39.5b dictates that the moment distribution, vertical displacements and external pressure related as follows:

$$M''(x) = \frac{\bar{E}h^3}{12} \delta^{IV}(x) = -p_o(x), \quad (39.6)$$

where  $p_o(x)$  is the resultant pressure acting on the film (i.e., the superposition of pressure on top and bottom). Thus, by combining a kinematic relationship between strain and displacement, a constitutive law and equilibrium, a differential equation is obtained for the displacements of the film in terms of the applied load.

One can integrate this result for any pressure distribution: the four integration constants are determined by the boundary conditions at either end. Force balance applied to the differential element of Figure 39.5b also dictates that the resultant vertical shear force is given by  $V(x) = M'(x) = (\bar{E}h^3/12) \delta'''(x)$ . This completes the possible boundary conditions that can be used to solve for unknown constants: for example, a clamped or bonded film implies zero displacement and slope, that is,  $\delta(x=0) = \delta'(x=0) = 0$  and  $\delta(x=L) = \delta'(x=L) = 0$ . Or, for free ends (i.e., cantilevers), the net moment and shear force acting at a free end is zero, such that  $\delta''(x=L) = \delta'''(x=L) = 0$ .

For the case of a uniform applied pressure (i.e.,  $p_o(x) = p_o$ ), the total potential energy of the system (for a slice across of the channel of width  $b$ ) is given by

$$U = b \int_0^L \int_{-h/2}^{h/2} 1/2 \sigma_{xx}(x, y) \varepsilon_{xx}(x, y) - bp_o \int_0^L \delta(x) dx, \quad (39.7)$$

where  $L$  is the length of the span that can deform. The first term is the strain energy in the deflected film and the second is the external work done by the applied pressure. Note that the last term is equivalent to the pressure times the volume of the bulge: this observation becomes important in calculation the ERR for bulge tests under fixed volume (see Section 39.4.2). Thus, for any uniform film that is subjected to constant pressure and dominated by bending deformation, the potential energy is given by

$$U = b \int_0^L \left[ \frac{\bar{E}h^3}{24} (\delta''(x))^2 - p_o \delta(x) \right] dx. \quad (39.8)$$

This result can be used with Equation 39.1 to determine the ERR for scenarios involving small deflections; Section 39.4.2.1 provides an illustration.

### 39.3.2.2 Large Deformation Membrane Behavior

Similar elementary results can be derived for deformation in the membrane limit, that is, when the centerline stretch of the film dominates bending. In this scenario, the strain-displacement relationship is

$$\varepsilon_{xx}(x) = u'(x) + 1/2 (\delta'(x))^2, \quad (39.9)$$

where  $u(x)$  is the displacement in the  $x$ -direction (see Figure 39.5). One can illustrate via energy minimization that the strain and hence the resultant stress  $\sigma_{xx}(x) = \bar{E}\varepsilon_{xx}(x) = \sigma_o$ , is uniform along the membrane.\* This stress is an unknown that must be determined. Additionally, the energy minimization implies the following equilibrium condition:

$$h\sigma_o\delta''(x) = -p(x). \quad (39.10)$$

Again, the solution by direction integration involves two constants; these constants, as well as the unknown membrane stress, are dictated by the displacements of the end points. Noting that the membrane stress is spatially uniform and integrating Equation 39.9 yields

$$u(L) = \frac{\sigma_o L}{\bar{E}} + \frac{1}{2} \int_0^L (\delta'(x))^2 dx. \quad (39.11)$$

For uniform applied pressure, the total potential energy of the membrane system is given by

$$U = b \int_0^L \left( \frac{h\sigma_o^2}{2\bar{E}} - p_o\delta(x) \right) dx = \frac{bhL\sigma_o^2}{2\bar{E}} - bp_o \int_0^L \delta(x) dx. \quad (39.12)$$

Once again, the last term represents the pressure times the volume of the bulge, which is relevant to interface fracture toughness measurements conducted by injecting a fixed volume (see Section 39.4.2.2).

## 39.4 PRACTICAL APPLICATIONS AND DEVELOPMENT GUIDELINES

### 39.4.1 DEBONDING OF MULTILAYERS FROM INTERFACE FLAWS AT EDGES

This section addresses interface failure between two elastic plates bonded together, as shown in Figure 39.6. Stresses are generated when the plates have different initial curvatures and/or different thermal expansion properties; the resulting stored elastic energy promotes debonding. It is assumed that two plates with different curvatures bond together after they have been pressed completely flat and their interfaces have been aligned. Put another way, the material on each side of the interface experiences relative sliding prior to bonding. This is an important assumption, because it implies that each layer will be stressed in the bonded state *even when their initial curvature, elastic properties*

\* One can derive equivalent expressions using force balances: however, the finite angles that are retained in membrane theory (e.g.,  $\cos \beta \approx 1 - (1/2)\beta^2$ ) make such derivations cumbersome.

**FIGURE 39.6** Geometry and variables used in the analysis of bilayer deformation and debonding: (a) initial configuration of curved plates, (b) it is assumed the plates are pressed flat prior to bonding, (c) resulting curved bilayer with continuous total strain distribution, and (d) schematic illustration of edge debonding and stress state in bonded region.

and thermal expansion coefficients are identical. This is a consequence of the fact that “opposite” faces are bonded: for example, if both plates have the same curvature, the compression side of the top plate will be bonded to the tensile side of the bottom plate (see Figure 39.6b).

The mechanical strain distributions in the thickness direction in each plate can be expressed as\*

$$\varepsilon_{xx}^f(y) = \varepsilon_o - \kappa \cdot y + \kappa_o^f (y - h_s - h_f/2) - \theta_f, \tag{39.15a}$$

and

$$\varepsilon_{xx}^s(y) = \varepsilon_o - \kappa \cdot y + \kappa_o^s (y - h_s/2) - \theta_s. \tag{39.15b}$$

Here,  $\kappa_o^i$  is the initial curvature of the  $i$ th layer (i.e., the layer traces a circular arc with radius  $R_o^i = 1/\kappa_o^i$ ) and the subscripts  $f$  and  $s$  refer to the film and substrate, respectively. Positive curvature is taken as concave up: if the curvature of the two layers opposes one another, the individual layer curvatures are of opposite sign.  $y$  is the distance from the bottom of the substrate. The thermal strain in the  $i$ th layer is defined as:  $\theta_i \equiv \alpha_i (T_i - T_o^i)$ , where  $\alpha_i$  is the coefficient of thermal expansion and  $T_i$  is the current temperature.  $T_o^i$  is the reference temperature at which there is no thermal strain, that is, the temperature at which the layer is fabricated.  $\varepsilon_o$  is the axial stretch along the bottom of the substrate (i.e.,  $y = 0$ ) and  $\kappa$  is the curvature of the bilayer after bonding; hence,  $\varepsilon_o$  and  $\kappa$  are the solution variables of interest.

\* The total strain is simply  $\varepsilon_{tot}(x) = \varepsilon_o - \kappa(x) \cdot y$ : one subtracts the thermal strains from the total strain to get the mechanical strain, that is, the strain used to determine stresses via  $\sigma = \bar{E}\varepsilon$ .

Absent any external loading on the bonded bilayer, the net resultant axial force,  $N$  and net resultant moment,  $M$ , are zero. This implies

$$N = \int_0^{h_s} \sigma_{xx}^s(y) dy + \int_{h_s}^{h_s+h_f} \sigma_{xx}^f(y) dy = 0, \tag{39.16}$$

and

$$M = \int_0^{h_s} \sigma_{xx}^s(y) \cdot y dy + \int_{h_s}^{h_s+h_f} \sigma_{xx}^f(y) \cdot y dy = 0 \tag{39.17}$$

Substituting  $\sigma_{xx}^i(y) = \bar{E}_i \varepsilon_{xx}^i(y)$  and performing the integration yield two linear equations for the unknowns  $\varepsilon_o$  and  $\kappa$ . The stored elastic energy of the bilayer can be calculated by integrating the strain energy density per unit volume,  $1/2 \sigma_{xx}^i \varepsilon_{xx}^i$ , throughout the volume, using the results for  $\varepsilon_o$  and  $\kappa$  with Equation (39.15); integration over thickness yields the strain energy per unit area in the plane of the bilayer.

The ERR for an edge crack such as that shown in Figure 39.6d can be trivially calculated using the elastic energy. Here, we assume that interface failure relieves all stresses in the layers, that is, they return to their undeformed configuration for portions of the plate that are no longer bonded.\* When the length of the interface crack greatly exceeds either layer thickness, edge effects are negligible; this case is referred to as the *steady-state* ERR, because the ERR is independent of flaw size. The steady-state ERR is the maximum possible—that is, for shorter interface flaws the ERR is smaller. The steady-state ERR is simply the change in strain energy per unit crack advance, that is,  $G = (U_{\text{bonded}} - U_{\text{cracked}})/(b\Delta a) = U_{\text{bonded}}/(b\Delta a)$ . This result can be written as†

$$G = \bar{E}_s h_s f_{sf} + \bar{E}_f h_f f_{fs}, \tag{39.18a}$$

where

$$f_{ij} = \frac{g_{ij}}{24} h_j^2 \left[ \kappa_i^2 - 2\kappa_i \kappa_j + 4\kappa_j^2 \right] + 6h_j \kappa_j \left[ h_i \kappa_j + 2(\theta_s - \theta_f) \right] + 3 \left[ h_i \kappa_j + 2(\theta_s - \theta_f) \right]^2 \tag{39.18b}$$

and

$$g_{ij} = \frac{\bar{E}_i h_i}{\bar{E}_j h_j} + 4 + 6 \frac{h_j}{h_i} + 4 \left( \frac{h_j}{h_i} \right)^2 + \left( \frac{h_j}{h_i} \right)^3 \frac{\bar{E}_j}{\bar{E}_i}. \tag{39.18c}$$

Note that the ERR is symmetric with respect to the film and substrate, that is, one can arbitrarily label the top or bottom film as the substrate.

This broadly general result has interesting and important implications, even when the two plates are these same material and thickness. For example, consider two identical plates with the same initial curvature: the ERR is

$$G = \frac{\bar{E} h^3}{12R_o^2} \quad (\text{curvature opposing}) \quad \text{or} \quad G = \frac{\bar{E} h^3}{16R_o^2} \quad (\text{curvature aligned}) \tag{39.19}$$

\* In some instances, the plates in the debonded region remain subject to out-of-plane constraints, such that they are not entirely stress-free: this requires slightly different algebra (see Reference 31).

† Note that the Einstein summation convention does *NOT* apply.

**FIGURE 39.7** Examples of energy release rates for several different bilayer scenarios: (a) glassy polymer film on glass, (b) two glassy polymers bonded at different temperatures, and (c) an elastomer film bonded to a glass substrate, and (d) two glass slides bonded at different temperatures.

These somewhat surprising results imply that aligning initially curved plates may not be remarkably effective in suppressing delamination. It should be noted that if the initial curvatures are aligned, the final curvature of the plate will be twice the initial curvature: the internal moments generated by the internal stresses introduced during pressing are complementary. Conversely, as one would expect, the final curvature of the bilayer is zero if the initial curvatures are opposed and identical.

As anyone in the microelectronics community can attest to, the true headaches begin when two different materials with different thermal expansion coefficients are bonded together, often times at different temperatures due to the fabrication process. In this case, the ERR arising from bonding perfectly flat plates is given by

$$G = \frac{1}{2g_{fs}} \bar{E}_f h_f (\theta_s - \theta_f)^2 \left( 1 + \left( \frac{\bar{E}_f h_f^3}{\bar{E}_s h_s^3} \right) \right). \tag{39.20}$$

The implications of these results for several scenarios relevant to microfluidic devices are illustrated in Figure 39.7, which depicts the ERR for bilayer debonding as a function of temperature change. Approximate numbers for interface toughness are also listed, based on an attempt to roughly summarize findings from a diverse range of interface studies. It is worth noting that the ERR for all cases is in the ballpark of the pure mode I interface toughness; this indicates that many common fabrication sequences inherently introduce stresses that are “large,” in that the device will be near the threshold for debonding. This rather thumbnail sketch illustrates the difficulty in identifying highly repeatable bonding processes. It must be noted, however, that many of the scenarios considered in Figure 39.7 will not necessarily delaminate; the presence of mode II deformation, for which the interface toughness is considerably larger (see table in Figure 39.7), implies greater stability. Nevertheless, it is clear that many common bilayer scenarios are not “far” from debonding, highlighting the need for more precise and systematic characterization of such systems.

**39.4.2 DEBONDING OF PRESSURIZED FILMS COVERING LONG CHANNELS**

Figure 39.8a depicts film debonding due to pressurizing a sealed cavity; the width (span) of the cavity is denoted as  $L$ . Recall from Section 39.2.1 that this length should be taken as the channel width plus any debonded region next the interior edge of the film/substrate interface (see Figure 39.2b). For PDMS-glass systems, this inclusion of a debonded region next to the channel involves no significant approximation, because the substrate is effectively rigid and the geometry of the unbonded region is not relevant. For glass-glass systems, the geometry of the unbonded substrate is relevant if the distance from the edge of the channel (see Figure 39.2b) to the crack tip is greater than several

**FIGURE 39.8** Side views of geometries relevant to debonding along channels: (a) edge debonding due to internal pressure, (b) debonding to release a “stuck” film.

times the film thickness. In the following, we assume that  $L$  refers to the total length of the debonded region, with the understanding that this must extend beyond the edge of the channel when considering glass-glass systems.

This section considers plate and membrane behavior, as opposed to scenarios where the film is thick enough to be considered an elastic half-space (as in Figure 39.2a). Thus, the applications in Section 39.4.2 thus correspond directly to the theory described in Section 39.3.2. The analysis of two relatively thick films (compared to crack length) requires numerical solutions not discussed in Section 39.3.2 and hence is discussed in Section 39.4.3.1 in conjunction with pressure-deflection relationships.

**39.4.2.1 Plate Behavior:  $L > \sim 10 h$  and  $\delta_{\max} < h$**

Figure 39.8b illustrates a pressurized film that adheres to an adjacent layer: this is a more general case of the simple span shown in Figure 39.8a. The film is subjected to a uniform pressure and is deflected at one end (from its initially stress-free position). Solution to Equation 39.6 subject to the boundary conditions  $\delta(0) = \delta'(0) = \delta'(L) = 0$  and  $\delta(L) = -\Delta$  yield the following deflection profile for the film

$$\delta(x) = \frac{p_o L^4}{2\bar{E}h^3} \left(\frac{x}{L}\right)^2 \left(1 - \left(\frac{x}{L}\right)\right)^2 - \Delta \left(\frac{x}{L}\right)^2 \left(3 - 2\left(\frac{x}{L}\right)\right), \tag{39.21}$$

where  $p_o$  is the resultant pressure, that is, the superposition of that acting on the top and bottom of the film. Plugging this into Equation 39.8, the ERR is

$$G = \frac{p_o^2 L^4}{24\bar{E}h^3} \left(1 \pm 6 \frac{\Delta \bar{E} h^3}{p_o L^4}\right)^2. \tag{39.22}$$

Despite the fact that the pressure seems to act purely to “open the crack,” it should be noted that there is a mode II component arising from bending of the film at the edge of the delamination: the phase angle is  $\psi = -45^\circ$ . This highlights the need for mixed-mode interface toughness measurements for material systems relevant to microfluidic systems.

When utilizing Equation 39.22, one must determine the proper sign of the operator in parenthesis. This operation depends on the stress condition at the interface. For instance, if the displacement of the film places the interface in tension (e.g.,  $G_1$  in Figure 39.8b where the film is debonding from the bottom of the channel), then a positive sign should be used in Equation 39.22. In this scenario, there is a driving force for debonding even when there is no internal pressure. Conversely, if one was to consider debonding at the upper left edge of the channel—labeled  $G_2$ —the displacement of the film acts to close an interface crack at the edge of the channel: for this scenario, the negative sign is used, since the displacement decreases the driving force. One may use the same reasoning to determine the sign of the contribution of the film displacement for interfaces created by the bonding of a third layer on top of the film.

With  $\Delta = 0$ , the result corresponds to debonding from an interface crack along the edge of a long, straight channel (Figure 39.8a). If the internal pressure is held constant, the ERR increases as the crack extends (i.e.,  $L$  increases). This corresponds to *unstable crack growth*: once debonding initiates,  $G > \Gamma_i$  for all subsequent debond lengths  $L$  and the crack will not arrest. Conversely, the crack extends in a stable manner if one injects a constant volume into a previously filled channel. The injected volume will initially be accommodated by the deflection of the film, as shown in Figure 39.8a. Integration of Equation 39.21 (i.e., the displaced profile of the film) yields the relationship between injected volume,  $V_i$  and the resulting pressure. This result is then used with Equation 39.8. Since the second term in Equation 39.8 refers to the pressure times the injected volume, it is constant with respect to crack length and it does not enter into the ERR calculation. Thus, the derivative of the potential energy is equal to the derivative with respect to the strain energy, that is, the first term only. This yields

$$G = \frac{7\bar{E}h^3 (15V_i)^2}{8bL^6}, \quad (39.23)$$

where  $b$  is the length of the channel (i.e., the distance in the  $z$ -direction over which the injected volume is distributed). This result indicates that crack extension due to injected volume will be stable, in that the ERR will decrease as the crack extends ( $L$  increases). This has important implications for both design (i.e., devices that operated under fixed volume conditions), as well as bulge testing to infer interface toughness (see Section 39.4.6.2).

#### 39.4.2.2 Membrane Behavior: $L > \sim 10 h$ and $\delta_{\max} > h$

For films that experience deflections that are much greater than the film thickness, the membrane models of Section 39.3.2.2 are appropriate. For a membrane covering a long channel of width  $L$ , the solution is found by integrating Equations 39.10 and 39.11 and imposing the boundary conditions  $\delta(x=0) = \delta(x=L) = 0$  and  $u(x=0) = u(x=L) = 0$ . The results are

$$\sigma_o = \frac{\bar{E}}{2 \cdot 3^{1/3}} \left( \frac{p_o L}{\bar{E}h} \right)^{2/3}, \quad (\text{membrane stress}) \quad (39.24)$$

and

$$\delta(x) = L \left( \frac{3p_o L}{\bar{E}h} \right)^{1/3} \left( 1 - \frac{x}{L} \right) \left( \frac{x}{L} \right). \quad (\text{membrane deflection}) \quad (39.25)$$

The ERR for constant pressure in the channel can be calculated from Equation 39.12: this yields

$$G = \frac{7p_o L}{8} \left( \frac{p_o L}{9\bar{E}h} \right)^{1/3}. \quad (39.26)$$

Once again, one can solve for the ERR that arises due to constant volume injection, using Equation 39.25 to calculate the volume for given pressure. In calculating the potential energy used in the ERR calculation, the second term (pressure times injected volume) is dropped. The result is

$$G = 126\bar{E}h \left( \frac{V_i}{bL^2} \right)^4. \quad (39.27)$$

Under constant volume injection, the ERR again falls as the crack extends (i.e.,  $L$  increases), implying stable crack extension under constant volume injection.

**39.4.3 PRESSURE–DEFLECTION RELATIONSHIPS FOR VALVE DESIGN**

The relationship between pressure, deformation and geometry plays a critical role in microchip design, as it essentially dictates the actuation pressure of valves and the fluidic capacitance introduced by deformable channels. Table 39.2 summarizes several classical results for simple geometries.

**39.4.3.1 Long Capped Channels: Plane-Strain Deformation**

Figure 39.9 presents the film displacements resulting from pressurizing a cavity, for small pressures (such that deformations are small compared to the film thickness) and *small spans that are comparable to the film thickness*. Results are shown for an elastomer film bonded to a glass substrate: due to the extreme compliance of the elastomer, the substrate is effectively rigid. The curves in Figure 39.9 were generated via numerical FEA of the two-dimensional, plane-strain geometry shown in the inset. Such techniques are required when the deformation of the film is not dominated by bending, as is the case for films that are of comparable thickness to the span.

For very thick films, the behavior is well described by results that assume the film behaves as a semi-infinite half-space. In this limit, the geometry corresponds to that of a pressurized crack, such that the inner surface of the film displaces according to the well-known analytical result (e.g., [33])

$$\delta(x) = \delta_{\infty} \sqrt{1 - \left(\frac{2x}{L}\right)^2}, \tag{39.28}$$

the maximum surface deflection is given by

$$\delta_{\infty} = \frac{pL}{E}. \tag{39.29}$$

Note that this analytical result is independent of the film thickness, which is a consequence of invoking the assumption that the film behaves as a half-space. The maximum displacement of the inner surface,  $\delta_{\infty}$ , is used to normalize the displacement results in Figure 39.9; hence, the curves asymptote to unity for small aspect ratios (note  $a/h = L/2h$ ).

Figure 39.9 illustrates that for shorter spans, the deflection of the top of the film will be considerably smaller than that of the bottom; this has significant implications for the actuation pressure of thick elastomer films used as valves. Monitoring the deflection of the top surface enables use of the

**FIGURE 39.9** Film deformation as a function of span to thickness ratio for elastomer films bonded to glass substrates, for long, straight-walled channels (plane-strain); results illustrate the transition from the half-space solution (where bending is negligible) to the plate solution (dominated by bending).

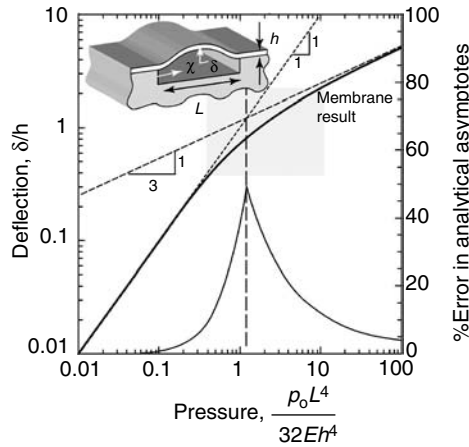

film as a pressure sensor to quantify the internal cavity pressure, or direct measurement of the fluidic capacitance of the channel. For larger spans where bending dominates, the deflection of the top (or outer) surface is identical to the bottom surface. When bending dominates, the film deflection is accurately described by the solution for a clamped plate. The deflections of the plate are given by Equation 39.21 with  $\Delta = 0$ .

The capacitance of the deformable film (discussed more fully in Section 39.4.5) is also shown: this is essentially the channel volume introduced by deformation of the film and is calculated by integrating the film’s spatial displacement profile obtained from the numerical analysis. These results are normalized by the volume obtained by integration of Equation 39.28. The capacitance results in Figure 39.9 can be reinterpreted as the ERR for debonding, with the crack length defined according to the convention discussed at the outset of Section 39.4.2. This reinterpretation involves replacing the normalized capacitance with a normalized ERR,  $G/G_0$ , where  $G_0$  is the ERR for a pressurized crack between two half-spaces: this quantity is given in Table 39.5. The coincidence of the normalized capacitance and that of the normalized ERR is not exact (i.e., there is no obvious analytical reason the two should coincide, at least not obvious to us), but rather an observation based on numerical results. The error is less than  $\sim 20\%$  over the range shown in Figure 39.9.

For films that are sufficiently thin to allow for bending, a central question is whether or not pressures are large enough to induce large deflections, in which case one must account for axial stretching of the film (along its centerline). At sufficiently low pressure or small deflections, the deflection varies linearly with pressure (i.e., plate behavior). At large pressures or large deflections, the film deflections scale with  $p^{1/3}$ . This is referred to as membrane behavior. The transition between plate and membrane behavior can be illustrated using a closed-form solution that implicitly defines the deflection of the film for a given pressure. The solution that describes the applied pressure and the deflection in terms of the axial tension developed in the membrane is [32]

$$\frac{p_0 L^4}{32 \bar{E} h^4} = \lambda = \frac{\hat{\sigma}^2 \sinh \sqrt{\hat{\sigma}}}{12 \left[ (24 + 4\hat{\sigma}) \cosh 2\sqrt{\hat{\sigma}} - 18\sqrt{\hat{\sigma}} \sinh 2\sqrt{\hat{\sigma}} - 24 - 16\hat{\sigma} \right]}, \tag{39.30}$$

$$\delta_{\max} = 12h\lambda \left( \frac{\sqrt{\hat{\sigma}} - 2 \tanh \left( \frac{\sqrt{\hat{\sigma}}}{2} \right)}{\hat{\sigma}^{3/2}} \right), \tag{39.31}$$

**FIGURE 39.10** Deflection–pressure relationship for films over *long, rectangular channels* (plane-strain deformation) illustrating the transition from plate-to-membrane behavior. The shaded region represents combinations of pressures and displacements for which simple analytical solutions have greater than 10% error.

where  $\lambda$  represents the normalized (dimensionless) pressure and is the normalized axial tension in the film:  $\hat{\sigma} = 3NL^2/\bar{E}h^3$  where  $N$  is the axial resultant (force per unit width of the film). Clearly, the deflection for a given applied pressure can be found by numerical solution to Equation 39.5 and substitution into Equation 39.6. However, it is often simpler to generate the load–displacement relationship via the parametric plotting features of commercial codes such as *Mathematica*. The outcome of this procedure is illustrated in Figure 39.10.

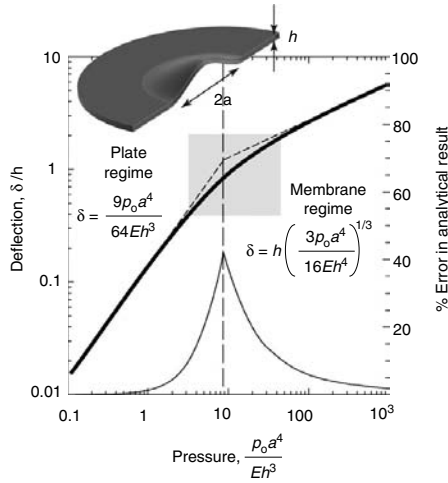

For sufficiently large pressure, one obtains the classical membrane solution, described by Equation 39.25. The shaded region in Figure 39.5 represents combinations of pressures and displacements for which simple analytical solutions have greater than 10% error.

### 39.4.3.2 Circular Films

Similar behavior is observed for circular films, although a closed-form expression for the pressure–deflection relationship in the transition region is not possible. Figure 39.11 illustrates the transition from plate-to-membrane behavior as the pressure applied to a circular film is increased. It should be noted that for circular (i.e., axisymmetric) films, the dependence on Poisson’s ratio is slightly different from that of the plane-strain case. Strictly speaking, the pressure–deflection relationship shown in Figure 39.11 depends on the Poisson’s ratio; however, the dependence is rather weak and tabulated elsewhere [39]. The asymptotic limits at low and high pressure (i.e., plate and membrane, respectively) are listed in Table 39.2; note that those listed inside Figure 39.11 are for  $\nu = 1/2$ .

### 39.4.4 DESIGN OF CHECK VALVES FOR SPECIFIC ADHESION ENERGY AND/OR DIMENSIONS

The results of the previous sections can be used to design check valves that control fluid motion in powerful ways. Consider the geometry shown in Figure 39.12 [40]: a wall of thickness  $w$  separates two fluidic channels within a single layer. At low pressure, the check valve closes the channel by seating on this wall. When a critical pressure is reached, the valve film debonds from its seat and allows fluid to pass from one channel to the other. Assuming displacements are much smaller than the film thickness (such that plate behavior applies) the critical pressure required to release the check

**FIGURE 39.11** Deflection–pressure relationship for *circular* films with  $\nu = 1/2$ , illustrating the transition from plate-to-membrane behavior. The shaded region represents combinations of pressures and displacements for which analytical solutions have greater than 10% error.

**FIGURE 39.12** Schematic diagram of a fluidic check valve: by modulating the dimensions (and/or interface adhesion energy), one can design valves that allow flow in only one direction, and achieve the desired deflection after debonding at the design pressure.

valve and allow for fluid flow is dictated by Equation 39.22 with  $\Delta = 0$ : that is,

$$p_1^c = \frac{\sqrt{24\bar{E}h^3\Gamma_i}}{L_1^2}, \tag{39.32}$$

where  $\Gamma_i$  is the adhesion energy of the interface formed by the film and the valve seat. Clearly, one may control the relative pressures to allow for flow from left-to-right (or vice versa) by suitable choice of the channel width,  $L$ . The ratio of activation pressures for forward (1 to 2) and reverse (2 to 1) directions thus scales as

$$\frac{p_1^c}{p_2^c} = \left(\frac{L_2}{L_1}\right)^2. \tag{39.33}$$

Above the critical pressure, the valve debonds, which connects the two fluid channels. The valve displaces according to Equation 39.21 with  $L = L_1 + L_2 + w$  and  $\Delta = 0$ .

Suppose that in the “open” position, the desired film displacement is  $\Delta$ ; presumably this is chosen to achieve a specific flow rate at the activation pressure of the valve. Alternatively,  $\Delta$  may represent the maximum allowable displacement of the valve film to prevent adhesion with overlying

layers, as shown in Figure 39.12. Thus, one can identify the combinations of material properties and dimensions that result in a valve that is either closed or open to a prescribed clearance by setting  $p_1^c = p_{\max}(\Delta)$ . This combination is

$$\frac{\Gamma_i}{\bar{E}h} = \frac{\left(\frac{\Delta}{L_1}\right)^2 \left(\frac{h}{L_1}\right)^2}{\left(1 + \frac{L_2}{L_1} + \frac{w}{L_1}\right)^8}. \quad (39.34)$$

In ideal world, one might modulate the adhesion energy of the valve seat to achieve the desired performance for a specific set of dimensions. This would likely be difficult as the chemistry of the fluidic environment, which obviously depends on the application, often affects interface toughness. However, one can measure the interface toughness for a given application and then choose the dimensions of the chambers to satisfy Equation 39.34: the result is a check valve that actuates to a specific clearance for a given interface condition.

One can naturally derive similar design guidelines for chamber dimensions comparable to the film thickness (i.e., the elastic half-space regime) or valve displacements greater than the film thickness (i.e., the membrane regime).

### 39.4.5 FLUIDIC CAPACITANCE

Any feature of the fluidic network whose internal volume changes with pressure acts as a fluidic capacitor, because those volume changes imply that additional mass will be “stored” inside the feature. This behavior can be exploited to alter the characteristic timing of flow inside a fluidic “circuit” (e.g., [41]). *Assuming density changes are negligible*, the mass flow rate can be written as

$$\hat{q} = \frac{dm}{dt} = \rho \frac{d}{dt} \left( V_0 + \frac{dV}{d(\Delta p)} d(\Delta p) \right), \quad (39.35)$$

where  $V_0$  is the initial fixed volume of the element,  $\rho$  is the mass density and  $\Delta p = p_{\text{in}} - p_{\text{out}}$  is the difference between pressure inside and outside the element. Obviously, the volume flow rate (at constant density) is simply  $\hat{q} = q/\rho$ . In terms of volume flow rate,

$$q = \frac{dV}{dp} \cdot \frac{dp}{dt} \equiv C\dot{p}, \quad (39.36)$$

where it should be noted  $dV_0/dt = 0$  by definition. Clearly, the flow rate is defined as positive towards the capacitance element inside the chamber: when the pressure inside is greater, the film deflects outward and the capacitor stores more fluid (positive flow rate). Hence, for any enclosed volume, the fluidic capacitance is defined as the change in volume with respect to the difference between internal and external pressure.

Table 39.2 lists the pressure-volume relationships for various geometries: the fluidic capacitance is found simply by differentiating with respect to pressure. For small deformations, volume varies linearly with applied pressure, such that the capacitance is not a function of the pressure: it merely defines the proportionality between increases in pressure and increases in “stored” mass. For such cases, the fluid circuit analysis is linear, because flow rate and pressure drops are related via linear expressions. For large deformations (i.e., the membrane limit), the fluidic capacitance is a function of the pressure: this implies that the fluidic circuit behavior will be nonlinear. Obviously, once the fluidic resistance, capacitance and inductance have been identified via geometry (and material properties), complicated networks can be analyzed using commercially available circuit analysis software such as SPICE [42].

### 39.4.6 MATERIAL PROPERTY MEASUREMENTS

This section outlines several approaches to characterizing the elastic modulus of thin films and the interface toughness when bonded to substrates. Naturally, there is an enormous variety of test configurations that can be used; attention here is limited to those with specimen fabrication that is similar to that used for typical microfluidic devices. The text by Freund and Suresh [32] describes additional test approaches, particularly those pertaining to quantifying the effects of mode-mixity on interface toughness.

#### 39.4.6.1 Indentation Modulus Measurements

As evident from the calculations in previous sections, the elastic modulus of a material must be known if a researcher hopes to predict interface toughness for a fabricated device. An increasingly prevalent method to characterize modulus is instrumented indentation, wherein an indenter tip of known shape is pressed into a surface: see Figure 39.13a. The plane-strain modulus of the material, that is,  $\bar{E} = E / (1 - \nu^2)$ , is extracted from the measured force–displacement relationship. The test method is particularly attractive because it requires minimal sample preparation and mounting: one must merely ensure that a nominally flat film can be attached to substrate that can be inserted into the apparatus. This makes it ideal for testing thin films, as samples can be deposited via spin casting, chemical vapor deposition and so on. Moreover, the dynamic ranges of force and displacement measurement continue to expand, enabling tests on a broad range of film thickness. Conventional micro-indenters typically apply forces in the Newton range and are capable of measuring displacements in the  $> 10$  micron range. Nanoindentation systems can accurately apply forces beneath a milli-Newton and measure displacements with nanometer precision over a broad dynamic range spanning tens of microns. Such systems are increasingly common and are becoming the de facto choice for thin film modulus measurements, due to sophisticated and automated test control and interpretation.\* The book chapter by Hay and Pharr [43] provides an excellent, detailed overview of the instrumentation and theory involved in indentation testing.

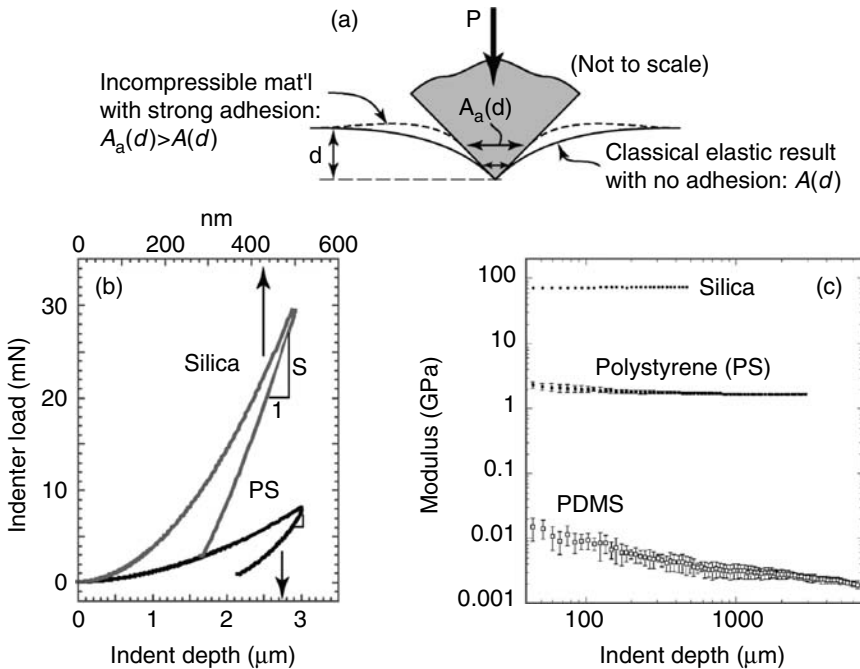

Typical load–displacement curves obtained from instrumented indentation experiments are shown in Figure 39.13b. Results are shown for silica ( $E = 72$  GPa,  $\nu = 0.2$ ) and polystyrene (PS,  $E = 2$  GPa,  $\nu = 0.4$ ). The load–displacement curve for PDMS ( $E = 1.5$  MPa,  $\nu \sim 0.5$ ) involve forces that are too low to appear on the scale used in Figure 39.13b, due to the fact its elastic modulus is three orders of magnitude lower than polystyrene.

Depending on the material being tested, the loading path is a complicated function of elastic and inelastic deformation (such as creep or plasticity). Conversely, the initial portion of the unloading curve is dominated by purely elastic deformation; it is this portion of the measurement that is used to extract the modulus. The initial slope of the unloading curve is often referred to as the contact stiffness and is denoted here as  $S$ . The postprocessing method for determining  $S$  by curve-fitting the unloading portion of the curve is described in detail in [43]. The basic relationship that is used is

$$\frac{EE_i}{(1 - \nu^2) E_i + (1 - \nu_i^2) E} = \frac{S}{\sqrt{A}(\delta_c)}, \quad (39.37)$$

where  $E_i$  is the modulus of the indenter and  $S$  is the measured stiffness (i.e., slope of the initial portion of the unloading curve).  $A$  is the area function of the indenter tip: this function describes the relationship between contact depth,  $\delta_c$ , and the projected contact area between the indenter tip and surface (see Figure 39.13a).

\* Indentation testing can also be performed with an atomic force microscope, which has pico-Newton force and angstrom displacement resolution at the lower end; the draw back is that the dynamic displacement range is limited to several microns. Moreover, on older systems, the control software, as well as that needed for test interpretation, may not be readily available.

**FIGURE 39.13** Typical measurements obtained using a commercial nanoindenter: (a) schematic of the contact area, (b) typical load–displacement measurements, and (c) inferred modulus as a function of penetration depth for several materials.

The accuracy of the test method relies critically on the accurate determination of the area function, which varies with tip geometry. At the scale of many nanoindentation experiments, minute differences in tip geometry—such as those caused by wear induced by repeated experiments—can have a large effect on the area function. For this reason, the area function is typically measured by indenting a known material to several depths and computing the function from Equation 39.37. This experimentally determined tip function is then used to interpret further tests on unknown materials. Fused silica (or quartz) is commonly used to “calibrate the tip,” that is, determine the area tip function, because its material response is nearly perfectly elastic and it does not exhibit adhesion with diamond indenter tips.

Provided one is testing relatively stiff material such as glassy polymers, ceramics and metals, the choice of indenter tip geometry is largely one of convenience; by far the most common is a diamond that has been cleaved on crystallographic planes to generate a well-defined tip profile. The resulting shape is that of a pyramid with  $65.3^\circ$  face angle and a three-sided base, known as a Berkovich tip. Other common indenter tips include Vickers (a pyramid with a square base), spheres, cones and even cube-corners (i.e., the corner of a cube that is lopped off and mounted such that the direction of indentation aligns with the diagonal of the cube). It should be emphasized that the actual geometry differs from these nominal shapes at small length scales; for example, a Berkovich tip will typically have a rounded tip with a radius of  $\sim 100\text{--}300$  nm after hundreds of indents on stiff materials such as ceramic or metals. This implies that careful tip calibration is critical for indents whose maximum penetration is smaller than several microns.

Modern hardware and testing protocols are capable of superimposing a small oscillatory component to the apply load. This effectively introduces a series of unloading cycles that can be used to extract the modulus; this technique is commonly referred to as the dynamic contact method (DCM) and is a standard option in commercial nanoindentation systems. The result is that one can measure

the modulus of the material as a function of indentation depth in one rapid test.\* Examples of data obtained from such nanoindentation testing are shown in Figure 39.13c for several materials: the results represent the average of a dozen tests, with the error bars indicating standard deviation. The results for the ceramic (silica) and glassy polymer (polystyrene) are typical of relative stiff materials whose modulus is greater than 1 GPa: for penetration depths greater than one hundred nanometers, the modulus is independent of probe depth. Moreover, for these stiff materials there is very little scatter. This indicates that the tests successfully probed the “bulk” material properties and were not unduly influenced by surface phenomena.

In contrast, the results in Figure 39.13c for the elastomer (PDMS) exhibit larger scatter and an elastic modulus that depends on depth. The indentation testing of elastomers is obviously relevant to microfluidic devices; unfortunately, such materials introduce a host of challenges that continue to be addressed by the mechanics community. First and foremost, such materials exhibit strong adhesion with indenter tips; adhesion obfuscates the inferred modulus by artificially increasing the contact area for a given depth (see Figure 39.13a). This increases the slope of the unloading curve and one infers a larger modulus than reality (see Figure 39.13c: the average modulus for strains less than 3% is 1.5 MPa). Second, such materials exhibit nonlinear stress–strain behavior, which strictly speaking, violates the models derived earlier. Even though the material is purely elastic (does not experience permanent deformation), this leads to ambiguity regarding the imposed strain level at which a modulus is extracted. The most desirable strategy that avoids these problems is to use a flat-ended punch; in this case, provided the indenter is not unloaded too far, adhesion plays no role during unloading because the contact area remains in compression and does not change.

Alternatively, one can indent a freestanding film (i.e., a blanket film covering a hole or microfluidic chamber) using an instrumented probe, as shown in Figure 39.14. With careful choice of dimensions, the measured load–deflection response is dominated by plate bending or membrane stretching, in which case analytical solutions are accurate (e.g., [38]). Adhesion is less of a factor, because the load–deflection response is dominated by behavior outside the contact area. In many regards, the instrumentation can be easier to set up; one can simultaneously measure load and displacement with the same probe (as opposed to pressure loading in “bulge tests,” (Section 39.4.6) where film deflection must be monitored separately from the applied pressure). This has been illustrated for macroscale elastomer films in the membrane regime (PDMS:  $\sim 100\ \mu\text{m}$  thick and 5 cm in diameter [38,44]). Similar tests in the plate regime have been demonstrated for ultrathin glassy polymers that cover microfabricated holes ( $\sim 750\ \text{nm}$  thick PMMA films over holes  $60\ \mu\text{m}$  in diameter: [45]), using a commercial nanoindenter as the instrumented probe.

### 39.4.6.2 Bulge Testing to Determine Modulus and Interface Toughness

The configurations shown in Figures 39.3, 39.10, and 39.11 can be used to probe mechanical properties of the system by monitoring film displacement while modulating the pressure: this is typically referred to as a “bulge test” (e.g., [31,32,46–48]). If the delamination crack front can be monitored while the pressure (or injected volume) is modulated, the interface toughness can also be determined. There are two design considerations for the test: (1) the range of strain imposed during the test and (2) the nature of the load–deflection relationship as dictated by the film thickness-to-span ratio. The former determines whether or not the strains are sufficiently small to allow for a linear elastic approximation and to prevent film rupture. Table 39.3 summarizes the relationships between applied pressure and the maximum strain in the film for various configurations. To address the second consideration, the film thickness and span is ideally such the range of applied pressure enables the accurate application of a simple closed-form analytical expression, that is, plate solutions or membrane solutions.

---

\* Or more importantly, one can extract an accurate area tip function by averaging the results of dozens of indents.

**FIGURE 39.14** Schematic illustration of deflection test on freestanding PDMS film (Dow Sylgard 184 with a 10:1 mixing ratio) [38].

**TABLE 39.3**  
**Estimate for Maximum Strain in the Film**

Long Channel: Plane Strain		Circular	
Plate	Membrane	Plate	Membrane
$\frac{p_0 L^2}{4\bar{E}h^2}$	$\frac{1}{6} \left( \frac{3p_0 L}{\bar{E}h} \right)^{2/3}$	$\frac{3p_0 a^2}{4\bar{E}h^2}$	$\left( \frac{(1-\nu)p_0 a}{2\bar{E}h} \right)^{2/3}$

Table 39.4 summarizes simple rules of thumb for designing microfluidic systems developed from the pressure-strain solutions presented in Section 39.4. Based on the resolution of the available instrumentation and anticipated modulus, these recommendations can be adjusted for film thickness and span as required. The broad generalizations of Table 39.4 can be specified more quantitatively using the results shown in Figures 39.9 through 39.11; that is, critical values of pressure and deflection can be identified such that deflections are within a specified percentage of the analytical solutions.

The bulge test described above can be used to characterize the interface as well as the film itself. Table 39.5 summarizes the ERR (G) for the half-space, plate and membrane limits, in terms of both applied pressure and injected volume. The same limits identified in Table 39.4 can be used to establish the limits of accuracy. The use of injected volume is preferred because the crack front advances in a stable manner: this implies that a single film can be used to make multiple measurements. In order to extract interface toughness, one must monitor the “crack length,” that is, the width of the debonded (or bulging) region. For transparent films, the gap between the bulging film and substrate creates enough contrast to monitor the position of the crack front using optical methods. Depending on the film thickness, optical methods are often sufficient even for opaque films, as the edge of the bulging region

**TABLE 39.4**  
**Design Guidelines for Accurate Closed-Form Pressure-Deflection Solutions**

Long Channel: Plane Strain		Circular ( $\nu = 1/2$ )	
Plate	Membrane	Plate	Membrane
$\delta_{\max} < h/3$	$\delta_{\min} > 2h$	$\delta_{\max} < h/3$	$\delta_{\min} > 2h$
$p_o^{\max} < 0.8\bar{E} \left(\frac{h}{a}\right)^4$	$p_o^{\min} > 30\bar{E} \left(\frac{h}{a}\right)^4$	$p_o^{\max} < 3\bar{E} \left(\frac{h}{a}\right)^4$	$p_o^{\min} > 40\bar{E} \left(\frac{h}{a}\right)^4$

**TABLE 39.5**  
**Summary of Energy Release Rates**

	Half-Space	Plate		Membrane	
	Pressure	Pressure	Volume Injection	Pressure	Volume Injection
Channel	$\frac{\pi p_o^2 L}{4\bar{E}} (*)$	$\frac{p_o^2 L^4}{24\bar{E}h^3}$	$\frac{3\bar{E}h}{2} \left(\frac{h}{L}\right)^2 \left(\frac{10V_i}{bL^2}\right)^2$	$\frac{7p_o L}{8} \left(\frac{p_o L}{9\bar{E}h}\right)^{1/3}$	$126\bar{E}h \left(\frac{V_i}{bL^2}\right)^4$
Circle	$\frac{2p_o^2 a}{\pi\bar{E}} (*)$	$\frac{3p_o^2 a^4}{32\bar{E}h^3}$	$\frac{24\bar{E}h}{\pi^2} \left(\frac{h}{a}\right)^2 \left(\frac{V_i}{a^3}\right)^2$	$\frac{5}{18} \left(\frac{3(1+\nu)p_o^4 a^4}{\bar{E}h}\right)^{1/3}$	$\frac{112\bar{E}h}{(1+\nu)} \left(\frac{V_i}{a^3}\right)^4$

(\*) These results assume the substrate is rigid compared to the film: if the film and substrate have identical elastic properties, these results should be multiplied by two.

is clearly visible (particularly when using white light interferometry). Alternatively, if the volume of injected material is known, the crack length can be inferred from the maximum deflection of the film. The toughness can be determined by least squares fit to the measured  $L = f(V_i)$  relationship, using  $G = \Gamma_i$  as the unknown fitting parameter. Monitoring small deflections generally ensures that the linearly elastic material assumption is valid; however, this also implies small injected volumes that may be difficult to achieve. Thus, one should design the test—that is, adjust film thickness and span—to lie in the appropriate regime of behavior based on the resolution limits of the volume injection and displacement monitoring.

**39.4.6.3 Peel Tests to Determine Interface Toughness**

Perhaps the most straightforward test to determine interface toughness is the peel test, wherein one measures the applied force required to peel a film from the substrate. The test is illustrated in Figure 39.15 and has the advantage of measuring at least part of the dependence of the interface toughness on mode-mixity. The ERR for this configuration is [32,49]

$$G = \sigma_a h (1 - \cos \theta) + \frac{\sigma_a^2 h}{2\bar{E}}, \tag{39.38}$$

where  $\sigma_a$  is the stress applied to the film at the end. (Note that this simply the force applied to the film divided by the cross sectional area of the strip being pulled.) The test involves mixed-mode loading due to bending of the film near the edge of the debonded region, except for the case where  $\theta = 0^\circ$  that corresponds to pure mode II. For compliant films on much stiffer substrates (i.e.,  $\alpha \approx -1$ ) the

**FIGURE 39.15** Schematic of the peel test, and associated mode-mixity phase angle for the case of a flexible film on a rigid substrate; mode II arises from bending near the debond edge.

phase angle of the test  $\psi$  is given by

$$\psi = -\tan^{-1} \left( \frac{\cos \theta - \sqrt{\frac{2(1-\cos \theta)}{\varepsilon_0} + \sin^2 \theta}}{-\cos \theta + \sqrt{\frac{2(1-\cos \theta)}{\varepsilon_0} + \sin^2 \theta}} \right), \tag{39.39}$$

where  $\varepsilon_0 = \sigma_a/\bar{E}$  is the level of strain in the film far from the debond edge. Care should be taken to ensure that the material is appropriately modeled using linear elasticity for the strain level at debonding.

The phase angle ( $\Psi$ ) is shown in Figure 39.15 as a function of peel test angle for several values of applied strain. In all cases, the phase angle is negative due to a negative mode II component: thus, the test is only capable of measuring mixed-mode interface toughness in this regime. When the film is pulled vertically (i.e.,  $\theta = 90^\circ$ ), the phase angle is  $\psi = -45^\circ$  regardless of the applied strain level: this is identical to the bulge test in the plate regime.

### 39.5 FUTURE PROSPECTS AND CONCLUDING REMARKS

The convergence of microfabrication technology developed for microelectronics, microelectromechanical systems (MEMS) and lab-on-chip technology is steadily progressing, and creating rapidly expanding opportunities for new types of miniaturized chemical analysis. It seems obvious that future of microfluidic systems lies in hybrid/composite devices, which incorporate a wide range of materials and geometric features and hence, fabrication techniques. Future chips will undoubtedly involve integrated metallic electrodes, piezoelectric materials for actuation, micropatterned polymers for chemical sensing and so on. The successful realization of such complex microfluidic devices relies critically on the translation of thin film mechanics to those material systems that differ from typical semiconductor and metallic devices. The theoretical and experimental approaches to predicting the mechanical response of multilayer systems outlined here provide a well-established foundation that should be applied to these material systems.

The increasing use of polymers in microfluidic devices, especially elastomers, is a significant departure from microelectronic devices that tend to rely on comparatively stiff ceramics and metals. Hence, there is a critical need for sustained and systematic experimental and theoretical characterization of polymer/ceramic and polymer/metal interfaces. The utility of such studies will be strongly

influenced by the successful partnering of chemists and engineers; it is clear that relevant material systems must be defined by those with an understanding of chemical compatibility and device performance requirements, while those familiar with mechanical integrity offer an efficient route to characterization.

A critical area that needs analysis is the initiation of interface failure at the corners formed by bonding capping layers over patterned channels. While there have been significant inroads to this problem from the mechanics community, it has largely been motivated by microelectronic devices. As such, the analysis of geometry and materials prevalent in microfluidic devices has received only cursory treatment. Similarly, the behavior of PDMS/glass interfaces is particularly important, due to their ubiquitous utilization in emerging devices. While there have been a number of studies in this regard, the understanding of interface toughness as a function of both mode-mixity and surface treatment requires significant additional study. Related to this, the role of nonlinear material behavior and large strain deformation in mechanics of interface delamination is largely unexplored, yet is likely to play an important role in successful device fabrication.

## NOMENCLATURE/GLOSSARY

- $a$  Radius of a circular span, used in expressions to describe the behavior of a deformable film bonded over a circular hole.
- $b$  The length of the crack front that experiences debonding, often taken as unity.
- $\alpha, \beta$  Dundur's parameters: dimensionless parameters that functions of the elastic properties of two materials on either side of an interface, which play a critical role in interface mechanics.
- $\alpha_i$  Coefficient of thermal expansion of the  $i$ th layer, used to include the effects of thermal strains introduced during deposition.
- $C$  Fluidic capacitance, that is, volume of fluid stored in a deformable element per unit pressure.
- $\delta$  deflection of a film or half-space in the direction normal to the interface (or axis of the film), may appear as a function of position along the film axis (i.e.,  $\delta(x)$ ).
- $\Delta$  The maximum or requisite displacement of a valve film, which generally is dictated by the fluidic channel depth.
- $\varepsilon$  Strain, usually refers to the direct strain (aligned with the major axis) of a deformable film.
- $\varepsilon_o$  The axial extensional strain resulting from bonding two layers.
- $E_i$  Elastic modulus (Young's modulus) of layer " $i$ ": if there is no subscript, then this refers to the modulus of the film (as the substrate is assumed to be rigid).
- $\bar{E}_i$  The plane-strain elastic modulus of the layer " $i$ ":  $\bar{E} = E/(1 - \nu^2)$
- $G$  The energy release rate, or "crack driving force," which is used to predict crack stability.
- $\Gamma_i$  The critical value of the energy release rate at which crack extension occurs, often referred to as the fracture toughness, or adhesion energy: the subscript indicates that the quantity refers to the interface toughness (as opposed to a bulk material).
- $h_i$  Thickness of layer " $i$ ": if there is no subscript, then this refers to the Poisson's ratio of the film (as the substrate is assumed to be rigid).
- $\kappa$  The curvature of a bilayer created by bonding together two layers.
- $L$  Total span (or crack length) across a long, rectangular channel.
- $M$  Resultant moment in a thin film.
- $N$  Axial force resultant in a thin film.
- $p_o$  The *net* pressure acting inside a cavity; that is, the sum of pressures acting on both sides of the film: assumed to be spatially uniform.
- $P, S$  Indentation load and stiffness (i.e., the slope of the load–displacement curve).
- $T_i, T_i^o$  Temperature and reference temperatures, respectively, of the  $i$ th layer: the reference temperature is defined as that at which there is no thermal strain, typically the fabrication temperature of the layer.
- $\theta_i = \alpha_i (T_i - T_i^o)$ , the thermal strain in the  $i$ th layer.

- $\sigma$  Stress.
- $\psi$  Phase angle describing mode-mixity of crack driving force: describes the relative amounts of mode I (opening) and mode II (sliding) deformation at a crack tip.
- $U$  Potential energy of the system, comprised of the strain energy of a deformed solid and the work done by applied loads.
- $\nu_i$  Poisson's ratio of layer "i": if there is no subscript, then this refers to the Poisson's ratio of the film (as the substrate is assumed to be rigid).

## 40.1 MICROFLUIDIC FLOW CONTROL INTRODUCTION

Maintaining precise control over fluid within confined microfluidic networks has arguably become one of the major hurdles in realizing the true potential of microfluidic science. The nearly 20-year-old promise<sup>1</sup> of integrating multiple processes into single devices—whether customized as miniature factories for synthetic purposes or as microscale total analysis systems ( $\mu$ -TAS) for sample processing and analysis—had fallen short of expectations until the recent implementation of practical and robust microfluidic valving systems.<sup>2,3</sup> With the basic valving systems now in place, there is enormous potential for many unique experiments relevant to a wide range of disciplines from fundamental physics to applied biology. Furthermore, the development of passive components to complement these active valves should prove to enhance control even further, while simultaneously reducing peripheral instrumentation.

This chapter is not intended to be a comprehensive review of microfluidic valving. On the contrary, we intend to provide a summary of the two most widely utilized valving strategies developed in the past decade.<sup>2,3</sup> Our approach is based on the practicality of implementing these types of valves.

In particular, we propose that the fabrication simplicity and compatibility of active elastomeric membrane valves<sup>2,3</sup> are key factors in their robustness and usefulness, a notion that is supported by the recent surge in related publications.<sup>4–15</sup> The various microelectromechanical systems (MEMS) approaches to microfluidic valving are typically limited by operational complexity and fabrication,<sup>5</sup> thus they are not discussed here; interested readers are referred to a recent review by Oh and Ahn.<sup>16</sup>

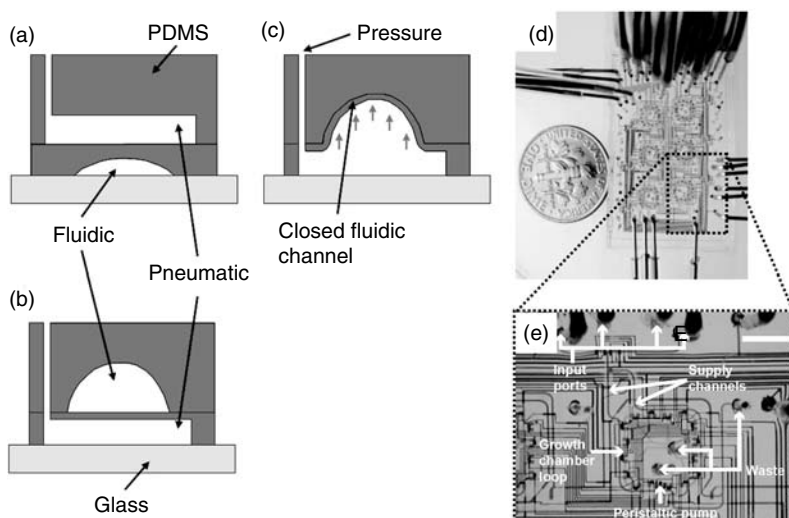

Throughout this chapter, flow control techniques that require an external (off-chip) stimulus are considered *active*, while those requiring no external stimulus are considered *passive*. The two dominant active valving techniques are discussed in Section 40.2 along with a simplified manual alternative, while some of the recent passive flow control methods are reviewed in Section 40.3. Various applications of the active valving systems are discussed in Section 40.4, which is followed by a section including guidelines that provide the reader with a “beginner’s knowledge” of implementing these types of valves (Section 40.5). Although this chapter places more emphasis on active valving for microfluidic flow control, we conclude (Section 40.6) by stating the importance of conducting further research into practical passive flow control methods that should allow more widespread use of microfluidic devices in general.

## 40.2 ACTIVE MICROFLUIDIC VALVING

Depending on the particular device, microfluidic volumes can range from picoliters to microliters, with typical total solution volumes in the nanoliter range. Before the development of robust valves that were simple to fabricate, first by the Quake and coworkers<sup>2</sup> and then by the Mathies and coworkers,<sup>3</sup> it was nearly impossible to reliably control these small volumes of fluid using practical fabrication methods. The central theme of these two approaches is the use of a flexible poly(dimethylsiloxane) (PDMS) membrane as a pneumatically actuated material to produce on-chip valves, or fluidic switches. While it should be noted that PDMS is not the only elastomeric membrane amenable to such application, it is the one that has been extensively used thus far. The use of PDMS in microfluidics was pioneered by the Whitesides and coworkers,<sup>17,18</sup> who developed the soft-lithography techniques used by Quake and coworkers<sup>2</sup> to fabricate their valves. The material is well suited for optical interrogation due to its transparency in the visible spectral region,<sup>17</sup> and it is also amenable to the integration of electrochemical detection,<sup>19</sup> making it well suited for analytical purposes. Included in this section are summaries of the architectures and functionalities of the normally open Quake valves<sup>2</sup> and the normally closed Mathies valves,<sup>3</sup> which are easily operated by computer control, followed by a brief description of a low-power, manually operated alternative proposed by the Whitesides and coworkers.<sup>20</sup>

### 40.2.1 NORMALLY OPEN<sup>21</sup> VALVES USING SOFT LITHOGRAPHY

Figure 40.1a and b illustrates the basic architecture of valves developed by the Quake and coworkers.<sup>2,22</sup> These normally open, pressure-actuated valves are fabricated in two configurations, push-down<sup>2</sup> or push-up<sup>22</sup> valves. The push-down valves (Figure 40.1a) require approximately an order of magnitude larger pneumatic actuation pressure to close than do the push-up valves (Figure 40.1b). Furthermore, the fluidic channels in the push-down configuration are restricted to a depth of less than  $\sim 20$   $\mu\text{m}$ , while the push-up valves will function with much deeper channels while simultaneously requiring lower pressures. A key feature of these types of valves is the essentially zero dead volume, as can be inferred from the illustration of pressure-actuated closing of the fluid channel (Figure 40.1c). With this advantage, the valves can be arranged into high-density architectures ( $\geq 30$  valves  $\text{mm}^{-2}$ ),<sup>23</sup> as shown in Figure 40.1d and e. With at least three valves coupled in series, peristaltic pumps can be created,<sup>2</sup> allowing the precise metering of solutions within the device at flow rates up to  $2.35$   $\text{nL s}^{-1}$ . Figure 40.1e shows a magnified view of Figure 40.1d, with labels for the peristaltic pumps and cell growth chambers used in this bacterial chemostat study.<sup>23</sup>

**FIGURE 40.1** Basic architecture of Quake's normally open valves. (a) Push-down configuration, which is typically limited to fluidic channels  $<20\ \mu\text{m}$ . (b) Push-up configuration, which requires approximately an order of magnitude less pressure to actuate than the push-down valves and can be used with deeper channels. (Adapted from Studer, V., et al. *J. Appl. Phys.*, 2004, 95, 393–398.) (c) Illustration of pressure-actuated closing of the fluid channel using a push-up valve. (d) High-density valve arrangements were shown in a microfluidic chemostat for programmed population control of bacteria. (e) Magnified view of device in (d). (From Balagadde, F. K., et al. *Science*, 2005, 309, 137–140. With permission from American Association for Advancement of Science.)

Since their development, these valves have been proven functional through their utilization in a wide variety of applications such as microfluidic large-scale integration,<sup>4</sup> protein crystallization,<sup>24</sup> nucleic acid processing,<sup>6</sup> and multistep radiolabel synthesis.<sup>9</sup> These applications will be discussed further in Section 40.4. One disadvantage of these valves is that, in order to actuate a large number of individually addressable valves, there must be an equal number of external pneumatic controls (typically computer-controlled solenoid valves). In this situation, the controlling instrumentation begins to overwhelm the microscale nature of the device. Although multiplexers have been developed,<sup>4</sup> these pose restrictions on individual addressability of the valves. In other words, a continuous external pressure is required on each valve to maintain actuation, thus a latchable fluidic control structure has yet to be developed in this valve configuration.

#### 40.2.2 NORMALLY CLOSED<sup>21</sup> VALVES USING HYBRID DEVICES

Alternatively, the valves developed by the Mathies and coworkers<sup>3</sup> are fabricated in a normally closed architecture, as shown in Figure 40.2a, and are actuated open by vacuum, with the option of pressure to promote closing. Rather than patterning the PDMS by soft-lithography, these valves are defined by patterned glass layers (chemically etched), which sandwich a PDMS membrane. The fact that the majority of the channel architecture can be made from glass is advantageous, parleying the rigidity and chemical resistivity of the glass substrate with the system, while maintaining valving capabilities. These valves can be fabricated in either three-layer (Figure 40.2a) or four-layer (Figure 40.2b) architectures, in which the four-layer design minimizes contact with PDMS surfaces that have a known incompatibility with certain solvents and analytes.<sup>25</sup> Figure 40.2c illustrates the actuation of the three-layer valves, where a vacuum is applied to the pneumatic control chamber to open the fluid path below; this valving action is mechanically equivalent to the four-layer valve actuation. Either type of valve can be arranged into a diaphragm pumping configuration (at least three valves), with reported flow rates up to  $380\ \text{nL s}^{-1}$ ,<sup>3</sup> approximately two orders of magnitude larger

**FIGURE 40.2** Basic architecture of Mathies' normally closed valves. (a) The three-layer configuration in PDMS-glass hybrid devices and (b) the four-layer configuration (used to limit PDMS-solution contact) can be (c) actuated open to fluid flow by applying a vacuum to the pneumatic chamber at the valve seat. (Adapted from Grover, W. H., Skelley, A. M., Liu, C. N., Lagally, E. T., Mathies, R. A. *Sens. Actuat. B*, 2003, 89, 315–323.) (d) An example of the assembled four-layer device that was used to detect evidence of life in extreme environments in the MOA. (e) The preassembled MOA device. (From Skelley, A. M., et al. *Proc. Natl. Acad. Sci. USA*, 2005, 102, 1041–1046. Copyright 2005. With permission from National Academy of Science, USA.)

than the Quake pumps. An illustration of an exemplary four-layer device is shown in Figure 40.2d (assembled) and Figure 40.2e (pre-assembly). This device was utilized for amino acid detection in extreme environments with the long-term goal of searching for evidence of life on Mars.<sup>8,14</sup> Since these valves were developed three years after the Quake valves, they have been utilized in fewer applications to date. However, recent reports describe the use of these valves for DNA computing,<sup>26</sup> pressure injections for electrophoresis chips,<sup>10,27</sup> DNA sequencing,<sup>28</sup> serial dilution circuits,<sup>29</sup> and fully integrated genetic analysis devices.<sup>11</sup> A disadvantage of these valves is that the dead volume is not negligible, which is also related to the lower achievable valve density compared to the Quake valves, although the valves can be designed for <10 nL dead volume<sup>3</sup> and have shown capable of injection of samples that are submicroliter in volume.<sup>10,27</sup>

An interesting modification of this valve configuration was recently made by the Mathies group, in which the researchers showed that it was possible to fabricate “latching” structures that no longer required a continuous external stimulus.<sup>12</sup> Vacuum pulses of 120 ms were sufficient to latch the valves for up to 2 min. This was an important advance in flow control technology, because it demonstrated that  $2^{(n-1)}$  valves could be controlled with only  $n$  control lines. Although the authors showed just five inputs to control 16 valves, it should be possible to extrapolate the concept, for example, to control 1024 valves with only 11 external control lines, thereby greatly reducing the complexity of the external hardware associated with valve control.

**FIGURE 40.3** The ISI Web of Science database was searched with the subject keywords of “microfluid\* AND (valv\* OR pump\*)” through December 2006. These results were plotted as a function of publication year (solid triangles), and the totals were further limited to those which cite the initial valve descriptions by the Quake (open circles) or Mathies (open squares) group. The surge of publication since the introduction of the Quake valves is evident in either the linear plot or the inset logarithmic plot. Ninety-seven percent of the total “microfluidic valve or pump” publications in 2006 cited either the Quake or Mathies. Key reasons for the success of these valves are simplicity of fabrication, valve actuation robustness, and design scalability.

### 40.2.3 ROBUST AND SCALABLE NATURE OF ELASTOMERIC VALVING

The Quake<sup>2</sup> and Mathies<sup>3</sup> valve configurations can arguably be considered as the most robust that have been developed to date. This argument is supported by the surge in publications that have referenced these valves. Using the ISI Web of Science database,<sup>30</sup> a search was performed including the terms “microfluid\* AND (valv\* OR pump\*)” through December 2006. These results were plotted as a function of publication year (Figure 40.3, solid triangles), and the resulting publications were further limited to those that cite the initial valve descriptions by the Quake (open circles) or Mathies (open squares) group. It is clear from Figure 40.3 that the number of publications including “valves” or “pumps” began to surge after the introduction of Quake’s valves, a fact that is visually confirmed in the inset logarithm-scale plot. Although the surge could have occurred due to general scientific progress alone, this notion is refuted by the fact that an average of 76% of all the publications referenced either Quake or Mathies since 2001, with 97% in 2006. While this representation of the literature is not infallible, Figure 40.3 demonstrates the general importance of these elastomeric membrane valves. The key reasons for the success of these types of valves are the simplicity with which they can be fabricated, the valve actuation robustness, and the design scalability. The keys to “fabrication simplicity” are that the fabrication methods necessary for either configuration<sup>2,3</sup> are essentially no more complex than typical microdevice fabrication,<sup>17,31</sup> and that they have been shown to be highly scalable, for example, with  $\geq 30$  valves  $\text{mm}^{-2}$ .<sup>4,5</sup>

### 40.2.4 MANUALLY OPERATED TORQUE VALVES

For certain applications, portability and power savings outweigh the need for highly scalable, computer-controlled valving. It should be clear to those experienced in elastomeric valving on nontrivial chip-based architectures that the external hardware also becomes nontrivial in both size and complexity. A useful alternative was presented by Whitesides and coworkers,<sup>20</sup> in which torque-actuated valves were used to collapse PDMS channels, thereby closing the channels to fluid flow. The mechanistic action of these valves was similar to the Quake valves,<sup>2</sup> in that a pressure was applied above a thin layer of PDMS to collapse a fluidic channel. However, since the torque-actuated valves (coined as TWIST valves) relied on a miniature machine screw to collapse the channels, they did

not require power to maintain the valves in either the open (flow on) or closed (flow off) state indefinitely, thus functioning as latchable fluidic switches. Moreover, these valves were also shown to be amenable to settings between “on” and “off,” thereby functioning as variable fluidic resistors. The machine screws were fixed into recessed regions of the PDMS devices through a simple photochemical curing process that embedded them into polyurethane, which simultaneously bonded with the PDMS. These devices were used to carry out sandwich immunoassays.<sup>20</sup> The TWIST valves have since been proven useful for the development of entirely portable microfluidic systems capable of flow rate control, sample introduction, filtration, mixing, and bubble generation.<sup>32</sup>

### 40.3 PASSIVE MICROFLUIDIC FLOW CONTROL

Although active valves have clearly been proven as effective fluid control elements, the ultimate usefulness of these valves is inherently limited by the pneumatic interfacing problem. As demands for functionality increase, the number of valves must also increase; therefore, the controlling instrumentation often begins to overwhelm the microscale nature of the device. In this section, several methods for passive fluid control are summarized. As before, we do not intend to provide a comprehensive review of passive flow control, only a sampling of the more popular methods. Although there is limited review literature on this subject, the interested reader is referred to an informative focus article on capillarity by Eijkel and van den Berg,<sup>33</sup> who refer to passive flow control methods as “a set of everyday forces that are ‘always there’ . . . gravity, suction, and the capillary force . . .” Whenever possible, these and other passive flow control strategies should be utilized as alternatives to active valving, and active valves should be used only when necessary. Since passive components require no external stimulus, careful management of active and passive methods—working in concert—should offer the most optimal balance of instrumentation and space.

#### 40.3.1 FLUIDIC RESISTORS FOR CONTROLLED FLOW-SPLITTING

A fundamental mode of design-driven passive flow control in microfluidic devices is to utilize differential fluidic flow resistances to direct the majority of flow through the least resistant path. This straightforward, yet powerful, technique is illustrated in Figure 40.4. When a pressure greater than atmospheric pressure is applied to the inlet channel of a device, and this channel is split, by design, into two exit channels, the flow rate of fluid through these channels depends on their relative flow resistance values. The flow resistance, in turn, increases with an increase in length or a decrease in cross-sectional area of the channel. In fact, Harrison and coworkers<sup>34</sup> have outlined a simple method to calculate flow resistance values, and they showed that highly accurate flow splitting could be achieved simply by designing the channel layout accordingly. The researchers started with the expression for the average linear flow rate,  $U$ , in a rectangular channel

$$U = \frac{wd}{\eta} \frac{\Delta P}{L} F, \quad (40.1)$$

where  $w$ ,  $d$ , and  $L$  are the half-width, half-depth, and length of the microchannel, respectively;  $\eta$  is the viscosity of the fluid; and  $\Delta P$  is the pressure difference along the channel. The value  $F$  refers to a geometric form factor that depends on the ratio  $d/w$  (when  $d \leq w$ ), which can be calculated by

$$F = \frac{w}{3d} - \frac{64w^2}{\pi^5 d^2} \sum_{n=0}^{\infty} \frac{\tan h \left[ \frac{(2n+1)\pi d}{2w} \right]}{(2n+1)^5}. \quad (40.2)$$

**FIGURE 40.4** Output fluid levels at an arbitrary time point illustrate the effects of length and cross-sectional area of opposing exit channels. (a) Conceptual device designed for equal flow resistance in both exit paths, forcing the output flow rates to be equal upon application of a pressure gradient. Other devices were designed for a 10-fold larger flow resistance in the left exit path using (b) increased channel length or (c) decreased cross-sectional area, thereby forcing the output flow rates in their right exit paths to be 10-fold larger than the opposing (left) paths. (d) This behavior can be modeled using simple electrical circuit diagrams as analogs to fluidic networks.

Equation 40.1 was then manipulated to give the pressure difference as follows:

$$\Delta P = \frac{Q}{A} \left( \frac{\eta L}{wdF} \right) = Q \left( \frac{4\eta L}{(wd)^2 F} \right), \quad (40.3)$$

where  $Q$  is the volumetric flow rate and  $A$  is the cross-sectional area of the rectangular channel (note that  $U = Q/A$ ). The right-hand side of Equation 40.3 represents the Ohm's law ( $\Delta V = IR$ ) equivalent for microfluidics, in which  $\Delta P$  is analogous to the voltage drop and  $Q$  is analogous to current flow through a wire, meaning that the term in parentheses on the right in Equation 40.3 represents the fluidic resistance,

$$R = \frac{4\eta L}{(wd)^2 F}. \quad (40.4)$$

In the device of Figure 40.4a, fluidic flow rates through each exit channel are equal due to their identical flow resistance values. However, in the devices of Figure 40.4b and c, the left exit channels were designed to be 10-fold more resistant to flow than the opposing (right) exit channel. This was accomplished in the Figure 40.4b device by simply designing a 10-fold longer channel in the left exit path, while the Figure 40.4c device accomplished the identical goal by reducing the cross-sectional area of the left exit path. Essentially independent of the magnitude of the input pressure, the flow rates through these devices is 10-fold larger in the right exit path (by design), as illustrated by the fluid levels at an arbitrary time point shown in Figure 40.4a–c. This flow behavior can be accurately modeled using the analogy to Ohm's law in electrical circuits, via Equation 40.3. The electrical circuit equivalent to the devices in Figure 40.4 is shown in Figure 40.4d, where  $R_1 = R_2$  in Figure 40.4a device, while  $R_1 = 10 R_2$  in the Figure 40.4b and c device.

Unfortunately, even though control of relative flow resistances within channel networks is straightforward, it appears to be somewhat overlooked by much of the microfluidic research community. Through more judicious design constraints, researchers could benefit greatly from this simple method. Harrison and coworkers<sup>34</sup> utilized relative flow resistances to reproducibly sample small

volumes for electrophoresis injections from a much larger sample introduction channel. Landers and coworkers also used this technique for microchip electrophoresis (ME) injections from on-chip diaphragm pumps,<sup>10,11</sup> where the injection plug size was minimized by carefully designed flow splitting ratios at the injection cross-tee. Lam et al.<sup>35</sup> combined valving with flow resistances, in this case to produce a digitally variable fluidic resistor with 16 possible flow resistance values. A different approach was employed by Whitesides and coworkers,<sup>36</sup> who were able to show analog/parallel computing capability using shortest-path determinations in microfluidic mazes. City maps were used as mask patterns to fabricate channel networks, and the shortest path between two points in the “city” were determined rapidly, suggesting that parallel computing with microfluidics is a viable alternative for some computationally difficult problems.

### 40.3.2 GRAVIMETRIC CONTROL

When possible, flow control based on gravity alone can provide a simple, yet useful, alternative to active valving. These siphoning effects can provide smooth pressure profiles based on Equation 40.5. The pressure difference between input and output reservoirs,  $\Delta P$ , can be described by

$$\Delta P = \rho g L \quad (40.5)$$

with a working fluid of density  $\rho$  and height  $L$ , where  $g$  is the gravitational acceleration constant. Although it is difficult to generate large pressures using this method, it can be sufficient for many applications using channels with sufficiently large cross-sectional area (small fluidic resistance). For example, Du et al.<sup>37</sup> utilized gravity-driven flows for an automated flow injection analysis system for on-chip core-waveguide spectrometric detection of the complexation of *o*-phenanthroline with Fe(II). Highly precise flow control was achieved by Whitesides and coworkers,<sup>38</sup> who utilized reservoirs on motorized stages to adjust the  $L$  term of Equation 40.5, providing switching between forward and reverse flow. This gravity-based flow was used to control droplet fluidics for encryption and decryption of signals coded in the intervals between droplets. Disadvantages of this method include pressure variability over time due to evaporation or source depletion, difficulty in flow switching, and interference from feedback pulses based on device compliance.<sup>39</sup>

### 40.3.3 CAPILLARITY

In the aforementioned focus article by Eijkel and van den Berg,<sup>33</sup> the authors highlight the fact that capillary forces scale better with miniaturization when compared to other passive forces such as gravity, suction, centrifugation, or evaporation. To this end, Walker and Beebe<sup>40</sup> showed that useful pumping work could be performed in microfluidic systems by simply controlling the shape of droplets at fluidic input ports. They showed that the highest pressure attainable for a given port radius is a hemispherical drop with a radius equal to that of the port. A flow rate of  $1.25 \mu\text{L s}^{-1}$  was demonstrated using only a  $0.5 \mu\text{L}$  drop of water, and the method was shown to be strong enough to pump against gravitational potential. In other words, based on the Young–Laplace equation, the smaller droplet possessed a higher internal pressure than the larger drop, thus was capable of pumping against a much larger droplet in an opposing reservoir simply based on the shape of the droplet at the air–water interface<sup>40</sup> (Figure 40.5). The change in volume with respect to time was described in the following equation:

$$\frac{dV}{dt} = \frac{1}{R} \left( \rho g L - \frac{2\gamma}{r} \right), \quad (40.6)$$

where  $r$  is the radius of the small spherical “pumping” drop,  $R$  is the microchannel resistance (see Equation 40.4), and  $\gamma$  is the surface free energy of the liquid. The pressure created by the larger outlet reservoir drop of density  $\rho$  and height  $L$  is represented by the gravimetric term  $\rho g L$  (see

**FIGURE 40.5** Capillarity was shown to be a more dominant force at the microscale by a passive pumping method. The small “pumping” drop (right) was designed to provide enough capillary force to overcome the gravimetric force from the large “reservoir” drop (left), thus the flow progressed from right to left in the figure (see Equation 40.6). (Adapted from Walker, G. M., Beebe, D. J. *Lab Chip*, 2002, 2, 131–134.)

Equation 40.6), which opposes the capillary pressure but is typically much smaller in magnitude in microscale systems. This technique was shown by Walker and Beebe<sup>40</sup> to be useful for injecting a plug within a microchannel for electrophoresis applications.

Eijkel and van den Berg<sup>33</sup> also noted that the capillary pressure can be tuned by changing the contact angle or the device geometry. When pumping in this a constant cross section, the meniscus within the channel proceeds with the square root of time due to the linear increase in flow resistance as the channel fills. Different geometries and cross sections can be used to control the relative wetting of channels within a microfluidic network, providing more precise control over these autonomous systems. Kim et al.<sup>41</sup> showed this method to be capable of passive control of two merging laminar streams whose widths could be tuned based on flow resistance of downstream channels. Capillarity can also be used to control sample and sieving polymer loading for DNA separations, as shown by Ono and Fujii.<sup>42</sup> This method allows for DNA injection and separation with a simple two-electrode system.

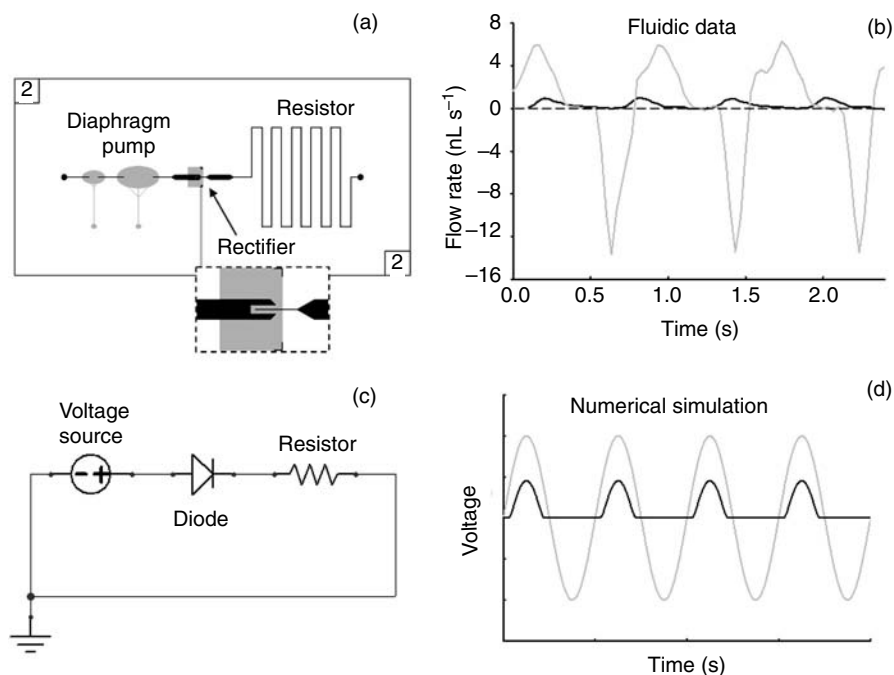

#### 40.3.4 PASSIVE STRUCTURAL COMPONENTS

Instead of merely exploiting microscale physical phenomena using simple straight-channel patterns with constant cross section, it is certainly feasible to make use of well-developed microfabrication methods for introducing flow control functionality into individual components. Although various MEMS approaches have been utilized for this purpose (as reviewed by Oh and Ahn<sup>16</sup>), many of these techniques require complex fabrication and will not be discussed here. This section focuses on more practical passive components that can be fabricated in PDMS or PDMS-glass hybrid devices, requiring minimal fabrication complexity in addition to the typical microchannel assembly methods.

Passive flow rectifiers analogous to electrical diodes have been developed by several groups.<sup>43–45</sup> In a single channel, these components allow larger flow rates in the “forward” direction over the “reverse” direction. The flow rectifiers developed by the Landers and coworkers<sup>45,46</sup> provide the most facile fabrication of any reported to date (mask design shown in Figure 40.6a, with magnified view of rectifier inset; fluidic layer in black, pneumatic in gray). These components can be fabricated alongside the normally closed valves/pumps developed by the Mathies and coworkers,<sup>3</sup> with no additions to the fabrication steps other than the essentially negligible additions to the mask design process. As shown in Figure 40.6b, the rectifiers<sup>45,46</sup> were shown to eliminate negative flow pulses that are inherent to the on-chip diaphragm pumps (flow rate of a diaphragm pump, gray trace; rectified flow, black trace). This behavior was shown to mimic the behavior of an electrical half-wave rectifier circuit (Figure 40.6c and d).

Easley et al.<sup>45,46</sup> also provided proof-of-principle data for discrete components referred to as “fluidic capacitors.” While the concept of fluidic capacitance is by no means a new concept, little work has been done to exploit this behavior in microfluidic networks. To the knowledge of the authors, only recently has there been a report that discusses the fluidic compliance of an entire microchip made up of a flexible polymer, PDMS.<sup>39</sup> In this work, which was concurrent with the work by Easley

**FIGURE 40.6** Fluidic flow rectifiers that require no additional fabrication steps above the steps required to construct the Mathies valves. (a) Mask design of a fluidic half-wave rectifier, including a diaphragm pump, flow rectifier (with inset image), and a fluidic resistor for flow visualization. Fluidic layer is in black, while the pneumatic layer is in gray. (b) Flow rate profiles from these rectifiers (black trace) revealed their success in eliminating negative flow pulses that are inherent to the on-chip diaphragm pumps (gray trace). The fluidic flow rate profiles matched qualitatively with the behavior of an analogous electrical circuit, (c) a half-wave rectifier using a voltage source in series with a single diode, where the (d) voltage profiles of the pump (gray trace) and the rectified flow (black trace) are shown here. (Adapted from Easley, C. J., et al. *Micro-Total-Analysis-Systems, 10th International Conference on Miniaturized Systems for Chemistry and Life Sciences*, Tokyo, Japan, November 2006.)

et al., Beebe and coworkers showed that the dynamic characteristics of the entire system were similar to a lowpass filter in electrical circuits. However, there were no attempts to exploit these effects using individual microfluidic components. Easley et al. proposed the use of discrete components to control the fluidic capacitance of individual fluidic networks within the same device.<sup>45,46</sup> This treatment was based on the electrical analogy, where the volumetric flow rate,  $Q$ , through microchannels in the presence of compliant membranes is dependent on the time derivative of the pressure,  $P$ , through the channel as below:

$$Q = C \frac{dP}{dt}, \quad (40.7)$$

where  $C$  is the fluidic capacitance in units of  $\text{mm}^3 \text{kPa}^{-1}$ , representing the volume stored in the compliant membrane per applied pressure. This way, the frequency response of a first-order system could be characterized based on similar equations. For example, a low-pass or high-pass filter could be characterized by its cutoff frequency,  $f_0$ , at which the power output of a circuit is reduced to one-half of its maximum value. Using the fluidic capacitance and resistance analogies presented above, the fluidic cutoff frequency can be calculated by

$$f_0 = \frac{1}{2\pi RC}. \quad (40.8)$$

**FIGURE 40.7** Characteristic frequencies could be shifted by an order of magnitude by locally altering PDMS membrane thicknesses (“fluidic capacitors”). Different curves represent different combinations of the thicknesses of two fluidic capacitor components in the same fluidic network. These fluidic bandpass filters provide the proof-of-concept of a new paradigm in microfluidic flow control, where actuation frequency could be used to passively control relative flow rates.

This equation was also deduced by Beebe and coworkers.<sup>39</sup> In fact, Easley et al.<sup>45,46</sup> have recently shown that multiple fluidic capacitor components could be combined to produce actuation-frequency-dependent control over flow rates through microfluidic networks. These fluidic bandpass filters with tunable fundamental frequencies, which should provide a new paradigm in flow control, are currently in development. As shown in Figure 40.7, the fundamental frequencies of the fluidic bandpass filters could be shifted by an order of magnitude, from 0.7 to 8.0 Hz, by simply altering the thicknesses of the deflectable PDMS layers (fluidic capacitors) at discrete locations within the network. Combinations of membrane thicknesses between 50 and 500  $\mu\text{m}$  were used in this work (see legend in Figure 40.7).

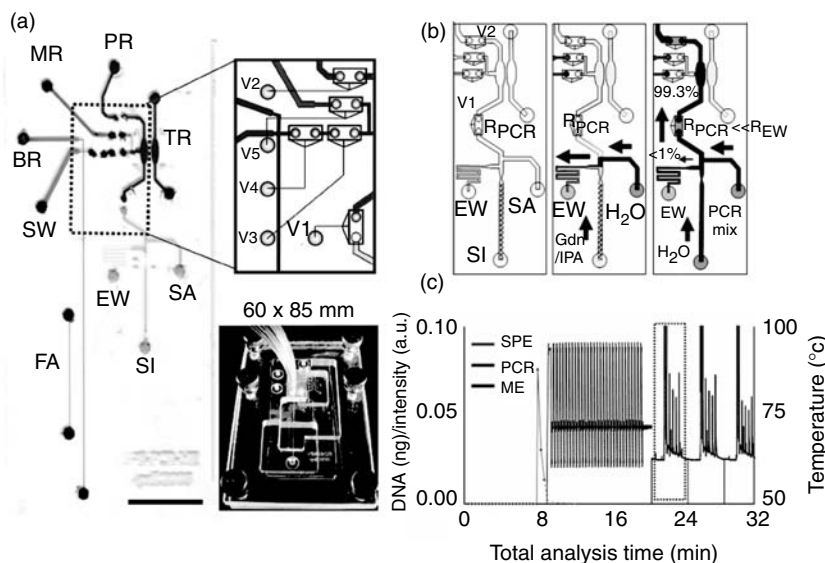

Finally, Kartalov et al.<sup>13</sup> recently presented a straightforward method for creating microfluidic vias, which allowed solutions to be passed between multilayers of channel networks. The fabrication of these vias was consistent with the multilayer soft-lithography methods<sup>17,18</sup> used by Quake and coworkers.<sup>2</sup> A novel, passive flow shaping component, coined an “autoregulator,” was enabled using these vias. The autoregulator was shown to provide the fluidic equivalent to an electrical current source, in which the output flow rate was essentially independent of input pressure above a certain threshold pressure.<sup>13</sup> These components were also shown to possess flow rectification character. With further development of the types of passive components outlined in this section—ones that are complimentary to the now well-developed valving techniques—the true potential of microfluidic flow control could be realized.

#### 40.4 APPLICATIONS OF ACTIVE VALVING SYSTEMS

As illustrated by Figure 40.3, microfluidic valving techniques have proven highly useful in recent years. The Quake valves, in particular, have been put to use for a wide variety of functionalities from synthesis to genetic screening. Hansen et al.<sup>24</sup> developed a method for the screening of conditions for protein crystallization based on free-interface diffusion. The researchers were able to accurately meter solutions on the picoliter scale in a highly integrated and parallel fashion. A spectrum of screening conditions, covered by 144 parallel reactions, was carried out with each using only 10 nL of protein sample, to allow growth of diffraction-quality crystals. The device was shown to outperform conventional techniques, while using a mass of protein sample that was smaller by two orders of magnitude. More recent work has shown this technique to be useful for crystallizing challenging proteins by using knowledge of phase behavior to generate more rational

screening tests.<sup>47</sup> Balagadde et al.,<sup>23</sup> with the device shown in Figure 40.1d and e, utilized the Quake valves to provide long-term programmed population control of bacterial in a microchemostat. A feedback mechanism, based on bacterial quorum sensing, was used to regulate the cell density of extremely small cell populations with single cell resolution over hundreds of hours. Lee et al.<sup>9</sup> fabricated a “miniature chemical factory” for multistep synthesis of a radiolabeled molecular imaging probe, 2-deoxy-2-[<sup>18</sup>F]fluoro-D-glucose, in an integrated microfluidic device. The device was able to carry out five sequential processes: [<sup>18</sup>F]fluoride concentration, water evaporation, radiofluorination, solvent exchange, and hydrolytic deprotection. This automated method provided high radiochemical yield and purity with shorter synthesis time relative to conventional automated synthesis, and the products were used successfully for positron emission tomography (PET) imaging in mice.

The Mathies valves have also found practical use for a variety of applications. Indeed, the slight chronological shift associated with the development of the Mathies valving system compared to the Quake system (Figure 40.3) suggests that the Mathies valves will perhaps adopt a similar trend. Skelley et al.<sup>8</sup> have developed a Mars Organic Analyzer (MOA) (device schematic shown in Figure 40.2d and e), which was capable of detecting a molecular signature of life (homochiral amino acids) in the Atacama Desert, Chile, and in the Panoche Valley, CA—two of the driest locations on Earth. The integrated and portable MOA system consisted of a microfabricated capillary electrophoresis instrument for sensitive amino acid biomarker analysis, along with the necessary high voltage power supplies, pneumatic controls, and fluorescence detection optics, and was capable of amino acid detection in mineral deposits as low as 70 parts per trillion. This system has since been shown to be capable of analyzing a wide variety of fluorescamine-labeled amine-containing biomarker compounds, including amino acids, mono and diaminoalkanes, amino sugars, nucleobases, and nucleobase degradation

**FIGURE 40.8** A clever combination of the Mathies valves and passive flow control methods allowed full integration of sample cleanup and analysis steps directly from blood or nasal aspirates, resulting in (a) a microfluidic genetic analysis (MGA) device. (b) The combination of valving, laminar flow, and differential channel resistances was used to prevent fouling of PDMS valves with incompatible solvents when transitioning from SPE to the PCR. (c) SPE and PCR were then coupled to ME using valve-based pumping to inject the purified DNA sample. The presence of *Bacillus anthracis* could be detected directly from murine blood in less than 24 min, and multiple injections were allowed using the valves to confirm the diagnoses. (From Easley, C. J., et al. *Proc. Natl. Acad. Sci. USA*, 2006, 103, 19272–19277. Copyright 2006. With permission from National Academy of Science, USA.)

products.<sup>14</sup> The Mathies group has also applied their valves to DNA sequencing on a microfluidic format,<sup>28</sup> integrating thermal cycling, sample purification, and capillary electrophoresis.

The Landers and coworkers<sup>27</sup> first utilized the Mathies valves to show their utility for pressure injection on a microfluidic format, then applied this technology to the integration of DNA amplification (polymerase chain reaction, PCR) with electrophoretic separation.<sup>10</sup> As shown in Figure 40.8, this technology was combined with upstream sample cleanup (solid-phase extraction, SPE) of crude clinical samples such as blood and nasal aspirates, providing fully integrated genetic analysis in <30 min.<sup>11</sup> The device architecture is shown in Figure 40.8a, flow control steps between SPE and PCR are illustrated in Figure 40.8b, and the results of a <24 min detection of *Bacillus anthracis* directly from the blood of an asymptomatic mouse are shown in Figure 40.8c. This work provided true sample-in, answer-out analyses of complex samples, as predicted by Manz et al.<sup>1</sup> over a decade ago. The work was carried out on a relatively simple device design, for the authors utilized a creative combination of active and passive flow control methods to interface the SPE and PCR steps (Figure 40.8c), where laminar flow and relative flow resistance values were exploited to prevent incompatible solvents from contacting the PDMS valves. Most recently, Guillo et al.<sup>15</sup> used these valves for pressure mobilization of focused protein zones following isoelectric focusing (IEF) to provide a robust microchip alternative to conventional IEF.

## 40.5 VALVE FABRICATION AND IMPLEMENTATION GUIDELINES

This section provides brief summaries of fabrication methods and instrumentation requirements associated with the microfluidic, pneumatic valving techniques outlined above. This section is meant to provide a general guide for fabrication. For more detailed descriptions of chip fabrication methods, see Chapter 10 by Legendre and Landers. Readers interested in implementing these valving techniques should refer to the original publications<sup>2,3,22</sup> for details and/or clarity. The organization of this section parallels that of Section 40.2 in that the normally open and normally closed valve configurations are separately described.

### 40.5.1 NORMALLY OPEN VALVES USING SOFT LITHOGRAPHY

In order to achieve either the push-down<sup>2</sup> or push-up<sup>22</sup> versions of the Quake valves, as shown in Figure 40.1a and b, standard multilayer soft-lithography equipment is necessary. For either valve configuration, typically a layer of SU-8 (negative) or AZ (positive) photoresist is spun onto two silicon wafers to the desired thicknesses. One wafer is then exposed to UV radiation using the fluidic photomask, while the other is exposed using the pneumatic photomask. The fluidic layer master is fabricated out of AZ photoresist, which can then be reflowed with heat to give a rounded channel profile, and the pneumatic layer is fabricated out of SU-8 photoresist. The methods deviate at this point, for the push-down valves (Figure 40.1a) require the fluidic layer to be below the pneumatic layer, while the push-up valves (Figure 40.1b) require the opposite. A thin PDMS film (10–100  $\mu\text{m}$ ) is then spun onto the lower layer's master (whether fluidic or pneumatic), with the thickness of the PDMS above the master determining the valving membrane thickness. A thick film of PDMS (1–10 mm) is simply poured onto the opposing layer's master, at which time the two layers are cured, then the upper layer is peeled from the master, aligned with the lower layer, and mated. In order to mate the two layers, it is often preferable to prepare the thin PDMS film with an excess of elastomer base ( $\sim 20:1$ , base:curing agent), while the thick film is prepared with an excess of curing agent ( $\sim 5:1$ , base:curing agent).<sup>2</sup> This way, the two layers can be essentially fused into one by heating postassembly at 60–80°C for 1–2 h. Finally, the PDMS device is peeled from the master, access holes are punched, and the device is completed by either mating with another (unpatterned) layer of PDMS or a glass slide.

Note that the push-down valves (Figure 40.1a) require approximately an order of magnitude larger pneumatic actuation pressure to close than do the push-up valves (Figure 40.1b) due to the preferential geometry of the push-up configuration.<sup>22</sup> Furthermore, the fluidic channels in the push-down configuration are restricted to a depth of less than  $\sim 20 \mu\text{m}$ , while the push-up valves will function with much deeper channels while simultaneously requiring lower pressures. However, in cases where sample contact with a glass substrate (or some other material mated to PDMS) is necessary, such as high-resolution confocal microscopy, the push-down valves must be used due to the lower position of the fluidic layer. On the other hand, the recently developed microfluidic via technology<sup>13</sup> may provide a remedy to this problem in some cases.

#### 40.5.2 NORMALLY CLOSED VALVES USING HYBRID DEVICES

When a normally open configuration is not sufficient, or when glass fluidic devices are preferred over PDMS devices, the Mathies valve configuration provides a useful alternative.<sup>3</sup> These valves also have two configurations, the three-layer (Figure 40.2a) or four-layer (Figure 40.2b) mode. When PDMS material compatibility is not an issue, the three-layer configuration should be adequate. However, if certain reagents are incompatible, the four-layer configuration can be used instead to minimize PDMS/solution contact. With either configuration, the photolithographic patterning is carried out in a glass substrate rather than PDMS. The PDMS portion of these devices can simply be purchased in thin sheets, and slices can be cut to the appropriate size. Glass slides can be purchased with prespun photoresist, and fluidic/pneumatic layers can be etched into these slides using standard wet etching methods with hydrofluoric acid (HF). (*Warning: Exposure to HF can produce harmful health effects that may not be immediately apparent, such as destruction of deep tissue and even bone. Extreme care should be taken when working with these solutions.*) For the three-layer configuration, the PDMS layer (valving membrane) is then sandwiched between the aligned fluidic and pneumatic layers. With the four-layer configuration, access holes must be drilled into another glass slide, in alignment with the valves (two holes per valve), and this slide must be thermally bonded to the fluidic layer.

Although the fabrication of these valves is relatively simple, common problems associated with these valves include delamination of the PDMS layer from the glass layers at higher fluidic or pneumatic pressures, resulting in sample or solvent leakage. In addition, the dead volume of these valves is not negligible, and care must be taken to avoid bubble trapping within the valve seats, especially in the four-layer configuration (Figure 40.2b). Then again, there appears to be no evidence of an upper-limit restriction on fluid channel depth, for the valve actuation dimensions are separate from those of the fluid channel.

#### 40.5.3 INSTRUMENTATION REQUIREMENTS

The common theme in these microfluidic valving systems is the requirement of a vacuum or pressure pump/compressor that is used to actuate the pneumatic lines that are interfaced with the on-chip valves. These pneumatic lines, in turn, are usually controlled individually using computer-operated solenoid valves with the corresponding circuitry and manifolds. Various tubing can be used to connect each solenoid valve to the corresponding microfluidic interface. Interfacing to the device can be accomplished through a variety of means, which are not discussed here. Interested readers should refer to the cited works that are particularly relevant to their own research.

#### 40.6 CONCLUDING REMARKS

In writing this chapter, the intent of the authors was to provide the reader with a rudimentary knowledge of the practical aspects associated with elastomeric valving technology—one that could be directly implemented in the laboratory. At this point, the reader should have a basic understanding of the mechanics of actuation for the two featured valving methods,<sup>2,3</sup> as well as an understanding

of how innovative design of passive components can considerably improve flow control with or without valves in place. It should be noted that for many microfluidic applications, the exquisite control of small volumes that is attainable with these valves and components is unparalleled. Thus, researchers should not be hesitant to implement these techniques in their laboratories. In the years to come, once microfluidic researchers have a set of tools comparable to the various active and passive circuit components available to electrical engineers, many previously undiscovered avenues of experimentation will undoubtedly be revealed.

## 41.1 INTRODUCTION

The amazing research field related to miniaturized systems has provided a true revolution in analytical and bioanalytical sciences in the past two decades. An exponential increase in the number of publications has been observed since the concept of a micrototal analysis system ( $\mu$ TAS) was first reported in the early 1990s. Short analysis time, reduced reagent consumption, low waste production, and unprecedented device portability are key features of a  $\mu$ TAS. These, combined with the integration of other analytical procedures, provide advantages that have stimulated the scientific community to explore the value of executing analysis in the microworld.<sup>1–4</sup> Since the first report in literature,<sup>5,6</sup> a large number of materials and microfabrication techniques have been theorized, investigated, and developed in microfabrication sciences.<sup>1–4</sup>

Standard techniques based on photolithographic processes have been extensively used to fabricate micromachined systems, and the details associated with these techniques can be found in Chapter 10 by Legendre. The initial development of  $\mu$ TAS was focused on glass or quartz substrates to create microdevices. Both materials imparted the advantages associated with low electric conductivity and high thermal conductivity, thus allowing the use of high voltages, providing good transparency for optical detection and most importantly, well-developed surface chemistry.<sup>5,6</sup> However, the conventional microfabrication processes are laborious, time consuming, and present a relatively high cost per device.

Furthermore, the standard processes can require some sophisticated instrumentation, particularly if located in costly cleanroom environments, some of which are not always readily accessible to the

researchers. For this reason, the quest for simple and low-cost procedures is a constant focus for all the scientific community.

As a result, the introduction of new types of materials has offered new ways for the fast, low-cost prototyping of microdevices of the disposable nature. In this light, the inexpensive nature of certain polymeric materials presents unique opportunities for microchip fabrication, and there is a significant interest in the development and use of these as substrates. One of the primary advantages of most polymeric devices is that they can be fabricated outside of the clean room environment.<sup>2–4,7</sup> The emerging use of polymers can be attributed largely to their enhanced biocompatibility, great flexibility, reduced cost, and easy processing.<sup>7,8</sup> Various polymeric materials have been used to create microfluidic devices including poly(methyl methacrylate) (PMMA),<sup>8,9</sup> poly(carbonate),<sup>10</sup> photoresists (e.g., SU-8),<sup>11</sup> Zeonor 1020<sup>12</sup> and, obviously, poly(dimethylsiloxane) (PDMS).<sup>13,14</sup> A variety of techniques have been utilized for the manufacture of polymeric microstructures including laser ablation, X-ray lithography, injection molding, and imprinting from masters templates.<sup>2–4</sup> Although these techniques are simpler, in some ways, than those used in glass and quartz  $\mu$ chip fabrication, they still require sophisticated instrumentation for the micromachining and production of the molding template.<sup>2–4</sup>

This chapter presents some detailed fundamentals of low-cost technologies that can be used to produce microchannels, microelectrodes as well as integrated systems using the low-cost instrumentation commonly found chemical/biochemical laboratories. The main goal of this chapter is to enable the reader with rapid prototype capabilities for lab-on-a-chip fabrication without a significant investment in specific instrumentation, cleanroom facilities or time.

All fabrication techniques presented here are based on the use of toner from office laser printers, which is used to print a layout on a transparency film or a wax paper sheet. The transparency film is essentially used as a poly(ethylene terephthalate) (PET) substrate for polyester-toner (PT) microchannels preparation. The wax paper is used as an initial surface onto which the pattern is printed—the patterns are subsequently transferred either to a recordable compact disks (CD-R) or a glass surface. In either case, this transference is carried out with heat and pressure using the type of heat transfer machine that is used for T-shirt transfer machine or, in more sophisticated form, a tool similar to that used for hot embossing.

## 41.2 FUNDAMENTAL ASPECTS

### 41.2.1 A BRIEF HISTORY

The potential for the use of toner in microfabrication technology has a short but promising history that originated at the beginning of this century. Tan et al.,<sup>15</sup> introduced a simple method for the fabrication of PDMS microchips by using a photocopier to produce a high-relief master on polyester film. This low-cost master was employed to produce channels in PDMS using a replica molding process. This pioneering work, using toner-assisted microfabrication science, yielded channels in a PDMS substrate in less than 1.5 h.

do Lago et al.<sup>16</sup> proposed a direct-printing process for fast and direct production of microfluidic devices at a very low cost. In this process, a laser printer is used to selectively deposit a toner layer on a polyester film, which is subsequently laminated against a blank polyester film (single toner layer, STL) or against a mirrored image of the layout (double toner layer, DTL). Compared to the proposed technique by Tan et al.,<sup>15</sup> the direct-printing process makes possible the fabrication of microchips in a matter of minutes, not hours. Furthermore, tens of devices can be simultaneously printed over a single transparency sheet. This simple and inexpensive technology has been used to fabricate electrophoresis microchips coupled to end-channel amperometric<sup>17–19</sup> and contactless conductivity detection.<sup>16,20</sup> Electro spray<sup>16</sup> and mixing<sup>21</sup> microdevices have also been proposed by using do Lago's process, as well as the production of printed masters for prototyping of PDMS microchips.<sup>22</sup>

Daniel and Gutz<sup>23</sup> have used this direct-printing process for quick production of both single or multiple coplanar gold electrodes and microfluidic flow cells, as well as microfluidic cells with interdigitated gold electrode array.<sup>24</sup> In their work, the layouts were laser printed on a wax paper, and thermally transferred onto the gold sputtered CDtrodes' surface. This same technology was used to fabricate disposable twin gold electrodes for amperometric detection in conventional capillary electrophoresis<sup>25</sup> (CE) and microchip electrophoresis.<sup>20</sup> Lowinsohn et al.<sup>26</sup> have recently reported the fabrication and characterization of inexpensive gold-disk CDtrodes using toner masks, while obtaining highly reproducible electrode area. The relative standard deviation (RSD) for the voltammetric response of 10 different CDtrodes was below 1% for a 2 mmol L<sup>-1</sup> solution of K<sub>4</sub>Fe(CN)<sub>6</sub>.

Recently, do Lago et al.<sup>27</sup> proposed a new process to fabricate glass-toner microdevices. In this new approach, laser printers do not print the layout directly over the glass surface. Alternatively, the layout is to be first printed on a wax paper and then transferred onto glass surface by heating under pressure. In fact, following the printing step, each layout can be cut out and positioned (like a decal) over a glass wafer for thermal transference. In a manner similar to the steps used for preparing CDtrodes,<sup>17,23–26</sup> heating under low pressure allows transfer of the toner from wax paper to the glass surface. These glass-toner devices present a specific functional advantage in that higher electroosmotic flow (EOF) is generated than in PT devices, primarily because of the greater silanol content in the bottom and top surfaces of the channels. Using the same approach, free-flow electrophoresis in glass-toner microchips have also been recently proposed by the same group.<sup>28</sup>

Liu et al.<sup>21</sup> proposed the use of the direct-printing process to fabricate passive micromixers in microfluidic devices. Micromixers were projected by applying a gray-scale coloring of the graphic software. This gray-scale effect provides the presence of toner particles into channel that act as obstacles to the flow stream for advection mixing, allowing these particles to be used as efficient mixing elements. Vullev et al.<sup>29</sup> used this concept of the direct-printing process to print positive-relief masters on smooth substrates. In fact, although the authors have not referenced previously reported works,<sup>16,17,22</sup> in this “nonlithographic” process, the masters were printed over a polyester film just as previously proposed for PT microdevices fabrication<sup>16,17</sup> as well as for the masters production for rapid prototyping of PDMS channels.<sup>22</sup>

### 41.2.2 THE WORKING PRINCIPLE

It is well known that UV photolithography is a standard protocol to transfer an image from a mask to a planar surface of a substrate such as glass, silicon, or quartz (see Legendre Chapter 10 for details). In this case, the layout drawn on a mask is exposed to UV-radiation and patterned on a photosensitive layer (photoresist). After light patterning step, a wet chemical or dry etching step is often employed to create channels in the substrate surface after removing the photoresist layer. In this step, the resulting channel can have an isotropic or anisotropic profile, depending on both the material and etch solution characteristics. The bonding of these etched channels is often performed by a thermal bonding step, which requires elevated temperature. Even though this high-end technology allows researchers to develop well-defined microstructures with desired aspect ratios, these steps are laborious, time consuming, and require expensive equipment, thus driving the search for alternative methods for fabrication with inherent simplicity and lower cost.

To the best of our knowledge, the direct-printing process proposed by do Lago et al.<sup>16</sup> is the simplest, easiest, fastest, and least expensive microfabrication process of all those described in the literature. Basically, this process can be explained by the working theory of a laser printer. When you design a layout by using graphic software, this layout is sent to a laser printer that selectively deposits a toner layer over a surface (paper or transparency film). The graphic software should be able to prepare the layouts on a 1:1 scale and for their printing without geometrical aberrations.

Toner is a complex powder deposited by a laser printer to form an image (in our case the channel walls). Laser printers force toner powder to form the desired image on the polyester film and as

**FIGURE 41.1** Typical EDX spectrum of (a) toner sample and (b) toner particle deposited by laser printer. (Reprinted from Coltro, W.K.T. *Fabrication and Evaluation of Electrophoresis Microdevices with Electrochemistry Detection*, Sao Carlos, 2004, 126 p. Dissertation (Master in Science). Institute of Chemistry at Sao Carlos, University of Sao Paulo. Online available at: <http://www.teses.usp.br/>)

a final step, the toner image is melted onto the surface. In this process, the toner started off as a powder, passed through a fluid, and ended up as a solid structure bonded to the transparency sheet or to wax paper surface. At the chemical level, toner is constituted mainly of iron oxide (50–55% w/w) and a polymeric resin (45–50% w/w). Other pigments or ingredients can be added according to the manufacturer. Figure 41.1a shows a typical spectrum obtained by energy dispersive X-ray (EDX) spectroscopy for a toner sample—the spectrum reveals the presence of iron and oxygen. The gold that is present results from the metal deposition for a previous scanning electron microscopy (SEM) analysis, presented in Figure 41.1b. In the EDX spectrum, it can also be seen that chlorine is present, probably the result of residual  $\text{FeCl}_3$ . Interestingly, the polymeric resin is composed of two components: PMMA (ca. 20%) and poly(styrene) (ca. 80%).<sup>16,17</sup> The other material used in this microchip preparation, the PET film, is coated with a thin layer of silica with a thickness that varies depending on the manufacturer. X-ray photoelectronic spectroscopy (XPS) experiments showed the presence of silicon (ca. 0.6% estimated as  $\text{SiO}_2$ ) over the polyester film.<sup>18</sup> While the magnitude of EOF on glass or PDMS chips basically correlates with the extent of deprotonation of the silanol groups, this is not trivial on PT chips. Here, the parameters affecting EOF in this hybrid, highly complex system are numerous and not well understood, since the bottom and the top of channel are made up of silica doped PET and the channel walls are made up of toner. However, the low abundance of silica in the channel explains the low EOF found in PT microchips, which is typically 10 times lower than glass and PDMS devices.<sup>17</sup>

As described previously,<sup>16,17</sup> the limitation of this low-cost fabrication technology is related to the laser-printer resolution. Theoretically, a laser printer with 600 dots per inch (dpi) resolution could be used to print 50- $\mu\text{m}$  width channels because such resolution (600 dpi) is about 42  $\mu\text{m}$ . However, toner layer is composed of smooth particles that are of irregular round or elliptical shape, with dimensions around  $6 \times 8 \mu\text{m}$  (see Figure 41.1b). Experimentally, it is possible to produce channels with 50- $\mu\text{m}$  width, however, with limitations such in the channel definition and possible appearance of edge regularity. Furthermore, the presence of some toner particles in narrow channels at the mentioned dimension (50  $\mu\text{m}$ ) can result in partially or completely obstructed channels. The RSD for channels with 50- $\mu\text{m}$  width is around 25% with the high RSD inherently related to the printing process. For channels having a width in the 150  $\mu\text{m}$  to 1 mm range, this parameter is decreased to 10% and 3%, respectively ( $n = 10$ ).

While glass, silicon, or quartz channels are often thermally bonded at high temperatures (550–650°C), the PT channels are bonded by a thermal lamination step in a standard office laminator. The lamination should be carried out at temperature high enough to provide a desired seal between

the toner and the polyester (STL), or to other toner layer (DTL). For STL channels, the printed channel is bonded against a blank transparency (i.e., a transparency cover without toner layer), while for DTL channels, the printed layout should be firstly aligned with its mirror image, and subsequently laminated together. During the lamination step, the toner layer binds by fusion on the blank transparency or against another toner layer providing a stable sealing. After the bonding process, a monolithic structure of polyester and toner results with channels and reservoirs produced where no toner was deposited.

### 41.2.3 REQUIRED INSTRUMENTATION

The direct-printing process does not require any sophisticated instrumentation. Basically, two pieces of equipment are required as fundamental tools: a computer equipped with graphic software (e.g., Corel Draw, AutoCad, Macromedia FreeHand, or Microsoft Power Point) and a laser printer (although different brands provide different results as will be discussed later). Accessories such as an office laminator, a heating press (T-shirt transfer machine), and a paper driller represent the low-cost tools we have used. Finally, polyester films (transparency films or overhead projector films), wax paper sheets, a commercially available toner cartridge, microscope slides (glass) and CDs are the consumables, since they are used to produce microchips, microelectrodes, and integrated systems at very low cost.

For the sake of comparison, the acquisition of this standard office equipment costs less than 3000 U.S. dollars. In contrast, the cost of a standard microfabrication laboratory including medium-size cleanrooms, photo exposure devices, and spinners, for example, is close to one million U.S. dollars. Even though a Class 100 laminar flow cleanhoods are substantially less expensive, the total amount involved is still elevated. In addition to hardware costs, the comparative price of consumables for the low-cost and standard techniques is staggering. While a toner cartridge, polyester films, CDs, and wax paper can be obtained for a few hundred dollars, the purchase of photoresists, developer, and remover solutions, as well as wafers (e.g., glass and silicon substrates) may amount to several thousand dollars. Furthermore, the mask price used in the UV-exposure step can range from \$20 to \$300, depending on the chosen technology.

## 41.3 THE DIRECT-PRINTING PROCESS

The direct-printing technology has been used for several applications including electrophoretic microchips,<sup>16–20</sup> Cdtrodes<sup>23–26</sup> for amperometric detection in conventional capillary<sup>25</sup> and microchip electrophoresis,<sup>17</sup> microfluidic cells with interdigitated Au–Cdtrodes,<sup>23,24</sup> electro spray,<sup>16</sup> and micromixers<sup>21</sup> devices. Electrophoresis microchips with integrated electrodes for contactless conductivity detection,<sup>20</sup> glass-toner chips,<sup>27</sup> microchip free-flow electrophoresis,<sup>28</sup> as well as glass-etched channels<sup>32</sup> have recently been proposed using the direct-printing technique in one or more stages during the device preparation.

### 41.3.1 PT MICROCHIPS FABRICATION

The PT microchip fabrication is depicted on Figure 41.2, where the production of both (A) STL and (B) DTL channels are shown. For both types channel microfabrication, the first step is related to the projection of the desired layout using any applicable graphic software such as Corel Draw, AutoCAD, and Macromedia Freehand. The drawn layout is sent to the laser printer that prints the image on a transparency film (I) carefully positioned on the printer tray. In this procedure, the white color is used, during the drawing step, for the regions where microfluidic channels and reservoirs (and consequently the channel width) are desired (II). On the other hand, the toner layer not only defines the channel walls but, consequently, also the channel depth. The thickness of the toner layer deposited on polyester surface depends of three main factors: (1) printing mode, (2) printer

**FIGURE 41.2** Step-by-step procedure of the direct-printing process for (a) STL and (b) DTL. (I) Polyester film; (II) printed layout over the PET film; (III) printed layout with aligned cover [blank polyester in (a), or printed mirror image in (b)] containing holes for accessing the microfluidic network; (IV) laminated STL and DTL chips; and (V) microdevices with solution reservoirs. In this scheme, the toner layer and the reservoirs glued on polyester film are depicted by A and B, respectively.

resolution, and (3) printer brand. Using a Hewlett Packard LaserJet printer and working at vectorial, best quality printing mode, the thickness is around  $7 \pm 1 \mu\text{m}$ . Minor differences have been observed in the channels defined by using laser printers with 600 or 1200 dpi resolution. The main observed difference is that, for 1200 dpi, the toner layer is more compact than for 600 dpi, which will be relevant only in toner-based lithography.<sup>32</sup> Significant alterations will appear when using high-resolution laser printers ( $\geq 3000$  dpi) similar to photoplotters commonly employed to print masks for photolithography.

For the simplest case shown at Figure 41.2, the STL channel, the printed channels are laminated against a blank polyester film (containing no toner), where the STL channel is defined solely by one toner layer. Consequently, the channel depth is close to toner layer thickness (i.e.,  $7 \mu\text{m}$ ). The DTL channels, require the use of two toner layers, which ultimately yields an improved aspect ratio. However, since office laser printers were not projected to have to meet the needs of the analytical microfabrication community, perfect alignment of both layers in repetitive printing steps is almost impossible. The strategy found for do Lago et al.<sup>16</sup> was to make these DTL channels by printing the desired layout and its mirror image simultaneously on the same polyester film. Then, both structures were aligned on top of each other for a DTL device.

Following the printing step, but before the lamination step, it is necessary to create access holes to the microfluidic network on PT chips, these can simply be made by using an office paper drill. This step is obviously much simpler (and faster) than preparing holes in glass channels with specialized drilling tools (see Chapter 10 by Legendre). The bonding step of the PT channels is provided by thermal lamination, but only after the printed channel and its cover (with holes) have been carefully aligned (III). For DTL channels, special attention should be given to this step because the alignment between the printed layout and its mirror image needs to be exact in order to avoid

channel obstruction during the lamination step. The use of alignment markers or guidelines on the layout optimizes repeatability in chip-to-chip fabrication.

The lamination step, typically taking 40–50 s for each microdevice, however, the temperature at which this is carried out represents an important variable. The optimum temperature is around the melting point of the toner (i.e., 120°C) if the working temperature is below this value, repetitive lamination steps (two or three times) will be required in order to avoid fluid leakage. Since the transparency film inherently is hydrophilic in nature, it is necessary to contain the buffer solutions in reservoirs; otherwise, the fluid will spread out over the surface via capillarity. The reservoirs can be prepared by gluing small cylinders (V), constructed from the base of 100  $\mu\text{L}$  pipette tips or poly vinyl chloride tubes onto the polyester surface using a bicomponent epoxy resin. It is strongly recommended that the internal diameter (i.d.) of these reservoirs be larger than the diameter of the access holes (access to the microfluidic network) in order to avoid blockage of the channel entrance. The glue curing time for the preparation of reservoirs consumes the longest portion of the fabrication time (ca. 10 min) in this low cost process. Likewise, a silicon or glass wafer can be explored to micromachine several layouts simultaneously, a polyester sheet can also be used to prepare many more devices in a same printing step. This advantage comes from the fact that a letter or A4 size sheet has a total area four times larger than the area of a standard wafer (25 in.<sup>2</sup>).

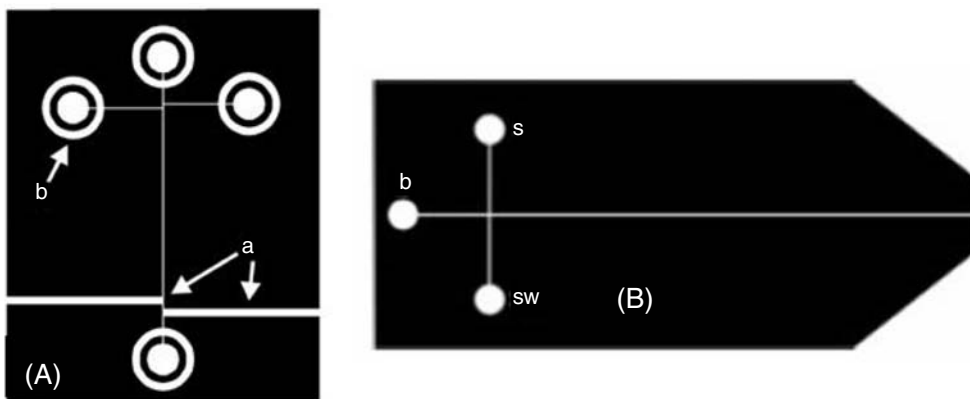

As described here, the direct-printing process is highly dependent on the laser-printer resolution. Consequently, in this respect, the definition of the PT channels is worse when compared to glass and PDMS chips produced by conventional photolithography. Figure 41.3 shows three micrographs obtained by SEM depicting the surface of channels typically obtained in PT (Figure 41.3a), the edge from channel to the bulk toner (Figure 41.3b), as well as a cross-sectional profile (Figure 41.3c) of two channels. The presence of many toner particles inside the channel as well as a significant roughness to toner wall is illustrated by Figure 41.3a and b. Figure 41.4 presents two examples of electrophoresis microchips fabricated in PT using DTL channels format. For capacitively coupled contactless conductivity detection (C<sup>4</sup>D) measurements, the PT chips have been projected with a double-T format injection channel,<sup>16,20</sup> while for amperometric detection, a simple cross-channel has provided satisfactory results.<sup>17–19</sup>

### 41.3.2 MICROELECTRODE PREPARATION

The toner material and the direct-printing approach may not only be used for PT microchannel fabrication but also to produce a great variety of features, devices, or elements for analytical microsystems. For example, other essential elements for electrophoresis microchips are the

**FIGURE 41.3** SEMs for an intersection of injection and separation 150- $\mu\text{m}$ -wide channels (a), toner surface at channel wall (b), and a transversal cut of a DTL channel (c). electrodes. The preparation of microelectrodes can also benefit from this direct-printing process, that is, electrodes for both electrokinetic control and electrochemical (EC) detection. Simultaneously to release of this technology, Daniel and Gutz<sup>23</sup> described an innovative method to manufacture gold microelectrodes using commercial recordable CD as metal source.<sup>31</sup> In this method, depicted in Figure 41.5, the direct-printing process is used to print the electrode design over a wax paper (a), of the same type used as a support for commercially available adhesive labels. Then, this printed image is thermally transferred onto the CD gold layer (b), from which the protective film was previously removed with  $HNO_3$ .<sup>31</sup> Commonly, the thermal transference is carried out in a thermal press at  $120^\circ C$  for 90 s under a pressure of approximately 0.1–0.5 MPa. Following the toner transference, the wax paper is easily removed from CD surface, similarly to a decal step. The toner-free gold areas are etched away (c) by a short exposure to an iodide/iodine solution. After this etching step, the toner is selectively removed with the help of a cotton swab soaked with acetonitrile, exposing the underlying gold layer (d) and, thus, producing the electrodes.<sup>23</sup> An amplified image from a dual electrode is presented in Figure 41.5e.

Richter et al.<sup>25</sup> have used this process to produce electrodes (see Figure 41.5) for EC detection in CE. These Au–CDtrodes were used first in a home-made CE system, in which an electrophoretic separation of iodide, ascorbic acid, dipyrone, and acetaminophen was successfully performed. Au–CDtrodes were later applied to an electrophoresis microchip fabricated with PT,<sup>17</sup> where the effectiveness of the proposed system was demonstrated with a separation of iodide and ascorbic acid. A series of 10 repetitive injections obtained in a conventional CE–EC system and one electropherogram obtained in miniaturized system are shown in Figure 41.6.

The use of these Au–CDtrodes in both conventional capillary and microchip electrophoresis presents some advantages. The first is that the low cost of electrode fabrication, considering that ca. 50 electrodes can be prepared from a single CD, aids in the quest of having cost-effective, disposable, single-use devices. The second is that, for both systems, the electrode replacement can be made quickly requiring only a new adjustment between the electrode and the capillary/channel extremity. A third advantage involves the use of the dual electrodes (see Figure 41.5) to simultaneously detect

**FIGURE 41.5** Au-CDtrode microfabrication process. (a) Drawing and printing of electrode layout on a wax paper; (b) thermal transference of the desired layout over a Au-CD surface; (c) Au etching step with iodide/iodine solution; (d) dual microelectrodes obtained after toner removal; and (e) amplified image from a dual Au-CDtrode with  $\sim 100\text{-}\mu\text{m}$  wide and gap  $\sim 100\ \mu\text{m}$ . Black and gray colors indicate the apparent toner and the Au surface, respectively. (Adapted and reprinted from Coltro, W.K.T., et al., *Electrophoresis*, 25, 3832, 2004. With permission.)

**FIGURE 41.6** Electropherograms obtained for conventional capillary (A) and microchip electrophoresis (B) coupled with end-column and end-channel amperometric detection, respectively. In (A) the sample is constituted of iodide (1), ascorbic acid (2), dipyrone (3), and acetophen (4). In (B) the sample is composed of iodide (a) and ascorbic acid (b). (Reprinted from Richter, E.M., et al., *Electrophoresis*, 25, 2965, 2004 and Coltro, W.K.T., et al., *Electrophoresis*, 25, 3832, 2004. With permission.)

both the oxidation and the reduction reaction at the electrodes. Since amperometry is a selective method, the dual detection can provide additional information. In addition to these advantages, the production of electrodes can be improved by using a high-resolution laser printer. With printer of higher resolution, narrower electrodes can be prepared, thus decreasing the peak broadening related to diffusion at electrode surface.

**FIGURE 41.7** Examples of electro spray devices fabricated in PT. (a) A drop of KCl solution at the channel outlet and (b) electro spray tip with Taylor's cone generated by electrostatic field. (Reprinted from do Lago, C.L., et al., *Anal. Chem.*, 75, 3853, 2003. With permission.)

### 41.3.3 FABRICATION OF OTHER MICROANALYTICAL DEVICES

The major contribution of this direct-printing process is that it is not restricted to the examples described above. One possibility that has not completely been explored yet is the use of micro-electrospray devices fabricated in PT. The generation of Taylor's cone from a microchannel outlet on a PT chips was shown by do Lago et al.<sup>16</sup> Owing to the hydrophilic nature the substrate, the edge of the device was dipped in a silicone solution to impart enough hydrophobic character to the external surface to prevent the aqueous solution from spreading. The electro spray phenomenon on the PT device was observed<sup>16</sup> for a solution drop hanging at the wedge-cut tip (Figure 41.7), but the coupling with mass spectrometry has not yet been shown and is currently under investigation in our laboratory.

The concept of  $\mu$ TAS suggests that several analytical steps should be integrated on the same chip. Different analytical operations have already been integrated using standard techniques and popular substrates.<sup>33–37</sup> For PT chips, this task is not trivial and requires creativity. As shown in Figure 41.3a, the presence of toner particles in the channel is a limitation associated with the direct-printing process. And while this may be viewed as disadvantageous, these toner particles can be exploited as obstacles to create convective mixing, or to adsorb analytes/reagents. In other words, toner particles could act as filter, preconcentrator, microreactor (the enhanced surface area is particularly enable with these latter two points), or obstacles that induce mixing. It is well established that using photolithographic techniques it is possible to create obstacles that have an ordered configuration inside the channel. In the direct-printing process, toner particle clusters can be generated by using a gray-scale effect from graphic software such as Corel Draw. This gray-scale effect allows the deposition of toner particles inside the channel, potentially creating obstacles for flow or turbulent mixing—although it remains to be seen whether this can be accomplished in an accurate way. Theoretically, it is possible to apply gray-scale effects ranging from 0% to 100%, with the lowest percentage providing no toner and 100% will generate a channel fully loaded with toner particles. Exemplary micrographs for the gray-scale effect applied to PT microchannels are depicted in Figure 41.8. Three different stages of this effect (0%, 50%, and 90%) are identified in a 150- $\mu$ m wide channel in Figure 41.8a, where it is possible to observe that the channel is almost totally obstructed at 90% gray. In previous experiments,<sup>30,38</sup> it has been estimated that beyond 80% of gray-scale effect, the channel is partially obstructed. Figure 41.8b shows this effect applied to the 500- $\mu$ m wide channel where Liu et al.<sup>21</sup> were able to show that this effect could be applied to create passive micromixers in these low-cost devices.

**FIGURE 41.8** SEM images showing a gray-scale effect applied to PT channels: (a) 150- $\mu\text{m}$  wide channel with a gradient of gray-tone applied to different points over the channel and (b) 500- $\mu\text{m}$  wide channel with 80% of gray-tone applied to the entire channel. (Reprinted from Coltro, W.K.T. *Fabrication and Evaluation of Electrophoresis Microdevices with Electrochemistry Detection*, Sao Carlos, 2004, 126 p. Dissertation (Master in Science). Institute of Chemistry at Sao Carlos, University of Sao Paulo. Online available at: <http://www.teses.usp.br/>)

**FIGURE 41.9** Example of electrodes produced by direct-printing process. (a) A schematic view of the microfluidic device with four interdigitated Au-CDtrodes. (1) and (4) inlet and outlet reservoirs, respectively; (2) and (3) reservoirs for reference electrodes;  $E_{1-4}$ , gold working electrodes. (b) amperometric response at all four electrodes for a  $\text{K}_4\text{Fe}(\text{CN})_6$  sample introduced into microchannel by FIA. (Reprinted from Daniel, D. and Gutz, I.G.R., *Talanta*, 68, 429, 2005. With permission.)

Daniel and Gutz<sup>24</sup> have also proposed the fabrication of microfluidic flow injection cells with interdigitated array of gold electrodes. Figure 41.9 presents a schematic diagram of this microdevice (a) as well as a sequence of amperometric response to a solution of  $\text{K}_4\text{Fe}(\text{CN})_6$  exposed to all four interdigitated gold electrodes in microfluidic flow cell (1.4 cm length  $\times$  0.1 cm width  $\times$  19  $\mu\text{m}$  depth) (b). The microfluidic channel was prepared by thermal transference of three toner layers over the polycarbonate CD base, with the bonding provided by a second polycarbonate slice. The fluid transport was carried out with a peristaltic pump for flow injection analysis (FIA) applications.

#### 41.3.4 FABRICATION OF GLASS-TONER MICROCHIPS AND TONER-MEDIATED LITHOGRAPHY

Polyester-toner devices present advantages such as low cost per device, as well as easy and speed of fabrication. In addition, dozens of devices can be prepared in parallel using a single transparency

film.<sup>16,17,30</sup> As mentioned earlier, the magnitude of EOF on PT devices is 10 times lower than that in common microfabrication substrates such as glass, quartz, and PDMS.<sup>17,30</sup> While the EOF in these popular materials can be raised by chemical or physical modification of the surface (activation by oxygen plasma or sodium hydroxide), similar treatment of PT chips does not yield the same enhancement. The use of sodium hydroxide is not recommended because it attacks the toner surface rapidly (in a few minutes), even at low concentration. However, the low EOF can certainly be an advantage for the analysis of analytes with similar electrophoretic mobilities. One strategy to obtain a simple microdevice but with greater EOF is the fabrication of glass-toner microchips.<sup>27</sup>

The toner layer cannot be printed over a glass surface since this substrate is not an acceptable substrate for commercial laser printers. Alternatively, the layout can be printed on a wax paper first, and then transferred to the glass surface using a thermal transfer press methodology already described. In this case, one or more toner layers can be sequentially transferred onto glass surface increasing the aspect ratio. The sealing of these channels is also provided by using thermal press, in which a glass cover binds to upper toner layer under heating and pressure. Recently, this technology has been used to fabricate microchips for free-flow electrophoresis.<sup>28</sup>

The problems related to toner porosity and weaker adherence of the toner to the glass surface, compared to PT devices, reveals a drawback of these glass-toner devices. In recent studies,<sup>32</sup> we improved the adherence of the toner to the glass surface allowing the exploration of the toner layers as layout masks for preparing glass channels by wet chemical etching (toner-based lithography). In this case, glass channels are obtained without the use of any photolithographic step during the process and the costs related to it. The toner possesses limited chemical resistance to hydrofluoric acid solution, which can be overcome by multilayer stacking. However, the resistance is substantial enough to create channels up to 40- $\mu\text{m}$  deep in less than 10 min. Figure 41.10 presents two SEM images, where it was possible to observe a cross-intersection (Figure 41.10a) and a transversal section of the bonded channel (Figure 41.10b) but, as expected, the channel did not present a perfect definition due to the limitation of the direct-printing process.

### 41.3.5 FABRICATION OF PT MICROCHIPS WITH INTEGRATED ELECTRODES

One of the most exciting applications using the direct-printing process is related to the fabrication of PT microchips with integrated electrodes for  $\text{C}^4\text{D}$ .<sup>20</sup> The  $\text{C}^4\text{D}$  system is an universal detection mode that has several advantages when coupled with conventional CE or microchip electrophoresis: (i) the electronic circuitry is simple, inexpensive, and decoupled from the high-voltage used for separation; (ii) the formation of bubbles at the electrodes is avoided; and (iii) electrochemical modification

**FIGURE 41.10** SEM images showing the glass channel obtained by toner-mediated lithographic process. (a) Intersection of injection and separation 200- $\mu\text{m}$ -wide microchannels and (b) sectional profile of a bonded glass-glass microchannel. (Reprinted from Coltro, W.K.T., Piccin, E., Fracassi da Silva, J.A., do Lago, C.L. and Carrilho, E., *Lab Chip*, 7, 931, 2007. Reproduced by permission of The Royal Society of Chemistry.)

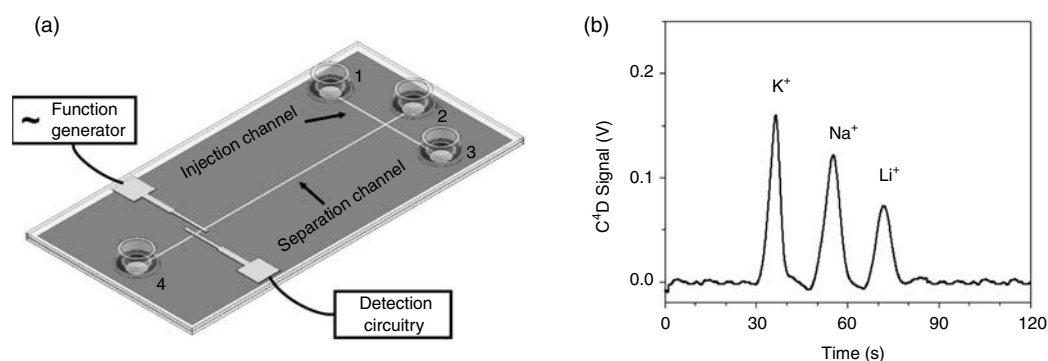

or degradation of the electrode surface is prevented, thereby, allowing a wide variety of electrode materials and background electrolytes.<sup>39,40</sup>

The detection electrodes for  $C^4D$  are often prepared by manually gluing copper stripes over the separation channel. This manual electrode positioning limits the repeatability on the chip-to-chip preparation, in which the accurate width, gap, and position over the separation channel are essential parameters. To minimize this problem, the integration of microfabricated electrodes on polyester films was a successful alternative. The electrodes for  $C^4D$  were prepared using toner masks for metal deposition via sputtering. Briefly, the electrode geometry was drawn and printed over a polyester film, followed by the sputtering of a thin layer, of titanium/aluminum over the printed electrode mask. The resulting electrodes were obtained by soaking the substrate in acetonitrile and dissolving the underlying toner layer. As the toner layer was removed with the solvent, the sputtered Ti/Al could be lifted off, and the electrode material remained anchored to polyester substrate. Note that aluminum was chosen due to its lower cost when compared to gold and platinum. The integration of these electrodes with PT channels was also carried by thermal lamination while maintaining the electrodes carefully positioned upwards, that is, isolated from contact with the solution in the channel by the thickness of the polyester film ( $100 \pm 10 \mu\text{m}$ ). The final  $C^4D$ -PT chip carries the detection electrodes on the outside of the top polyester film and the microfluidic network is directly printed on the bottom polyester film.

Figure 41.11a presents one layout of this integrated system as well as a typical electropherogram obtained on this device (Figure 41.11b). In addition to enhanced chip-to-chip repeatability, the use of integrated electrodes improved the signal-to-noise ratio. The use of toner masks for preparation of electrodes can be also extended to other EC modes such as amperometry, voltammetry, and potentiometry. Furthermore, the use of copper tapes as electrodes is limited to the classical format (antiparallel design), while the use of toner masks allows one to investigate different electrode design for  $C^4D$ .

#### 41.4 CONCLUDING REMARKS

As seen in this brief chapter, the direct-printing process, based on laser printing of layouts on polyester films or wax paper, has the potential to become a powerful technology for the rapid prototyping of microfluidic devices at very low cost, and even a source of low-cost production of disposable devices. This is supported by the fact that the required instrumentation is commonly found at offices and chemistry laboratories. Besides the typical injection and separation channels for electrophoresis, this technology has shown that mixing, preconcentration, clean-up, reactor devices,

**FIGURE 41.11** Representation of a (a) PT microdevice with integrated electrodes for  $C^4D$  and (b) a typical electropherogram obtained for a mixture of inorganic cations ( $25 \mu\text{M}$  each) in this device. FIGURE 41.12 Examples of devices, elements, and features that can be achieved using the toner-based technology.

as well as electrodes can also be incorporated into PT channel design using graphic resources and toner masks. Currently, our main goal is focused in the development of a working  $\mu$ TAS by exploring just the direct-printing process. Furthermore, the versatility of the direct-printing process has been demonstrated with microelectrodes for amperometric detection in conventional CE and microchip electrophoresis, microfluidic cells with interdigitated electrodes, electrospray, micromixers, and free-flow electrophoresis devices, as well as glass-toner and glass-etched microdevices that can be fabricated and explored for specific applications.

Overall, as presented here in some detail, this technology presents the opportunity to all scientists in any laboratory interested in lab-on-a-chip technology, requiring only common tools, easily found in offices/general laboratories. To conclude this chapter, we present in Figure 41.12 a portfolio of many devices prepared using toner technology.

## 42.1 INTRODUCTION

In 1828, when attempting to prepare ammonium cyanate from silver cyanide and ammonium chloride, Friedrich Wöhler accidentally synthesized urea [1]. Contemporary wisdom at the time held that organic compounds could only be created from a “vital force,” which existed within living organisms. In a letter to Jöns Jakob Berzelius, Wöhler’s excitement was apparent; “I can no longer, so to speak, hold my chemical water and must tell you that I can make urea without needing a kidney, whether of man or dog; the ammonium salt of cyanic acid is urea.” Although Wöhler’s discovery was not the first synthesis of an organic compound it sparked huge interest in making organic compounds from nonliving substances and marked the beginning of organic chemistry as an academic and industrial discipline.

Since that time, organic chemistry (the study of the structure, properties, composition, reactions, and synthesis of carbon-containing compounds) has flourished and is of vital importance to the pharmaceutical, chemical, cosmetic, petrochemical, and textile industries. For the vast majority of the time, since (and for centuries before) Wöhler's synthesis of urea, the chemist's toolkit has predominantly consisted of macroscopic components fabricated from glass. Examples of such components include round-bottomed flasks, test tubes, distillation columns, reflux condensers, Erlenmeyer flasks, drying tubes, separation funnels, recrystallization tubes, and burettes. Despite the enormous advances that have been made in experimental, mechanistic, and theoretical organic chemistry over the past 150 years it is noteworthy that the basic experimental techniques and associated laboratory equipment remain largely unaffected. Perhaps this is unsurprising, since standard laboratory glassware provides a fitting environment in which to perform the vast majority of synthetic transformations. Glass as a generic material is robust, possessing good chemical inertness. It also exhibits high thermal conductivity, low electrical conductivity, and good transparency within the visible region of the electromagnetic spectrum. This means that standard glassware can be used to process most chemical reagents under a wide range of temperatures and pressure. A more pragmatic reason for the adoption of macroscale glassware in organic synthesis relates to the fact that chemists as individuals feel comfortable performing reactions in environments, which they can easily manipulate, control, and observe. Nevertheless, although a chemist may prefer to perform a reaction within a round bottom flask, at the molecular scale it makes little difference if a reaction is processed within a volume of 100 mL or 100 pL. What is more important is that the "ideal" chemical reactor should provide an environment in which chemical state functions are precisely controllable, allowing the rapid synthesis of a desired product in high yield. To this end, over the past decade, the application of micromachining techniques cultivated within the semiconductor and microelectronics industries have allowed the creation of a new instrumental platform able to efficiently process and analyze molecular reactions on the micron to nanometer scale. This chapter aims to provide an introduction to the concept of reaction miniaturization. The theory of miniaturization is discussed and followed by a practical assessment of the use of microfluidic systems in synthetic chemistry.

## 42.2 THEORETICAL BACKGROUND

### 42.2.1 FLUID FLOW ON THE MICROSCALE

The foremost reason why microfluidic systems provide attractive environments in which to perform synthetic chemistry lies in the dependency of fluid flow on scale. Put simply, fluid handling within microfluidic environments differs markedly from typical macroscale flow [2]. A variety of phenomena manifest themselves upon moving from the macroscale to the microscale, which in turn have a profound effect on both the efficiency and manner in which chemical reactions proceed.

A chemical reaction is initiated by bringing the required reactants into intimate contact. Efficient execution of this process often defines the efficiency of the reaction and, therefore, requires considered examination when designing a reaction system. The physical transport of a component along a concentration gradient by molecular diffusion and turbulent convection is known as mass transfer. The transport of mass through an interface between two media or phases of the same medium is extremely important, since chemical reactions are normally coupled to the mass transfer efficiency. The mass transfer coefficient is used to quantify the efficiency of mixing in macrofluidic systems and is given by

$$K_c = \frac{N_A}{C_s - C_B}, \quad (42.1)$$

where  $K_c$  is the mass transfer coefficient ( $\text{m s}^{-1}$ ),  $N_A$  the molar flux ( $\text{mol m}^{-2} \text{s}^{-1}$ ),  $C_s$  the concentration at the phase boundary ( $\text{kg m}^{-3}$ ), and  $C_B$  the concentration in bulk solution ( $\text{kg m}^{-3}$ ).

A conspicuous effect of reactor miniaturization is that fluid properties become increasingly controlled by viscous forces rather than inertial forces as reaction volumes are reduced [3]. In macroscale environments, reagents are brought into intimate contact by turbulent flow. In such a regime, fluid elements (of varying sizes) travel randomly and create a mixture that is highly segregated with a finely dispersed structure. These eddies are a product of areas of circulatory motion in the fluid created by the inertial forces of flowing liquids. The mixture that is produced, although finely dispersed, is still heterogeneous at the molecular level and mixing of these fine fluid elements is subsequently achieved through the random, diffusive motion of the component molecules. The degree of turbulence in a system depends on its scale and the density and viscosity of the fluid. For example, in large systems such as fluidic jet streams, where turbulence is high, fluid elements can move large distances and therefore mixing is much faster than mixing by molecular diffusion alone.

Fluid flow in the absence of turbulence is described as being laminar. In such a situation, viscous forces dominate inertial forces and eddies are no longer present. Laminar fluid flow can be conceptualized as consisting of concurrently flowing parallel streams with little or no mixing between streams. Since the same viscous forces that restrain the fluid streams in laminae also dampen out irregularities and streamlines, laminar flow is not disturbed by obstacles and instead maintains a smooth path. With the removal of the highly segregated structure created by eddies, mixing must be achieved by molecular diffusion alone.

The Reynolds' number is a dimensionless number used in fluid dynamics to determine dynamic similitude [4] and is generically defined as

$$Re = \frac{v\delta}{U}, \quad (42.2)$$

where  $v$  defines the mean fluid velocity,  $\delta$  is a characteristic dimension of the reactor and  $U$  defines the kinematic viscosity of the fluid. Significantly, the Reynolds' number provides a measure of the ratio of inertial forces to viscous forces and is most commonly used to assess whether flow will be laminar or turbulent. In simple terms, viscosity describes the resistance of a fluid to deformation under shear stress and encourages fluid to flow in parallel layers, with no disruption between the layers (laminar flow), while inertia describes the tendency of the fluid to resist acceleration and thus counteract laminar flow. For microfluidic systems, such as capillaries or blood vessels in the body or the microchannel networks common to microfluidic systems, Reynolds' numbers are typically much less than  $10^2$ . This represents a situation where the flow regime may be considered essentially laminar and contrasts with macroscale pipes or reactors (exhibiting Reynolds' numbers in excess of  $10^4$ ), where flow regimes are almost always turbulent. This behavior has a direct consequence on mixing within microfluidic systems. Before a reaction between two reagents can occur, intimate contact between the component molecules must be realized through mixing. Mixing within microfluidic systems in its simplest manifestation is achieved by bringing together pure fluid component streams within channels having characteristic cross-sectional dimensions measured in tens of microns. Since low Reynolds' and Peclet numbers (which measure the relative importance of mass transport due to convection with respect to diffusional mass transport) are typical of such environments, mixing can only be accomplished through diffusion, rather than the fast convective processes that dominate in turbulent systems. Thus under these conditions, two or more distinct fluid streams moving in the same channel do not develop turbulence at the interface between them, or at the interface with the channel walls and the only mechanism of mixing of their components is diffusion across the former interface.

Diffusive mixing efficiencies can be assessed using the Fourier number, which is defined by

$$Fo = \frac{Dt}{l^2}, \quad (42.3)$$

where  $D$  is the molecular diffusion coefficient,  $t$  is the contact time, and  $l$  is a characteristic length over which diffusion occurs. Broadly speaking, adequate mixing of fluidic streams occurs for Fourier numbers of 0.1, with complete mixing defined by Fourier numbers greater than 1 [5]. Equation 42.3 illustrates that diffusive-mediated mixing timescales increase with the characteristic dimension of the reactor. Consequently, although mixing via diffusion is highly inefficient for reactors with characteristic dimensions greater than 1 mm, when diffusion distances are reduced below 100  $\mu\text{m}$  mixing times can become small. For example, a small molecule such as fluorescein in water exhibits a mixing time of approximately 90 ms across a diffusion distance of 10  $\mu\text{m}$ .

#### 42.2.2 MIXING AND CHEMICAL REACTIONS

The effect of mixing on the extent of a chemical reaction and the resulting product distribution is crucial when designing microfluidic reactors. It is generally recognized that first-order irreversible reactions are unaffected by local turbulent mixing, but are controlled by the residence time of the reaction and the conversion of such systems can therefore be easily calculated. However, in the case of fast reactions, where two or more reagents are initially present in separate streams, reaction rarely occurs throughout the whole volume uniformly. As the mixture is initially highly segregated with a heterogeneous and dispersed structure the reaction is stifled until mixing occurs. In this situation, the rate of reaction is no longer related to the rate constant but instead is limited by the rate of diffusion. In the case of fast reactions, where a single reaction product is produced, the yield can be regarded as a direct measure of the degree of mixing in the reaction vessel. In the case of fast reactions with two or more products, the product distribution has similar connotations. In this way, the product distribution can be manipulated by increasing or decreasing the amount of segregation or the efficiency of mixing within the reactor. The relationship between the rate of a reaction and the rate of mixing in a reaction falls into one of three main categories. These are the chemical regime, the diffusional regime and the mixed chemical/diffusional regime. The interaction between chemical reactions and fluid dynamics is described by the Damkoehler number, which represents the contribution of these two systems [6]. The Damkoehler number can be represented in either of two forms,  $N_{DaI}$  and  $N_{DaII}$ , where  $N_{DaI}$  is a ratio of the chemical reaction rate to the bulk mass flow rate and  $N_{DaII}$  is the ratio of the chemical reaction rate to the molecular diffusion rate. In the chemical regime, the mixing time is fast in comparison to the reaction rate and is represented by a Damkoehler number that is close to zero. In this situation, the chemical reaction is slow compared to the mass transfer and the reaction system can be regarded as an unreactive fluid. That is to say that mixing is complete before significant amounts of products are present and once mixed, the reaction proceeds uniformly throughout the reaction volume. In the case of a competitive-consecutive reaction as detailed in Scheme 1.1, the smallest amount of secondary products is formed. In the diffusion regime (where  $N_{Da} \approx \infty$ ), the chemical reaction is very fast and thus the reaction is limited by the rate of mixing. In this condition, the area available for reaction is reduced from the volume of the entire reaction vessel at  $N_{Da} \approx 0$  to a plane between reacting streams at which each reagent has zero concentration. When a chemical reaction occurs, microscopic concentration gradients are introduced increasing segregation, which in turn leads to a decreased level of mixedness. The reaction rate is then independent of the rate constant and the formation of secondary products in this situation is the greatest for the reaction system detailed in Scheme 1.1. In a mixed chemical/diffusional regime ( $N_{Da} = 1$ ), the greatest interaction between chemical reactions and fluid dynamics occurs and the product distribution depends on both the chemical

**Scheme 1.1** The competitive reaction of the product R with the initial reagent B leads to the formation of by-product S and a reduction in the overall yield of R.

factors, (e.g., rate constants) and also on the diffusional factors (e.g., efficiency of mixing). In this situation, the amount of secondary product formed lies between the extremes of the chemical and diffusional regimes. Some practical examples, where micromixing has a profound effect on the product are fast consecutive competing reactions, polymerizations and precipitations. In competitive-consecutive reactions, a reaction occurs between two reagents (A and B) to produce a product (R) at rate  $k_1$ . The product in this situation is then able to react with one or more of the initial starting reagents in a competitive manner at rate  $k_2$  to form a by-product (S), leading to a reduction in the initial product (Scheme 1.1). The competitive reaction of the product R with the initial reagent B leads to the formation of by-product S and a reduction in the overall yield of R. In the case of fast competitive-consecutive reactions  $k_1$  is much larger than  $k_2$  and  $k_2$  is still large. If a small amount of B is mixed with a large excess of A, R is instantaneously formed. If the fluid is completely mixed, R and B are dispersed throughout the reaction volume, B is consumed by the excess of A and R is preserved. If a small amount of B is mixed with a large excess of A and the fluid is a segregated mixture, R stays at the fluid interface of B. In the presence of B, R is immediately converted to S, the concentration of which then may be used as a measurement of segregation or unmixedness in the vessel.

## 42.3 MICROFABRICATED REACTION SYSTEM

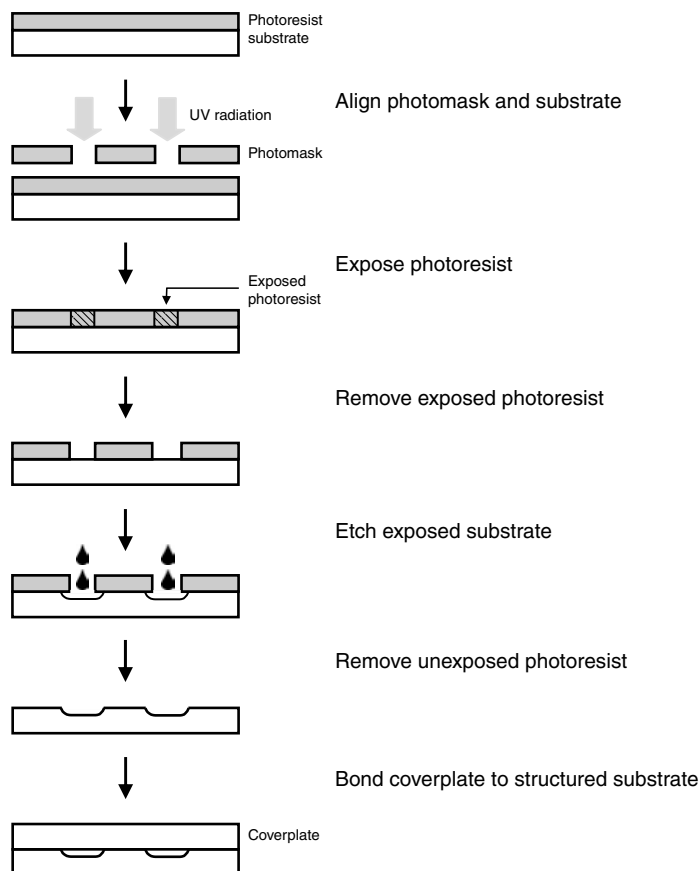

### 42.3.1 FABRICATION OF MICROFLUIDIC REACTORS

Over the past decade a diversity of microfluidic systems have been designed for the rapid mixing of pure fluid components. Microfluidic devices can be manufactured using a diversity of fabrication techniques originally developed in the semiconductor and microelectronics industries. Since most system features are relatively large ( $>1 \mu\text{m}$ ), fabrication is straightforward and can be achieved using well-established lithographic and microstructuring methods. Although, extensive details of common fabrication methods can be found in excellent articles elsewhere [7], a brief description of a common protocol for the fabrication of planar glass (or silicon) microfluidic reaction systems is provided (Figure 42.1).

In the simplest case, a fluidic channel pattern is structured within a planar substrate using a combination of photolithography, wet-etching, and bonding. Initially, a photosensitive polymer resist is deposited on to a glass substrate and then exposed to ultraviolet (UV) radiation through a mask (which defines the fluidic topography). Subsequent development in a solvent allows the removal of portions of photoresist, which have been exposed (or unexposed) to radiation, leaving a polymerized resist pattern with high chemical resistance in some areas and exposed substrate in others. Etching of the substrate material then allows the two-dimensional resist pattern to be transferred to the substrate material. Typically, wet etching protocols, involving the use of aqueous etchants, such as HF,  $\text{HNO}_3$ , KOH, and tetramethyl ammonium hydroxide, are used to create three-dimensional structures in the substrate material. The final stage in the fabrication of a basic microfluidic reaction system involves the assembly of the structured substrate with an unstructured coverplate (typically glass or silicon) to form the enclosed chip structure. Anodic bonding is used to bond glass and silicon substrates, while for glassy materials thermal bonding ( $450\text{--}900^\circ\text{C}$ ) provides the simplest way to assemble substrates.

### 42.3.2 FLUID MOTIVATION

An important factor to consider when using microfluidic reactors to perform chemical synthesis is the method by which reagents are moved through the microdevice. Normally, pressure-driven flow using infusion pumps is used to force fluid through microchannels. The wide volumetric flow rate ranges (pL/min to mL/min) and applicability to all solvent systems makes hydrodynamic pumping the most versatile and popular method of flow motivation. In addition, electroosmotic pumps can be used to generate fluid flow by application of a potential difference through a conductive solvent [8].

**FIGURE 42.1** Schematic representation of component processes in the fabrication of a basic glass microfluidic reactor using photolithography, wet-chemical etching, and thermal bonding.

The primary advantage of such an approach is that it creates a flat flow profile, and thus allows definition of precise flow rates and narrow residence time distributions. Nevertheless, electroosmotic flow (EOF) pumps are severely limited in their widespread application to molecular synthesis due to a need for a conductive solvent and the fact that varying electrophoretic mobilities of reagents and products leads to time-dependent concentration gradients within the reactor that can degrade performance.

### 42.3.3 MIXING MODALITIES

A wide range of microfluidic systems have been designed to efficiently mix pure fluid components [9]. Broadly, all of these systems can be classified as being either passive or active in operation. Passive mixers rely on the geometric properties of the channel shape and fluidic streams to achieve mixing, whereas active mixers rely on time-dependent perturbations of fluid flow to achieve mixing. In general, passive systems are simple to fabricate and integrate with other functional components, while active systems require the integration of external actuators and involve more complex fabrication techniques. Passive mixing is realized via a diversity of mechanisms including serial or parallel flow lamination, chaotic advection, and injection of substreams of one component into a primary stream of another component and microdroplet formation. Similarly, active mixers exploit actuation via pressure, electrohydrodynamic, dielectrophoretic, acoustic, thermal, and electrokinetic mechanisms.

Detailed reviews of the structure, function, and mode of operation of microfluidic mixers are provided elsewhere.

Of particular interest in relation to reactive microfluidic systems have been recent developments in the use of chaotic advection to accelerate mixing. In many situations, practical limitations (such as minimum feature dimensions) mean that basic flow lamination is inefficient at generating high degrees of mixedness within short times. Rapid mixing with low reagent consumption is, however, readily achievable using chaotic advection [10]. Chaotic advection may enhance mixing in laminar flow systems by continuously “stretching” and “refolding” concentrated solute volumes, thereby creating an exponential decrease in striation thickness. In microfluidic systems, this can be achieved by introducing obstacles within channels or by modifying channel geometries. Chaotic advection has been shown to generate efficient mixing within both high and low Reynolds’ number regimes. For example, zigzag-shaped channels have been shown to cause chaotic advection at high Reynolds’ numbers by recirculation around turns [11], while generation of chaotic flow at low Reynolds’ numbers has been achieved through the use of grooves on channel surfaces [12].

The ability to achieve rapid mixing of fluids while minimizing the deleterious effects of dispersion is a significant challenge when creating synthetic systems. Put simply, dispersion acts to increase residence time distributions within continuous-flow [13], which in turn causes significant variation in the yield, efficiency and product distribution. Although chaotic flow can be used to reduce dispersion in microfluidic systems, localization of reagents within discrete droplets has been shown to be effective at entirely eliminating this phenomenon [14]. Indeed, a number of recent studies have exploited the formation of droplets with microfluidic channels to perform a variety of synthetic processes [15]. In these reports, droplets are made to spontaneously form when multiple lamina streams of aqueous reagents are injected into an immiscible carrier fluid. The formed picoliter droplets are isolated from channel surfaces and other droplets, with each one acting as an individual reaction vessel. Importantly, the use of winding channel geometries is highly efficient in generating chaotic mixing within droplets and allows rapid and dispersion free mixing.

## 42.4 APPLICATION OF MICROFLUIDIC REACTORS IN SYNTHETIC CHEMISTRY

### 42.4.1 KEY BENEFITS OF MICROFLUIDIC SYSTEMS IN SYNTHESIS

Small molecule synthesis forms the basis of the pharmaceutical and fine chemical industries. These industries have to address sometimes competing concerns: the synthesis of high purity compounds and the synthesis of large quantities of a compound. Microfluidic systems have been employed to address these concerns and show many advantages over existing techniques. Many of these advantages are case specific, but nevertheless certain key areas can be considered.

From a synthetic point of view, the essential features of the microscale are functions of mass and energy transfer. The rapidity and efficiency of mixing is often one of the limiting factors on the rate of reaction for chemical processes. The other commonly found limit is the rate at which heat can be transferred out of (or less commonly into) the reaction vessel. As we have seen previously, mixing on the microscale is a rapid and controlled diffusive process, limited only by the diffusion coefficients of the solutes themselves. Given small enough diffusive distances, such as can be found in multilaminar microfluidic mixers, homogeneity can be achieved faster than is possible in macroscale systems, and the mixing is easily quantifiable [16]. Mass transfer between phases in microfluidic reactors is also rapid, though more complex than the simple case for diffusive mixing. The flow regimes within microreactors are normally strictly laminar and so readily quantifiable into flow modes. Even so, the prediction of flow modes is complex and strongly dependent on local conditions such as solvent viscosity and phase compressibility. Irrespective of this, work on microfluidic multiphase reactions

has shown that an acceleration of the rate of mass transfer of at least two orders of magnitude is experienced in microfluidic systems compared to commonly quoted laboratory scale reactions [17]. Studies on slug flow reaction systems have demonstrated convincing benefits to employing microreactors for phase-transfer reactions due to the enhanced rate of transfer between phases in these systems [18].

Heat transfer is limited by a “cube/square” relationship. Heat is generated throughout the reaction volume, but can only be removed at the reactor surface. From this point of view, it can be argued that the traditional spheroidal reaction vessel is perhaps the worst configuration imaginable for effective heat transfer from the vessel to the surroundings. Given the very high surface area-to-volume ratios present in microfluidic reactors these systems represent a very efficient heat transfer system indeed. The limitation on the system in these devices is often found to be the intrinsic conduction properties of the reactor materials themselves, rather than the heat transfer between the reaction medium and the vessel wall [19]. The precise control of local thermal and concentration gradients possible within microfluidic reactors enable much greater control of synthetic processes. Many systems have a narrow optimal range of conditions for efficient and specific synthesis and benefit from the greater control of these factors inherent in micron scale reactors. In general, it is fair to say that different areas within the chemical and pharmaceutical industries require different approaches within the broader theme of microfluidic flow systems. These requirements are briefly discussed below.

## 42.4.2 FIELDS OF APPLICATION

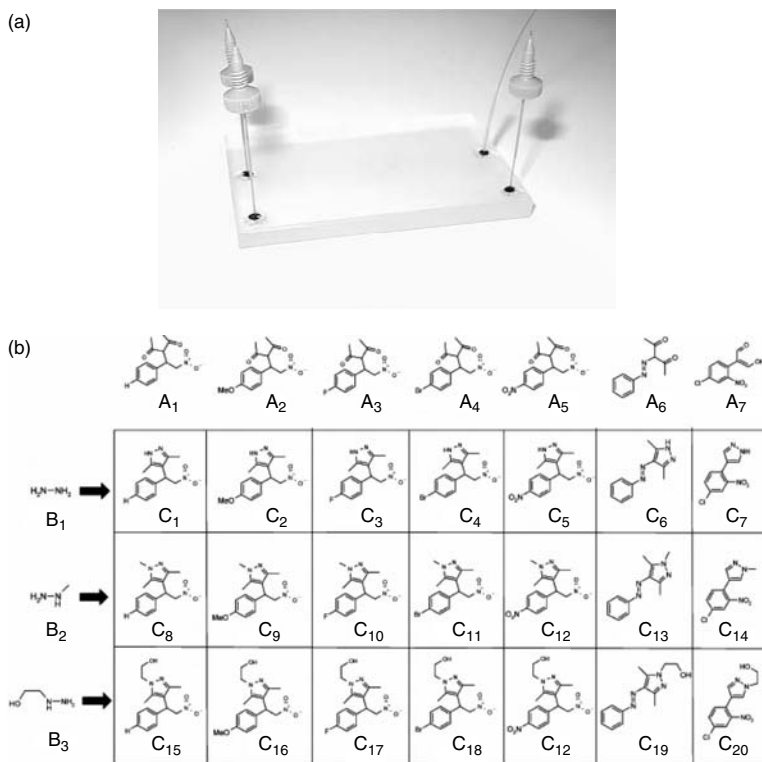

### 42.4.2.1 High-Throughput Synthesis

In high-throughput synthesis, the chief problems that have to be overcome are the time it takes to perform individual syntheses and the purity of the products. The volume of product produced is not of primary concern in most cases because the target compounds synthesized are destined for lead screening, a process requiring milligram amounts or sometimes less. The chief aim within this area is to produce as many pure compounds as possible within the shortest possible space of time with high target purity. The compound libraries thus generated are then evaluated in a process often completely divorced from the original synthesis. Traditional approaches toward library generation have relied upon two divergent paradigms: solid phase synthesis and automation.

Solid phase chemistry has been the technique of choice for research into high-throughput synthesis toward the generation of large compound libraries. In this approach, the synthetic targets are attached by a linker group to insoluble functionalized, polymeric material, allowing them to be readily separated from excess reagent, soluble reaction by-product or solvents. Such an approach involves immobilization of substrates on a polymeric resin or beads using linker groups followed by a synthetic sequence and finally a cleavage step to obtain the free product.

This approach suffers from problems related to the influence of the support on reaction chemistries and the optimization of solid-supported chemistries, which may have completely different kinetics from their solution-phase analogues. Difficulties exist in assessing product purity or structure of compounds in the solid phase, often leading to expensive spectroscopic solutions. Working in the solid phase also limits the range of chemistry, which can be applied to a synthetic problem, not least because many solid phase approaches are so dependent upon amide bond formation. A further issue arises from the need for the perfect linker: uncleaved in normal reaction conditions but perfectly cleaved when desired, preferably without a footprint in the target molecule.

The above limitations with solid phase chemistries have necessitated the pursuit of solution-phase chemistries for library generation. The advantages of solution-phase syntheses are legion, but the major benefits include; unlimited numbers and types of reaction, lower requirements of solvents and reagents compared to solid phase syntheses and that such chemistries can be developed and monitored with relative ease. A conventional solution-phase chemical synthesis involves the use of arrays of sub millimeter wells as discrete reaction vessels to which the reagents are delivered using automated robotic systems. Although such systems have been successful, the batch nature of

**FIGURE 42.2** (a) Continuous-flow glass microfluidic reactor used for generating combinatorial libraries. (b) The formation of a  $7 \times 3$  pyrazole library was programmed and executed in the automated platform using the device in part (a). (Taken from Garcia-Egido, E., et al., *Lab on a Chip*, 2003, **3**: 73–76.)

the general approach is not ideal for efficient process optimization and high-throughput chemical processing.

The use of microfluidic systems in high-throughput chemistry offers great advantages. Reactions can be run in the solution phase, while still allowing rapid reaction throughput and with no detectable cross-contamination. For example, work by Mitchell et al. [20] using an integrated continuous-flow reaction/detection system (expressed as a logic gate) showed that the rapid generation of a small library of compounds via a multicomponent reaction could be accomplished with ease. Using such an approach, valuable information about reaction intermediates can be gathered in real time with the entire process being readily controlled by simple automation protocols. Garcia-Egido et al. [21] also showed that using slugs of reagents as separate reaction vessels small libraries of thiazoles could be generated then purified and analysed by in-line LC-MS (Figure 42.2), with a noticeable improvement in turnover compared to bulk systems and no detectable cross-contamination. Indeed utilizing similar systems, the synthesis of libraries of cycloadducts [22], pyrazoles [21], nitrostilbene esters [23], and thioethers [24] has been accomplished.

Although the bulk of these systems represent only one synthetic step, multistep combinatorial processes have been undertaken, notably by Sakai et al. [25]. High-throughput synthesis on the microfluidic scale has been proven to be advantageous in terms of the available chemistries, product purity and, ease of separation. Table 42.1 lists most of the successfully advantageous examples of synthesis performed within microfluidic reactors and recorded within the literature. One other advantage that has been demonstrated is that the same chemistry used to produce the sample can be used to produce large quantities of product. This multiscale nature of microfluidic reactors is one of enormous potential value to the chemical and pharmaceutical sector.

#### 42.4.2.2 Multiscale Synthesis

In traditional synthetic schemes, the transition from small scale production to large-scale production is a troublesome one. Reactions will almost never perform in the same way on a production scale as they do on a laboratory scale. Some reactions may be simply too dangerous to perform on a large scale, especially if they involve a dangerous intermediate, or a strong exotherm. Scale-up of a chemical process can, for these and other reasons, take years.

Continuous-flow processes allow greater access to laboratory reactions than batch processes. This is because the instantaneous reactor size is smaller, better simulating laboratory conditions and the assay of any dangerous intermediates generated can be kept small. Microfluidic reaction systems offer one superlative advantage over other methodologies: that of scale-out. Scale-out (or numbering up) is a simple proposition. If one microfluidic reactor produces a small quantity of product, when more is desired the number of reactors and not the scale of the reactor, is increased. Because microfluidic devices are easily mass produced, this system of parallel reactors is relatively cheap. Furthermore, because of the continuous-flow nature of the reaction environment a surprisingly large amount of product can be produced in a short space of time and the reaction conditions within the production reactor exactly mimic those of the research reactor. In other words, no scale-up development work is necessary. An excellent example of this approach is in the pioneering work undertaken by R.D. Chambers and coworkers in the use of elemental fluorine for fluorinations.

Direct fluorination is a process that is generally viewed as unscalable. The highly exothermic nature of the system ensures that large-scale reactions are problematic and the use of fluorine gas in large assay is in itself undesirable. Early work on microfluidic fluorinations showed that the direct reaction was comparable in selectivity to the industrial Schiemann process [26] and that the system could be applied to a wide range of compounds [27]. In a series of papers, Chambers et al. [28,29] showed that by the simple numbering up of reactor channels a commercially viable reactor could be constructed with no loss of reaction efficiency or selectivity.

The numbering up of microfluidic systems is a powerful tool in the rapid development of synthetic processes from the laboratory to fine scale and beyond and is only beginning to show its versatility [30] (Figure 42.3).

#### 42.4.2.3 High-Selectivity Synthesis

The highly ordered mass and heat transfer processes within microreactors often produce very selective reactions. As will be seen later this has implications for nanomaterial synthesis, but even within well-known reactions this selectivity can be important. Burns and Ramshaw [31] showed that nitration processes within microfluidic systems produce cleaner products than bulk scale systems. Similarly high yields and low by-product formation has been reported in on-chip peptide formation [32]. This is almost certainly attributable to the thermal flatness found within microfluidic channels and the ordered and predictable mixing within the system. It appears that reactions within the microfluidic regime are cleaner and often quicker, than their bulk equivalents.

#### 42.4.2.4 Catalytic Systems

The use of microfluidic systems for catalytic reactions has several advantages. The high surface area-to-volume ratios encountered on the microscale allow for good contact between heterogeneous catalysts and the reaction medium, and the thermal flatness eliminates hotspot formation. This has made microfluidic systems a valuable tool for process development in systems dependent upon a limited range of catalyst temperatures for optimal operation. For example, Worz and coworkers [33] at BASF showed that by using this approach, the efficiency of their catalytic process was increased and the reliability of the catalyst improved. Worz [33] states that the use of this technology represented a considerable saving in development time. For heterogeneous catalysis, many systems have been

**FIGURE 42.3** A modular microreactor system for the direct fluorination of ethyl acetoacetate by fluorine gas. The design allows for multiple channels to be supplied from single reservoir sources and a multichannel device to be constructed in a facile manner from a disposable channel plate. (Taken from Chambers, R.D., et al., *Lab on a Chip*, 2005, 5: 191–198. With permission.)

used from packed beds [17] through solid supports [34] to derivitized channel walls [35–37], each with advantages for particular catalytic systems. Indeed the breadth of application for microfluidic reaction systems in catalytic process development is hard to overestimate.

## 42.5 REAL WORLD APPLICATIONS

Real world synthetic problems are rarely solved in one step, but are more normally addressed by a combination of factors leading to complex solutions. The “plug and play” nature of microfluidic components makes them a flexible tool in problems of this nature, even when the whole process in question cannot be transferred onto a single microfluidic device. The following section outlines some illustrative examples of such applications.

### 42.5.1 POINT OF USE MANUFACTURE

Synthesis of short half-life radiotracers positron emission tomography (PET) is an emerging field within radiography. The technique utilizes positron-emitting radiotracers to trace metabolic activity directly within the body. The chief disadvantage of this methodology is the need for the tracers themselves: the short half-lives dictate that the compounds must be synthesized close to the point of use and the fiercely radioactive nature of the isotopes used entails prodigious shielding. The general approach toward these syntheses is to use automated robotic synthesis stations, often custom built, to perform the necessary synthesis and processing within a shielded compartment known as a hot cell. Space within these cells is at a premium and the number of automated stations per cubic metre is the major constraint on the procedure.

Recent work by Jeffery et al. [71] showed that many of the standard synthetic operations that are necessary in the synthesis of  $^{18}\text{F}$ FDG (a major PET radiotracer) could be incorporated into microfluidic devices. Moreover, Lu et al. [72] showed that the methodology was also applicable to  $^{11}\text{C}$  compounds. In an elegant recent study, Lee and coworkers [73] showed that all of the major processes in  $^{18}\text{F}$  radiolabeling tracer compounds could be integrated onto a single device. Such

advances are revolutionizing the field, with continuous-flow syntheses on microfluidic devices being more efficient in terms of throughput, space and indeed energy requirements than their conventional counterparts.

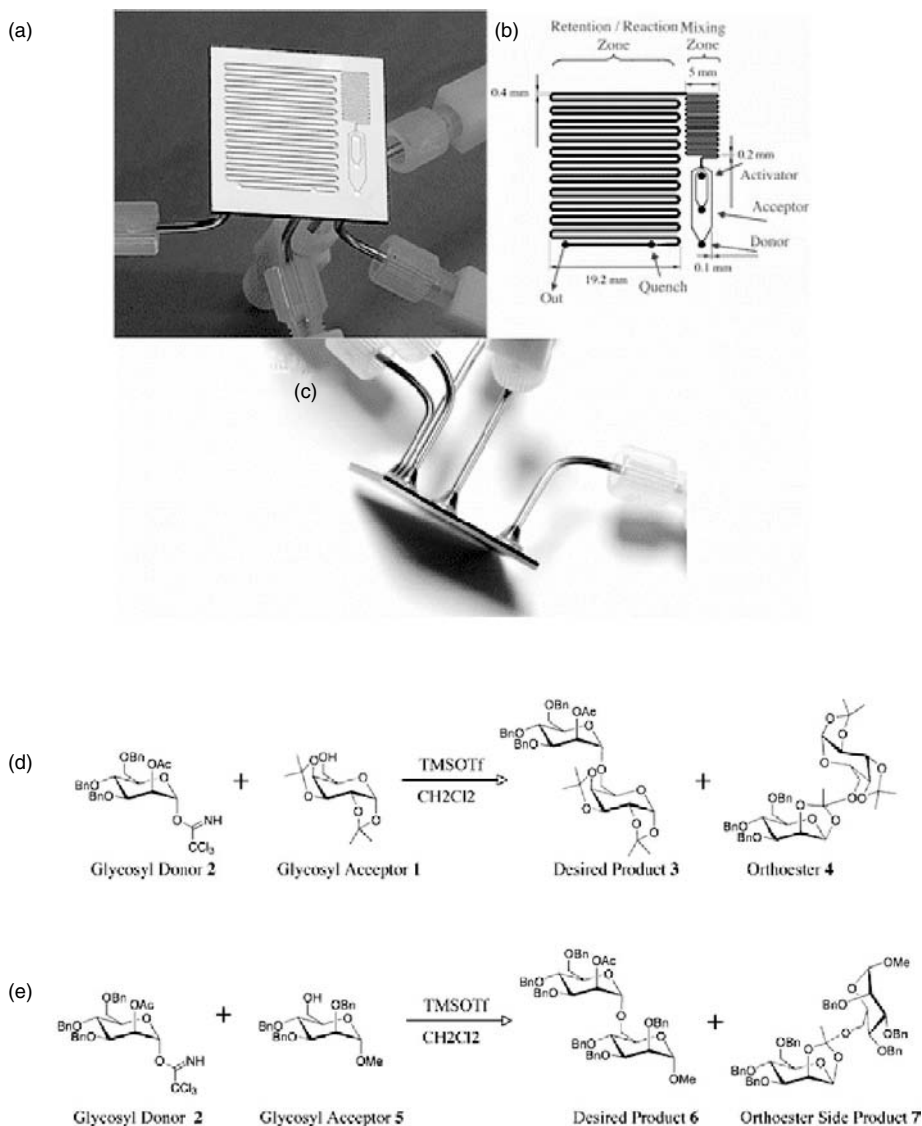

#### 42.5.2 MEASUREMENT OF CHEMICAL PHASE SPACE

All chemical processes are optimized to some degree. This entire procedure can be thought of as finding a set of localized optimal conditions within a reaction's output. The most common way of quantifying this form of relationship is by using phase space, an  $n$ -dimensional notional space, where each input to or output from a reaction is dealt with as a separate dimension. Using this model allows an intuitive handling of data. The main problem with applying the phase space model to reactions in the real world is the lack of data. When each experiment takes 3 h to run the number of data points generated will be quite low unless the optimization process has an unlimited budget. Automation of kinetic and calorimetric data gathering has made some improvements and allows the use of Design of Experiments algorithms, which can help to find minima quickly. However, using microfluidic devices it is possible to speed up the data gathering process. Studies by Le Bars and coworkers [74] has shown that calorimetric readings can be taken in continuous flow in a microfluidic device. Furthermore, in-line monitoring using, inter alia, NMR spectroscopy allows real-time evaluation of reaction conditions [75]. In addition, a useful demonstration of the benefits of microfluidic devices for reaction optimisation was presented by Ratner et al. [68] who investigated the influence of systematic variations in reaction time and temperature on glycosylation reactions (Figure 42.4).

In a series of studies our group demonstrated that not only could reactions be monitored on-line [76] and these data used for very rapid optimization [77], but also that this information could be used to plot local phase space in detail rarely attempted before. Several thousand data points per minute can be generated using appropriate in-line sampling and control techniques, allowing detailed phase space surfaces to be plotted [78]. This represents an increase in speed of over four orders of magnitude when compared to conventional methods.

#### 42.5.3 MICROFLUIDIC SYSTEMS FOR NANOMATERIAL PRODUCTION

As discussed, microfluidic systems are well suited for performing reagent mixing in a rapid and controllable manner. This combined with control over other variables, such as reactor temperature, concentration gradients and pressure dictate that continuous-flow processing on the microscale can be used to synthesize species of specific yet variable characteristics. Perhaps the most interesting demonstration of this feature is in the synthesis of nanomaterials (such as nanoparticles, nanotubes, and nanorods). The physical characteristics of nanocrystallites are primarily determined by quantum confinement effects with properties such as the optical band gap often differing considerably from the bulk material. Consequently, they are seen as customized precursors for functional materials in applications such as biological sensing and optoelectronics [79]. Since the electronic and optical properties of these materials are ultimately controlled by the physical dimensions of the crystallites, there is considerable interest in processing routes that yield nanoparticles of well-defined size and shape. Synthetic approaches for nanomaterial synthesis involve particle growth on an atom-by-atom or molecule-by-molecule basis until the desired size is achieved [80]. Such growth takes place spontaneously in super-saturated solutions and has been successfully used to create crystallites of well-defined size and shape. "Bottom-up" or synthetic approaches are attractive due to their versatility and ease of use; however, standard syntheses rarely yield product size distributions better than  $\pm 5\%$ . This means that it is almost always necessary to use some form of post-treatment (including electrophoresis, chromatography, precipitation and photocorrosion) to extract particles of well-defined size. Although nanoparticles with extremely narrow size distributions can ultimately be extracted, the starting point for all such methods is a polydisperse sample and thus product yields and conversions are necessarily low.

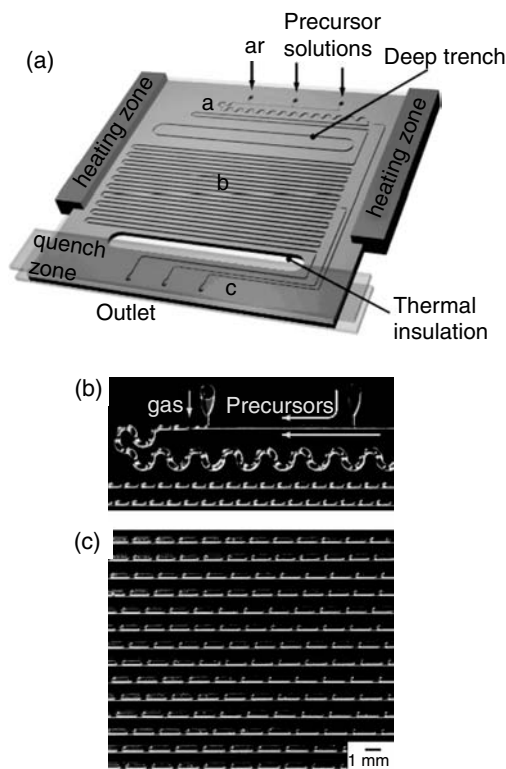

**FIGURE 42.4** (a) Silicon microfluidic reactor for performing glycosylation reactions over a wide range of experimental conditions. (b) Schematic representation of microfluidic circuit, which comprises three primary inlets, a mixing and reaction zone, a secondary inlet for quenching reagent and an outlet for analysis/collection. (c) Side view of microreactor. (d and e) Glycoside coupling reactions. (Taken from Ratner, D.M., et al., *Chemical Communications*, 2005, 578–580. With permission.)

At a fundamental level monodisperse nanoparticle populations can be created by ensuring that initial nucleation of solute molecules (to form “seed” particles) occurs on a timescale, which is rapid compared with the growth process (in which the seed particles confine dissolved solutes) [81]. Moreover, nuclei formation and growth should occur within an environment in which state functions are precisely controlled throughout. When these circumstances are not met, the size of nuclei and the particle growth rates vary according to location and result in a wide distribution of particle sizes. Unsurprisingly, a number of recent studies have demonstrated the effectiveness of continuous-flow microfluidic reactors in performing controlled nanoparticle synthesis [82]. These systems generally utilize simple flow regimes, whereby pure fluid component streams are mixed within low Reynolds’

number regimes. Variation in reaction residence times and reagent concentrations can be used control average particle size, while product polydispersity is minimized through reduction in residence time distributions and precise control of chemical state functions. For example, silver, cobalt, copper, cadmium sulphide [83,84], cadmium selenide [14,85], gold [86,87], palladium [88], titania [89,90], and CdSe-ZnS [91] core-shell have all been produced within a range of microfluidic reactors. In all cases low-polydispersity nanoparticles of varying size could be synthesized with space-time yields significantly higher than corresponding macroscale approaches.

More recent studies have addressed the issue of minimizing particle size distributions through the development of segmented flow reactors. For example, Ismagilov and coworkers [92] have reported multistep chemical production of CdS and CdS/CdSe core-shell nanoparticles within a microdroplet-based reactor. Importantly, such an approach allowed for millisecond time control and also enabled multiple reactions to be initiated by flowing additional reagent streams directly into individual droplets. In addition, Chan et al. [93] have reported the use of microfluidic droplet reactors for the high-temperature synthesis of CdSe nanoparticles, while Yen et al. [94] have used a gas-liquid segmented flow reactor containing multiple temperature zones (Figure 42.5) for the synthesis of high quality CdSe quantum dots. In all studies, enhanced mixing and reduced residence time distributions provide the driving force for improvements in reaction yield and size distribution.

**FIGURE 42.5** Microfluidic reactor for nanoparticle production. (a) Schematic illustrating the key components of the reactor. The reactor performs precursor mixing (section a), controlled particle growth (section b) and reaction quenching (section c). A halo etch region allows localization of temperature zones for reaction ( $>260^{\circ}\text{C}$ ) and quenching ( $<70^{\circ}\text{C}$ ). (b) Photograph of heated inlets and (c) photograph of main channel section. Red segments show the reaction solution, with dark segments defining argon gas. **TABLE 42.1**  
**Diversity of small-molecule syntheses performed within microfluidic reactors.**

Reaction	Product(s)	Conversion	Comments	Year/Reference
Bayer–Villiger oxidation	Lactones	<99%	Increased reactivity and selectivity	2006/[38]
Baylis–Hillman reaction	Baylis–Hillman adducts	<95%	C–C bond forming	2006/[39]
Autocatalytic nitration	Nitrophenols	65–76%	Autocatalysis	2005/[40]
Catalytic dehydrogenation	Toluene	88%	Gas-solid heterogeneous catalysis	2005/[41]
Suzuki–Miyaura coupling	Functionalised biphenols	<76%	Hydrodynamic pumping	2005/[42]
Grignard exchange reaction	Pentafluorobenzene	92%	Formation of Grignard reagents	2005/[43]
Friedel–Crafts aminoalkylation	1-( <i>N</i> -Butyl- <i>N</i> -methoxycarbonylaminomethyl)-2,4,6-trimethoxybenzene	96%	Improved selectivity with highly reactive substrates	2005/[44]
Imine hydrogenation	Amines	Quantitative		2005/[45]
Stereoselective alkylation	C–C bond	41% (ee 82%)	Using chiral auxiliary	2004/[46]
Hydrogenations	Alkenes	Quantitative	Triphase reaction system immobilized Palladium	2004/[47]
Michael addition	1,3-Diketones	95%	Stopped flow technique	2002/[48]
Suzuki coupling	Functionalized biphenols	70–100%	Microwave assisted	2004/[49]
Heterocyclic synthesis	1,2-Azoles	98–100%	Significant improvement on batch	2004/[50]
Fluorination	Fluorinated diketones	70%	Safety enhancement	1999/[27]
Esterification	Benzoic acid esters, phenyl esters	100%	EOF	2003/[51]
Photo-oxygenation	Ascaridole	85%	Safety enhancement	2002/[52]
Sandmeyer reaction	Diazonium intermediates	Various	Control over unstable intermediate	2003/[53]
Carbamate synthesis	Methyl carbamates	91%	Control over exothermic conditions	2004/[54]
Ring expansion (6–7 membered ring)	<i>N</i> - <i>tert</i> -Butoxycarbonyl-5-ethoxycarbonyl-4-perhydroazepinone	89%	Safety and control of reactive ethyl diazoacetate reagent	2004/[54]
Nitration	Nitrobenzene	65%		2001/[55]
Wittig reaction	Alkene C=C bond formation	39–59%		2001/[23]
Peptide synthesis	Peptides	100%	Quantitative yield in 20 min	2001/[32]
Aldol reaction	C–C bond via enolate	100%	Enolate generated via silyl enol ethers	2001/[56]
Enamine formation	Enamines	42%	Formation using DCC	2001/[57]

*Continued*

**TABLE 42.1**  
**(Continued)**

Reaction	Product(s)	Conversion	Comments	Year/Reference
Ugi 4 component coupling	$\alpha$ -Dialkylacetamide	—	Detection of reaction products and intermediates	2001/[58]
Dehydration of alcohols	Alkene	85–95%	Sulfated Zirconia catalyst	2000/[59]
Kumada–Corriu coupling	Coupling of aryl halide and Grignard reagent	60%	Nickel chelated to immobilised salen ligand	2001/[60]
Knoevenagel condensation	Condensation followed by hetero Diels–Alder reaction forming cycloadducts	50–68%	2 × 2 combinatorial array produced four products	2002/[61]
Phase transfer diazo coupling		~100%	Increased surface area, rapid diffusive phase transfer	2001/[62]
Phase transfer alkylations	Alkylated $\beta$ -keto esters	71–96%	Increased surface area, rapid diffusive phase transfer	2003/[63]
Hantzsch synthesis	2-Aminothiazoles	58–99%	Yields improved over bulk—heated under EOF	2002/[64]
Knorr reaction	Pyrazoles	52–99%	Sequential synthesis of 7 × 3 library	2003/[21]
Acid catalyzed esterification	Pyrenebutyric acid ethyl ester	83%	Surface area related rate enhancement	2003/[65]
Swern oxidations	Carbonyl compounds	81–100%	Room temperature conversions—Batch Swern usually below –50°C	2005/[66]
Photochlorination	1-Chloromethyl-2,4-diiocyanatobenzene	55%	80% selectivity (big increase over batch)	2002/[67]
Glycosylations	Glycosidic link for oligosaccharide assembly	—	Small quantity of glycosylating agent required	2005/[68]
Heck coupling reaction	Ethyl cinnamate	99%	Using a modular microreaction system	2005/[69]
Hornet–Wadsworth–Emmons	Olefins	91%	Using a modular microreaction system	2005/[69]
Diels–Alder cycloaddition	Cycloadduct	100%	Using a modular microreaction system	2005/[69]
Henry reaction	2-Nitro-1-phenylethanol	76%	Nitroaldol addition	2005/[69]
Reimer–Tiemann formylation	Formylated $\beta$ -naphthol	10%	Yields similar to bulk, allowed study of temperature effects	2005/[70]

## 42.6 CONCLUSIONS

The nature of the microfluidic environment allows for a control over physical properties such as energy transfer, mass transfer and mixing that is difficult to achieve using other approaches. The consequences of this for the synthetic chemist are that processes, which are controlled in large part by these properties, can be exploited to produce a range of products that are otherwise inaccessible. The control on the microscale leads to faster, cleaner and more specific reactions. In addition to this, the nature of the relationship between surface and bulk properties in the microfluidic environment ensures that reactions involving rapid exchanges of energy become manageable in a way that is not possible in larger reaction vessels.

Microfluidic approaches also show strong advantage in high-throughput systems, whether these be for catalyst screening or for combinatorial synthesis. The rapidity of data generation, which has already revolutionized the science of genomics, is also a major bonus in the application of microfluidics to these synthetic problems.

## 43.1 INTRODUCTION

As the genetic bioanalytical community continues to search for ways to improve DNA analysis for human identification, pathogen detection, and disease diagnosis, affecting more rapid, efficient, and timely results, the development of new analysis platforms becomes paramount.<sup>1,2</sup> Microfluidic systems have become increasingly attractive analytical tools for applications in many fields. Polymerase chain reaction (PCR)<sup>3–6</sup> and high-resolution DNA separations<sup>7–13</sup> are now readily carried out on-chip, as well as microfluidic purification of DNA or a variety of applications, including those in the clinical, biohazardous, and forensic sectors.<sup>14–19</sup> With successful microchip adaptation of these processes now commonplace, research focus has shifted toward the integration of these methods and with other sample processing steps (cell lysis and sorting, DNA quantitation)—the first step toward creation of a standalone device with full-genetic profiling capabilities. Due to the multistep nature of the DNA analysis process, careful consideration of solution compatibility and chemistry, fluidic interfacing and device engineering, as well as computer control and automation must be undertaken for seamless integration of these sample processing technologies. That is, the firmware, hardware, and “chemware” must all be carefully considered and optimized to create a multi-component, multi-functional design that can accommodate the complex process of genetic analysis. As a result, much attention is now being paid to device design and concept, interfacing diverse and complex chemical analyses, and computer-controlled automation, and, as a result, multi-component, microfluidic sample processing is now becoming a reality.

Integrated microfluidic platforms offer unique solutions to many of the problems currently facing genetic analysis for numerous applications. First, traditional genetic analyses necessitate multiple, time-consuming sample processing steps, often requiring different instrumentation and sample handling steps for each process, creating ample opportunity for contamination or loss of sample

during transfer.<sup>1</sup> Integrated microfluidic systems put forward the opportunity to have automated sample handling, reducing the user intervention and sample manipulation, as well as instrumentation required to perform the analysis.<sup>1,2</sup> In addition to reducing the time, cost, and handling required to accomplish these processing steps, a reduction in the amount of sample required for analysis is inherent to integrated microfluidic systems. By reducing sample and reagent consumption, a more efficient analysis is achieved. Consequently, a shift to microfluidic technology for genetic analysis will be impelled by the benefits of faster, more efficient, more automated and integrated sample processing that produces timely and accurate results with the reduced possibility of contamination and/or loss of sample.

Although microchips have been used for a variety of applications, this chapter is not a comprehensive review of this diverse field; rather, it will focus on the development of the “chemware” required for microfluidic sample processing for genetic analysis. In particular, the discussion will center on nucleic acid purification and PCR amplification, with highlights of efforts to develop other on-chip sample processing techniques, such as sample cleanup, cell sorting and lysis, and DNA quantitation, both alone and as components of integrated multi-process devices. Particular attention will be paid to the development of solid-phase purification of DNA and RNA in microfluidic systems due to the lack of review publications on this subject. The development of microfluidic hardware will also be addressed; however, the preponderance of this chapter will be devoted to the enhancement and integration of sample processing from a chemware perspective. In addition, this chapter will detail the development of integrated microfluidic processing devices for multiple genetic applications, as well as the utilization of microchips to enable fast, reproducible sample handling for human identification, rapid disease diagnosis, and pathogen detection.

## 43.2 DNA PURIFICATION

As the microfluidic community looks to develop systems capable of performing a full genetic evaluation, purified DNA or RNA is essential for most of these analyses. PCR-based methods for detection of disease and infection, as well as for human identification and other specific genetic analyses, have become the standard for many applications. In order for PCR to work efficiently and effectively, however, the DNA or RNA template used in the reaction must be free of contaminants that will inhibit the polymerase or interfere with other reagents necessary for the reaction to proceed. Consequently, a DNA purification step is vital to ensure that the starting template for PCR is free of contaminants and suitable for this enzymatic amplification. Thus, the inclusion of a DNA purification step in any functional genetic analysis micrototal analysis system ( $\mu$ TAS) is imperative. DNA purification (as opposed to cell isolation) prior to amplification provides many advantages, including, most importantly, the removal of sample PCR-inhibitors that can include cellular constituents (either proteins or lipids) in cell lysates, such as hemoglobin,<sup>20</sup> and an as yet unidentified factor in eosinophils that specifically inhibits reverse transcription-PCR.<sup>21</sup> In addition to these endogenous contaminants and inhibitors, in forensic science, the removal of environmental exogenous impurities such as humic acid from soil<sup>22</sup> and pollen,<sup>23</sup> is also vital, as the presence of these contaminants will also prevent successful amplification. Effective removal of both of these external and sample-based inhibitors is imperative to affect robust and efficient downstream PCR.

In addition, because many benefits associated with performing PCR in microdevices are achieved only when the volume of the PCR chamber is reduced, the use of a concentrating method for DNA isolation is not only advantageous, but also necessary, especially for samples that contain a low number of DNA template starting copies. Solid phase extraction (SPE) methods, such as those described herein, are not only effective at extracting highly purified DNA for subsequent analysis, but can also function as a concentrating step prior to PCR amplification. This concentration effect is not only beneficial for interfacing microfluidic techniques, but also could allow for a more successful PCR amplification in cases where low starting copy numbers are present, by providing the sample to be amplified in a smaller volume. Consequently, DNA purification, both as a means to remove

endogenous and exogenous contaminants and as a concentration step, is a critical component of microfluidic sample processing.

Although purification of DNA from biological samples has been accomplished using a variety of methods (see Rudi et al.<sup>24</sup> for a more comprehensive review), more recently developed conventional and commercially available techniques for DNA purification exploit silica SPE methods, these methods reducing the time required for the extraction while maintaining recovery, sample purity, and integrity. These techniques typically rely on a three-step bind/wash/elute protocol to purify DNA from interfering proteins and cellular debris. In addition to enabling faster sample preparation, these protocols are more easily translated into microdevice formats; as a consequence, solid phases such as silica beads or sol-gels, which can be easily packed into microdevices to create a SPE bed or column for DNA purification, have become some of the more common phases utilized for microscale purification, as will be discussed in the next section.<sup>14,15,18,19,25–27</sup> In addition, a variety of novel silica solid phases can be created in microdevices during the fabrication process<sup>16,17</sup> that are suitable for sample purification. All of these phases will be highlighted in detail in the text.

Silica-based methods such as those referenced above typically rely on DNA adsorption to the silica phase in the presence of a chaotropic agent, followed by elution of proteins with an isopropanol or ethanol wash, and subsequent DNA elution in water or buffer. DNA, a strong polyelectrolyte carrying two negative charges per base pair at most pHs, has a large negative surface charge. In addition, the surface of silica is also negatively charged, due to weakly acidic silanol groups, with an average  $pK_a$  ranging from 5 to 7.<sup>28</sup> This heterogenous, negatively charged silica surface makes the net electrostatic repulsion of the fixed charges on the DNA and the silica surfaces strongly disfavor adsorption at low ionic strength.<sup>28</sup>

In high ionic strength environments, however, the situation is markedly different. The dissolution of the chaotropic agent, guanidine hydrochloride (GuHCl) in water, is an endothermic process with a positive entropy change.<sup>28</sup> One molecule of GuHCl will bind, on average, 4.5 molecules of water (maximum six), which enables the effective dehydration of the DNA molecule and the surface of the silica at high concentrations.<sup>29</sup> Decreasing the water activity in solution through the addition of a chaotropic salt results in a decrease in solvent-accessible surface area, a loss of water bound, and an increase in entropy of the solution. In addition, the loss of water at high ionic strength conditions greatly reduces the electrostatic penalty for placing the negatively charged DNA adjacent to the negatively charged silica surface. Finally, when the pH of the solution is lowered from 8 to 5 (a pH  $\sim 6$  is typically utilized in many silica-based purifications), there is an increase surface hydroxyl groups on the silica phase, thus increasing the ability of the silica to form hydrogen bonds with the DNA in solution, and a decrease in free hydroxyls that diminishes solution competition with DNA for these hydrogen-bonding sites on the silica surface.<sup>28</sup> These combined effects are the major driving force behind DNA adsorption to silica: an increase in the entropy of the water molecules released from the DNA and silica surface and the reduction of the negative potential at the silica surface by the pH of the solution. In combination, they allow for the binding of nucleic acids to silica and the subsequent purification of nucleic acids from high ionic strength (6–8 M) chaotropic solutions.

The first reference of a true microchip-based, silica solid phase extraction exploiting this purification technique was published by Christel et al.<sup>17</sup> in 1999. In this research, a microdevice containing silica pillars with high surface-area-to-volume ratios to increase DNA adsorption was designed for the purification and concentration of DNA for PCR amplification. This represented the first microchip-based DNA purification accomplished; however, the fabrication of this device relied on a complex reactive ion etching technique, which limits the potential utility of this format. In addition, capture efficiencies reported with this device using prepurified stock lambda DNA were only 50%, considerably lower than what would be expected (upward of 80% for other silica-based methods) for a sample that did not contain proteins or other cellular debris (such as blood) limiting its utility for low copy number samples where effective retention and release of DNA is imperative. This device, however, provided the first example of a truly miniaturized DNA purification system and, consequently, set the stage for other microfluidic, silica-based extraction methods. Cady et al.<sup>16</sup> employed

**FIGURE 43.1** Examples of solid phases used for DNA purification in microdevices. (a) Scanning electron micrograph of silica pillars microfabricated into a DNA extraction microdevice. The spacing between pillars was 10  $\mu\text{m}$  and the depth and height of the pillars was adjusted between 20 and 50  $\mu\text{m}$ . (Figure adapted and reproduced from Cady, N. C., et al., *Biosens. Bioelectron.*, 2003, 19, 59–66. Copyright 2003. With permission from Elsevier.) (b) Micrograph (500 times) of a microchannel packed with silica particles immobilized with sol-gel resulting in a high-surface area silica solid phase for DNA purification. (Figure adapted and reproduced from Breadmore, M. C., et al., *Anal. Chem.*, 2003, 75, 1880–1886. Copyright 2003. With permission from American Chemical Society.) (c) Photomicrograph of a microchannel containing immobilized beads for DNA extraction. (Figure adapted and reproduced from Chung, Y. C., et al., *Lab Chip*, 2004, 4, 141–147. Copyright 2004. With permission from Royal Society of Chemistry.)

a similar design concept (depicted in Figure 43.1a), fabricating a device containing high surface area pillars, with the goal of providing a system with higher binding capacity ( $>200$  ng) the capable of handling large input volumes. It was, however, difficult to effectively evaluate this device design for sample preparation as no extraction efficiencies were reported in this manuscript. In addition, while effort toward the development of devices capable of extracting DNA from large volume samples is certainly needed, any purification method that will be effective in a microfluidic system must also yield concentrated DNA (in a small elution volume) amenable to downstream processes (e.g., PCR, where typical reaction volumes range from nanoliters to picoliters). With DNA eluted from the solid phase in an unusually large volume (250  $\mu\text{L}$ ) in this work, the likelihood that such a method could be effectively integrated with other microchip processes is limited. Devices that contain pillars created during the fabrication process do, however, represent one potential silica-based design that could provide reproducible and robust microscale solid-phase purifications of nucleic acids.

In a more direct translation of current macroscale, silica-based, SPE protocols other, microchip-based purification systems have focused on utilizing a packed silica-bead bed or silica sol-gel matrix solid phase for purification. This type of extraction was first miniaturized in a capillary format, to demonstrate the utility of the proposed method in the microscale, by Tian et al.,<sup>25</sup> who utilized a 500 nL capillary-based chamber packed with silica particles to establish that PCR-amplifiable DNA (with 80–90% of proteins removed during the load and wash steps) could be obtained from white blood cells with high extraction efficiencies (70%). This demonstrated the feasibility of incorporating such silica-based column purification methods into microfabricated devices and the effectiveness of such methods for the purification of DNA from a wide variety of biological species (white blood cells, cultured cells, and whole blood).

This same microscale extraction technique was extrapolated to the microchip by Wolfe et al.,<sup>18</sup> who evaluated a variety of silica and silica bead/sol-gel matrices for microchip DNA purification. In this work, a potential problem associated with using silica beads or particles in a microdevice was highlighted, that is, the tendency of these particles to pack tightly under flow during repetitive use, thus affecting the reproducibility of flow and the repeatability of the extractions. Recently, however, it has been suggested that if the devices are single use (which would be typical of devices designed for many applications), packed silica-bead solid phases are acceptable purification phases for DNA or RNA extraction, as demonstrated in Easley et al.,<sup>30</sup> Bienvenue et al.,<sup>31</sup> and Hagan

et al.,<sup>32</sup> and highlighted elsewhere in this chapter. Alternatively, the use of sol-gels (liquid colloidal suspensions of silica-based materials that can be acid or base catalyzed to gel in place), as described by Wolfe et al.,<sup>18</sup> have been demonstrated as efficient, reusable solid phases. These solutions are simply flowed into microchambers and, by controlling the catalyzed reaction, allowed to gel and form a porous DNA extraction bed with enough surface area for the binding of DNA, as demonstrated by Wu et al.,<sup>19</sup> who utilized this phase to extract DNA from bacterial (anthrax), viral (varicella zoster and herpes simplex), and human (blood) sources, with greater than 65% extraction efficiency demonstrate from blood. In a more recent translation of this work, Wen et al.<sup>27</sup> have employed the use of a photopolymerizable sol-gel monolith to extract DNA in a capillary-based system, which was further extrapolated to a microchip-based extraction. The photopolymerization step allows for easy and precise formation of the solid phase within the microdevice, without the use of retaining weirs or other microfabricated features, making it attractive for use in integrated systems. In addition, this solid phase has recently been incorporated into a novel two-stage microdevice that was developed for DNA extraction from blood—a C18 reverse phase column for protein capture (Stage 1) in series with a monolithic column for DNA extraction (Stage 2). This device has a high capacity for DNA in blood (>240 ng) and was found to achieve ~70% extraction efficiency, with effective removal of contaminating proteins. Consequently, sol-gels, like column-based solid phases, have been effectively employed as reproducible phases for DNA purification in microfluidic systems.

In addition to being used as solid phase for DNA purification, the sol-gel extraction medium can also be used as a “glue” to immobilize a silica-bead phase,<sup>33</sup> thus maintaining a hybrid, reproducible extraction column from run-to-run. This hybrid sol-gel/bead solid phase (depicted in Figure 43.1b) was evaluated extensively by Breadmore et al.,<sup>15</sup> who optimized flow rates and loading pH to effect a sample purification in 15 min from bacterial sources (anthrax and salmonella) and whole blood, with amplifiability of the resultant purified DNA demonstrated. In addition, intra- and interdevice reproducibility was demonstrated, with extraction efficiencies as high as 79% reported. The utility of this hybrid solid phase and extraction protocol was also demonstrated for DNA purification from sperm cells, with a view to the analysis of sexual assault evidence,<sup>14</sup> as described in Chapter 37. These results demonstrated the potential of microchip-based extraction methods for forensic analysis. In addition, this group has utilized silica beads alone as a purification phase, both for the purification of DNA<sup>30,31</sup> and RNA.<sup>32</sup> The purification of RNA from biological samples remains a challenging and often overlooked sample processing step. The work of Hagan et al.<sup>32</sup> represents the first example of a silica-based purification of RNA from crude samples, those of both clinical (cells lines of alveolar rhabdomyosarcoma (ARS) tumors) and forensic (semen stains) interest. The only other instance of a microfluidic purification of RNA present in the research to date was published by the Quake group<sup>34</sup> and is discussed later in this section.

Another unique silica-based approach to microscale DNA extraction currently under development utilizes a serpentine channel design, combined with an immobilized silica-bead solid phase and fluidic oscillation. This method, developed by Chung et al.,<sup>35</sup> relies on silica beads immobilized on the plasma-oxidized surface of the polymethylmethacrylate (PMMA) channels, instead of a packed-silica solid phase, as depicted in Figure 43.1c. Following bead immobilization, the solutions required for DNA binding, purification, and release are flowed back-and-forth through the device. This fluidic oscillation over the immobilized phase results in marked improvement of recovery and extraction efficiency over the same extraction methods with free beads. This method represents yet another variation of silica-based purifications that has been accomplished in microfluidic systems, exploiting previously optimized chemistries. In summary, the development of macroscale, commercial, silica SPE protocols has enabled the facile translation of DNA, and now RNA, extraction into microfluidic systems for a variety of applications.

Although silica-based purifications of DNA and RNA are, by far, the most common microfluidic methods for isolation of nucleic acids, there have also been other solid phases and methods explored

for DNA purification that deserve mention. Like more recently developed commercial technologies for nucleic acid purifications, pH-induced methods for extraction have also been miniaturized. Cao et al.<sup>26</sup> have utilized chitosan-coated silica beads that extract DNA at pH 5 and, subsequently, release the DNA into solution at pH 9. With this purification technique, the PCR inhibitory reagents typically utilized in silica-based purifications (isopropanol, ethanol, GuHCl, etc.) are not necessary, thus eliminating a major source of inhibitory contamination. Extraction efficiencies upward of 92% from biological samples including blood were reported and the purified nucleic acids were suitable for PCR amplification. Nakagawa et al.<sup>36</sup> have also reported a novel purification method for DNA using a microchannel coated with 3-aminopropyltriethoxysilane (APTES) or 3-[2-(2-aminoethylamino)-ethylamino]-propyltrimethoxysilane (AEEA) to introduce amine groups on the surface. Relying on surface electrostatic interactions between amine groups and DNA, this method also relies on a pH change (from 7.5 to 10.6) to elute DNA from the device and these researchers were able to recover 27–40% of the DNA, which was PCR-amplifiable, from a whole blood sample.

Quake and coworkers<sup>34</sup> have utilized an affinity column purification of both DNA and RNA in microfluidic devices, packing a microfluidic channel with derivatized polymer magnetic beads. Cell lysates can then be passed over the beads, the DNA or RNA retained on the column, and eluted in a wash step. With this system and a moderately abundant target (zinc finger OZF), sensitivity of detection on the order of 2 to 10 cells was obtained. In addition, the device was also utilized for DNA purification, with PCR-amplifiable DNA successfully isolated from *Escherichia coli* (*E. coli*) culture samples, demonstrating that the device design and method were versatile enough to accommodate both nucleic acid types. Additionally, Witek et al.<sup>37</sup> have utilized a photoactivated polycarbonate (PPC) device for isolation of DNA from both cell lysates and whole blood. The PPC chip was fabricated by exposing pristine polycarbonate surfaces to ultraviolet (UV) radiation that resulted in the formation of surface carboxylate groups through a photo-oxidation reaction. Subsequently, DNA can be precipitated onto the activated polycarbonate using a PEG/NaCl ethanol buffer, as seen in Figure 43.2, the proteins rinsed away, and the purified DNA eluted with deionized water. Extraction efficiencies of this device with prepurified DNA were upward of 85% and the DNA purified from blood was also suitable for PCR amplification. Finally, in a slightly different approach, Lee et al.<sup>38</sup> as described in more detail in a latter section of this chapter, have developed a way to use carboxyl-terminated beads to isolate DNA from lysed sample. By selectively binding and removing the proteins in the sample using these magnetic beads, the resultant purified DNA is left behind in solution and is PCR-amplifiable. This unique approach lends itself well to single-chamber purification/amplification sample processing devices, as will be described. Each of the solid-phase purification methods described here, although not as thoroughly characterized as their silica-based counterparts, exploits unique chemistries to purify DNA from interfering species and each may be appropriate in the development of diverse biological genetic analyses.

**FIGURE 43.2** Fluorescence microscopic images of the photoactivated surface of the channel incubated without gDNA (a) and then, incubated with gDNA labeled with YOPRO-1 (b). Note the presence of fluorescently labeled DNA bound to the channel. (Figure adapted and reproduced from Witek, M. A., et al., *Nucleic Acids Res.*, 2006, 34, 74. Copyright 2006. ### 43.3 PCR AMPLIFICATION

Polymerase chain reaction, an enzymatic process in which a specific region of DNA is replicated repeatedly to yield many copies of a particular sequence, was first described by Mullis et al.<sup>39</sup> in 1985. PCR is, theoretically, an exponential amplification of a target DNA sequence, that is, for every cycle completed, the number of target fragments doubles, such that after 30 cycles, approximately 30 billion copies of the target region of the DNA template have been created.<sup>39</sup> This amplification process relies on the heating and cooling (thermocycling) of samples using precise thermal control, typically through three temperatures, to allow for denaturing of the DNA (94°C), specific primer annealing (~60°C), and extension of the PCR fragment (~72°C). Thermocycling for PCR amplification can be accomplished in a number of ways. Conventional systems use thermal blocks that are heated and cooled to, in turn, heat and cool the reaction tubes that contain the reaction solutions. This indirect heating, combined with the large reaction volumes typically required (10–50  $\mu\text{L}$ ), limits cycling rates and results in 1–2 h amplification times for many clinical analyses and over 3 h for standard forensic amplifications.

Miniaturization of the reaction vessel provides one mechanism for decreasing the overall amplification time; by increasing the surface area-to-volume ratio, as accomplished in microfluidic devices, homogeneous solution temperatures can be achieved more rapidly, thus reducing the time required for thermocycling (for a more thorough discussion of microfluidic PCR systems, see the following reviews).<sup>40,41</sup> In addition, microfluidic-based miniaturization allows for a number of different heating methods to be exploited. Many groups<sup>3,6,38,42–56</sup> have chosen to utilize direct contact methods for microchip thermocycling, similar to those used to accomplish conventional thermocycling. With these methods, the microdevice is either in direct contact with a heating element or a heating element is fabricated into the system. With noncontact methods, the solution in the chamber is heated directly, independent of the chamber itself, to perform thermocycling and affect a more rapid analysis, as pioneered by Landers and coworkers<sup>4,5,57</sup> and demonstrated by Ahn and coworkers.<sup>58</sup>

Contact methods for PCR thermocycling are, by in large, the most common techniques used for amplification in microfluidic systems. By utilizing microdevices and contact heating, a number of groups<sup>42,44–52</sup> have significantly reduced the volume of sample and reagents required for amplification (on the nanoliter to picoliter range) and the importance of accomplishing PCR amplification in reduced volumes cannot be underestimated. In addition to potentially reducing the time required to perform amplification and the reduction in cost associated with the reduction in reagents used, the volume of solution generated is amenable to upstream and downstream processing and analysis components. To date, Quake and coworkers<sup>45</sup> have accomplished the lowest volume PCR amplifications, performing 450 pL RT-PCR on a 72-chamber chip. Although this paper has set the lower limit of reaction volume, speed of analysis was not the major focus and thermocycling was performed by placing the entire device in a conventional thermocycler. Consequently, even with a reduced reaction volume ideally leading to extremely fast thermocycling times, over an hour was still needed for RT-PCR amplification of a 240 bp fragment of human  $\beta$ -actin RNA. Although not all of the nanoliter–picoliter amplification devices cited previously accomplished rapid thermocycling, the reduction in volume permitted by these microprocessing systems will be an important component of successfully integrated microfluidic systems.

In addition to reducing the sample and reagent volume necessary to perform PCR amplification, multiple groups<sup>5,6,38,53–56,59</sup> have focused on reducing the time required to carry out thermocycling for PCR. Once again, using contact methods for heating in one of the fastest amplifications accomplished on-chip to-date, Hashimoto et al.<sup>6</sup> used a flow-through device consisting of discrete temperature zones (depicted in Figure 43.3) produced by electrical resistance heaters to amplify a 500 bp region of  $\lambda$ -phage DNA in 1.7 min and a 997 bp fragment of the same target in 3.2 min. It was determined, however, that the starting copy number of DNA will affect the speed at which PCR amplification can be performed and with a linear velocity of 10 mm/s, the lowest DNA starting copy to provide amplified signal in 20 cycles was  $1 \times 10^7$  copies. Consequently, without refinement, low copy number samples would be difficult to process with this system. Obeid et al.<sup>54</sup> also described

**FIGURE 43.3** Schematic views of the flow-through PCR device layout and model. The device on the right was used in the experiments described and had 50-mm wide channels separated by 250 mm. The device on the left had 50-mm wide channels separated by 50 mm and was not used in the research presented, however, it illustrates the versatility of the flow-through design. (Figure adapted and reproduced from Hashimoto, M., et al., *Lab Chip*, 2004, 4, 638–645. Copyright 2004. With permission from Royal Society of Chemistry.)

a flow-through amplification system that used four heating blocks, three for PCR amplification and the fourth for reverse transcription, which was utilized to perform 30 cycles of PCR in 6 min. Once again, however, the lower limit of starting copies required for this device was  $6.25 \times 10^6$ , making usage of this device problematic for situations where low template copy numbers are suspected. The amplification was, however, accomplished in 700 nL, making this device not only capable of rapid PCR but also lower volume amplification.

Finally, using infrared-mediated heating, a noncontact method has been developed to accomplish rapid PCR amplification. With this method, near-infrared (IR) radiation is utilized to selectively heat the reaction solution through excitation of vibrational modes of water molecules.<sup>4,5,57</sup> By doing so, the time required to heat the solution is dramatically decreased, resulting in a concomitant decrease in amplification time. In addition, by etching away the glass surrounding the PCR chamber, the thermal mass of the glass can be decreased, contributing to faster cycling rates. This modified glass device and indirect heating method has been utilized to perform rapid amplification, accomplishing 30 cycles in less than 5 min.<sup>60</sup> This technique has also been utilized to perform RT-PCR in a device with two IR-heating regions: one for the RT incubation and a second for PCR thermocycling.<sup>58</sup> The further development of this and other rapid thermocycling techniques presented herein represents a considerable step forward in the development of rapid, microfluidic PCR amplification and, combined with the reduced volume techniques described previously, provides a significant advancement of current technology. In addition, by executing low-volume, rapid thermocycling techniques, microfluidic PCR amplification will integrate more seamlessly with other microscale sample processing and genetic analysis steps, helping to facilitate the ultimate goal of an integrated total analysis system.

### 43.4 CELL SORTING, CELL LYSIS, AND DNA QUANTITATION

The selective isolation of different cell populations can be an important step in sample processing for a number of different genetic analyses. As described in Chapter 37, separation of sperm cells and vaginal epithelial cells is an important step for the effective analysis of sexual assault evidence and clinically, cell-sorting techniques have typically involved the isolation of specific cell types (i.e., cancer cells) from mixtures of other interfering species. A variety of methods can be exploited to separate different cell types, including dielectrophoresis, separation on the basis of the different physical and chemical properties of cell types (see Chapter 37), and acoustic differential separations. A number of groups have utilized microscale dielectrophoresis, the manipulation of particles in nonuniform electric fields, for separating different cell types (for comprehensive reviews on detailing the use of dielectrophoresis for cell sorting, see References 61 and 62). Typically, for these methods, electrodes are fabricated into the microdevice and differences in the dielectric makeup of the cells are exploited to allow for separation when these particles are placed in an electric field. Consequently, dielectrophoresis has become a noninvasive way to isolate different cell populations that is easily miniaturized in microfluidic systems.<sup>61,62</sup>

In addition, as described in detail in Chapter 37, cell populations that have inherent physical differences (such as sperm and vaginal epithelial cells) can be separated by simply exploiting these innate dissimilarities.<sup>63</sup> Also exploiting the size variation of different cell types to promote their facile separation, Yuen et al.<sup>64</sup> have utilized a weir-filter design to effectively isolate white blood cells (12–15  $\mu\text{m}$ ) from red blood cells (7–8  $\mu\text{m}$ ), as will be described later in this chapter. In addition, Quake and coworkers<sup>65,66</sup> have developed a pressure-driven cell sorter that can selectively isolate fluorescently-labeled cell populations. Austin and coworkers<sup>67</sup> have translated magnetic-activated cell sorting (MACS) to microscale using antibody-coated magnetic beads in a high magnetic field; however, to date there has been no published data showing the successful sorting of cells with this method. The same group,<sup>68,69</sup> however, has utilized deterministic lateral displacement to isolate red and white blood cells, and as well as platelets, from whole blood and for total cell removal from whole blood for plasma preparation. Finally, the development of microfluidic acoustic technology has enabled the separation of cells for a number of applications<sup>70–74</sup> including its employment for differential extraction (see Chapter 37). Selective cell sorting, although not the focus of this chapter, is a technique that lends itself well to microfluidics and provides for efficient sample enrichment prior to other sample processing techniques.

The lysis of cells on-chip (either after a cell-sorting step or from mixed sample sources) will, undoubtedly, be an important step in the development of sample processing microfluidic devices for total sample handling of crude biofluids. There are many examples in the literature that describe the lysis of cells in microfluidic systems and that can be easily divided into two categories: (1) those that utilize a chemical-based lysis and (2) those that employ a physical breakdown of the cell. Chemical cell lysis has been demonstrated using a variety of buffers and reagents<sup>14,75–78</sup> and typically involves flowing the particular lysing reagent on-chip to mix with the cells of interest. Physical breakdown of the cell can be caused by a number of different methods that disrupt the cellular structure and release the nucleic acids into solution. Electroporation,<sup>79,80</sup> electric field,<sup>81–84</sup> thermal lysis,<sup>85–88</sup> sonication,<sup>89</sup> laser/vibrationally induced,<sup>38</sup> and mechanical lysis with beads<sup>90</sup> or barbs<sup>91</sup> are all methods that have been utilized to rupture cells on chip. Successful release of cellular constituents through effective, complete, and rapid cell lysis is essential for downstream sample processing steps, such as SPE and PCR. Consequently, although often overlooked, microscale cell lysis is an indispensable component of any microfluidic sample processing systems.

Finally, on-chip DNA quantitation will undoubtedly be an important feature of microfluidic sample processing for a number of different applications where the amount of input DNA for downstream genetic analysis is crucial. As discussed more extensively in Chapter 37, quantitative PCR (qPCR) methods in microfluidic systems have not been demonstrated to date. However, there are a number of publications describing real-time PCR in microdevices and it is likely only a matter of time before

these methods will be extended to include qPCR (for a more detailed discussion of real-time PCR, see Chapter 37).

In addition to on-chip qPCR, another approach being developed to accomplish quantitation involves a more direct translation of current macroscale approaches to the microscale. Using a fluorescence-based assay, a valved device is used to generate a calibration curve, which is used to quantitate an unknown sample with on-chip mixing of the DNA with an intercalating dye.<sup>92</sup> This method was designed with the goal of integrating this technology with microscale solid phase purification techniques, for post-purification/pre-PCR quantitation, making it a potentially facile inclusion in sample preparatory genetic analysis chips. Although less focus has been paid to developing microfluidic techniques for on-chip determination of DNA concentration, this sample processing step is no less a necessity than the other more routinely miniaturized techniques and will be an important inclusion in the development of genetic  $\mu$ TAS for a number of applications.

The discussion of on-chip sample processing presented here is by no means exhaustive, rather it is meant to highlight the progress made in miniaturizing the main genetic processing steps required to affect a total analysis. The methods described represent some of the first and most recent examples of microchip-based sample preparation for downstream sample processing and a major step toward the development of microfluidic systems capable of accepting crude samples for DNA analysis. As advancement of these technologies has continued, the focus has shifted from basic method development of these and other individual processing techniques to the integration of several sample treatment steps in multi-process devices.

### 43.5 INTEGRATION OF MICROFLUIDIC HARDWARE: DESIGN, ENGINEERING, AND FLUIDIC CONTROL

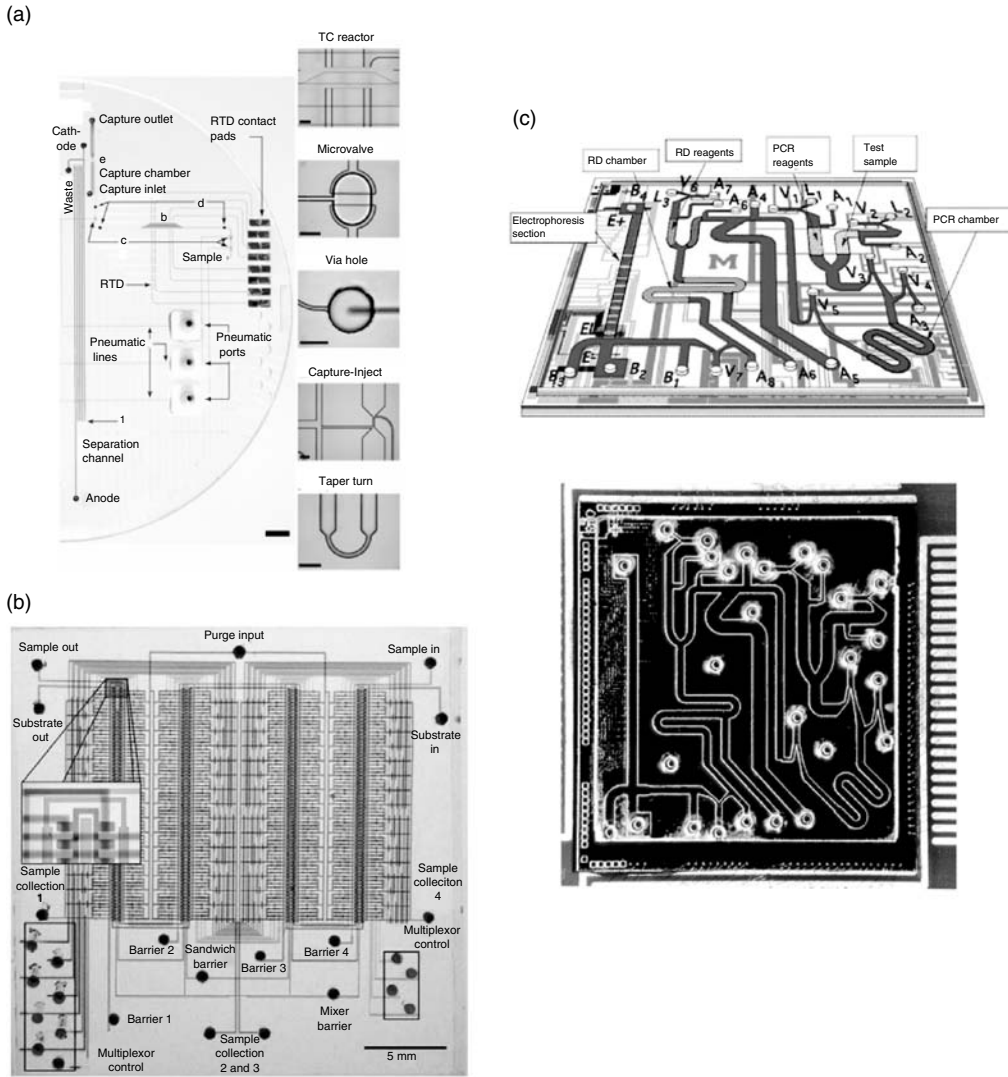

Although this chapter highlights sample processing in microfluidic systems in both stand-alone, single process devices and integrated multi-process systems (i.e., the development of the “chemware” to support miniaturized genetic analysis), it is of critical importance to note that the successful integration of such diverse chemistries would not be functionally possible without the concomitant advancement of microfluidic hardware. Advances at the device level have included innovative engineering to allow for elegant chip fluidic control through valving<sup>48,93–98</sup> and novel device designs,<sup>30,34,99–102</sup> as well as fluidic modeling of these systems where the surface-area-to-volume ratios are radically different from the macroworld (see Chapter 40 by Easley). The complexity and functionality of integrated microfluidic devices, as depicted in Figure 43.4, has made rapid sample processing and analytics for genetic typing possible. Without these advancements, the integrated “chemware” that will be detailed in the remainder of this chapter would simply not be feasible and consequently, it is worth nothing these achievements and recognizing that it is these innovations that have permitted the functional microfluidic integration of genetic analysis.

### 43.6 INTEGRATED SAMPLE PROCESSING WITHOUT ONLINE DETECTION

Recent literature has provided descriptions of several devices that have integrated sample processing steps, such as on-chip cell lysis, cell selection, DNA purification, and PCR amplification. In one of

---

**FIGURE 43.4 (Continued)** (c) An integrated microfluidic device designed by the Burns group. (*Top*) Schematic representation of the device, containing multiple different liquid entry channels (“L,” sample, PCR reagents and RD reagents), several metering channels, drop mixing intersections, a sealed PCR chamber, an open RD chamber, individually controlled valves, and an electrophoresis channel. (*Bottom*) Photograph of an assembled device (1.5 cm by 1.6 cm), which can control discrete liquid drops that are 100–240 nL, with fluidic channel dimensions of 200–600- $\mu$ m wide and 50- $\mu$ m deep. (Figure adapted and reproduced from Pal, R., et al., *Lab Chip*, 2005, 5, 1024–1032. Copyright 2005. With permission from Royal Society of Chemistry.)

**FIGURE 43.4** (a) The bioprocessor developed by the Mathies and coworkers. A photograph of the microdevice, showing one of two complete nucleic acid processing systems is shown (left), with sequencing reagent, capture gel, separation gel, and pneumatic channels. (Scale bar, 5 mm). The pictures on the right show multiple different components of the device, including (from top to bottom): a 250-nL thermal cycling reactor with RTDs (Scale bar, 1 mm), a 5-nL displacement volume microvalve, a 500- $\mu\text{m}$ -diameter via hole, a capture chamber and cross injector, and a 65- $\mu\text{m}$ -wide tapered turn (Scale bars, 300  $\mu\text{m}$ ). (Figure adapted and reproduced from Blazej, R. G., et al., *Proc. Natl. Acad. Sci. USA*, 2006, 103, 7240–7245. Copyright 2006. With permission from National Academy of Sciences.) (b) An optical micrograph of a nanofluidic system developed by the Quake and coworkers that can be used for parallelized high-throughput screening of fluorescence-based single-cell assays. The various inputs have been loaded with food dyes to show the channels and subelements of the fluidic logic. This chip has 2056 valves, which are used to manipulate 256 compartments containing bacterial cells expressing an enzyme of interest (or a library of mutants of that enzyme) that are combined on a pairwise basis with 256 other compartments containing a fluorogenic substrate used to assay for a desired activity. Cells that display a particularly interesting activity can be selected and recovered from the chip using valve-based addressing of the compartments. (Figure adapted and reproduced from Hong, J. W., et al., *Nat. Biotechnol.*, 2003, 10, 1179–1183. Copyright 2003. With permission from Nature Publishing Group.) **(Caption continued opposite on page 1216.)**

**FIGURE 43.5** On-chip lysis of sperm cells integrated with microchip-based DNA extraction. All panels show a section of the microchip extraction channel ( $\sim 1$  mm) at the front edge of the silica bed by either light (Panels a and b) or fluorescence (Panels c through f) microscopy. No inherent fluorescence was seen in the channel when irradiated with 480–550 nm light (b), before cell loading. DEAD Red<sup>TM</sup>-labeled sperm cells were flowed into the channel and packed up against the beads, while the silica bed front was visualized (Panel c). After flow of the dual-lysis/loading buffer was subsequently initiated (Panel d), the fluorescence decreased over the next few minutes in (Panels e and f) and was essentially nonexistent after 5 min (data not shown). (Figure adapted and reproduced from Bienvenue, J. M., et al., *J. Forensic Sci.*, 2006, 51, 266–273. Copyright 2006. With permission from Blackwell Publishing.)

the more simplistic integrations of two sample processing steps, cell lysis and nucleic acid extraction were demonstrated in the same microdevice by Bienvenue et al.,<sup>14</sup> who developed a method for loading whole sperm cells into a device containing a hybrid silica-bead/sol-gel extraction column. The cells packed against the leading edge of the silica-packed column, penetrating only slightly into the solid phase, as depicted in Figure 43.5. Following the packing step (Figure 43.5a through c), a dual cell lysis/DNA loading buffer was flowed over the packed cells and column (Figure 43.5d through f), lysing them and releasing their contents into solution for subsequent binding to the silica bed. Purification was then carried out as would typically be accomplished for silica-based methods, with an isopropanol wash to remove interfering species, and finally elution with water. The resultant eluate was subjected to forensic short tandem repeat (STR) amplification and the genetic profile compared to that obtained using standard conventional silica methods. The microchip-obtained profile was consistent with the profile generated using the kit-based purification, demonstrating that not only was the dual-process device as least as functional as the open-system conventional methods, but also that this closed microfluidic system have potential as a forensic sample processing tool, where prevention of contamination is of paramount importance.

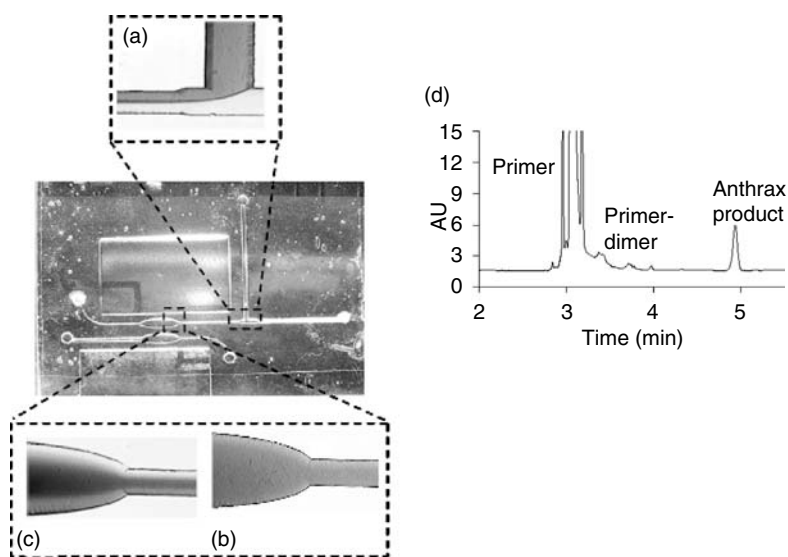

In 2001, Yuen et al.<sup>64</sup> published a report describing an integrated system that performed cell isolation and direct PCR amplification. Using weir-type filter constructed of silicon that spanned the microfluidic channel to perform the isolation, blood ( $<3 \mu\text{L}$ ) was flowed into the channel. Owing to their larger size (12–15  $\mu\text{m}$  in diameter as opposed to 7–8  $\mu\text{m}$  in red blood cells), the white blood cells were trapped between the top of the weir and the bottom of the microdevice cover plate. Held there, the PCR master mix was flowed into the chamber and the device subjected to thermocycling (and thermal lysis of the cells) using a copper block heater fabricated into a plexiglass

holder. With this system, successful cell isolation and PCR amplification of a 236 bp fragment of the human coagulation Factor V was accomplished; however, the authors note that the presence of too many white blood cells resulted in significant inhibition of amplification, most likely due to the inhibitory factor in eosinophils.<sup>21</sup> These results suggested that although the cell separation and direct PCR method presented was a functional means to obtain sequence-specific genetic results, the inclusion of a true DNA purification step will still be essential for further development of such a technique.

In addition to this work, Hong et al.<sup>34</sup> described a nanoliter-scale processor that performs cell isolation, cell lysis, and nucleic acid purification on a single platform. In their work, a device was designed that contained 100  $\mu\text{m}$  wide fluidic channels, in which three holding chambers (lysis buffer, cell, and bead) were created using valve isolation. The various reagents required for each different step of the analysis were flowed into the chip through different inlets, with cells mobilized in the device and retained in cell holding chambers. Following cell retention, the valve between the cell chamber and the lysis buffer chamber was opened, allowing lysis buffer to mix with and lyse the cells. The resultant corresponding cell lysate was then flowed over an on-chip mRNA affinity column (as described previously in the extraction section of this chapter), during which the desired mRNA was retained on the beads. The beads were then removed from the device and used directly in the off-chip RT-PCR amplification. This device and method were utilized to isolate mRNA from samples containing single cells, with two different targets ( $\beta$ -actin, a high-abundance transcript and zinc finger OZF, a moderate-abundance transcript). This report also described the development of a DNA purification chip, a device capable of cell lysis and affinity purification. Unique to this device was the use of novel channel designs and flow patterns, as well as the use of rotary mixers that provide comprehensive on-chip mixing of cells and lysate—a process that would require consume hours to complete relying on diffusive mixing. Once again, the beads were removed from the device subsequent to DNA capture, and the amplification of the gene encoding prelipin peptidase-dependent protein (*ppdD*) was accomplished off-chip. Importantly, these two devices demonstrated the feasibility of incorporating multiple sample processing steps in microfluidic systems for the preparation of both DNA and RNA for genetic interrogation, successfully integrating cell lysis and nucleic acid purification in devices with unique architectures and precision fluidic control elements.

Collectively, these reports highlight the importance of integrating multiple sample processing steps into single multi-purpose microdevices. By incorporating on-chip cell lysis or cell sorting with either purification or amplification, more efficient processing was accomplished in closed, microfluidic systems, reducing not only the opportunity for contamination and the degree of user intervention required, but also the volume of sample and reagents consumed. Although each of these designs requires further refinement and inclusion of additional sample processing and/or analytical steps before they can be considered complete, through these examples, great progress has been made toward the development of a lab-on-a-chip,  $\mu\text{TAS}$  device capable of total sample preparation and analysis.

The integration of DNA purification and PCR amplification remains a formidable and much-overlooked undertaking. As argued earlier, purification of DNA before PCR amplification is imperative for a variety of reasons—yet there are only a few reports of integrated DNA purification and amplification devices in the literature to-date.<sup>31,38,103,104</sup> The inherent incompatibility of the reagents (chaotropic salts, organics, etc.) necessary to perform many types of nucleic acid purifications (particularly silica-based nucleic acid isolation) with the polymerase chain reaction, make fluidic coupling of these two dramatically and inherently different processes a challenging task. Legendre et al.<sup>103</sup> circumvent these problems with a valveless chip design that used the previously described silica-bead hybrid solid phase and combined with a conventional block thermocycler for PCR. Using a dual syringe system, reagents from the load and wash step of this silica-based purification were simply passed through the PCR domain and out of the device. DNA could then be eluted from the SPE domain directly into the PCR chamber, while master mix containing the reagents necessary for PCR was flowed in through a side channel for subsequent amplification, removing the

**FIGURE 43.6** Microfluidic mixing in the integrated purification/amplification device. (a) Blue dye was flowed through the side channel, while yellow food dye was flowed through the SPE bed. Note the laminar flow. (b) After entrance into the PCR chamber, blue and yellow dyes were only mixed in the center of the channel, due to diffusion. (c) Following the initial denaturation step of thermocycling, green color was observed in the PCR chamber indicating adequate mixing of the two streams. (d) Electropherogram showing the results of application of the integrated DNA purification/amplification device to biowarfare agent detection. Anthrax spores on a nasal swab were eluted in lysis buffer and loaded onto the device for purification of DNA, integrated with IR-mediated PCR. The capillary electropherogram depicts successful amplification of a 211 bp product peak of *B. anthracis* and this total sample processing was accomplished in the total analysis time less than 23 min. (Figure adapted and reproduced from Legendre, L. A., et al., *Anal. Chem.*, 2006, 78, 1444–1451. Copyright 2006. With permission from American Chemical Society.)

offending contaminating solvents from the device. Co-mobilization of the reagents delivered through two separate syringes allowed for 1:1 mixing of the eluting DNA and the PCR reagents in the PCR chamber (as depicted in Figure 43.6a through c), where the mixture was could be thermocycled for DNA amplification using a conventional thermocycler. This dual-process microdevice was utilized for the successful purification of DNA from a diversity of biofluids, including buccal cells, blood, and semen followed by target-specific amplification.<sup>103</sup> In addition, this microdevice was also utilized to accomplish the microfluidically integrated purification and targeted DNA amplification of sequences from *Bacillus anthracis* (*B. anthracis*) isolated from a mock nasal swab with a total analytical time of less than 23 min,<sup>103</sup> as depicted in Figure 43.6d, using the IR-mediated, noncontact thermocycling method described earlier in this chapter. This work represented the initial efforts to integrate DNA purification and PCR amplification, with a view toward the development of a sample processing device capable of handling of a wide array of input samples for a wide variety of applications.

A similar device design was also utilized to explore the integration of DNA purification and multiplexed amplifications for forensic analysis.<sup>31</sup> In this work, device design and capacity were further explored and methodologies to incorporate the commercially-available reagents commonly utilized for forensic analyses were investigated. The challenges associated with microfluidic integration for forensic analysis are complicated by the need to develop systems that utilize established, validated, and commercially available reagents/protocols, as described in Chapter 37. As a consequence, microfluidic systems must be developed that interface seamlessly with existing, validated, and court-tested reagents, protocols, and technology, providing a substantial decrease in reagents and sample consumed by the analysis, as well as cost per sample, and significant improvements in time to result and prevention of contamination. These changes will provide the motivation to

move beyond previously established techniques and promote the inclusion of microfluidic systems in general casework analysis. The simple device described earlier was used to demonstrate the feasibility of microfluidic sample processing in a closed system, utilizing common benchtop equipment and commercially-available, kit-based reagents. It was utilized to purify DNA from semen (a commonly encountered biofluid in sexual assaults) and perform integrated, multiplexed amplification using the standardized kit-based reagents employed for conventional forensic genetic interrogation, as highlighted in Chapter 37.

Each of the devices described in this section has functionally integrated two or more sample processing steps. Using novel chip designs, multiple sample processing steps (including cell sorting, cell lysis, DNA purification, and PCR amplification) could be accomplished in an integrated system, providing more automated and more efficient sample handling. The basic integration of these steps has served as a catalyst to the development of fully integrated systems with both sample processing and analytical capabilities. The functional development of these integrated chemware systems has and will continue to impel, the evolution of  $\mu$ TAS for genetic analysis.

### 43.7 INTEGRATED-SAMPLE PROCESSING WITH ONLINE DETECTION

It is important to distinguish integrated-sample processing devices from devices that have incorporated both sample processing and an endpoint analysis step. All of the devices highlighted in the previous section are capable of sample manipulation, but do not have an online detection step in their microfluidic architecture. The following section will detail  $\mu$ TAS that are capable of both sample handling and analytical detection for genetic analysis. Building in complexity, these devices contain the hardware and “chemware” necessary to perform integrated total analysis, providing a genotypic “answer” following sample handling, and will be discussed in detail in the next section. In addition, although the focus of this chapter is on the development of sample processing, both in stand-alone microfluidic devices and integrated processing systems, it is important to note that the integration of PCR amplification and microchip electrophoresis has been accomplished by a number of groups.<sup>42,99,100,105–116</sup> Integration of PCR with electrophoretic analysis is an important and essential step toward the development of  $\mu$ TAS devices for genetic interrogation; however, we have chosen to focus this chapter on the integration of multiple sample processing steps, leaving the integration of sample processing and analytical steps for future discussion, except in the rare cases where an analytical step was incorporated with multi-process sample handling. Consequently, detailed explanations of integrated PCR-(ME) devices will not be explored.

In one of the earliest examples of a device capable of performing multiple, integrated sample processing steps followed by analysis, Waters et al.<sup>88</sup> described a device in which that represents one of the first examples of integrated sample processing combined with an analytical step to affect a more complete analysis in a closed microfluidic system. In this particular device, thermal cell lysis, followed by direct PCR amplification and electrophoretic sizing was accomplished. With this method, whole *E. coli* cells were loaded into the device along with PCR master mix. Following loading, the entire device was placed into a conventional benchtop thermocycler and subjected to a typical PCR amplification. During the initial 4-min heating step (94°C), the cells were lysed, releasing their DNA into solution, which could then be amplified during thermocycling, ultimately followed by electrophoretic sizing using microchip electrophoresis. Although this method was successfully employed to perform integrated cell lysis, amplification, and electrophoretic analysis, without the inclusion of a DNA purification step in this method, this device would be limited to use with samples that do not contain significant concentrations of PCR inhibitors. It does, however, represent one of the first examples of integrated sample processing, combined with an analytical step, to affect a more complete analysis in a closed microfluidic system.

As a more complex example of integrated sample processing, Lagally et al.<sup>117</sup> developed a device capable of dielectrophoretic cell sorting and on-chip cell lysis, followed by sequence-specific

**FIGURE 43.7** On-chip trapping of cells was accomplished using the integrated microfluidic system described by Lagally et al. (a) An epifluorescence image taken after 10 min of cell flow over the interdigitated microelectrodes without DEP voltage applied. Nonspecific binding does not occur and no cells are visible. (b) The same microelectrodes after 10 min of flow with 7 V applied at 1 kHz, as pictured, cells are captured by DEP onto the electrodes where they can be further processed. (Figure adapted and reproduced from Lagally, E. T., et al., *Lab Chip*, 2005, 5, 1053–1058. Copyright 2005. With permission from Royal Society of Chemistry.)

hybridization. This device was used to affect a 160-fold increase in cell concentration by trapping and concentrating the cells in a continuous flowing stream (100  $\mu\text{L}/\text{h}$  for 10 min) using positive dielectrophoresis in a 100 nL plug and an on-chip valving system. Following cell trapping (as depicted in Figure 43.7), the lysis buffer and molecular beacon are added to the cells and detection of *E. coli* MC1061 cells was accomplished via the sequence-specific hybridization of the beacon to rRNA of the bacteria with fluorescence measured by laser scanning confocal microscopy. By using high concentrations of guanidine thiocyanate (4 M), not only was cell lysis promoted, but also a more rapid hybridization of target DNA to the molecular beacon probe was achieved (immediate binding versus upward of 40 min when placed in TE buffer), due to a decrease in the melting temperature of the nucleic acid/molecular beacon probe hybrids. Detection of as few as 25 cells in less than 30 min was accomplished in this manner, making this device a rapid total analysis tool capable of taking in crude sample, performing integrated sample processing, followed by an analytical/detection step to produce sequence-specific results.

Yeung et al.<sup>118</sup> have described a device for integrated thermal cell lysis, specific target DNA isolation, followed by PCR amplification and hybridization detection. In this work, intact cells were broken down by thermal lysis (at 90°C) in the presence of biotinylated genome capture probes. Following cell lysis, the temperature of the chamber was lowered to 50°C, where the probes bound to their target sequences and, following the addition of avidin-coated magnetic particles, specific genome sequences were isolated from cellular debris and interfering proteins by washing away the unbound species. The captured DNA was then amplified using asymmetric PCR and the resultant amplicon hybridized to detection electrodes, labeled with gold nanoparticles, and detected by electrocatalytic silver deposition and electrochemical silver dissolution. With this method, two different bacterial species (*E. coli* and *Bacillus subtilis* (*B. subtilis*)) could be detected in a mixed sample, however, the device was only evaluated with cultured cells, so its performance with more complex biofluids is unknown at this time.

In another example of integrated sample processing, Lee et al.<sup>38</sup> accomplished cell lysis, DNA purification, and PCR amplification for pathogen detection using a single-chamber device. In this work, the authors developed a Laser-Irradiated Magnetic Bead System (LIMBS) for cell lysis and

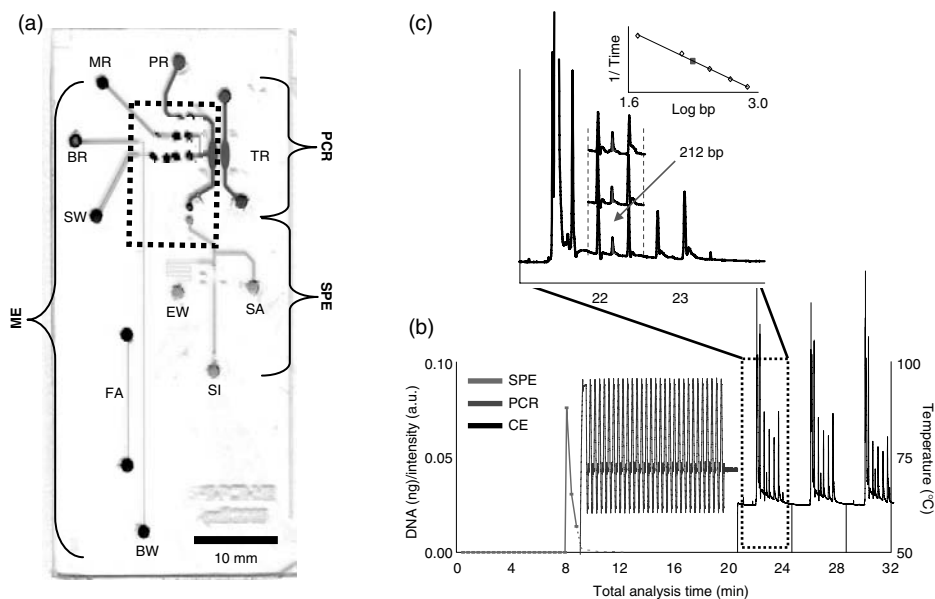

DNA purification from pathogens. With this method, pathogen and carboxyl-terminated magnetic beads were loaded into the microchip and placed into a chip guide module. A high-power laser beam (808 nm) was then applied to the microdevice while it was simultaneously vibrated to facilitate lysis of the cells. In addition to promoting cell lysis, when the laser was fired, the proteins were adsorbed to the surface of the magnetic beads, while the DNA remained free in solution. Following removal of the beads, the resultant DNA-containing solution was suitable for real-time PCR amplification. Although extraction efficiencies with this method were not reported, this single-chamber protocol was utilized to successfully lyse *E. coli* and Gram-positive bacterial cells, as well as hepatitis B virus mixed with human serum, with a higher efficiency of DNA release using the LIMBS method than that of other conventional cell lysis methods (e.g., boiling). In addition, successful lysis, purification, and real-time PCR amplification was performed in this single-chamber device using cultured *E. coli* cells, demonstrating the potential of this method for pathogen detection.

To date, only a few examples can be found in the literature describing a singular microfluidic chip capable of accepting crude sample lysate (from complex biofluids), purifying and extracting the DNA, accomplishing a target-specific amplification, and then performing online genetic analysis. In 2004, Liu et al.<sup>85</sup> described an integrated microfluidic system that performed multiple sample processing steps and integrated detection of target amplicon. In this system, sample and immunomagnetic capture beads were loaded into a chamber for incubation. Following successful isolation of the target cells, a washing step was performed, followed by loading of the chamber with the necessary PCR reagents. Subsequently, thermal lysis and PCR thermocycling was carried out, followed by incubation with and acoustic mixing of the amplicon for a hybridization reaction. Following immobilization of the DNA, ferrocene-labeled signaling probes hybridized with the target DNA, were bound to the immobilized probes, and could be detected on-chip. The isolation and detection of *E. coli* from a mock *E. coli*/rabbit blood mixture, as well as single-nucleotide polymorphism analysis directly from diluted blood were demonstrated. This device is the earliest example of a fully functional microanalytical system capable of accepting crude sample and producing a genotypic readout, establishing that multifunctional, microfluidic devices could function as viable automated genetic analysis systems.

More recently, Cady et al.<sup>104</sup> have described a method for integrating sample processing with detection, by developing a device capable of silica-based purification using the silica-coated pillar design described earlier in this chapter, integrated with online, real-time PCR. With this device, a silica-based purification was achieved for the pathogenic bacterium *Listeria monocytogenes*—a rod-shaped bacterium that is the causative agent in listeriosis, a serious infection caused by eating contaminated food—followed by integrated real-time amplification using SYBR Green, in an average of 45 min. In addition, this integrated system could detect as few as 104–107 cells, making this a sensitive screening technique that combines both sample processing and analytical analysis in a simple two-component device.

Finally, late in 2006, Easley et al.<sup>30</sup> described a valved microdevice with discreet functional domains: a silica-bead-based purification chamber, fluidically integrated to a PCR chamber suitable for IR-mediated thermocycling and connected to an electrophoretic domain, where separation and detection of amplicon was accomplished. This microgenetic analysis (MGA) device was the first of its kind that was capable of accepting sample as crude as whole blood and performing complete sample processing and genotypic analysis. As depicted in Figure 43.8, the device was evaluated with blood drawn from a mouse infected with *B. anthracis* before prior to the onset of symptoms. Purification of nucleic acids from less than 1  $\mu\text{L}$  of this sample was accomplished in less than 10 min, followed by target-specific amplification in 11 min. Utilizing the sophisticated valve system, amplicon could then be repeatedly co-injected with sizing standard (both via pressure) for separation, detection, and accurate sizing using microchip electrophoresis in less than 3 min, making the total time required for this analysis less than 24 min.

In addition, the versatility of the same microdevice and method was demonstrated by application to the complete genetic analysis of 1  $\mu\text{L}$  of nasal aspirate from a patient symptomatic of whooping cough. The presence of *Bacillus pertussis* (*B. pertussis*) was confirmed by the amplification of a

**FIGURE 43.8** The integrated  $\mu$ TAS described by Easley et al. used for the integrated-sample processing and detection of *B. anthracis* in murine blood. (a) The IgA device with dyes placed in the channels for visualization. Domains for DNA extraction, PCR amplification, injection, and separation are connected through a network of channels and vias. SPE reservoirs are labeled for sample inlet (SI), sidearm (SA), and extraction waste (EW). Injection reservoirs are labeled for PCR reservoir (PR), marker reservoir (MR), and sample waste (SW). Electrophoresis reservoirs are labeled for buffer reservoir (BR) and buffer waste (BW). Additional domains patterned onto the device include the temperature reference (TR) chamber and fluorescence alignment (FA) channel. The flow control region is outlined by a dashed box. Device dimensions are  $30 \times 63.5$  mm, with a total solution volume less than 10 mL. (a) Detector responses during all three stages of sample processing and analysis are portrayed in terms of total analysis time. The SPE trace (green) was taken from an offline DNA extraction of the same murine sample and is representative of the total DNA concentration observed in a typical extraction. The temperature and fluorescence intensity represent online data, with a total analysis time of less than 24 min. Three sequential injections and separations were carried out to ensure the presence of amplified product. (c) Magnified view of the first separation shown in (b), with the product peak marked and sized. The second and third runs are overlaid with the time axis cropped. The inset plot shows the sizing curve of inverse migration time versus log (base pairs) with both the sizing standard peaks (open diamonds) and product (red square) plotted for all three runs shown in (a) (error bars included). From this data, the product was sized as  $212 \pm 3$  bp. (Figure adapted and reproduced from Easley, C. J., et al., *Proc. Natl. Acad. Sci. USA*, 2006, 103, 19272–19277. Copyright 2006. With permission from National Academy of Sciences.)

fragment of the *IS481* repeated insertion sequence, as confirmed by sequencing of the amplicon. With a total analysis time again of less than 24 min, this application further demonstrated the versatility and robustness of the method and system, thus highlighting the potential of this type of total analysis device for application to rapid, point-of-care testing for a variety of applications. Like the work presented by Liu et al.,<sup>85</sup> this device integrated multiple sample processing steps in a single microfluidic device. However, improving upon this earlier work, Easley et al. were able to establish a rapid analysis (<24 min versus 3.5 h) and utilize two crude input samples (infected murine blood from asymptomatic mice and human nasal aspirate versus a mock rabbit blood/bacteria mixture). This  $\mu$ TAS and the other integrated devices described here represent the first in what will surely be a long line of increasingly more sophisticated integrated sample processing and analytical devices for genetic interrogation and total genetic profiling.

### 43.8 CONCLUDING REMARKS

The path to creating integrated microdevices for bioanalysis is not only riddled with cutting-edge scientific challenges, it is ripe with cutting-edge engineering challenges as well. The  $\mu$ TAS field today has reached a milestone, solving or circumventing many of these critical challenges, both with hardware and “chemware,” to generate the integrated multi-functional microdevices described herein. This has required clever design and novel approaches to integrating the necessary the hardware, firmware, and “chemware” into the microdevice in a functional manner. Compartmentalization for isolation of different chemistries in different functional domains, as described in the examples presented herein represents a breakthrough in terms of functional bandwidth for microfluidic devices. In addition, the development of precision fluidic control components and novel device designs has enabled the advancement of integrated chemistries; providing the necessary hardware to support the “chemware” as an essential component of integrated microfluidics.

The successful development of integrated microfluidic systems for genetic analysis represents an important approach to the improvement of analytical technology for many applications (e.g., forensics, clinical analysis). The advancement of reproducible, optimized methods for microchip DNA purification, PCR amplification, and other sample pretreatment techniques has enabled the subsequent development of integrated sample processing systems; without consistent, reliable standalone microfluidic processing, successful and consistent integrated analyses are an impossibility. The work presented here describes the development of these sample processing devices, highlights the flexibility of microfluidic systems for accomplishing a wide variety of genetic analysis applications, and the underscores importance of the inclusion of pretreatment steps in the development of  $\mu$ TAS.

Future work with integrated sample processing microdevices will likely focus on the development of systems capable of total sample manipulation, with the versatility to handle multiple input samples. In addition, new generation devices will likely be able to perform sample-dependent processing, that is, the device will have many different fluidic handling steps incorporated, and the steps applied in the processing can be tailored to the type of input sample. Automation of these devices will be essential and the integration of these sample processing techniques with microfluidic analytical technologies will be imperative. The continued successful development of a genetic  $\mu$ TAS will hinge on sustained effort directed toward the advancement of enhanced microfluidic sample processing and integrated handling systems.

## 44.1 INTRODUCTION

There is an urgent need to find means to efficiently separate and manipulate cells and particles in microfluidic chips because conventional mechanical separation concepts are not readily amenable to downscaling as the channel dimensions and the particle sizes are approaching each other and thus, physical restrictions in the flow paths tend to cause channel blockage. Therefore, noncontact modes to induce forces on particles are of interest. Recently, ultrasonic standing waves have proven beneficial in the quest for techniques that generate relatively large forces, which simultaneously are compatible with microchip technologies and system integration.

## 44.2 BACKGROUND

Manipulation and spatial control of particulate matter in microspace are gaining interest within the microtechnology community. This has become especially attractive when combining microfluidic structures with physical concepts that induce controlled forces on particles inside microchannels. Modern lithographic techniques enable the design and fabrication of static microstructures that allow mechanical separation and capturing of cells and particles in streaming microsystems. On the other hand, concepts that allow noncontact cell separation and capturing offer an enhanced functionality in terms of nonclogging continuous flow separation with low mechanical stress, that is, low shear rate and low surface interaction. The literature is well provided with mechanical filter concepts, ranging from conventional slits<sup>1,2</sup> for size exclusion separation to advanced Patchinco-style single-cell capture devices.<sup>3</sup> Recent developments by the Seki<sup>4</sup> group demonstrate elegant microscale solutions to laminar-flow-based size selection of particles and cells that, for example, enable clear discrimination of erythrocytes from leukocytes.<sup>5</sup> A similar approach was pioneered by the Austin group<sup>6,7</sup> demonstrating the deterministic lateral displacement separation device that enables discrimination of particles with size differences of tens of micrometers. Common to these concepts are all the uses of sieving features or laminar flow splitting schemes in a continuous flow.

In contrast, techniques that induce an external force on a particle in a microfluidic environment, not necessarily requiring a continuous flow mode for stable operation, are gaining attention. The use of an optically induced force, optical tweezers, for spatial control of cells under microscope surveillance has since long been a valuable research tool<sup>8,9</sup> and is now available as commercial instrumentation. Likewise, the use of the dielectrophoretic properties of cells and particles have been widely researched and utilized in the development of microsystems for particle and cell separation and trapping.<sup>10–14</sup> More recent developments have taken dielectrophoresis electrodes to a single-sided chip layout, thereby, vastly reducing complexity in dielectrophoretic chip designs.<sup>15,16</sup> Further work by Voldman<sup>17</sup> has also demonstrated particle separation based on combined physical features such as iso-dielectrophoresis where lateral ion gradients orthogonal to the induced dielectrophoretic force serve as the basis for spatially defining a particle's zero dielectrophoretic force position in a channel.

With the advent of biofunctionalized magnetic microparticles, magnetophoretic separation has also recently emerged as a potential mode of advanced particle separation. Pamme and Manz<sup>18</sup> have reported fundamental developments in microchip-integrated particle separation based on the net force acting on the particles streaming in a flow orthogonal to the direction of the applied magnetic field. This principle was later also employed to the magnetic bead-based extraction of mouse macrophages and human ovarian cancer cells.<sup>19</sup>

An alternative to dielectrophoretic or magnetic force manipulation of microparticles in suspension is the use of acoustic standing wave forces, which also have served as the basis for particle and cell manipulation in microfluidic devices. Historical work by Kundt<sup>20</sup> demonstrated early on the ability to move cork particles in a standing wave pattern. The fundamental acousto-physical principles have been well researched and described in the literature by King<sup>21</sup> and Gorkov.<sup>22</sup>

Normally, particles are trapped in the pressure node of the acoustic standing wave and standing wave patterns can thus be utilized to concentrate and aggregate particles in the pressure nodes. Numerous applications have utilized the aggregation effect, for example, demonstrating yeast cells concentration,<sup>23,24</sup> blood plasma clarification,<sup>25,26</sup> hybridoma cell aggregation,<sup>27</sup> and cell retention in general.<sup>28</sup> These are all examples of systems developed as macroscale devices in stagnant systems where aggregated cells are collected at the bottom of a chamber. Efforts to realize continuous flow separation systems based on acoustic focusing of particles and cells have, for example, been reported by Yasuda et al.<sup>29</sup> and Benes et al.<sup>30</sup> The true benefits of continuous flow separation becomes evident as the scale is reduced and the flow becomes truly laminar at low Reynolds numbers, reducing influence on separation from unsteady flow or turbulence. This fact clearly speaks for acoustic separation to be most efficiently applied in combination with microfluidic-based devices in a laminar flow mode, serving as a non-fluid-contact mode of controlling and separating microparticles.

When reducing the dimensions, that is, going into the microscale domain with channel dimensions smaller than 500  $\mu\text{m}$ , inherent benefits in terms of an increased primary acoustic radiation force is obtained due to the higher resonance frequency of the resonator.

With the progress within the lab-on-a-chip field, the need for new modes of controlling cells and particles in a gentle but precise way is highly sought and acoustics combined with microfluidics is now emerging as one strong candidate in this respect. This chapter will cover recent developments within microchip-based cell and particle separation and manipulation. Applications in continuous-flow blood component separation and blood purification will be outlined along with new modes of cell trapping and in-chip manipulation.

## 44.3 THEORY

### 44.3.1 STANDING WAVE FORCES

#### 44.3.1.1 Primary Axial Radiation Force

The primary axial radiation force (PRF) acting on a spherical particle in an acoustic standing wave is defined by

$$\begin{aligned} F_{\text{PRF}} &= \frac{-\pi \cdot P_0^2 \cdot V \cdot \beta_0}{2\lambda} \cdot \sin\left(\frac{4\pi \cdot z}{\lambda}\right) \cdot \left(\frac{(5\rho_p - 2\rho_0)}{(2\rho_p + \rho_0)} - \frac{\beta_p}{\beta_0}\right) \\ &= \frac{-\pi \cdot P_0^2 \cdot V \cdot \beta_0}{2\lambda} \cdot \Phi \cdot \sin\left(\frac{4\pi \cdot z}{\lambda}\right) \end{aligned} \quad (44.1)$$

$$\Phi = \left(\frac{(5\rho_p - 2\rho_0)}{(2\rho_p + \rho_0)} - \frac{\beta_p}{\beta_0}\right), \quad (44.2)$$

where  $P_0$  is the applied acoustic pressure amplitude,  $V$  defines the particle volume,  $\beta_p$  is the compressibility and  $\rho_p$  is the density of the particle in a fluid with compressibility  $\beta_0$  and density  $\rho_0$ ,  $\lambda$  is the acoustic standing wavelength, and  $z$  is the position along the wave propagation axis.  $\Phi$  is commonly denoted as the acoustic contrast factor. Force equation, Equation 44.1, was presented by Gould and Coakley<sup>31</sup> and is based on the theory on acoustic forces on small particles in a fluid presented by Gorkov.<sup>22</sup> Basic theory on the interaction between particles and acoustic pressure fields assuming a rigid sphere and a friction-less liquid was presented by King.<sup>21</sup> Later, Yosioka<sup>32</sup> extended the theory to also encompass compressible particles.

### 44.3.1.2 Primary Lateral Acoustic Radiation Force

The acoustic forces acting on the particles based on the theory by Gorkov are described in a three-dimensional (3D) space using the negative gradient of a 3D potential function given by the standing wave field. Equation 44.1 determines the axial force but there are also lateral/radial forces acting on the particles from radial gradients in the standing wave field that will force the particles toward the central axis. For particles with density and compressibility higher than the surrounding medium, the PRF will be directed toward the nearest pressure node in the standing wave fields. When performing acoustic focusing of particles in a continuous flow the particles will be retained in the pressure node, that is, being trapped there as long as the drag force on the particle/cluster from the surrounding medium is lower than the acoustic force. Normally, the axial force is larger than the radial force.

### 44.3.1.3 Secondary Forces

As particles gather and the interparticle distances become small, the influence of scattered sound from neighbouring particles increases, which in turn gives rise to an interparticle acoustic force that is commonly named secondary forces, or Bjerknes forces named after Bjerknes.<sup>33</sup> He first described the theory behind this phenomena, Equation 44.3, where  $a$  is the radius of the particle,  $d$  is the distance between the particles, and  $\theta$  is the angle between the centre line of the particles and the direction of propagation of the incident acoustic wave.

$$F_B(x) = 4\pi a^6 \left[ \frac{(\rho_p - \rho_0)^2 (3 \cos^2 \theta - 1)}{6\rho_0 d^4} v^2(x) - \frac{\omega^2 \rho_0 (\beta_p - \beta_0)^2}{9d^2} p^2(x) \right] \quad (44.3)$$

As an acoustic standing wave starts to act on a particle suspension, particles are driven toward the standing wave nodal plane by the primary radiation force in an initial stage. As the particle density in the nodal plane increases, the average interparticle distance becomes small and thus the influence of the secondary force increases. This can be observed as particles moving toward one another, forming clusters of densely packed particles. If monodispersed particles are used, nice periodic hexagonal particles patterns are formed in the primary focal nodal plane, Figure 44.1.

## 44.3.2 MICROSCALE ACOUSTIC STANDING WAVE SEPARATORS

Acoustic standing wave separators are commonly designed as so-called layered resonators, where the boundaries of a resonance chamber is defined at one side by a transducer (or a coupling layer

**FIGURE 44.1** Fluorescently labeled polystyrene particles gathered in the pressure nodal plane (in plane with the image focus) of an acoustic standing wave by the primary acoustic radiation force in a 70  $\mu\text{m}$  deep microchannel. The microbeads are also clustered in a dense hexagonal pattern by Bjerknes forces.

**FIGURE 44.2** Schematic of a layered resonator design.

**FIGURE 44.3** A microfabricated layered resonator for continuous flow particle enrichment. (Reproduced from Harris N.R., et al., *Sensors and Actuators B: Chemical*, 95, 425–434, 2003. With permission from Elsevier.)

linked to a transducer) and a highly reflecting surface at the opposing side (Figure 44.2) generating an acoustic standing wave pressure node in the centre of the fluid chamber.

The common design typically encompasses a quarter wavelength ( $n \times \lambda/4$ ;  $n = \text{odd numbers}$ ) coupling layer, a half wavelength fluid layer, and a quarter wavelength ( $n \times \lambda/4$ ;  $n = \text{odd numbers}$ ) reflecting layer. The reflecting layer can alternatively be defined by a second acoustic element. In this case, the phase shift between the two transducers can be tuned to position the standing wave pressure node at an arbitrary position along the direction of the wave propagation.

These types of layered separators have been researched by several groups and were applied to various particle and cell separation applications. A microfluidic separation device was later developed by Hawkes and Coakley<sup>34</sup> by electrodischarge machining of stainless steel films to fabricate microchannels in a high  $Q$ -value material. The sidewalls were subsequently fine polished to obtain a good acoustic reflecting surface and the component was assembled as a layered resonator device. The separator was realized both in the form of an H-separator as presented by Benes et al.<sup>35</sup> and as a Y-shaped separator. This rather complicated procedure of fabricating a qualitative microscale resonator clearly speaks for the transition into microfabrication technology for the acoustic separator fabrication.

An early initiative to utilize microfabrication technology in this respect was presented by Harris et al.<sup>36,37</sup> who employed both anisotropically wet-etched silicon and isotropically etched glass that were anodically bonded together, forming a separation device (Figure 44.3). A single inlet was employed via the silicon chip and a flow-through cavity etched in the opposing acoustically reflecting glass chip forming a resonator between the transducer surface and the glass recess and focused the incoming particles into a sheet. The device had two outlets via the silicon chip, which allowed to balance the flows at the two outlets such that the particle-enriched fraction was collected at one of the outlets and the clear fraction at the other.

A common drawback with layered resonators is that visual inspection generally is not possible as the reflecting glass layer serves as the observation window and thus, cells and particles are focused in the plane of the observing window.

An optional mode of microscale resonator design, the Lund method, was proposed by Nilsson et al.,<sup>38</sup> describing a microchip with a rectangular-shaped acoustic focusing channel that was anisotropically etched in standard  $\langle 100 \rangle$  silicon. The end of the separation channel was provided with a trifurcation flow splitting outlet. The chip was sealed by an anodic bonding of a glass lid. Figure 44.4a shows a schematic cross-section of the separation chip and Figure 44.4b shows the

**FIGURE 44.4** Schematic view of an acoustic particle concentrator according to the Lund method, enabling online visual quality control of the particles focusing. (a) Cross-section of the Lund method acoustic focusing chip. (b) Schematic top view of the Lund method acoustic focusing chip.

top view of the chip in operation. The almost perfect vertical silicon channel sidewalls served as the acoustic reflecting surfaces, thus providing a standing wave nodal plane orthogonal to the visual inspection window, which offers direct feedback on the performance of the separation.

As the chip is actuated from underneath and an acoustic standing wave is induced in the flow channel since the excitation frequency is set to match the  $\lambda/2$  resonance criterion of the channel width. It should be noted that the obtained standing wave in the flow channel is orthogonal to the incident wave propagation direction. This fact enables acoustic control of particle and cell displacement in the lateral direction, in plane with the microchip, which in turns opens the route to simple integration with other downstream acoustic separations steps or other microfluidic unit operations.

The following section of this chapter will outline several applications of using the Lund method of ultrasonic standing wave particle/cell focusing, where the feature of visual control is of utmost importance.

## 44.4 PRACTICAL APPLICATIONS

### 44.4.1 BINARY MODES OF ACOUSTIC SEPARATION

#### 44.4.1.1 Acoustic Manipulation Based on Density Properties

Acoustic differentiation of cells and particles based on the primary acoustic radiation force equation, Equation 44.1, inherently opens the route to design acoustic microparticle and cell separation systems. The most straightforward system configuration is to make a binary separation (separation of mixed particles into one or two populations) where the primary radiation force has different signs for, for example, two population of particles. This situation is obtained when the acoustic contrast factor,  $\Phi_s$  in Equation 44.2 has different signs for the two particle populations to be separated. The decisive factors for this are the density ratio and the compressibility ratio for the particle versus the carrier solution. Most commonly, a sign shift in the acoustic contrast factor can be obtained by a proper selection of carrier fluid density versus the density of the particle to be separated. A natural system that nicely illustrates this can be seen in the focusing of lipid emulsions in milk into the pressure antinodes along the sidewalls of the acoustic resonator rather than into the central pressure node. Figure 44.5 shows milk streaming at the outlet of a Lund-separator without (44.5a) and with (44.5b)

**FIGURE 44.5** (a) Milk streaming through a Lund-separator without ultrasonic actuation. (b) Lipid emulsion in milk focused in the acoustic standing wave pressure antinodes along the sidewalls of a Lund-separator.

the ultrasonic actuation at 2 MHz. Once the lipid emulsion is focused along the channel sidewalls, the laminar flow directs the lipid emulsion to the side outlets at the channel trifurcation.

#### 44.4.1.2 Carrier Media Density Manipulation

In situations where particles are difficult to separate owing to similar size and acoustic contrast factors, it may still be possible to accomplish a good separation of the species by adapting the density of the carrier media such that the acoustic contrast factor displays a sign shift for one of the particles to separate. As tabular data on cell or particle density many a times are lacking, one way to find the correct carrier media density for a qualitative separation is to perform a series of centrifugation runs in which the carrier medium density is titrated. The buffer density at which the particle populations are differentiated into the sedimentation pellet and the supernatant, respectively, defines the buffer for a successful acoustic separation. Petersson et al.<sup>39</sup> demonstrated this approach when failing to separate 3  $\mu\text{m}$  red coloured polystyrene particles (density 1.05  $\text{g}/\text{cm}^3$ ) from 3  $\mu\text{m}$  white polymethyl methacrylate (PMMA) particles (density 1.22  $\text{g}/\text{cm}^3$ ) suspended in distilled water. By adding CsCl (0.22  $\text{mg}/\text{mL}$ ) to the aqueous carrier, the medium density was adjusted to 1.16  $\text{g}/\text{cm}^3$ , which is between the densities of the two particle types to be separated. Centrifugation experiments clearly confirmed this situation, collecting the white PMMA particles in the sedimentation pellet and red particles were recovered in the supernatant. When running this buffer system in the acoustic separator, 88% of the polystyrene particles were recovered in the side outlet and 96% of the PMMA particles were collected from the centre outlet.

These findings clearly identify binary acoustic separations as a chip-integrated modality matching density media centrifugations. Centrifugation is a major workhorse in all bio-oriented labs and the vast variety of centrifugation kits using adapted density media for extracting cells or biological particles can now be directly applied to acoustic separation systems.

#### 44.4.1.3 Acoustic Manipulation Based on Frequency Switching

An optional mode of performing a binary particle separation utilizes the mobility of the particle species to be separated. The motion of each particle is defined by its individual primary acoustic radiation force and the opposing hydrodynamic drag force, Equation 44.4, where  $v$  is the fluid velocity,  $\mu$  is the fluid viscosity, and  $D_p$  is the particle diameter:

$$F = 3 \cdot \pi \cdot \mu \cdot D_p \cdot v \quad (44.4)$$

**FIGURE 44.6** Particle separation by means of resonance frequency switching where separation is performed based on the different migration velocities of differently sized particles. By accurate tuning of the frequency, switching size discrimination to the first harmonic and the fundamental resonance nodes are obtained.

The net force acting on the particle defines a unique travelling speed in the acoustic standing wave field for each particle type. If the actuation frequency is switched from the fundamental channel resonance ( $\lambda/2$ ) to a  $\lambda$  resonance criterion before the particles have reached their equilibrium position in the channel centre, the particles will start to migrate to the pressure nodes defined at the  $\lambda/4$  position from each channel wall. By repeating the frequency switching, a situation can be accomplished where particles of different sizes can be separated. This is accomplished due to the particle-specific primary acoustic radiation force and the varying magnitude of the standing wave field with respect to the spatial position in the channel. Figure 44.6 gives a schematic representation of the separation of particles by means of acoustic resonance frequency switching. The schematic depicts six sequential time points during the acoustic switching process.

At T1, the channel is actuated in a single wavelength (first harmonic of the resonator) standing wave resonance at 4 MHz, driving particles to the pressure nodal planes  $\lambda/4$  from each sidewall, T2. When switching to the fundamental resonance (2 MHz), T3, the particles will migrate toward the pressure nodal plane in the channel centre. Larger particles move faster due to a higher net force. If the frequency is switched back at the right moment to a double node resonance mode, T4, the larger particles will, at the switching occasion, be located close to the centre of the channel, where the axial PRF is at its minimum in the first harmonic resonance. The smaller particles, on the other hand, will have moved only a small distance from their original position and start to move back to the position seen at time T2 under the influence of a higher radiation force. After switching frequency again, T5, the larger particles will be closer to the centre than at T2 while the smaller will be closer to their original double node position. If the switching continues, the larger particles will end up in the center of the resonator channel and the smaller ones one-quarter of the channel width from each sidewall. If this is performed in a continuous flow mode in a Lund-separator as presented by Siverson et al.,<sup>40</sup> the switching system can be tuned such that the two particle types are aligned in laminar flow lanes that can be diverted to different outlets at the end of the separation channel. Figure 44.7a shows the outlet of a Lund separator operated in frequency switching mode. The particle suspension enters the

**FIGURE 44.7** (a) Microscope image of the situation when the ultrasound is turned off. Both 3  $\mu\text{m}$  polystyrene and 8  $\mu\text{m}$  PMMA particles exit through the side outlets. (Reproduced from, *Chemical Society Reviews*, 36, 492–506, 2007. With permission from The Royal Society of Chemistry.) (b) Microscope image of the situation when the ultrasound is turned on. The 8  $\mu\text{m}$  particles are focused in the fundamental resonance pressure node and exit through the centre outlet while the 3  $\mu\text{m}$  particles are gathered in the first harmonic pressure nodes and exit through the side outlets. The fundamental resonance and the first harmonic were typically active for 800 and 200  $\mu\text{s}$ , respectively (total flow rate: 90  $\mu\text{L}/\text{min}$ ). (Reproduced from *Chemical Society Reviews*, 36, 492–506, 2007. With permission from The Royal Society of Chemistry.)

separation channel via two side inlets where the particles are seen laminated against the sidewalls. In Figure 44.7b, the acoustic switching is in operation showing 8  $\mu\text{m}$  PMMA beads being routed to the center outlet and 3  $\mu\text{m}$  polystyrene beads directed to the side outlets.

#### 44.4.2 APPLICATIONS OF ULTRASONIC STANDING WAVE MICRORESONATORS TO BLOOD COMPONENT HANDLING

##### 44.4.2.1 Lipid Microemboli Separation

The Lund-method has been developed to address several clinical needs in blood component handling where the direct visual access to the quality of separation has been instrumental for the platform development. In thoracic surgery, a substantial loss of blood commonly occurs resulting in shed blood being recovered from the chest cavity for retransfusing the blood to the patient. As the shed blood is contaminated by tissue debris from the surgery as well as triglycerides, leaking from adipose tissue undergoing surgery, the blood has to be purified before returning the blood to the patient. Normally a mechanical filter with cutoff of about 40  $\mu\text{m}$  serves as the main purification step. Centrifugal instrumentation developed for this purpose is also available. In spite of these measures, a substantial amount of triglycerides in the form of lipid microdroplets still prevail in the retransfused blood. An increasing awareness now pinpoints lipid microemboli as an important source of cognitive dysfunction in conjunction with major surgery where autotransfusion of shed blood is standard. The lipid microemboli that cause cognitive dysfunction are in the size range of approximately 8  $\mu\text{m}$  and larger. As neither mechanical filters nor centrifugation eliminate lipid microemboli from shed blood sufficiently well, new means of separation are needed. In view of these needs, acoustic separation has recently emerged as a new potential and mild way of purifying shed blood. The components to separate are erythrocytes and triglyceride microdroplets and as discussed earlier, a correctly tuned acoustic standing wave binary separation mode should be feasible. When analyzing fundamental acousto-physical data for the two components, it is evident that the two should be possible to separate in a standard acoustic resonator operated at its fundamental resonance criterion (Table 44.1). The negative acoustic contrast factor,  $\Phi$ , for triglycerides and the corresponding positive factor

**TABLE 44.1**

	Density (kg/m <sup>3</sup> )	Compressibility (ms <sup>2</sup> /kg)	Velocity (m/s)	$\Phi$
Triglycerids	913	5.34E-10	1435	-0.31
Erythrocytes	1100	3.48E-10	1616	0.29
Plasma	1010	4.40E-10	1500	

**FIGURE 44.8** Proof of principle of lipid particle separation from blood. Milk mixed with blood is shown in the perfused nonactuated chip, left, and the same chip is shown when actuated at the fundamental resonance frequency, 2 MHz, of the resonator channel. The erythrocyte fraction is clearly seen exiting via the center outlet and the lipid fraction (white streaks along the sidewalls) in the side channels.

for erythrocytes shows that erythrocytes should be possible to collect at the center outlet of the a Lund-separator and the lipid microemboli in the side channels.

A proof of concept of this hypothesis was performed on a mixture of blood and milk, where the lipid emulsion in milk modeled the triglyceride suspension in real blood.<sup>41</sup> Figure 44.8 shows a binary separation of erythrocytes from the milk lipid fraction in a mixture of blood and milk. The corresponding studies on blood and triglycerides were reported by Petersson et al.<sup>42</sup> demonstrating triglyceride microdroplet removal from blood at efficiencies as high as 95%. Figure 44.9 shows the triglyceride elimination efficiency as measured on a radioactively labeled triglyceride emulsion (0.3  $\mu\text{m}$  droplet size) spiked at 1% level in blood. The separation was performed at a flow rate of 300  $\mu\text{L}/\text{min}$ .

Clinical requirements on a separation system for autolog blood washing and transfusion request throughputs of at least 1000 mL/h. In view of the limited throughput of the reported acoustic lipid elimination microsystem, a clinical implementation of this separation strategy seems, at a first glance, not feasible. However, when considering the potential of microfabrication to generate large arrays of identical acoustic separation channels, this can very well be accomplished. A clear benefit of the Lund-method is that multiple channels may be actuated simultaneously by the same transducer, which reduces the requirements on the actuation unit in an instrumental setup for clinical purposes.

An effort to demonstrate the possibility of upscaling the throughput was presented by Jönsson et al.<sup>43</sup> Eight parallel separation channels, 350  $\mu\text{m}$  wide and 125  $\mu\text{m}$  deep each, were connected in

**FIGURE 44.9** Acoustic separation of lipid particles from blood at varying erythrocyte concentrations. Flow rate =  $300 \mu\text{L}/\text{min}$ . (Reproduced from Petersson F., et al., *The Analyst*, 129, 938–943, 2004. With permission from Royal Society of Chemistry.)

**FIGURE 44.10** To increase the throughput of the acoustic separation device, eight parallel channels were connected in a bifurcation network. The image shows two eight channel separators on a  $3''$  silicon wafer.

a microfluidic bifurcation structure such that the chip was supplied with a single inlet for blood, a single outlet for purified blood, and a set of outlets at the chip backside for the triglyceride fraction. The separator was operated at a flow rate of  $60 \text{ mL}/\text{h}$ . Triglyceride elimination was recorded to range up to 90%. It should also be noted that the processing of the blood in the acoustic resonator did not induce any measurable hemolysis above the background already present in the inlet blood fraction. Figure 44.10 shows an early version of two eight-channel separator structures connected in bifurcation structures on a  $3''$  silicon wafer.

#### 44.4.2.2 Blood Cell Washing by Carrier Media Switching

The ability to spatially manipulate cells in a streaming medium as outlined in this chapter opens new routes to perform online cell manipulation tasks. A fundamental unit operation is to be able to change the buffer conditions for a particle or cell in suspension. This is commonly done by centrifugation, removal of the supernatant, and finally resuspension in the new buffer. These steps can be directly implemented in a streaming acoustic half wavelength resonator (Figure 44.11) by allowing particles suspended in buffer I to enter a separation channel via two symmetrical side inlets to a main channel that is provided with buffer II. The particle suspension is thus laminated in its original buffer fluid along the sidewalls of the flow channel. Figure 44.11 schematically shows this setting and as the ultrasonic standing wave is activated, the particles start to migrate to the pressure node in the centre of the channel (Figure 44.11), which is occupied by the buffer II stream.

This mode of operation has been investigated using the Lund-separator to wash blood contaminated by inflammatory components and coagulation factors, which is the case for drainage blood collected from patients in the intensive care units in the postsurgery state. Normally, this blood is centrifuged and retransfused to the patients after removing the supernatant and resuspension in plasma replacement fluid. Petersson et al.<sup>44</sup> demonstrated an acoustic resonator microchip with a channel configuration as outlined in Figure 44.11. Figure 44.12 shows a close up of the outlet from such a separation chip where a model system with white polyamide particles, 5  $\mu\text{m}$ , are suspended in a buffer together with the colour compound, Evans blue. The nonactuated chip, Figure 44.12a, shows the particles exiting the chip together with the original blue coloured buffer via the side outlets. As the acoustic actuation is turned on, the particles are immediately transferred into the uncoloured buffer stream in the centre of the channel, see Figure 44.12b.

Blood washing using the proposed particle switching strategy demonstrated wash efficiencies up to 95%. To meet the needs for throughput, the same approach to parallel channel design as proposed for the lipid microemboli removal chip can be implemented. Switching of particles between different media is a powerful contact-free microfluidic unit operation for cell manipulation on chip where, for example, protocols for compound testing and receptor activation ranges can be titrated.

**FIGURE 44.12** (a) White particles suspended in a blue colour compound, Evans blue, are seen to follow their original buffer stream to the side outlets of the separation chip. As the chip is actuated at the resonance frequency, 2 MHz, of the resonator channel, the particles are forced by the axial primary radiation force into the central uncoloured buffer stream and exits the chip via the centre outlet (b).

#### 44.4.3 GUIDELINES TO A STANDARD LUND-SEPARATOR

A separation chip, according to the Lund-method, is most easily made by anisotropic etching of a  $\langle 100 \rangle$ -oriented silicon wafer. The channel mask should be aligned  $45^\circ$  offset to the  $\langle 110 \rangle$ -cut phase of the wafer, Figure 44.13a, to accomplish the desired rectangular channel cross-section, Figure 44.13b.

After performing the photolithography and etching of the  $1 \mu\text{m}$  surface oxide on the wafer in buffered hydrofluoric acid (HF), the flow channel is etched in KOH (potassium hydroxide, Merck KGaA, 64271 Darmstadt, Germany), 40 g in 100 mL deionised water to the desired channel width and depth. Normal etch rates are approximately  $1 \mu\text{m}/\text{min}$ . After terminating the anisotropic etching, the remaining surface oxide is stripped in HF, washed and blown dry. Inlet and outlet holes should be etched from the backside of the wafer to provide an inspection area at the channel side, free from

connecting tubings. The chip is sealed by anodic bonding of a Pyrex glass lid to the channel side of the chip. Finally, silicone rubber tubings are glued to the backside of the wafer with standard silicone rubber elastomer.

The ultrasonic transducer was a PZ26 piezoelectric ceramic disc (Ferroperm Piezoceramics A/S, Kvistgard, Denmark). The transducer should be designed to operate in the region of the resonance frequency of the resonator channel.

The piezoelectric element is glued to the backside of the chip with epoxy (2 Ton Clear Epoxy, ITWDevcon, Danvers, MA, USA). Alternatively, a small aliquot of ultrasonic coupling gel can be clamped between the transducer and the resonator chip (Figure 44.4a). Normal actuation voltages range between 5 and 20 V for performing a standard acoustic particles-focusing experiment. A power amplifier may be required for the driving of the piezoelectric element. Flow rates are normally in the range of 10–200  $\mu\text{L}/\text{min}$  for a  $350 \times 125 \mu\text{m}$  channel (width  $\times$  depth). Fluid is preferably aspirated through the chip, that is, syringe pumps are connected to the chip outlets, drawing fluid from reservoirs in which the inlet tubing is immersed.

#### 44.4.4 ACOUSTIC TRAPPING

As have been mentioned earlier, trapping of particles will occur in an acoustic standing wave field if the retaining forces from the acoustic field are larger than the drag forces exerted from a surrounding fluid flow (Equations 44.1 and 44.4). The standing wave field may either be generated along the fluid flow lines for longitudinal trapping or transversal to the fluid flow lines for lateral trapping. According to the theory given earlier in this chapter, the trapping force is stronger in the longitudinal case compared to the lateral for a given acoustic intensity.

##### 44.4.4.1 Longitudinal Trapping

An example of a system using longitudinal trapping is shown in Figure 44.14. An 8.5 MHz focused PZT-transducer, 20-mm in diameter, is used together with a molybdenum reflector to generate a standing wave inside a quartz capillary.<sup>45</sup> Figure 44.15 shows trapped 4.7  $\mu\text{m}$  latex spheres inside a 75  $\mu\text{m}$  i.d. capillary. The standing wave pattern is clearly visible after the particles have been trapped. The system was used to demonstrate size selective separation, where 4.7  $\mu\text{m}$  latex particles were retained in the capillary while the majority of 3.0  $\mu\text{m}$  particles passed through the trap. This method generates several trapping points along the capillary and it is quite difficult to selectively trap particles in a certain position. The advantage is that the primary axial radiation force used will generate a stronger trapping force for a given acoustic intensity, as discussed earlier. Alternatively, the acoustic intensity can be decreased while maintaining trapping.

**FIGURE 44.14** Experimental setup for the longitudinal capillary ultrasonic trap. (Reproduced from Wiklund M., et al., *Ultrasonics*, 41, 329, 2003. With permission.)

**FIGURE 44.15** Fluorescence images of  $4.7 \mu\text{m}$  latex particles inside the  $75 \mu\text{m}$  I.D. capillary without (a) and with (b) activated transducer. (Reproduced from Wiklund M., et al., *Ultrasonics*, 41, 329, 2003. With permission.)

The same group has also presented an alternative way to couple acoustic energy into a microfluidic chip using a flat transducer and a refractive element placed on top of the chip.<sup>46</sup> This setup is used in combination with dielectrophoretic (DEP) forces with an outlook to combined manipulation of bioparticles or individual cells using the two forces simultaneously.

#### 44.4.4.2 Lateral Trapping

In the case of lateral trapping, the standing wave is applied perpendicular to the fluid flow through the trapping device. A multilayer resonant structure is commonly used to generate the standing wave (cf. Figure 44.2). Basically, two different transducer configurations have been presented in the literature. The transducer is either connected via an intermediate coupling layer to the trapping cavity or is in direct contact with it. The trapping cavity is normally sealed with a glass lid acting as both acoustic reflector and inspection window. The trapping cavity height should be a multiple of  $\lambda/2$ , depending on the number of desired trapping positions. The glass resonator should be an odd number of  $\lambda/4$  in thickness and if an intermediate coupling layer is used between the transducer and the trapping cavity, this is normally chosen to have a thickness of  $\lambda/4$ .

A transducer with an intermediate coupling layer was used in a setup by Bazou et al. (Figure 44.16).<sup>47</sup> A circular resonator was designed for cell manipulation experiments. A 1.5 MHz disc transducer, 12 mm in diameter, was glued to a steel coupling layer ( $3\lambda/4$  thick) forming the bottom of the resonator. The resonator cavity (height: 0.5 mm) was sealed by a 1 mm quartz glass lid and the device was driven at 1.57 MHz, corresponding to the resonance frequency of the resonator cavity. The cell suspension was filled into the resonator and the fluid flow was stopped as the ultrasound was activated. The cells moved into the resonator nodal plane within 1 s (Figure 44.17).

Wiklund and coworkers<sup>48</sup> used a similar setup with a glass-liquid-glass resonator activated by a 5 mm in diameter external transducer (Figure 44.18). The channel height ( $\lambda/2$ ,  $260 \mu\text{m}$ ) was defined by a polydimethylsiloxane (PDMS) spacer. The glass coupling layer and the glass reflector were both chosen to have a thickness of  $\lambda/4$ ,  $550 \mu\text{m}$ . The system was run at a frequency close to 3 MHz and was used for investigation of adherent COS-7 cell viability after being exposed to the ultrasound in the trap under continuous perfusion with cell medium. No adverse effect was found for exposure times up to 75 min.

#### 44.4.4.3 Integrated Transducers

Trapping devices may also be designed without the coupling layer between the transducer and the resonance chamber, that is, the transducer is in direct contact with the liquid in the chamber. This has been demonstrated by, for example, Spengler et al.<sup>49</sup> A  $5 \times 15 \text{ mm}$  transducer was used in contact with a 5 mm wide channel formed by a 0.8 mm polytetrafluoroethylene (PTFE) spacer. The channel height corresponded to one wavelength, that is, two pressure node planes were generated

**FIGURE 44.16** Acoustic resonator for cell trapping experiments. Its main components were a 1.5 MHz disk transducer that was glue-attached to a steel acoustic coupling layer, a sample volume, and glass acoustic reflector. The thicknesses of the different layers were selected to give a highly resonant system. (Reproduced from Bazou D., et al., *Ultrasound in Medicine and Biology*, 31, 423, 2005. With permission.)

**FIGURE 44.17** Neural cells suspended in the ultrasound trap 30 min after initiation of ultrasound. Scale bar is 70  $\mu\text{m}$ . (Reproduced from Bazou D., et al., *Ultrasound in Medicine and Biology*, 31, 423, 2005. With permission.)

when driven at 1.93 MHz. The channel was closed by a 0.75 mm thick quartz glass lid acting as an acoustic reflector.

A similar configuration using miniaturized transducers was demonstrated by Lilliehorn et al.<sup>50</sup> Transducer elements measuring  $0.8 \times 0.8$  mm were mounted on a printed circuit board (PCB) and cast in epoxy that was polished down to the upper surface of the transducers (Figure 44.19). A cavity was drilled in the PCB underneath the transducer to ensure air backing of the transducer, which is important for the operation of the resonant system with a minimum off loss (high  $Q$ -value). The flow channels ( $\lambda/2$  height) were structured on a soda-lime glass plate using a photosensitive polymer, SU-8, for defining the walls. The glass plate acted as a reflector and the thickness was 1.55 mm that corresponded to an odd number of  $\lambda/4$ . The system was operated at around 10 MHz. A higher frequency is advantageous to use since the forces acting on the particles will be larger for a given acoustic intensity (Equation 44.1). When studying the resulting trapping behavior of the device, it was

**FIGURE 44.18** (a). Top view of the glass–PDMS–glass microfluidic chip with an integrated PDMS block containing two separate inlets with tubing and needles. (b). Cross-section of the microfluidic chip showing the circular 3-MHz PZT transducer and the three-layered structure. **FIGURE 44.19** A side view schematic of the microfluidic trapping device using miniature transducers. The acoustic forces trap the particles in clusters in the center of the channel as illustrated in the insert. (Reproduced from Evander M., et al., *Analytical Chemistry*, 79, 2984–2991, 2007. With permission.)

seen that the 5  $\mu\text{m}$  polyamide particles were trapped in several clusters above the transducer surface in the centre of the channel, as indicated in Figure 44.19. This was theoretically and experimentally shown to be a result of the nearfield pattern in the acoustic intensity generated by the transducer (Figure 44.20). The acoustic field varies spatially across the transducer surface since the wavelength of the acoustic signal is much shorter than the dimensions of the transducer, which results in an interference pattern.

#### 44.4.4.4 Bioassays, Dynamic Arraying

The intention of the device presented by Lilliehorn et al.<sup>50</sup> was to utilize the miniaturized transducers in combination with the laminar flow conditions in microfluidic systems to create a dynamic arraying device holding several individually controlled transducers as envisioned in Figure 44.21.<sup>51</sup> Here, an array of 16 transducers are loaded with different functionalized beads in a first step. The beads are acoustically trapped in the positions given by the transducers. In a second step, samples are supplied through the orthogonal channels and the response is, for example, read by fluorescence. The transducers are then deactivated and the beads are flushed out of the device and the whole procedure is repeated again for a new set of beads and samples.

**FIGURE 44.20** Spatial variation of the acoustic field across the transducer surface. The actual trapping positions are given by the near field pressure distribution as shown in the 3D-image. Particles will be trapped in clusters at the local pressure minima, indicated by the peaks in the figure. (Reproduced from Evander M., et al., *Analytical Chemistry*, 79, 2984–2991, 2007. With permission.)

**FIGURE 44.21** Illustrations of the concept of dynamic arraying showing insertion of the solid phase of different specificity (a) through inlets (A, B...X), trapping of bead clusters using the ultrasonic transducer array (b) and perfusion of sample (c) through inlets (A, B...Y) followed by fluorescence read-out. (Reproduced from Lilliehorn T. et al., *Sensors and Actuators B*, 106, 851, 2005. With permission.)

A simplified model system is shown in Figure 44.22 using three ( $550 \times 550 \mu\text{m}$ ) transducers. A channel structure (width  $600 \mu\text{m}$ , height  $61 \mu\text{m}$ ) incorporating hydrodynamic focusing of the sample inlet was fabricated by wet etching of glass. Beads were trapped from a continuous flow and moved between the different transducers by activating them in a sequence. A simple bioassay was performed by trapping  $6.7 \mu\text{m}$  biotinylated polystyrene beads and perfusing them with fluorescently tagged avidin through the orthogonal channels (marked “Analyte inlet” in Figure 44.22).

#### 44.4.4.5 Cell Trapping and Culturing

There is a clear trend today within the bioanalytical and biomedical fields toward more frequent use of cell-based studies. The dimensions of microfluidic systems are well matched to meet the demand on cell-based systems. Still, new methods are needed that can efficiently handle and manipulate cells in those formats. Examples have already been given in this chapter where acoustic forces are used to trap and manipulate cells. The device in Figure 44.22 has been further developed for use in cell-based bioassays.<sup>52</sup> The temperature characteristics of the device have been examined to be able to control the temperature during the cell experiments. The major source of heat in the acoustic resonance systems presented here is the power dissipation in the transducer itself. The power dissipation follows a

**FIGURE 44.22** The microfluidic acoustic resonator is based on a PCB with three miniature PZT-transducers,  $550 \times 550 \mu\text{m}$  (a). The PCB provides fluidic and electric connections to the transducers. A glass lid with microfluidic channels placed over the PCB defines the resonator cavity over each transducer (b), and the entire assembly is fixed by a brass holder (c). A schematic of the channels with the transducers, that is, trapping sites, marked with grey (d). (Reproduced from Evander M., et al., *Analytical Chemistry*, 79, 2984–2991, 2007. With permission.)

**FIGURE 44.23** Growth of yeast cells trapped in the acoustic device while being perfused with cell medium. The images show the increase of the number of cells in the cell cluster after 2, 4, and 6 h of cultivation. (Reproduced from Evander M., et al., *Analytical Chemistry*, 79, 2984–2991, 2007. With permission.)

quadratic dependence on the drive voltage. Experiments have shown that it is possible to select a drive voltage amplitude that gives both good trapping conditions and an appropriate temperature profile for cell-based experiments. Figure 44.23 shows the results from growing yeast cells in the trapping device. The cells were cultivated for 6 h under continuous perfusion of cell medium. Images were recorded every hour to follow the growth of the cells.

#### 44.4.4.6 Cell Enrichment

An interesting application of the acoustic trap is to use it for enrichment of particles/cells from a dilute sample. The origin may be a rare event experiment or a sample where everything but

**FIGURE 44.24** Channel structure with the sample inlet, S, and the hydrodynamically focusing buffer inlet, B, together with with the valve-less switching inputs G1 and G2.

**FIGURE 44.25** Principle of cell enrichment using the acoustic trapping. (a) The transducer is activated, (b) the sample is supplied, (c) the particles/cells in the sample liquid are trapped at the transducer, and (d) the switching flow is switched and the transducer is deactivated. The trapped particles/cells are released to the exit down left.

the cells/particles of interest have been lysed or dissolved. This has been demonstrated using the transducer plate shown in Figure 44.22a together with new design of the glass channel system, shown in Figure 44.24. Hydrodynamic focusing is used for the sample inlet (Inlet B and S) to ensure high trapping efficiency.<sup>52</sup> Two inlets have been added (G1 and G2) for valveless switching of the flow between the two outlets below. If the flow in G1 is significantly higher than the flow in G2, the sample/buffer flow will be directed to the right outlet and vice versa. The channel dimensions at the transducer were 900  $\mu\text{m}$  width and 70  $\mu\text{m}$  height. The system was operated at 10.8 MHz.
