The operation of the device is shown in Figure 44.25 using polystyrene beads in a dye as model sample fluid. The transducer is activated and the hydrodynamically focused sample flow is supplied. The switching flows (inputs G1 and G2) are set for guiding the sample flow to the right outlet after passing the transducer. The particles/cells in the sample flow meeting the conditions for trapping are retained at the transducer in a cluster (Figure 44.25c). After optional washing of the cluster, the flows in inlets G1 and G2 are switched to address the left output and the transducer is deactivated. The trapped cluster is released and supplied to the output for further processing.

This system has been used for sample preparation for enhanced analysis of sexual assault evidence.<sup>53</sup> A sample containing sperm cells and lysed female epithelial cells was infused into the device during 5 min. The sperm cells were trapped at the transducer. After finished infusion, the

cells were washed with PBS for another 5 min, then released and collected at the outlet for qPCR analysis. The original sample contained 5% male fraction and 95% female fraction. After processing in the trapping device, the collected liquid at the female outlet (down right in Figure 44.25) contained 0.5% male fraction and 99.5% female, while the collected liquid at the male outlet (down left in Figure 44.25) contained 85% male fraction and 15% female fraction, that is, a 17-fold enrichment of the male fraction.

## 44.5 CONCLUSIONS

Acoustic standing wave manipulation of particles in microfluidic systems offers the implementation of a wide range of particle/cell handling unit operations without introducing any moving parts, where binary separations, buffer media switching, particles sizing, cell enrichment, and cell trapping can be accomplished. Cell manipulation in microfluidic systems using ultrasonic standing waves have proven to be a mild and yet robust technique well suited for performing chip-integrated cell handling tasks. In contrast to dielectrophoretic and optical tweezer technology, higher throughputs are offered in acoustically controlled systems. The low device complexity and the fact that changes in ionic strength of the carrier buffer does not affect the acoustic forces induced on the cells to be handled make acoustic separators an especially attractive platform for cell handling in their native body fluids and in long-term experiments with, for example, gradient perfusion systems.

With the rapid development of cell-based microfluidic systems in the lab-on-a-chip field, ultrasonic standing wave manipulation and control of cells in microspace can be anticipated to play an increasing role in future microfluidic systems.

## 45.1 INTRODUCTION

Several detection techniques adapted for the capillary format have been applied to fluidic microchips, including optical, electrochemical, and mass spectrometric detection. While the aim of this chapter is not to review all of these various techniques, interested readers are directed to several recent discussions presented in the literature.<sup>1-6</sup> Instead, the focus will be on optical methods, which will be

described briefly along with some examples—the reader is also referred to the complimentary chapter on capillary-based systems by Sweedler in Chapter 9. Because of its broad application in microchip electrophoresis, a significant amount of discussion will be paid to laser-induced fluorescence (LIF) detection, which has played a key role in many of the microchip advancements achieved to date. This discussion will include a practical guide to assembling and aligning an LIF detection setup. Other optical techniques presented include ultraviolet (UV) absorption, chemiluminescence (CL) and electrochemiluminescence (ECL), Raman spectroscopy, thermal lens microscopy (TLM), surface plasmon resonance (SPR), and refractive index (RI) detection.

## 45.2 OPTICAL DETECTION SYSTEMS

The optical detection methods applied to microchip-based analysis are, for the most part, similar to those employed in capillary electrophoresis (CE). The main differences, however, are that UV absorbance is not as common and that the microchip format creates the possibility of incorporating additional functionality during the fabrication steps (especially in plastic devices). Each of the optical methods described here includes specific requirements, such as the nature of the analyte and the microchip substrate, and these must be taken into consideration when choosing and implementing a system.

### 45.2.1 LASER-INDUCED FLUORESCENCE

Despite the increase in alternative methods of optical detection, laser-induced fluorescence (LIF) remains the most widely applicable detection method in microchip electrophoresis systems. There are several reasons why LIF is ideally suited to the microchip format; these include (1) its high sensitivity, (2) its compatibility with microchannel dimensions, (3) its fast response time, (4) its noncontact interrogation, and (5) its addressable nature. When Harrison and coworkers<sup>7</sup> initially miniaturized a CE channel onto a planar glass chip in 1992, the fluorescent signals obtained for fluorescein and calcein dyes were used to evaluate the feasibility of performing CE separations on a microchip (Figure 45.1). Since then, LIF detection had been used in many different applications on-chip including single molecule detection and DNA sequencing. A more thorough examination of various aspects of LIF detection, including setup and alignment of a confocal system, can be found later in this chapter.

**FIGURE 45.1** First published microchip electropherogram using LIF. A mixture of fluorescein and calcein (concentrations shown) were injected for 30 s across a separation channel and subsequently electrophoresed past the detector. (Reprinted from Harrison, D.J., et al., *Analytical Chemistry*, 64, 1926, 1992. Copyright 1992. With permission from American Chemical Society.)

### 45.2.2 ABSORBANCE

Although it is a universal detector in CE and high pressure liquid chromatography (HPLC), absorbance detection has not found the same success in microchip applications. This is primarily due to the short optical path lengths (i.e., channel depths) and the difficulty in coupling light into and out of the microchip, resulting in detection limits several orders of magnitude higher than LIF. One of the earliest examples of UV detection on-chip was the imaging of an isoelectric focusing (IEF) channel with a charge-coupled device (CCD) camera. Sample was loaded onto a quartz chip and excited at 280 nm using a Xe lamp. With the benefit of the concentrating effect of the IEF step, the detection limit of myoglobin was found to be  $30 \mu\text{g}\cdot\text{mL}^{-1}$ .<sup>8</sup> In most microchip applications, however, there is no concentration step and the short optical path lengths present a challenge. An initial attempt to increase the path length involved the patterning of a silicon flow cell that achieved path lengths up to 5 mm using successive reflections in a channel 50  $\mu\text{m}$  deep. However, there was significant amount of loss at each surface.<sup>9</sup> This was addressed by another group that fabricated a multireflection absorbance cell in a glass microchip using a three-mask process to deposit aluminum mirrors above and below the flow channel. With entrance and exit apertures patterned into the mirrors, optical path lengths of 50–272  $\mu\text{m}$  were obtained in the multireflection absorbance cell (compared to channel depths of 10–30  $\mu\text{m}$ ), increasing the sensitivity 5- to 10-fold over single-pass devices.<sup>10</sup> Another approach exploited total internal reflection (TIR) to form a liquid-core waveguide by sandwiching Teflon tubing embedded in a polydimethylsiloxane (PDMS) block between two silica plates containing fluidic channels. By increasing the optical path length to 5 mm while maintaining a detection volume less than 1  $\mu\text{L}$ , the limit of detection (LOD) for crystal violet was found to be  $\sim 1 \mu\text{M}$ .<sup>11</sup>

The different approaches for coupling light into the absorbance cell primarily involve optical fibers and planar waveguides. Using fibers alone, a separation of peptides was shown by Jindal and Cramer<sup>12</sup> using on-chip electrochromatography with a UV absorbance detector. Optical fibers for excitation and collection were positioned above and below a hybrid quartz/PDMS device, which featured an optical path length of only 23  $\mu\text{m}$ , yet resulted in a LOD of 167  $\mu\text{M}$  for thiourea. A similar approach involved embedding a ball lens in a layer of PDMS that sealed against a glass microchannel. An optical fiber brought incident 668 nm light into the lens, which then collected the reflected light from a layer of aluminum patterned on the other side of the channel. Calcium levels were monitored through a reaction with arsenazo III, and a detection limit of 85  $\mu\text{M}$  was found for calcium before applying the assay to clinical urine samples.<sup>13</sup> The alternative approach for coupling light with the absorbance cell was taken by Kutter's group, where fiber couplers and planar waveguides were fabricated into the microchip along with the fluidic channels. Using deep-reactive ion etching (DRIE) to form high-aspect ratio channels in silicon, an effective optical path length of 1.2 mm was obtained in a U-shaped channel (Figure 45.2). By eliminating propagation loss along the waveguides, the detection limit for paracetamol at 254 nm was found to be  $3 \mu\text{g}\cdot\text{mL}^{-1}$ , at present the most sensitive waveguide device in the literature, and a three-component separation was shown on the device.<sup>14</sup> The U-shaped channel design was initially presented by Liang and Harrison<sup>15</sup> in a microchip that featured a dual absorbance and fluorescence cell, with 488 nm light brought into the device with an optical fiber. This work provided an excellent comparison between UV and LIF detection on microchip, as detection limits were found to be 6  $\mu\text{M}$  (for fluorescein isothiocyanate) and 3 nM (for fluorescein), respectively.

### 45.2.3 CHEMILUMINESCENCE

Chemiluminescence refers to the release of light energy from a chemical reaction. This is based on the type of reaction first apparent to scientists in the form of "cold" light from fireflies. The firefly's glow mechanism, which hinges on the oxidation of firefly luciferin, is incredibly efficient, as 80% of reacting molecules present generate a photon of light. The inherent benefit of a CL system is that no

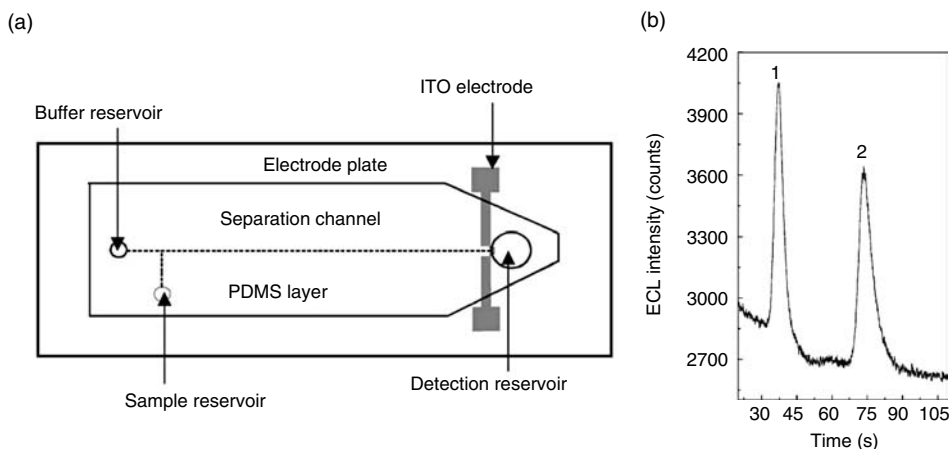

**FIGURE 45.2** Scanning electron micrograph of the U-shaped detection region of a microchip designed for absorbance detection using integrated waveguides. (Reprinted from Mogensen, K.B., et al., *Electrophoresis*, 25, 3792, 2004. With permission.)

excitation source is required, making it ideally suited to a miniaturized analysis system. Xu et al.<sup>16</sup> used this feature, along with the benefit of the reduced reagent consumption in a microreactor chip, to monitor chromium III from aqueous samples. A detection limit of 100 nM was obtained in the continuous flow system, where the CL yield was observed to benefit from the short (<1 s) mixing time. Liu et al.<sup>17</sup> examined two model CL systems (the ion-catalyzed luminol-peroxide reaction and the dansyl species conjugated peroxalate-peroxide reaction) using three different designs in PDMS microchips, and sub- $\mu\text{M}$  concentrations were detected. Importantly, the identification of three metal cations in the first system and the chiral recognition of dansyl phenylalanine enantiomers in the second was shown in <1 min, demonstrating the utility of CL detection coupled with a separation mode. Some other analytes examined on microchip using CL detection include dopamine and catechol (detection limits of 20 and 10  $\mu\text{M}$ , respectively),<sup>18</sup> glucose (detection limit of 10  $\mu\text{M}$ ),<sup>19</sup> and the cancer marker, *immunosuppressive acidic protein* (detection limit of 100 nM).<sup>20</sup>

#### 45.2.4 ELECTROCHEMILUMINESCENCE

Electrochemiluminescence detection is similar to CL, except that the luminescent reaction is effected by electrochemical stimulation. Along with the advantages of CL, the stimulation reaction allows the time and position of the light-emitting reaction to be controlled.  $\text{Ru}(\text{bpy})_3^{2+}$  is one of the most efficient and thoroughly examined ECL molecules and, while the reaction scheme may change depending on the analyte, the excited product is always  $\text{Ru}(\text{bpy})_3^{2+*}$ , which emits light at a maximum intensity at 620 nm when returning to its ground state.<sup>21</sup> In 1998, a fully integrated probe was designed that featured a gold interdigitated microelectrode array (IDA) and a photodiode detector on a silicon microchip to perform ECL. The device was applied to the model system of  $\text{Ru}(\text{bpy})_3^{2+}$  and tripropylamine, and a 500 nM detection limit was obtained for the ruthenium complex.<sup>22</sup> L'Hostis et al.<sup>23</sup> fabricated an ECL detector using a hybrid silicon and SU-8 photoresist device. The detector (with a platinum IDA) was initially evaluated using a reaction of codeine and  $\text{Ru}(\text{bpy})_3^{2+}$  (detection limit of 100  $\mu\text{M}$ ), and it was then incorporated into an enzymatic microreactor (with a carbon IDA) to assay glucose (detection limit of 50  $\mu\text{M}$ ). Applying an ECL detector to a micellar electrokinetic chromatographic (MEKC) separation on a glass microchip, a U-shaped floating platinum electrode was placed across the separation channel to perform both direct and indirect detection.<sup>24</sup> Applying ECL to clinical samples, the antibiotic lincomycin was analyzed using a microchip CE system with an integrated indium tin oxide (ITO) working electrode (Figure 45.3). Without pretreatment, lincomycin was analyzed in urine in <40 s with a detection limit of 9.0  $\mu\text{M}$ .<sup>25</sup> A benefit of using ECL is that

**FIGURE 45.3** Microchip design and sample data using ECL detection. (a) The microchip was fabricated in PDMS using a glass mold and the ITO electrodes were patterned with an etch step. (b) The separated mixture contains 100  $\mu\text{M}$  each of lincomycin (1) and clindamycin phosphate (2), which were detected using  $\text{Ru}(\text{bpy})_3^{2+}$ . (Reprinted from Zhao, X., et al., *J Chromatography B*, 810, 137, 2004. With permission.)

it can be combined with EC detection, as demonstrated by Qiu et al.<sup>26</sup> in the determination of the neurotransmitter dopamine and several pharmaceuticals.

### 45.2.5 RAMAN SPECTROSCOPY

Raman spectroscopy is similar to IR spectroscopy, but superior in microchip systems because water is virtually Raman transparent. Similar to LIF, sample is typically excited with a laser and spectra can be collected from a very small volume. A real benefit of Raman spectroscopy is the ability to monitor structural changes or the progress of a chemical reaction on chip. Pan and Mathies<sup>24</sup> used a chip-based flow experiment to examine the chromophore structure of rhodopsin photointermediates as well as changes in protein–chromophore interactions in a glass microchip at room temperature. Fletcher et al.<sup>27</sup> used a Raman microscopic spectrometer to observe the formation of ethyl acetate from ethanol and acetic acid in a glass microreactor (Figure 45.4). Using an excitation wavelength of 780 nm, it was shown that the spectral intensities of Raman bands specific to each species were proportional to the concentration present in the microreactor at a given time, providing the time dependence of the product formation. A similar system was used to optimize the catalytic oxidation of isopropyl alcohol to acetone in a continuous flow microreactor.<sup>28</sup> Ramser et al.<sup>29</sup> utilized the microchip environment to trap a single red blood cell and follow the dynamics of an oxygenation cycle after environmental stimulation using Raman spectroscopy in real-time. Of the various optical methods presented in this chapter, Raman spectroscopy possesses the greatest promise as a microchip detection technique, especially considering the signal enhancement (up to  $10^{14}$ )<sup>30</sup> that can be obtained performing surface-enhanced Raman spectroscopy (SERS) on a surface that has been coated with silver or gold.

### 45.2.6 THERMAL LENS MICROSCOPY

The Kitamori group has pioneered the use of TLM in microchip systems, where both an excitation and a probe beam are focused into a liquid sample—an example of its utility is provided with immunoassay in Chapter 34. The energy of the excitation beam is absorbed by the sample species and results in a localized temperature increase that affects the refractive index (RI) within the medium. The probe beam, which is selected such that there is no absorption, is subject to the “thermal lens

**FIGURE 45.4** Three-dimensional plots of Raman intensity where two laminar flow streams come together. The region was probed for specific bonds to identify (a) acetic acid at  $893\text{ cm}^{-1}$  and (b) ethanol at  $882\text{ cm}^{-1}$ . effect” that results from the change in RI due to the increased temperature (Figure 45.5). Because the probe beam is modulated by RI changes, the resulting change in intensity can be recorded with a photodetector. The sensitivity of this detection method has been reported at subsingle-molecule detection for a nonfluorescent species. To demonstrate this, a test sample of Pb(II) octaethylporphyrin was prepared in benzene and analyzed in a  $100\text{ }\mu\text{m}$  deep quartz microchannel. The concentrations used corresponded to 0.4–3.4 molecules with a detection limit of 0.34 (and an average temperature rise for a single molecule of  $3.1\text{ }\mu\text{K}$ ).<sup>31</sup> Another impressive demonstration of the TLM technique was in the two-dimensional imaging of a single cell to monitor the release of cytochrome *c* during the apoptosis process with a spatial resolution of  $\sim 1\text{ }\mu\text{m}$ .<sup>32</sup> A review of the advances made by the Kitamori group can be found in the literature,<sup>33</sup> but it should be noted that another group has recently developed a portable thermal lens spectrometer and shown a  $30\text{ nM}$  limit of detection for xylenecyanol in a fused silica microchip.<sup>34</sup>

#### 45.2.7 SURFACE PLASMON RESONANCE

Surface plasmon resonance is a surface-sensitive method for chemical sensing based on RI changes on the surface of a metal film. Variations in light intensity reflected from the back of the film are

detected, thus, no labeling is required. Because the SPR signal is strongest when measuring near the sensor surface, it is often used to detect the surface binding characteristics of biomolecules. Yager and coworkers<sup>35</sup> developed a special microscope for performing SPR detection, and applied it to characterize protein absorption on the microchannel surface of Mylar devices. An amplification technique was then developed using a precipitating enzyme to increase the signal reflectivity by up to 70%.<sup>36</sup> Furuki et al.<sup>37</sup> sputtered gold onto glass before sandwiching a UV resin between glass layers to define a microchannel. The gold surface was then chemically modified with a photobiotin layer to promote the specific adsorption of avidin at a concentration of  $25 \mu\text{g}\cdot\text{mL}^{-1}$ , probing with a 670 nm laser diode. PDMS microchips have also been used for SPR, and have been demonstrated for protein binding to a gold surface in both flow-through microchip (using a commercial SPR detector)<sup>38</sup> and microarray<sup>39</sup> formats. A review of SPR technology and applications can be found elsewhere.<sup>40</sup>

#### 45.2.8 REFRACTIVE INDEX DETECTION

Refractive index detection is based on the factor by which light is slowed down (relative to vacuum) as it travels through a medium. RI is sensitive to changes in temperature, pressure, and flow rate, and, as previously discussed, plays a role in other detection techniques. Before those methods, however, a holographic RI detector was applied to the separation of carbohydrates on chip.<sup>41</sup> In the setup, an incident laser beam passed through a holographic optical element that divided the beam into two. One beam served as a reference and passed solely through the glass substrate while the probe beam passed through the solution in the separation channel. A photodiode array was placed to collect the fringe pattern from the interfering beams, and this pattern changed whenever an analyte passed through the separation channel (Figure 45.6a). Using this system, a proof of principle separation of three sugars was performed in less than 17 s, although their concentration was high (33 mM). An alternative method was demonstrated by Costin and Synovec,<sup>42</sup> who detected the angular deflection of a diode laser beam incident on adjacent laminar flow streams. The beam entered the PDMS microchannel orthogonal to the direction of flow and the diffusion gradient of the two streams, and the resulting angle of the beam corresponded to a RI gradient (Figure 45.6b). The device was evaluated as a molecular weight sensor for poly(ethylene glycol) solutions and was found to be sensitive to changes in RI of  $4.5 \times 10^{-6}$ .

### 45.3 FLUORESCENCE DETECTION

The main considerations when performing LIF detection include the target analyte, the instrumentation, and the microchip, and these will be discussed in the following sections. Some advances in microchip-based LIF will also be presented, including multichannel and multicolor detection, single molecule detection, and integrated optics.

#### 45.3.1 FLUORESCENT MOLECULES

While one of the limitations of LIF detection is that few target molecules exhibit native fluorescence, especially biologically relevant proteins and DNA of clinical interest, several different labeling approaches both on- and off-chip have been demonstrated. For the former, the microchip fabrication steps provide the ability to incorporate additional structures into the design, in many cases without adding more steps (or cost) to the fabrication process. Examples include the additional channels and reaction chambers used to perform both precolumn<sup>43</sup> and postcolumn<sup>44</sup> labeling of amino acids.

##### 45.3.1.1 Native Fluorescence

There are few examples in the microchip literature that feature analytes of interest exhibiting native fluorescence, such as the phycobiliproteins present in cyanobacteria and some algae.<sup>45,46</sup> Recently,

**FIGURE 45.6** Different experimental approaches for RI detection. (a) Principle of holographic RI detection, where a reference and probe beam interact to produce an interference pattern that changes when an analyte passes through the channel. (From Burggraf, N., et al., *Analyst*, 123, 1443, 1998. Reproduced by permission of The Royal Society of Chemistry.) (b) Illustration of angular detection as a gradient forms between two different laminar flow streams to create an RI gradient. (Reprinted from Costin, C.D. and Synovec, R.E., *Analytical Chemistry*, 74, 4558, 2002. Copyright 2002 American Chemical Society. With permission.)

however, deep UV fluorescence detection has been demonstrated on microchip using 266 nm excitation (using a frequency quadrupled Nd:YAG laser). Hellmich et al.<sup>47</sup> demonstrated UV-LIF of the amino acid tryptophan (detection limit of 17  $\mu\text{M}$ ) and a protein mixture of 500  $\mu\text{M}$  lysozyme C and 125  $\mu\text{M}$  avidin in hybrid PDMS/glass devices. With a similar system, Schulze et al.<sup>48</sup> demonstrated UV-LIF of several different proteins including a mixture of lysozyme (900 nM), trypsinogen (500 nM), and chymotrypsinogen (500 nM) using fused silica devices.

Still, the majority of literature describing naturally fluorescent molecules analyzed on-chip deal primarily with novel device, separation, and detection technologies. In these studies, fluorescein and rhodamine dyes are most common because they can be readily obtained in various derivatized forms.<sup>49</sup> For example, our group used a combination of fluorescein and carboxy-X-rhodamine dyes in an electrophoresis experiment to evaluate an on-chip pressure injection,<sup>50</sup> and later added rhodamine 6G to the test mix to evaluate a scanning multicolor detection platform.<sup>51</sup> Also, fluorescent dyes can be used to perform indirect fluorescent detection of nonfluorescent species, as demonstrated by Munro et al.<sup>52</sup> by adding fluorescein to the run buffer to analyze amino acids in urine. Sirichai and de Mello<sup>53</sup> also added fluorescein to the run buffer to perform quantitative analysis on a commercial photographic developer solution and reported detection limits of 5  $\mu\text{g}\cdot\text{mL}^{-1}$ . Recently, deep UV fluorescence detection has been demonstrated on microchip using 266 nm excitation (using a frequency quadrupled Nd:YAG laser). Hellmich et al.<sup>47</sup> demonstrated UV-LIF of the amino acid tryptophan (detection limit of 17  $\mu\text{M}$ ) and a protein mixture of 500  $\mu\text{M}$  lysozyme C and 125  $\mu\text{M}$  avidin in hybrid PDMS/glass devices. With a similar system, Schulze et al.<sup>48</sup> demonstrated UV-LIF of several different proteins (Figure 45.7) including a mixture of lysozyme (900 nM), trypsinogen (500 nM), and chymotrypsinogen (500 nM) using fused silica devices. This technique is promising because it offers the benefits of LIF detection while enabling native detection of biomolecules,

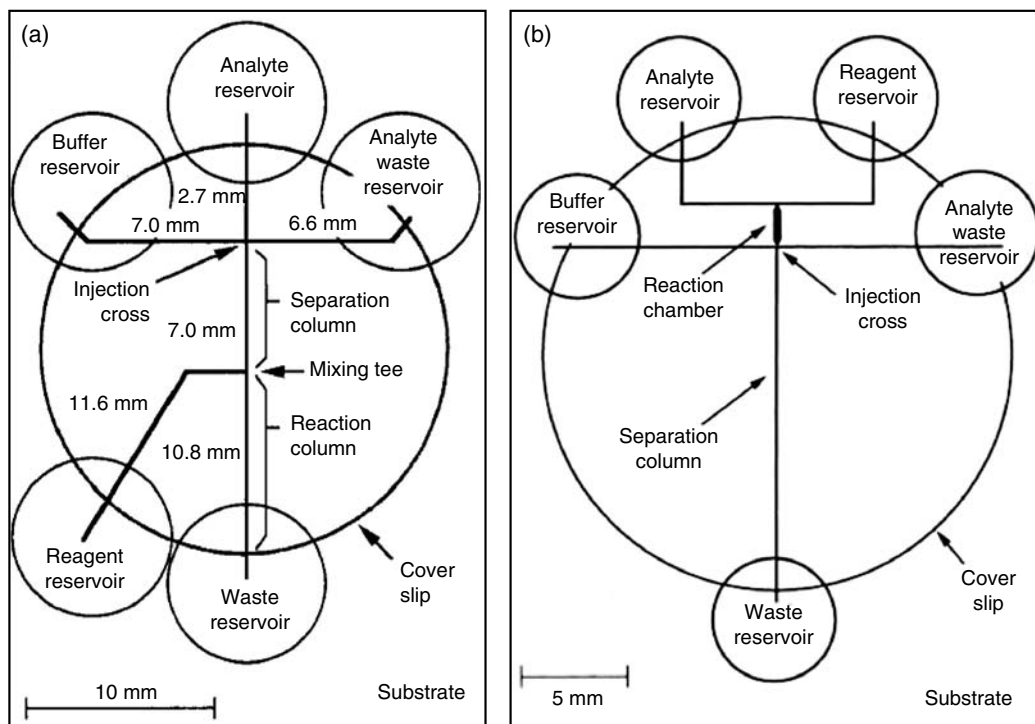

**FIGURE 45.7** Peaks collected using deep UV-LIF detection. The electropherogram in the foreground represents a mixture of (1) serotonin, (2) propranolol, (3) 3-phenoxy-1,2-propanediol, and (4) tryptophan, each at a concentration of  $40 \mu\text{g}\cdot\text{mL}^{-1}$ . The same mixture is shown in the inset with concentrations closer to their limits of detection. (Reprinted from Schulze, P., et al., *Analytical Chemistry*, 77, 1325, 2005. Copyright 2005 American Chemical Society. With permission.)

however, there are greater demands on the optics and microchip substrate to provide high UV transmittance with low autofluorescence.

#### 45.3.1.2 Protein Labeling

As mentioned earlier, the ability to integrate precolumn and postcolumn labeling of amino acids brought an increased functionality to the microchip format that is not readily achieved on capillary alone. The initial report of a postcolumn reactor contained a mixing tee after the separation column where an additional reagent reservoir, separated from the reservoirs used for the injection and separation steps, electrokinetically introduced the fluorescent tag *o*-phthaldialdehyde (OPA). The OPA then mixed with the partially separated amino acids by diffusion (Figure 45.8a) in the reaction column as the separation continued.<sup>44</sup> With the precolumn reactor, the analytes and OPA were introduced into the same chamber prior from separate reservoirs before diffusing into the separation channel in a gated injection scheme (Figure 45.8b).<sup>43</sup> Both integrated techniques, performed in glass devices, enabled the labeling and separation to occur in very small volumes ( $<1 \text{ nL}$ ) in a matter of seconds, demonstrating the benefits of using microfluidic analysis systems. The same group later used a postcolumn reactor to label proteins noncovalently with a NanoOrange dye, which offered fast reaction kinetics and high fluorescence yield.<sup>54</sup> This dye also proved effective for dynamic on-column labeling, resulting in a detection limit of  $500 \text{ ng}\cdot\text{mL}^{-1}$  for bovine serum albumin.<sup>55</sup> Another precolumn labeling reaction was demonstrated on a glass/PDMS device using dichlorotriazine fluorescein (DTAF), a derivatizing agent for biogenic amines. In addition to fast reaction kinetics ( $<60 \text{ s}$  for on chip mixing and reaction), detection limits were reduced to  $1 \text{ nM}$ .<sup>56</sup>

### 45.3.1.3 DNA Labeling

Laser-induced fluorescence is the most common detection method in DNA sizing and sequencing applications, on both capillary and microchip, owing to the different ways to incorporate fluorophores. In double-stranded DNA (dsDNA) separations, intercalating dyes are typically added to the separation matrix. Upon binding the DNA strand, the dye exhibits a significant increase in fluorescence yield over unbound dye. While a wide variety of nucleic acid stains are available, depending on the application,<sup>49</sup> the protocol for dsDNA separations in our lab involves adding the monomeric cyanine dye, YO-PRO<sup>®</sup>-1 iodide (Invitrogen), to the sieving matrix at a 0.1% v/v concentration.<sup>57</sup> For single-stranded DNA (ssDNA) separations, fluorescently tagged primers are incorporated into the target DNA by the polymerase chain reaction (PCR) method. This allows multiple fluorescent labels to be incorporated in a single application step and is commonly used in four- and five-color sequencing and genotyping applications. Derivatization chemistries enable conjugations of most dyes to oligonucleotides,<sup>49</sup> and fluorescent labels can often be added (for a fee) when ordering DNA primers. In many commercial multiplexed PCR amplification kits (i.e., Applied Biosystems AmpFISTR<sup>®</sup> kits) proprietary dyes are used, but the Mathies group has designed and synthesized fluorescent oligonucleotide primers using the principle of fluorescence resonance energy transfer (FRET),<sup>58</sup> and have used their dyes in sequencing<sup>59</sup> and genotyping<sup>60</sup> applications on microchip.

**FIGURE 45.9** Schematic of a confocal LIF detection system with source, optics, and detector shown. The optics include mirrors (M), laser line filter (LF), half-wave plate ( $\lambda/2$ ), polarizer (pol), dichroic beamsplitter (DB), microscope objective (MO), pinhole (ph), filter, and achromat lenses (achr). The source shown is an argon ion laser, and the detector is an avalanche photodiode (APD). While the electrophoresis channel shown here is in a capillary (CE), the system could be readily applied to a microchip. (Reprinted from Johnson, M.E. and Landers, J.P., *Electrophoresis*, 25, 3515, 2004. With permission.)

### 45.3.2 LIF INSTRUMENTATION

A typical method for performing LIF detection on a microchip is to bring the excitation light into the microchannel orthogonal to the device plane, which is relatively simple to align, and to then focus the beam into the channel using a microscope objective or some combination of achromat lenses. LIF emission is then collected with a separate objective or lens combination, spatially and spectrally filtered, and recorded on a photodetector. Confocal detection systems are quite popular in the literature, first demonstrated by Guzman and coworkers<sup>61</sup> for LIF detection on a capillary in 1991, where the focusing and collection optics are the same and the excitation and emission wavelengths are separated with a dichroic beamsplitter (Figure 45.9). Variations in LIF detection setup exist, however, and He et al.<sup>62</sup> present a detailed illustration of their laser-induced detection system where the excitation is brought into the microchannel from an angle. A recent review on the fundamentals and practice of LIF detection in microanalytical systems presents a thorough examination of ultrasensitive systems (sub-pM concentration).<sup>63</sup> While the goal of this discussion is not necessarily to achieve ultrasensitivity, the principles and considerations are very much the same.

#### 45.3.2.1 Sources

The most commonly used excitation sources for LIF detection on microchip are helium-neon and argon ion gas lasers, both of which feature various emission lines. Typical laser powers range from 0.5 to 50 mW. Benefits of these lasers include their beam quality and long lifetimes, but they are still costly and bulky relative to the microchip scale. There have been other reports of excitation sources, including dye lasers (i.e., rhodamine 6G), metal-vapor lasers (i.e., HeCd), and solid-state lasers (i.e., Nd:YAG), and semiconductor lasers (i.e., laser diodes), but these still present size and cost issues. What is promising is the recent use of light-emitting diodes (LEDs) for LIF detection because, in addition to being small and cheap, they can be incorporated into the devices themselves.

It is important to note that there are several probes and dye labels available that are ideally suited to the different laser excitation wavelengths.<sup>49</sup>

### 45.3.2.2 Detectors

Photomultiplier tubes (PMTs) remain a common choice for detection. PMTs consist of a photocathode, a series of dynodes, and an anode. Incident photons strike the photocathode surface, causing electrons to be emitted by the photoelectric effect. These electrons are accelerated toward the first dynode, which is held at a positive potential, and collide to release additional electrons. This process is repeated several times, with each dynode held at a higher potential, until the final accumulation of cascading electrons (multiplying a signal by orders of magnitude) reach the anode. This results in a sharp current pulse indicating that photons have been detected by the PMT. While PMTs are quite common as photodetectors for microchip LIF, some of the other detectors that have been used include avalanche photodiodes (APDs) and CCD arrays. While the former is most often used to achieve ultrasensitive detection,<sup>63</sup> the latter is typically used in whole channel imaging and multidimensional applications, which will be described next.

## 45.3.3 MULTIDIMENSIONAL APPROACHES

### 45.3.3.1 Multichannel Detection

While several different glass types have been reported in the literature for microchip separations, they are all compatible with LIF detection due to their optical transparency. This is significant because it creates the opportunity to interrogate any region of the microchip, offering more flexibility than the capillary format. Because the glass capillaries used in CE are coated with a polymer layer that must be removed to expose the glass window for excitation, there is inherent limitation to where detection can be performed. In addition to performing LIF detection at a single location, several techniques have been shown for multipoint (within a single channel) or multichannel detection. The former includes the incorporation of waveguide structures into the microchip design to create several excitation points along a single channel, which was used to perform velocity measurements of particles flowing a microchannel.<sup>64</sup> Several approaches for multipoint detection have been demonstrated for microchip IEF as an alternative to mobilizing resolved peaks past a fixed detection point.<sup>65</sup> Similar to the approach for detecting IEF by UV absorbance,<sup>8</sup> Yao et al.<sup>66</sup> collected the fluorescence signal from an IEF separation using a CCD array for whole column imaging. Interestingly, the excitation source was also an array, featuring organic LEDs. As opposed to imaging the entire IEF channel, Raisi et al.<sup>67</sup> designed a scanning fluorescence detector based on a computer-controlled translation stage with a single PMT and were able to scan the entire separation channel every 9 s to collect temporal and spatial measurements. It is ironic this approach parallels that devised by Hjerten<sup>68</sup> and reviewed more than half a century ago. Another scanning approach using a single PMT is presented using an acoustooptic deflector (AOD) system (described later) to sweep the excitation beam across an IEF channel during the focusing step.<sup>69</sup>

Considering the capabilities of current capillary instrumentation, which routinely handle bundles of capillary at a time, the ability to increase the number of parallel analysis channels and, therefore, sample throughput is arguably one of the biggest challenges (and successes) in the microchip field. Modest increases in throughput have been achieved featuring both moving and nonmoving parts for beam displacement to address multiple channels. Cheng et al.<sup>70</sup> used a mirror attached to a galvanoscanner to raster an excitation beam across a six-channel device designed to perform independent immunoassays simultaneously (Figure 45.10). The galvanoscanner changed its position in an arc in response to a change in current. Huang et al.<sup>71</sup> used an AOD to change the diffraction angle of an incident laser beam to address an eight-channel device designed for parallel DNA separations. The AOD featured no moving parts, relying solely on the interaction of the laser beam and an acoustic

**FIGURE 45.10** Multichannel approach for LIF detection on a microchip. A mirror attached to a galvanoscanner was used to position the excitation beam so that all eight channels on the device (named SPIDY) could be addressed to monitor parallel immunoassays. (Reprinted from Cheng, S.B., et al., *Analytical Chemistry*, 73, 1472, 2001. Copyright 2001 American Chemical Society. With permission.)

wave propagating through the crystal to scan across the channels, and exhibited fast response times ( $\sim 200$  ns). Most impressive, however, are the advances made by the Mathies group with their radial devices for DNA analysis, which have achieved parallel processing of 96<sup>72</sup> and 384<sup>73</sup> samples. Using circular devices, with analysis channels extending from the center, the detection points can be kept close together, and a circular scan path enables high scan rates and positional accuracy. A description of the radial scanner, which includes a rhomb prism at the top of a hollow rotating shaft, can be found in the literature.<sup>74</sup>

### 45.3.3.2 Multicolor Detection

In multicolor LIF experiments, the most common technique for sampling at multiple emission wavelengths is to add additional photodetectors along with the appropriate dichroic beamsplitters to separate the fluorescent signal. This is the approach taken by several groups to perform multi-DNA sequencing<sup>75</sup> and genotyping<sup>76</sup> on microchip. Despite the existence of commercial capillary instruments that utilize a spectrograph to disperse the emission wavelengths onto a CCD array, this technique has seldom been reported in the literature for microchip LIF detection. However, Backhouse et al.<sup>77</sup> used a diffraction grating to disperse the LIF emission onto a CCD array for four-color sequencing, and Simpson et al.<sup>78</sup> used a transmission imaging spectrograph with a wide imaging area to disperse LIF emission from a two-color genotyping experiment run in 48 parallel channels onto a CCD array. In the CCD systems, the diffracted emission wavelengths are displaced and then binned in rows or columns of CCDs. Recently, a system was developed to complement the microchip platform by featuring a single acoustooptic tunable filter (AOTF) and a single PMT.<sup>51</sup> The filter behaves similar to the previously described AOD, except that when an acoustic wave traveling through the crystal at a specific frequency interacts with the light, only select wavelength bands are diffracted by the crystal and collected by the PMT. Capable of addressing several wavelengths with only a single photodetector (19 are shown in Figure 45.11), an AOTF-based detection system has

**FIGURE 45.11** Three-dimensional multicolor data collected with an AOTF. A mixture of three dyes (FL: fluorescein, R6G: rhodamine 6G, and ROX: carboxy-X-rhodamine) was injected and separated on chip while scanning the AOTF through 19 wavelengths. (Adapted from Karlinsey, J.M. and Landers, J.P., *Analytical Chemistry*, 78, 5590, 2006.)

been shown for four- and five-color genotyping applications on microchip.<sup>79</sup> In all of these cases, the appropriate optics are placed after the pinhole in the confocal detection setup.

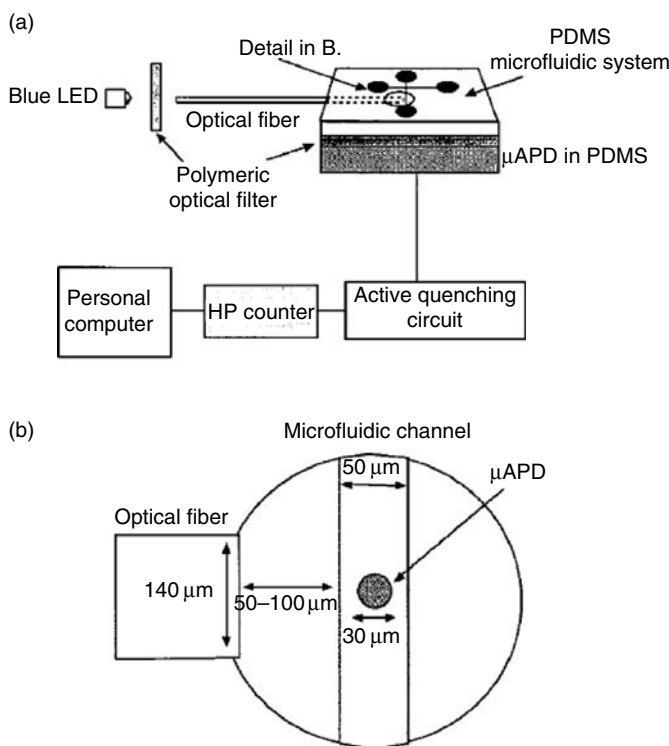

#### 45.3.4 SINGLE MOLECULE DETECTION

The earliest report of single-molecule detection on microchip was in 1998, with concentration detection limits of 1.7 pM for rhodamine 6G and 8.5 pM rhodamine B separated in 10  $\mu\text{m}$  deep glass channels in less than 35 s. The fluorescent molecules were excited with the 514 nm line from an argon ion laser at 540  $\mu\text{W}$ , a 100 $\times$  objective was used in a confocal setup, and a single-photon avalanche diode was used to collect the signal.<sup>80</sup> Shortly afterward, single-molecule detection was applied to DNA separations, focusing the sample through a 1  $\mu\text{m}$  diameter focused laser beam. Using the 488 nm line from an argon ion laser and a 100 $\times$  objective in a confocal microscope, thiazole orange intercalator was excited to detect single DNA molecules during the separation of a 100–1000 bp DNA sizing ladder.<sup>81</sup> Foquet et al.<sup>82</sup> patterned nanochannels in fused silica, creating channel volumes  $\sim 100$  times smaller than the observation volumes obtained using conventional confocal optics. This enabled single-fluorophore detection to be achieved at a higher concentration

(2 nM) than typically reported (pM). Although the examples presented here involve LIF detection, single-molecule detection using TLM has also been demonstrated (see earlier).<sup>31</sup>

### 45.3.5 INTEGRATED OPTICS

Recently, several groups have integrated optical components into their devices, and some of the more impressive examples are presented here. In some cases, no additional fabrication steps are required, as the optics are patterned along with the fluidic features. After pioneering microchip fabrication in PDMS, the Whitesides group assembled an integrated fluorescence detection system including an optical fiber embedded in the patterned fluidic layer to couple excitation light into the channel, a microavalanche photodiode ( $\mu$ APD) embedded in a second PDMS layer, and a colored polycarbonate filter placed between the two layers (Figure 45.12). The device was then used to detect proteins and small molecules separated on the chip, and a detection limit of  $\sim 25$  nM was obtained for fluorescein solution.<sup>83</sup> A microoptical system was designed in glass that involved the additional patterning of microlens arrays and aperture arrays deposited on both sides of the chip to enable the detection of a 3.3 nM dye solution, comparing favorably with confocal systems.<sup>84</sup> Polystyrene chips were fabricated by Maims et al.<sup>85</sup> with an embossed diffractive element to obtain fluorescence and absorption spectra using laser and LED sources. One research group integrated an optical waveguide network with fluidic microchannels to perform particle sorting.<sup>86</sup> Optical trapping was performed by focusing a femtosecond pulsed laser into fused silica to form the waveguide, and the

**FIGURE 45.12** Diagrams for a PDMS chip containing integrated optics. (a) The microchip consists of three layers containing the fluidics, a filter, and an APD detector. Light from an LED source is coupled in the microchip through an optical fiber embedded in the fluidic layer. (b) Top-down view of the microchip that shows the spatial relationship between the channel, detector, and optical fiber. (Reprinted from Chabinyc, M.L., et al., *Analytical Chemistry*, 73, 4491, 2001. Copyright 2001 American Chemical Society. With permission.)

trapped particles (exhibiting different fluorescence signals) were then sorted into different flow paths. Miniaturized spectrometers have been assembled by combining molded elastomeric microchannels with filtered silicon detector arrays, and a solution of Bromophenol Blue was detectable down to the sub- $\mu\text{M}$  range by monitoring its absorption at 588 nm.<sup>87</sup> Thin-film photoelements have been incorporated into PDMS devices to serve as both excitation sources and detectors. Using a confocal detection setup, a thin-film polyfluorene LED was used to excite fluorescein and carboxyfluorescein dyes in an electrophoresis experiment, with a detection limit of 1  $\mu\text{M}$ .<sup>88</sup> A thin-film organic diode was implemented as a photodetector for a CL assay on chip, with a preliminary detection limit of  $\sim 1$  mM.<sup>89</sup>

## 45.4 PRACTICAL APPLICATION OF LIF

The following sections are designed to assist someone interested in assembling a microchip LIF detection setup, or merely to help reinforce some of the considerations for those already collecting data. It is by no means the only way to perform microchip LIF, and it is probably not the best. However, one should be able to routinely achieve 1–100 nM detection limits on the system described herein using a fluorescein dye in a typical CE buffer system.

### 45.4.1 EXPERIMENTAL LIF SETUP

The confocal epifluorescent detection scheme we use is common among many who use this detection mode<sup>90</sup> and features a cube-and-rail assembly system, specifically the microbench system from LINOS Photonics (Milford, MA) on an optical breadboard to maintain proper alignment of components (Figure 45.13). The excitation source is a multiline argon ion gas laser (model Reliant 150 m, Laser Physics, West Jordan, UT) that features user-selectable wavelengths (457, 488, and 514 nm)

**FIGURE 45.13** Confocal epifluorescent detection setup. Laser excitation (dark shading) enters the cube assembly from the steering mirrors and is reflected off of the dichroic beamsplitter before being focused into a microchannel. LIF emission (light shading) is then collected with the objective, passed through the beamsplitter and off a mirror before focusing onto a pinhole. The light passing through the pinhole and subsequent filter is finally collected by the photodetector. The microchip and microchip stage, which should feature translation in the  $z$ -axis and at least one of the  $x$  or  $y$ -axes, have been left out of the diagram. Frontal views are provided of some components when their features are not clear in the side-view. (1: mounting post, 2: steering mirror, 3: iris diaphragm, 4: cube assembly, 5: dichroic beamsplitter on 45° adapter (with three positioning knobs), 6: objective adapter, 7: microscope objective, 8: mirror on 45° adapter, 9: 90° adapter plate, 10: pinhole holder with  $x$ - $y$  positioning, 11: emission filter holder, 12: PMT detector, 13: rail, 14: rail mount.)

and can be operated in multiline mode up to 150 mW. The excitation wavelength enters normal to one of the cubes and is incident on a dichroic beamsplitter tilted at a 45° angle. The dichroic is selected with a particular cutoff wavelength, below which light is reflected and above which light is transmitted. Reflected excitation light is directed into the back end of a microscope objective where it is then focused into the microchannel. The fluorescence emission that is collected by the same objective is then transmitted through the dichroic beamsplitter and focused onto a pinhole placed at the appropriate distance from the objective. The pinhole serves as the spatial filter in the image plane of the objective and defines the collection volume. An appropriate emission filter is placed after the pinhole, and the filtered emission light is then incident on the fluorescence detector where signal is collected for analysis. Both the dichroic beamsplitters and emission filters we use are obtained from Omega Optical (Brattleboro, VT), and the pinhole is from National Aperture (Salem, NH).

In a true confocal system, a point source for excitation is imaged onto the sample and the resulting fluorescence is imaged onto a spatial filter, although most microchip systems use a laser beam as the source. Several discussions regarding the selection of optics, including the objective and pinhole, can be found in the literature.<sup>63,90</sup> The standard microchip LIF setup used in our lab features a 488 nm excitation beam diameter of 2 mm and a 16× magnification objective (model 04 OAS 012, Melles Griot) with a focal length of 10.8 mm and a numerical aperture (NA) of 0.32, yielding a theoretical spot size of 3.4 μm. Aberrations, however, such as those arising from RI mismatches at the air/glass and glass/buffer interfaces, enlarge the effective spot diameter, but our channel widths are typically 30 μm across at their narrowest point (due to the narrowest linewidths we can pattern on our photomasks). Assuming a typical isotropic etch depth of 40 μm, a hemispherical channel is formed with a bottom width of 30 μm (the initial line width on the photomask) and a top width of 110 μm (the initial line width in addition to the etch in each direction). Imaging the channel onto a 1 mm pinhole using the 16× objective, therefore, probes a 62.5 μm spot, which is adequate for sampling from the middle of the channel. When increased sensitivity is desired, a 40× objective (model 440864, Zeiss) with an NA of 0.6 and a correction ring to adjust for cover glass thickness is used, experimentally increasing the signal almost two-fold. By switching objectives, the excitation spot size increases to 7 μm and the collection spot decreases to 25 μm, and so the channel is probed more efficiently.

#### 45.4.2 ALIGNMENT OF THE OPTICS

Alignment of the optical system is critical to the LIF detection, and a technique for setting up and/or aligning a cube-and-rail system is presented here. While this technique is not the only approach, it is relatively straightforward and easy to adapt for various applications. Before alignment, it is helpful to assemble the cube system containing the dichroic beamsplitter and mirror cubes (both containing adjustable 45° adapters), objective adapter, emission filter holder, 90° adapter plate, pinhole holder with x-y positioning, and appropriate rails and rail mounts.

1. The excitation beam must first be aligned parallel to the optical table or breadboard. A way to insure that the height is maintained along the table is to position an iris diaphragm at an appropriate height (i.e., where the light exits the laser), and alternately move it along the beam path from a point close to the laser output to a point as far away as possible, while still on the table. This works best if the beam path follows the predrilled holes on the optical table. Depending on the laser system, this may involve leveling a box enclosure or adjusting the mounts on a tube enclosure.
2. Once the beam is parallel, a set of two steering mirrors are used in tandem to position the beam at a height that matches the center of the top cube containing the dichroic beamsplitter. The mirrors should be mounted at 45° angles on mirror mounts with adjustable pitch and should be placed so that the first mirror reflects the excitation beam perpendicular to the table and the second reflects the beam parallel to the table, with the beam incident at

the desired height. The steering mirrors are then adjusted to align the beam parallel to the table, again using the iris diaphragm. The iris should be centered at the height of the center of the top cube and moved alternately between two holes on the optical table, one close to the steering mirrors and one further away. The pitch on the initial mirror mount should be adjusted while the iris is located close to the steering mirrors, and the pitch on the second mirror should be adjusted after moving the iris further away. This step is repeated until the beam is parallel at the appropriate height to enter the cube. The iris diaphragm can then be fixed in place before the entrance of the cube assembly with the iris diameter adjusted slightly smaller than the beam.

3. The excitation beam should be normal to the cube assembly, and this is tested by placing a microscope slide across the face of the cube. A mirror held against the slide should reflect the excitation beam back through the iris. Once the cube assembly is positioned, it should be fixed to the table. By maintaining an excitation path parallel to the holes in the optical table, the cube assembly should already be centered using the appropriate rail mounts.
4. With the microchip objective removed, the dichroic beamsplitter should be adjusted so that the excitation beam exits the assembly perpendicular to the table. This will put the dichroic at the desired  $45^\circ$ . The position of the beam on the dichroic beamsplitter should then be checked using a mirror above the objective adapter to direct the excitation beam back out of the cube assembly. This is easily observed with the iris still in place. If the beam is not centered, the dichroic mount can be moved back and forth along the beam path. This may require the use of a washer between the cube and the mount to back it out sufficiently.
5. The alignment of the dichroic and the microscope objective must then be checked. The best way to check this is to place a card with a hole in it above the beam exiting the top of the cube assembly, leaving enough space for the objective to be put in place. After lining the hole up with the beam, the objective should be placed in the adapter. With proper alignment, the beam exiting the objective will be centered on the hole. If the beam does not line up, the dichroic adapter should be adjusted accordingly. After this is done, step 4 should be repeated and the alignment of the microscope objective should be rechecked.
6. Once the dichroic beamsplitter is positioned, the mirror adapter in the bottom cube should be adjusted to direct the emission beam parallel to the table as it exits the cube assembly. Because of the filtering behavior of the dichroic, this step is most easily performed with a multiline laser (with a mirror above the objective adapter and the microscope objective removed), but a concentrated solution of fluorophore can also be used to generate a strong signal for alignment (with the objective in place and the beam incident on a filled microchannel). Since the dichroic is aligned, the beam incident on the mirror is normal to the table and so the mirror should be adjusted for a  $45^\circ$ . This is done by setting an iris diaphragm to the height of the center of the bottom cube, and placing it alternately close to the assembly and further away, while adjusting the adapter knobs until the beam is parallel. Because the  $45^\circ$  adapter has three adjustable knobs, only two should be adjusted at a time to ensure that all three are used to align the exit beam.
7. The  $x$ - $y$  positioner with the pinhole should then be placed at the appropriate distance from the shoulder of the microscope objective (the top of the objective adapter). This distance is the tube length (typically 160 mm, specified on the objective housing) minus 10 mm (that accounts for the placement of the eyepiece in finite-corrected light microscopes). Once the pinhole is in position (in this case, 150 mm from the shoulder of the objective) a fluorophore-filled microchannel should be placed above the objective with the focused excitation beam in the channel. Adjusting the  $z$ -axis should increase or decrease the size of the focused emission beam on the pinhole. The  $x$ - and  $y$ -axes should be adjusted on the positioner to align the pinhole. The easiest way to do this is to adjust the  $z$ -axis until

the outer fringes of the focused emission beam are visible around the pinhole, allowing it to be centered easily.

8. After all of the key components are aligned, the emission filter and detector, typically a PMT, can be placed in the setup. Depending on the detector, additional optics, such as focusing lenses or a spectrograph, may be placed after the pinhole. The setup should then be covered to reduce background signal from stray light. The main source of background signal is scattered excitation light, which can be blocked with a notch filter. This type of filter is very expensive, however, and should only be necessary for ultrasensitive fluorescence detection experiments.

The benefit of using fluorescence detection is that it is path length independent and, therefore, the microchannel dimensions (which commonly range from 5 to 200  $\mu\text{m}$ ) do not limit the effectiveness of the detection. However, it is important that the probe volume is located within the channel. While the lateral position of the focused beam is readily identified by eye, observing the sidewalls of the channel that scatter the light and provide an overhead image like a contour map, the depth of the focus within the channel is more difficult to discern. The most sensitive alignment in the  $z$ -axis is achieved by observing a fluorescent signal while adjusting the  $z$ -position. In some applications, such as when using a DNA intercalating dye that exhibits a weak fluorescent signal when unbound, there is enough signal present to maximize the emission signal. However, in most cases, the separation channel is filled with run buffer or polymer matrix that does not exhibit a fluorescence signal. Instead of optimizing the  $z$ -position by adding a fluorophore to the analysis channel, and therefore contaminating the detection region, it is recommended that a separate alignment channel, characterized by the same width and etch depth as the separation channel, be included in the microchip design. Once the  $z$ -position of the microchip stage is tuned using the alignment channel, the chip can then be repositioned with the beam focused in the analysis channel.

### 45.4.3 EVALUATION OF THE DETECTION SYSTEM

One of the more problematic issues when working with glass microchips is the glass–glass bonding step, usually performed by cleaning the bonding surfaces and thermally annealing at high temperatures ( $>600^\circ\text{C}$ ) between ceramic plates with some added weight to generate pressure. Not only is this a time-consuming step (typically performed overnight), but it can also introduce optical defects in the glass due to the combination of high temperature and pressure. It is not unusual to observe “frosting” in the glass following one or more bonding cycles. In regions of the chip where the glass is frosted or clouded, it is difficult to both focus the excitation beam and collect the fluorescence emission. It is recommended, following thermal bonding, that the analysis channels in a microchip be inspected using the LIF detection system before running any samples, in order to identify appropriate windows for interrogation.

When evaluating a detection setup, it is most efficient to do so in the context of a given set of experimental conditions (i.e., device dimensions, buffer system, etc.). These conditions can be standardized within a research group or lab setting for comparison between users and instruments, as well as to evaluate any changes to a system. There may be times, however, when a specific application (i.e., DNA sequencing) merits its own evaluation of the LIF setup. In these cases, it is important to maintain similar conditions in evaluating the detection as will be implemented in the analysis. For example, an off-chip desalting of PCR product before being loaded into the sample well on a microchip will have a significant effect on the amount of sample that gets injected into the separation channel. In this case, the change is not made to the detection setup, but the fluorescence emission collected from the sample will be very different compared to a test sample that may not have been desalted.

## 45.5 CONCLUDING REMARKS

Using primarily LIF detection, the microchip community has achieved the analysis speeds and reagent reductions proposed some 15 years ago, and the process of miniaturizing and integrating optical components onto and around the microchip has already begun. While a universal detector is yet to be developed, researchers have increased the capability of LIF detection systems by integrating additional complexity on the devices themselves, incorporating multiple reaction steps as well as optics. At the same time, the number of microchip analysis techniques is steadily growing. According to SciFinder (which offers access to the Chemical Abstracts database), the number of publications per year regarding microchip detection techniques doubled in the years 2003–2004 and is currently holding steady. Using the optical methods presented in this chapter along with various other forms of chip-based analysis, including electrochemical detection, mass spectroscopy, and even nuclear magnetic resonance, it will be the responsibility of the microchip community to find new applications and elucidate more processes in the future as we increase our ability to control solution flow and mass transfer on the micro- and nanoscale.

## 46.1 INTRODUCTION

The first microfabricated separation system introduced by Harrison et al. [1,2] highlighted the unique marriage of photolithography with analytical chemistry to perform ultrafast, high-resolution separations of subnanoliter volume samples. The lab-on-a-chip concept that grew from these early papers leveraged two important aspects of microfabrication. First, the ability to integrate complicated electrical and mechanical structures directly with the separation channels enables prepurification sample preparation, a concomitant reduction in manual sample handling steps and costly reagent volumes, and the eventual miniaturization of the “lab” for point-of-analysis studies. The second advantage that microfabrication adds is the ability to create arbitrarily complex arrays of channels on the same substrate. The photolithographic techniques used are equivalent regardless of whether the desired channel geometry is simple or complex, in sharp contrast to conventional capillary arrays where each additional capillary exponentiates the complexity and decreases robustness. Thus, microfabricated capillary electrophoresis (CE) systems are ideally suited to perform high-throughput analysis.

The first microfabricated capillary array electrophoresis ( $\mu$ CAE) device appeared in 1997 [3] featuring 12 separation channels interrogated by a scanning laser-induced fluorescence (LIF) detector.

**FIGURE 46.1** The evolution of high-throughput  $\mu$ CAE devices. The earliest devices were fabricated on large microscope slides and used rectilinear arrays of channels, which terminated at a common anode. More complex rectilinear arrays were clearly not scalable and were replaced by modern radial arrays. Radial channel arrays are simple to design and operate and are easily scalable by increasing the wafer diameter.

A race for extending and maximizing the density of channel arrays quickly followed. As Figure 46.1 illustrates, arrays grew in channel density first to 48, then 96, and ultimately to 384 channels [4]. To accommodate the growing number of channels, the “microchips” on which they were fabricated also grew from the size of microscope slides to window-size plates half a meter in length [5]. Much of the growth in channel number and areal density was facilitated by an early shift from rectilinear to radial arrays of channels [6] and the simultaneous development of rotary confocal detection systems.

Despite the great increase in throughput provided by  $\mu$ CAE systems, they are only half way to displacing conventional separation formats. While the resolution and sequencing read lengths of  $\mu$ CAE systems are on par with their conventional counterparts and the time required for similar separations is shorter, they are much closer to a capillaries-on-a-chip than they are to labs-on-a-chip. The next step in the evolution of lab-on-a-chip devices for high-throughput analysis is the integration of sample preparation components before separation. DNA amplification processes such as the polymerase chain reaction (PCR) and Sanger cycle sequencing are the most attractive sample preparation steps and have been integrated with CE exploiting the development of on-chip temperature and valve control elements [7]. On-chip extraction techniques have also been recently demonstrated for purification of DNA directly from clinical samples that often contain an array of inhibitory background molecules [8]. Sample cleanup steps have also been developed to desalt and concentrate Sanger extension fragments before electrokinetic injections, greatly increasing the performance of high-resolution DNA-sequencing separations [9]. The integration of these elements into multichannel arrays has advanced with the recent demonstration of four-channel PCR-CE systems [10,11]. Total integration of sample preparation techniques with on-chip CE analysis came of age in 2006 with the demonstration of single-channel systems for DNA sequencing [12] and

infectious disease typing [13]. Clearly, the successful implementation of integrated components is the next step in  $\mu$ TAS lab-on-a-chip systems.

The demand for high-throughput electrophoretic analysis, which grew exponentially after the birth of PCR in 1988 [14] and with the sequencing of the human genome [15] has only increased in recent years. New metagenomic tests are being used to sample the genomes of environmental specimens [16], mitochondrial barcodes are now used to catalog the world's animal species [17], and increasingly DNA evidence has become the gold standard for human identification in criminal investigations. Taken further, human identification by electrophoresis can be used beyond the crime lab in cases of parental determination and to identify victims of mass disasters [18].

DNA electrophoretic techniques are also becoming increasingly relevant not only in the understanding of cancer but also, enabled by recent breakthroughs in so-called targeted therapies, in charting a course for its treatment. The Lazarus-like response of certain patients to the lung cancer drug "gefitinib" was explained by mutations in the growth factor receptor EGFR, which were found by DNA sequencing [19]. More recently, the identification of a metagene construct for evaluating the severity of nonsmall cell lung cancers promises a more accurate determinant of individual patient therapy than the traditional staging system [20]. Because of the genetic variability of both cancers and patients, it is likely that the need for high-throughput genetic screens will only increase in the future. Thus, it is imperative that electrophoretic techniques be pushed toward higher-throughput, lower cost, and smaller size to truly enable the coming generation of personalized medicine. Such developments in integrated  $\mu$ CE systems incorporating sample purification, amplification, and analysis with robust temperature and fluidic control have recently begun to emerge [21] and will provide an effective foundation on which to build future bioanalysis devices.

## 46.2 BACKGROUND AND EVOLUTION $\mu$ CAE SYSTEMS

The first high-throughput arrayed CE microdevice was demonstrated 5 years after the first single-channel analysis system and consisted of 12 channels with linear scanning detection [3]. The design of the 12-channel  $\mu$ CAE device presented in Figure 46.1 is a modification of the original cross-injector design set out by Harrison et al. [22] and proven by Woolley and Mathies [23] for CE separations of DNA. The injectors of the various channels are arrayed to minimize the dimensions of the chip (maximizing channel density) while leaving sufficient space between reservoirs to maintain electrical and sample isolation. Each of the 12 channels terminates at a common anode reservoir located just below the detection point, for a total of  $3N+1$  drilled reservoirs where  $N$  is the number of samples. Interrogation of the channels is performed by linearly translating the  $\mu$ CAE device below a laser confocal fluorescence point detection system.

The 12-channel  $\mu$ CAE devices were fabricated on glass microscope slides by using photolithography and wet chemical etching to 8- $\mu$ m depths. The etch depth of the channels, in this case, was limited because during photolithography the photoresist was patterned directly on the surface of the wafers without the use of a thin-film "hard" mask layer. Photoresists typically exhibit poor adhesion to hydrophilic surfaces such as glass, resulting in significant undercutting of the photoresist during wet chemical etching steps. This undercutting introduces defects in the etched surface, especially with long etches, and significantly reduces the resolution of the photolithographic pattern.

The 12-channel  $\mu$ CAE device was successfully demonstrated by genotyping twelve individuals for mutations in the human *HLA-H* gene in a restriction fragment length polymorphism (RFLP) assay. Samples were noncovalently labeled with DNA intercalating dyes and run simultaneously with DNA standards for accurate sizing. The 0.5% hydroxyethylcellulose (HEC) separation matrix has low viscosity facilitating its loading into the shallow channels. Despite the differing channel routing in the  $\mu$ CAE device, the electropherograms presented in Figure 46.2 display little channel-to-channel variation, achieved resolution of better than 10 bp, and were complete in 160 s.

**FIGURE 46.2** Electropherogram of a HLA-H genotyping separation using the 12-channel  $\mu$ CAE device. Fluorescent labeling is achieved by the noncovalent intercalating dyes thiazole orange and butyl TOTIN. Separations were monitored by linearly translating the device under a laser confocal detection system focused just upstream of the common anode shared by all channels. A pBR *MspI* digest is added as a sizing standard. (Reproduced from Woolley, A.T. et al., *Anal. Chem.*, 69, 2181, 1997. With permission.)

#### 46.2.1 ADVANCING TO 96 SAMPLES

The next significant step in the evolution of  $\mu$ CAE devices required transitioning from glass microscope slides to larger, 100-mm diameter wafers made from Borofloat glass, which is more compatible with microfabrication processes because of its low sodium content and also exhibits lower autofluorescence, improving detection limits. A 48-channel  $\mu$ CAE device built on the larger wafers is presented in Figure 46.3 and features 96 sample reservoirs, pairs of which share the forty-eight 10-cm long separation channels [24]. The 48-channel  $\mu$ CAE chips were microfabricated using an amorphous silicon hard-mask deposited by plasma-enhanced chemical vapor deposition. The addition of this hard-mask step was critical to achieving high-fidelity microfabrication of 21- $\mu$ m deep channels by wet chemical etching. These deeper channels permit higher-viscosity sieving matrices to be used, which enable higher resolution separations. Interrogation of the channels is performed by a linear galvoscanner to successfully sample each channel at a rate of 40 Hz.

The 48-channel  $\mu$ CAE device employs 96 sample reservoirs, 6 cathode reservoirs, 24 waste reservoirs, and a common anode reservoir. This design reduces the number of necessary reservoirs to  $5/4N+7$ , which is close to the theoretical minimum of  $N+3$  for the case where the anode, cathode, and waste reservoirs are all shared. This minimization of total reservoirs is important because the reservoirs are the largest consumer of area on the chip surface. Not only are they 1.25-mm in diameter, but positional error in drilling places limits on the reservoir density. The 48-channel  $\mu$ CAE chip was

**FIGURE 46.3** Design of the 48-channel  $\mu$ CAE chip. The unique cross-injector design allowed two sample reservoirs (S) to utilize the same separation channel in succession. The total number of reservoirs necessary for operation is greatly reduced by grouping waste (W) and cathode reservoirs. Each channel has a 10-cm effective separation length terminating in a common anode. Detection is achieved using a galvoscaner along the indicated linear path. (Adapted from Simpson, P.C. et al., *Proc. Natl. Acad. Sci. USA*, 95, 2256, 1998. With permission.)

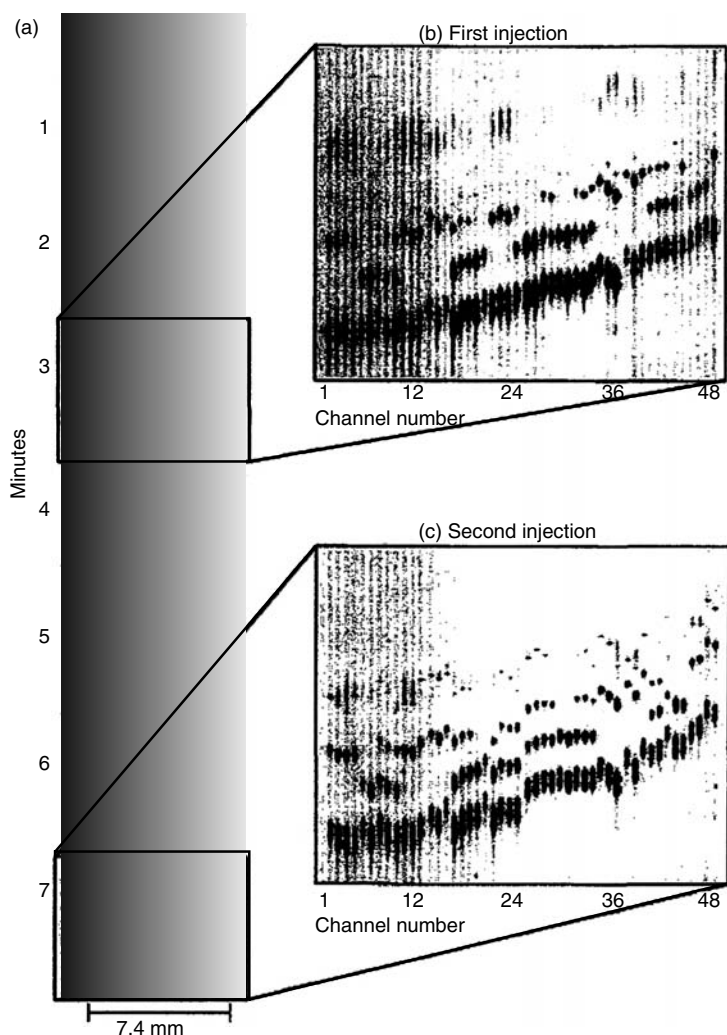

demonstrated by genotyping 96 individuals for the C282Y mutation in the human *HFE* gene using a PCR-RFLP assay. Each separation channel in the 48-channel device is used to serially analyze two separate samples. Figure 46.4 presents the results from such a double-injection run of 96 *HFE* genotyping samples. Electrophoresis is complete within 8 min for both sets of samples but significant variation in peak retention times is observed, possibly as a result of channel geometry or variation of electrode position in the reservoirs.

The rectilinear layout of this chip enables quick sample loading via multichannel pipettors, but this design paradigm scales poorly for higher channel density arrays. Similarly, the integration of sample preparation components is clearly difficult for such designs because of the limited area around each sample reservoir. Another concern is that while channel lengths are equalized in this design, they still incorporate right-angle turns that were later revealed to be a significant source of dispersion in on-chip electrophoretic separations [25].

#### 46.2.2 TRANSITION TO RADIAL FORMATS

Further improvements in high-resolution, high-throughput  $\mu$ CAE necessitated a paradigm shift from rectilinear to radial arrays of channels and a concomitant advancement in detection technologies. The first radial  $\mu$ CAE device [6] arrayed 96 separation channels around a central common anode on a 100-mm diameter glass substrate as presented in Figure 46.5. Pairs of channels are grouped into doublet structures that share common cathode and waste reservoirs. The design of this radial  $\mu$ CAE device offers significant advantages over previous rectilinear arrays. First, all the channels have equivalent lengths and geometries, negating any variability in electrophoretic conditions that might be present in irregular channels. Second, the radial array paradigm is perfectly complimentary to the circular wafers used in microfabrication processes, maximizing utilization of existing wafer

**FIGURE 46.4** Electrophoresis pseudo gel image from a genotyping separation performed on the 48-channel  $\mu$ CAE device. The 96 samples are analyzed in two successive runs, successfully discriminating between full-length 167-bp fragments and 111 or 140-bp digested fragments. (Reproduced from Simpson, P.C. et al., *Proc. Natl. Acad. Sci. USA*, 95, 2256, 1998. With permission.)

area by positioning the drilled reservoirs at the edge of the wafer where the per-channel-area is greatest. Positioning the reservoirs at the periphery of the wafer in a radially symmetric fashion also allows simple construction of electrode arrays to address each reservoir. Third, the separation channels in a radial array  $\mu$ CAE device can be straight between the injection point and the detection zone. While longer separation channels generally yield higher resolution than shorter channels, any turns in those channels can act as a source of dispersion in the bands. Fourth, radial arrays of channels are clearly the best design for scaling to ultrahigh-throughput analysis devices, as wafer sizes  $>100$ -mm diameter are readily available and the tools for processing of wafers up to 300-mm diameter are well developed and commonplace in the semiconductor industry. Thus, increasing the number of channels can be accomplished by increasing wafer size to accommodate the necessary number of sample, cathode, and waste reservoirs. Further, integration of sample preparation steps into a  $\mu$ CAE design becomes viable when the sample reservoirs are at the periphery of the analysis

device where there is more available surface area. Components of such an integrated device can then be incorporated by placing them distal to the sample reservoirs, and the number of pre-separation steps will be limited only by the ultimate size of the substrate.

The shift to radial channel arrays also necessitated a shift in detection methodology from linear scanning to rotary scanning as presented in Figure 46.6. The current generation rotary scanner directs excitation from an Ar<sup>+</sup> laser up through a hollow rotating shaft atop which sits a rhomb prism and objective that respectively deflect the laser 1-cm off the axis of rotation and focus the beam into the microchannels. Fluorescence is collected along the same path as excitation, passing through a dichroic beamsplitter and into a four-color confocal photomultiplier tube (PMT) detector array. In addition, the Berkeley rotary confocal fluorescence scanner is an inverted optical system, which puts all the optical elements on the underside of the chip and all electrical connections on the opposite, top side of the chip, thereby maximizing flexibility of the chip design.

The performance of the 96-channel, 100-mm diameter  $\mu$ CAE device was demonstrated by simultaneously genotyping 96 individuals for the C677T mutation in the human *MTHFR* gene [6]. Electrophoresis was performed at 200 V/cm through a 1.0% w/v HEC sieving matrix and used dimeric intercalating dyes for noncovalent fluorescent labeling. Separations on the 3.5-cm long channels were complete within 120 s, corresponding to a sample throughput of approximately 0.5 samples/s. The utility of this radial design was further advanced by increasing the diameter of the substrate from 100 to 150 mm. By increasing the wafer size, the effective separation length of each channel was increased from 3.5 to 5.5 cm, which increased analysis time, but also increased the ultimate resolution of the  $\mu$ CAE device. This increase in resolution enabled more demanding analyses such as the short tandem repeat typing assays commonly used in forensic identification, which require near single-base resolution. Medintz et al. [26] performed the first  $\mu$ CAE short tandem repeat (STR) separations using a covalent fluorescent multiplexing scheme, demonstrating extremely high-resolution separations in under 8 min with <1% sizing variance. Results from a single multiplex STR genotyping separation are presented in Figure 46.7. The improvement in resolution over previous separations can be attributed not only to the increase in effective separation length from 3.5 to 5.5 cm, but also to the use of a high-performance, denaturing linear polyacrylamide (LPA) separation matrix. The development of a simple and robust high-pressure gel loader and washer by Scherer et al. [27] facilitated the use of high-viscosity LPA in the 150-mm  $\mu$ CAE chip. By applying pressurized helium gas to the sieving matrix, it can be forced into the channels of  $\mu$ CAE device through the common central anode reservoir in under 10 min. After the completion of an electrophoretic run, sieving matrix can then be washed from the radial  $\mu$ CAE chip with water and dried using the same apparatus.

### 46.2.3 OPTIMIZING MICROCHIP DNA SEQUENCING

The ultimate test of any electrophoretic separation system is DNA sequencing of Sanger extension fragments. Sequencing separations not only require single-base resolution, but also require that degree of resolution over 2–3 orders of magnitude of sample fragment size. In addition, the longer the DNA sequencing read length, the more value it has during the final sequence assembly step. The read lengths demonstrated by microfabricated DNA separation systems by 2000 had been significantly less than the 500+ base reads from commercial capillary array systems [28,29]. Notable exceptions include straight-channel microdevices with separation lengths from 11 to 40 cm [30,31], which achieved DNA sequencing reads of up to 800 bases. However, the increased size and complexity of fabrication and design of these longer “capillary-on-a-window” style separation devices negated many of the advantages of miniaturization that are the hallmarks of microfabricated separation systems. The obvious solution was to increase the effective separation length of channels on  $\mu$ CAE chips without increasing substrate size by folding the channels back along themselves. However, turns are effective sources of dispersion in  $\mu$ CE separations [25,32,33]. The dispersion is due to the racetrack effect, in which species all traveling at the same velocity will pass through a turn more quickly along the shorter inside track of the turn than along the longer outside track. This effect is

**FIGURE 46.5** The first radial array  $\mu$ CAE chip featured 96 sample channels arrayed about a single, common anode on a 100-mm diameter glass substrate. Utilization of space was maximized by placing reservoirs at the periphery of the wafer and grouping pairs of channels into a doublet structure, which shared cathode (C) and waste (W) reservoirs. Detection was performed along a circular path 1 cm from the anode with the scanner described in Figure 46.6. (Adapted from Shi, Y.N. et al., *Anal. Chem.*, 71, 5354, 1999. With permission.)

**FIGURE 46.6** The Berkeley rotary confocal fluorescence scanner developed by James R. Scherer. Laser excitation is directed up through the hollow drive shaft of a stepper motor, deflected off axis by a rhomb prism, and is then focused with a microscope objective, tracing a 1-cm radius circular detection path on the chip. Fluorescence is collected along the same path and then spatially and spectrally filtered by a four-color PMT array. The inverted nature of this system allows easy access to the upper surface of a  $\mu$ CAE device for electrical, pneumatic, and sample interfacing.

**FIGURE 46.7** (See color insert following page 810.) Electropherograms from a multiplexed short tandem repeat sizing separation on a 150-mm diameter, 96-channel  $\mu$ CAE device. Separations are successful in all lanes and sizing against DNA standards (blue and red) was accurate to within 1% of known values. (Reproduced from Medintz, I.L. et al., *Clin. Chem.*, 47, 1614, 2001. With permission.)

exacerbated in electrokinetic transport because the shorter inside path also has a lower resistance than the outside path, and will thus experience a higher electric field strength that further increases the difference in transit time between the inside and outside tracks. In an elegant series of experiments, Paegel et al. [34] discovered that the racetrack dispersion of bands passing through turns could be almost eliminated simply by narrowing the width of the channel for the duration of the turn.

The development of these hyperturns was a critical advance toward development of a  $\mu$ CAE system for high-throughput DNA sequencing by enabling the longer separation lengths necessary for high-resolution separations. By folding the separation channels back on themselves with hyperturns it was possible to extend the channels on a 150-mm diameter wafer to a total effective separation length of 15.9 cm (see Figure 46.8). The total combined separation length on the  $\mu$ CAE device presented in Figure 46.8 is 15.25 m, with the channels taking up the majority of the surface area of the wafer. Maximizing the amount of utilized space on the wafer surface was also found to significantly improve the success rate of thermal bonding of  $\mu$ CAE devices for two reasons. The smaller contact area between the wafers will experience greater pressure during bonding and the presence of the channels provides convenient escape routes for gas trapped between the wafers during bonding.

**FIGURE 46.8** Design of the 96-channel  $\mu$ CAE sequencer. Channels are grouped into doublets and folded back on themselves twice for an effective separation length of 15.9-cm. Each turn uses the indicated hyperturn geometry to minimize turn-related dispersion. The lengths and widths of channels in the 250- $\mu$ m offset cross-injector are balanced to provide equal fluidic resistance during gel loading. (Adapted from Paegel, B.M. et al., *Proc. Natl. Acad. Sci. USA*, 99, 574, 2002. With permission.)

The performance of the 96-channel  $\mu$ CAE sequencer was demonstrated by simultaneous electrophoresis of 96 identical *M13mp18* vector DNA sequencing standards as presented in Figure 46.9. Electrophoresis was performed at 240 V/cm through LPA under denaturing conditions resulting in continuous DNA sequencing reads of 430 bases with >99% accuracy in 24 min [35]. This level of accuracy, corresponding to a Phred score of 20 is recognized as the standard metric for determining read length. The longer time required for separations of DNA sequencing fragments is necessary because of the increased length of the channels, the more efficient long-chain sieving matrix, and the upper practical limit placed on the electric field due to the onset of biased repetition of the larger fragments. The longer electrophoresis times necessary for high-resolution separation of DNA sequencing fragments also necessitated an increase in the buffering capacity of the cathode and anode reservoirs. This volume increase was made possible by affixing Plexiglas moats to the surface of the chip, and filling the moats with 3 mL of Tris-TAPS-EDTA run buffer. The added buffer volume was necessary to offset the hydrolytic production of hydroxyl ions at the cathode and protons at the anode reservoirs. These hydrolytic products titrate and then acidify the anode buffer, creating a local pH drop that reduces the net negative charge on the DNA and significantly reduces the overall separation efficiency.

The 96-channel  $\mu$ CAE sequencer proved to be a robust high-resolution separation platform that is easily extended to other applications. Through creative fluorescent multiplexing, Blazej et al. [36] used the  $\mu$ CAE sequencer to mine two human mitochondrial genomes for mutations, analyzing an entire genome versus a reference genome in a single electrophoretic run. More recently, Yeung et al. [37] demonstrated the utility of the  $\mu$ CAE sequencer to high-resolution STR typing separations for forensic DNA identification. The system performed separations with resolution and sensitivity equal

**FIGURE 46.9** Results from a DNA sequencing separation of *M13mp18* standards on the 96-channel  $\mu$ CAE device. Average sequencing read lengths of 430 bases of  $\geq 99\%$  accuracy were obtained, and only one of the 96 lanes failed. (Reproduced from Paegel, B.M. et al., *Proc. Natl. Acad. Sci. USA*, 99, 574, 2002. With permission.)

to conventional capillary systems in less than half the time, and proved useful not only for standard sizing ladders but also for actual (nonprobativ) casework samples.

#### 46.2.4 TO THE ULTIMATE 384 LANE MICRODEVICE

Increasing throughput beyond what was demonstrated for 96-channel  $\mu$ CAE devices require an increase in the wafer diameter. Figure 46.10 presents the design of a 384-lane  $\mu$ CAE device for ultrahigh throughput genotyping [4]. This channel density is close to the practical maximum for radial arrays and the Berkeley rotary confocal fluorescence detection and required the replacement of standard cross-injector with a direct injector. The direct injector used in the 384-lane  $\mu$ CAE bioanalyzer provides significant savings of area by eliminating the waste reservoirs associated with a cross-injector and also groups channels into quartets, which share a common cathode reservoir. Thus, the total number of reservoirs is reduced to  $5/4N+1$ , but the elimination of the cross-injector comes at a cost of reduced resolution because of the larger direct-injected plug size. Much of this lost resolution is made up by the increased 8.0-cm effective separation length afforded by the larger diameter wafer, achieving theoretical plate numbers of up to  $4 \times 10^6$  for separations of DNA size standards. The performance of the 384-channel  $\mu$ CAE bioanalyzer was demonstrated by simultaneously genotyping 384 individuals for the H63D mutation in the human *HFE* gene via an RFLP assay. The electrophoretic separation was performed at 260 V/cm and was complete within 325 s for an overall throughput of  $> 1$  samples/s. Results of the separation presented in Figure 46.11 reveal excellent reproducibility between channels and the 98.7% success rate of the separations stands as a testament to the robustness of both the radial array concept and the rotary confocal fluorescence scanner.

The design, manufacture, and operation of the 384-lane  $\mu$ CAE bioanalyzer likely represents a practical maximum for throughput in microfabricated electrophoresis systems. The fabrication

**FIGURE 46.10** Design of the 384-lane  $\mu$ CAE bioanalyzer. Channels are grouped into quartets, which share a common cathode reservoir. To save space on the 200-mm diameter substrate, a direct injection scheme is used in place of a cross-injector. The resolution lost by the transition to direct injectors is partially recovered by an increased effective separation length of 8.0 cm. (Adapted from Emrich, C.A. et al., *Anal. Chem.*, 74, 5076, 2002. With permission.)

of larger devices requires significant investments in new tools, specialized and time-consuming hole drilling equipment, and robotics for performing sample loading. A similarly high-throughput system for DNA sequencing was recently demonstrated by Aborn et al. [5] fabricated on  $25 \times 50$  cm rectangular glass substrates. This system also utilizes a rotary confocal fluorescence scanner for detection, but the size and complexity of the  $\mu$ CAE devices necessitates a complex and costly robotic station for sample and buffer loading, gel filling, and cleaning of the wafers. Further, the cross-injector design necessary for impressive, high-resolution sequencing increases the complexity of design of the device enough to require nonuniform separation channel lengths.

Overall,  $\mu$ CAE devices presented in the literature thus far offer only limited advantages over conventional capillary electrophoresis systems for high-throughput bioanalysis: a decadic improvement in speed, and no change in detection limits. Thus,  $\mu$ CAE systems are not as compelling an upgrade as CAE was over slab gel systems (i.e., automatable technology,  $10\times$  faster analysis, simplified and more sensitive detection methodology). To offer the same kind of paradigm shift in high-throughput analysis,  $\mu$ CAE systems will need to leverage integration of sample preparation components to fully exploit the advantages in speed, and reductions in both manual sample handling and reagent volumes that microfabricated analysis systems offer.

#### 46.2.5 INTEGRATION: THE FINAL FRONTIER

The cross-injector enables analyses with microfabricated systems an order of magnitude faster than capillary-based systems. This advantage is due to the extremely small sample zones that can be injected ( $\leq 1$  nL) with the cross-injector, but the consequence of these minute zones is that the cross-injector is extremely inefficient. Samples are typically pipetted at  $1\text{--}2$   $\mu$ L volumes into the drilled reservoirs on a microdevice. Even when considering large injected sample plugs of 1 nL and a low-volume, pipetted sample (1  $\mu$ L), the cross-injector is only 0.1% efficient. That is, despite the excellent low-volume fluid-handling promises of microsystems, they still require input volumes

**FIGURE 46.11** Results of a single run on the 384-lane  $\mu$ CAE bioanalyzer demonstrating high resolution ( $4.0 \times 10^6$  theoretical plates) and low lane-to-lane variation in peak elution time (overall RSD < 2%). Fragments were typed for the H63D mutation in the human *HFE* gene by RFLP successfully in 379 of the 384 lanes. Electrophoresis was carried out at 260 V/cm through a PDMA sieving matrix and used a fluorescent intercalating dye for labeling. (Adapted from Emrich, C.A. et al., *Anal. Chem.*, 74, 5076, 2002. With permission.)

hundreds or thousands of times larger than the volume of sample that is ultimately analyzed. The scale of inefficiency of the cross-injector should not be underestimated. If slab gel electrophoresis were 0.1% efficient with respect to the analyzed volume of loaded sample, each sample would need to be loaded in 10 mL aliquots, instead of the 10  $\mu$ L volumes typically used.

The use of on-chip PCR reactors both decreases the analysis time by taking advantage of the low thermal mass of microfabricated systems and also increases the efficiency of the cross-injector. PCR reactors in microfabricated devices are typically  $\sim 250$  nL in volume and are directly coupled to the cross-injector [7]. The reduction in initial sample size increases the scale of efficiency 5- to 10-fold when compared to a drilled reservoir, but introduces another drawback: injection bias in high-salt

samples. Any electrokinetic injection is biased toward high-concentration, high-mobility species. The injected fraction  $f$  of any species  $i$  is given by

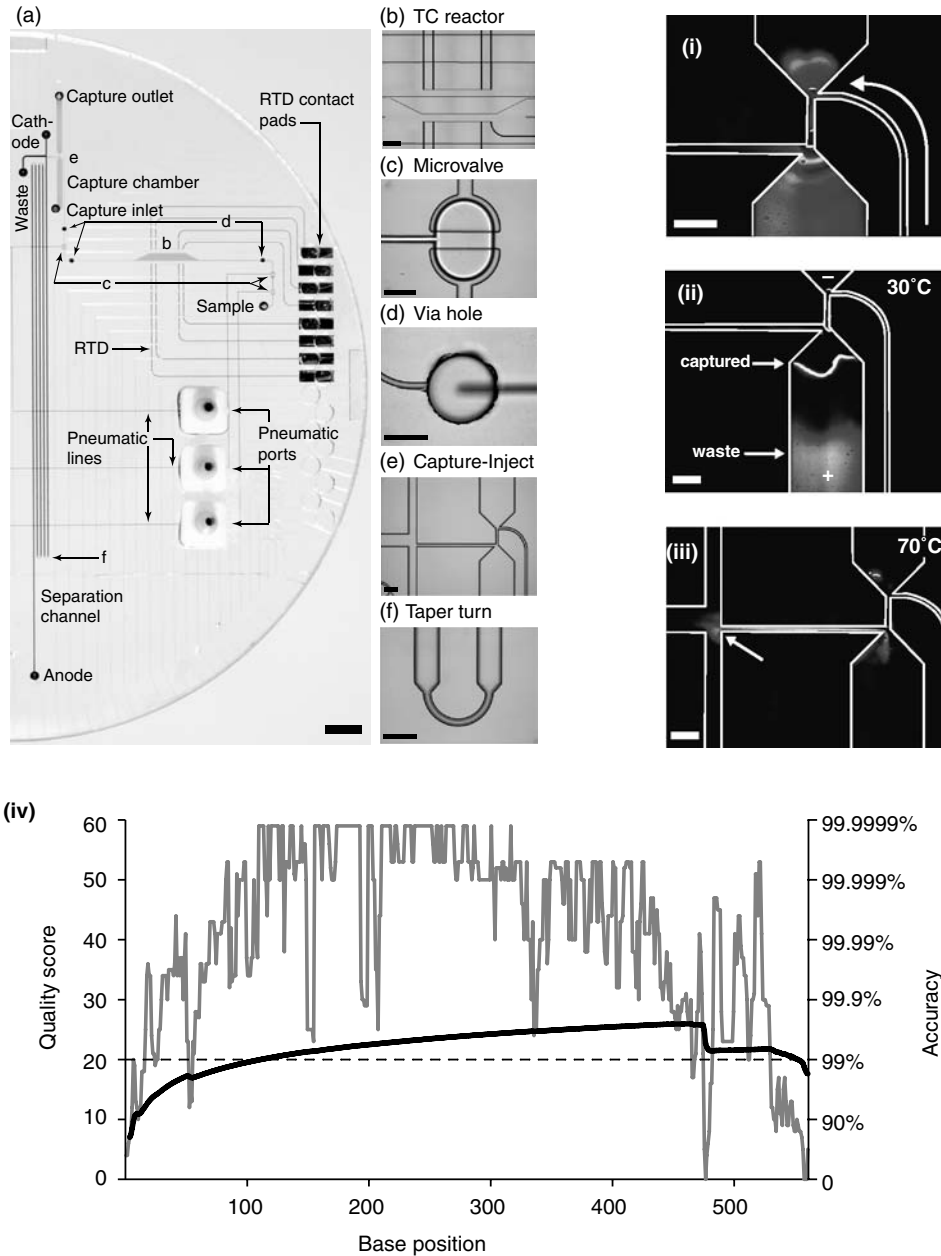

$$f_i = \frac{c_i \mu_i}{\sum_i c_i \mu_i}, \quad (46.1)$$

where  $c$  is concentration and  $\mu$  is electrophoretic mobility. According to Equation 46.1, high-concentration, high-mobility species, such as salts, will be injected preferentially over scarce, low-mobility DNA. This problem is significant for samples that have been amplified by PCR, which typically contain  $\geq 50$  mM  $\text{Cl}^-$ , and  $\sim \mu\text{M}$  dNTPs. Both will be injected preferentially with respect to lower-concentration amplified products. This deconcentration event is the reverse of sample stacking phenomena [38] that are used to concentrate samples before or at the outset [39] of many separations. For example, the high-salt buffer (50 mM Tris-HCl, 100 mM NaCl, 10 mM  $\text{MgCl}_2$ ) used in *MboI* digestion of samples in [4] necessitated the manual desalting of all 384 samples analyzed to obtain satisfactory injections and separations.

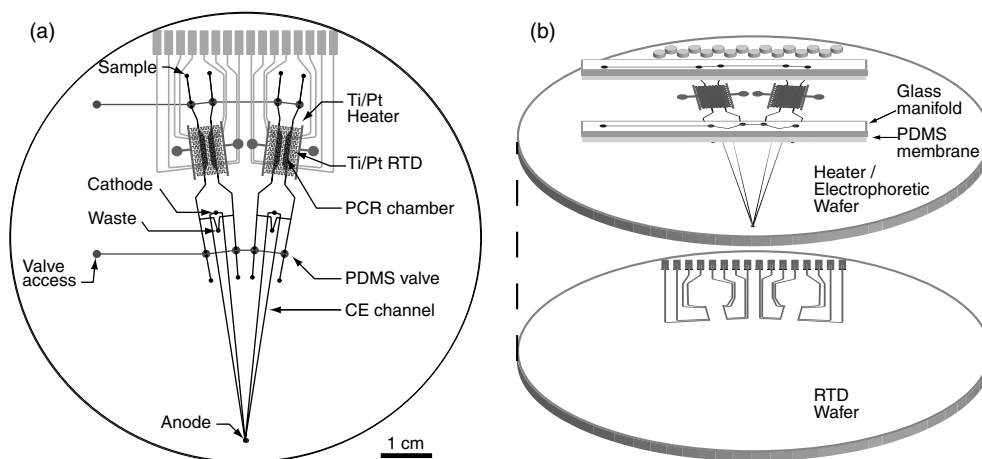

Various approaches have been investigated to mitigate the extreme inefficiency of the cross-injector, most by performing on-chip concentration and desalting of analytes before cross-injection [9,40,41]. Paegel developed an oligonucleotide-capture chamber to purify and concentrating DNA-sequencing extension fragments [9]. This capture system used a LPA gel copolymerized with an Acrydite-modified oligo that is complimentary to a sequence of the product to be captured. Under an applied electric field, amplified products are electrophoresed through the gel, where they are captured by the tethered oligos, allowing other charged species such as salt, excess primers, and dNTPs to pass through into a waste reservoir. The captured products, in this case *M13mp18* sequencing extension products, are then released by heating to  $T > T_m$  and injected for CE analysis. This scheme resulted in significant concentration of the sample (up to the  $\mu\text{M}$  concentration of the capture oligo) and obviated the time-consuming and labor-intensive ethanol precipitation step commonly used for purification of DNA sequencing fragments.

Recently, Blazej et al. combined this oligo-capture system directly with a thermal-cycling reaction chamber to create the first fully integrated sequencing device. The design of the device is presented in Figure 46.12 and incorporates on-chip thermal control elements [7] and pneumatic fluid control elements [42] to perform a Sanger cycle sequencing reaction, the products of which are then fed into an oligo-capture chamber. Purified extension fragments are then thermally released and electrophoretically separated at 167 V/cm on a 30-cm long folded channel and detected on a four-color fluorescence scanner. The device was able to generate 556 continuous bases of sequence with  $\geq 99\%$  accuracy starting from only 1 fmol of template, which is a  $>10\times$  reduction in the amount of necessary template and reagents for sequencing versus conventional methods. This device achieves at last the vision for integration set forth by Harrison in 1993 [2] by combining microfabricated components in a way that exceed the performance of commercial systems in terms of input volume, reagent consumption, analysis time, and sensitivity.

Adapting similar integrated systems to multichannel array systems has been challenging due to the difficulty inherent in designing robust microfluidic elements that can be controlled with a minimum of complexity. The first steps toward such integrated array CE systems were recently taken by Liu and Toriello, who developed a high-sensitivity PCR-CE microdevice [10,11] capable of high-throughput genetic analysis with very low limits of detection. The microdevice, presented in Figure 46.13, consists of a “standard” four-layer glass sandwich structure that incorporates thin-film metal heaters and temperature sensors optimized for maximal thermal uniformity and scalability with 380-nL PCR reactors. The four-layer structure consists of a PDMS membrane layer (0.25 mm thick) sandwiched between a pair bonded of glass wafers for CE and a glass wafer for pneumatic actuation (each 1.1 mm thick). This structural paradigm allows for high-resolution CE separations to take place in all-glass channels and allows fluidic routing paths to cross the separation channels, greatly extending design flexibility. Pneumatic control is afforded by PDMS membrane valves that

**FIGURE 46.12** Design and operation of a fully integrated high-resolution DNA sequencing microdevice. (a–f) Thermal control elements are embedded together with a pneumatically sealed chamber for Sanger cycle sequencing. Product fragments are then directed by pneumatic pumping (i) to a separate chamber for purification by affinity capture (ii), injected with a cross-injector (iii) and then separated on a 30-cm long folded channel. (iv) Sequencing reads of at least 99% accuracy, corresponding to a Phred score of 20, were reproducibly obtained to lengths of >500 bases. (Reproduced from Blazej, R.G. et al., *Proc. Natl. Acad. Sci. USA*, 103, 7240, 2006. With permission.)

**FIGURE 46.13** Design of an integrated PCR-CE array system featuring four PCR chambers (380 nL each) coupled to four 5-cm long CE channels. Individual elements are arrayed radially for detection with a rotary LIF scanner. (b) Exploded view of the four-layer structure of the array PCR-CE device. (Reproduced from Liu, C.N., et al., *Anal. Chem.*, 78, 5474, 2006. With permission.)

**FIGURE 46.14** Limits of detection of the array-PCR device shown in the previous figure demonstrate that successful amplification and CE analysis can be performed starting with as few as 10 template copies in the 380-nL PCR reactors. The total analysis time for this four-layer integrated analysis device, including 30 cycles of PCR was less than 30 min. (Reproduced from Liu, C.N., et al., *Anal. Chem.*, 78, 5474, 2006. With permission.)

are actuated through a glass manifold. Both the manifold and the PDMS membrane are replaceable so that intrarun carryover of DNA can be eliminated. The adoption of a modular valve design that allows disassembly was critical to the development of a reproducible, reusable, and robust array PCR-CE system. Each of the reactors and CE channels in this microdevice are arrayed radially for detection with the Berkeley rotary scanner and to enable the facile radial layout scaling. The performance of the microdevice was demonstrated in two sets of experiments, the first of which performed amplification on both purified DNA templates and from whole bacterial cells [10] to a limit of 10 initial template copies in only 27 min (Figure 46.14). The second set demonstrated the utility of the array-PCR

microdevice for RNA analysis by reverse-transcription analysis of bacteria with subcellular detection limits and analysis of RNA splice site variations associated with human breast cancer [11]. Both sets of experiments demonstrated excellent reproducibility and low limits of detection. Moreover, these devices present a scalable layout that forms the foundation of next-generation integrated  $\mu$ CAE devices for high-throughput bioanalysis.

### 46.3 CONCLUSIONS AND PROSPECTS

The last decade has seen the birth and growth of  $\mu$ CAE systems from simple rectilinear to complex radial designs. The radial array paradigm and rotary LIF scanners enabled  $\mu$ CAE systems to reach a practical limit of nearly 400 channels with analysis times shorter than their conventional CAE counterparts, in some cases reaching throughputs of  $>1$  sample per second. Further increases in throughput and continued growth in the capabilities of  $\mu$ CE systems will be realized by integrating sample preparation components directly with CE analysis. The first step toward integrated sample preparation components with high-resolution separations has already been taken, marking significant progress along the path toward true lab-on-a-chip systems. Among the most critical steps to be made are the development of modular functional components that are easily combined and incorporated into  $\mu$ CE systems. Thus executed, the development of  $\mu$ CAE systems in the coming decade will be more fruitful than the last.

### ACKNOWLEDGMENTS

We thank all the members of the Mathies group for their support, and Robert Blazej and Stephanie Yeung for assistance in figure preparation. This work was supported by NIH grant HG003583 and the donors to the UC Berkeley Center for Analytical Biotechnology.

## 47.1 INTRODUCTION AND BACKGROUND

History of chromatographic separation processes is closely related to particulate packings for more than a century. Tsvett<sup>1</sup> used powdered calcium carbonate to achieve the separation of chlorophylls. Separation of biomacromolecules in both low-pressure size-exclusion and ion-exchange chromatographic modes became available after introduction of stationary phases based on modified natural polysaccharides in the 1950s.<sup>2–4</sup> High-performance liquid chromatography (HPLC) commenced in the 1960s partly because bonded porous silica particles were available.<sup>5,6</sup> The shape of these particles has changed from relatively large irregular pieces to current regular beads, the size of which can now be even less than 2  $\mu\text{m}$ . The porous structure and surface chemistry also have evolved to reach current high standards. Typically, particulate separation media are prepared in larger batches and a small portion of these porous beads with well-defined size, shape, porosity, and chemistry are packed into columns that are subsequently used for chromatographic separations. Despite the many advantages that led to their widespread use, columns packed with typical particulate materials also have some limitations. The necessity of packing procedure, the slow diffusional mass transfer of high molecular weight solutes into the stagnant phase present in the pores of the beads, and the large void volume between the packed particles, are the most important and best-known limitations of the present day column technologies.<sup>6,7</sup>

Separation scientists realized that some of these restrictions could be eliminated by using separation media with limited discontinuity. For example, R. Synge<sup>8</sup> envisioned “a continuous block of porous material” and its use for the separation. Unfortunately, suitable materials were not available

and his idea could not be materialized.<sup>9</sup> The first experimental attempt to create via polymerization a “single piece” of gel-like separation medium that did not contain interparticular voids date back to the late 1960s.<sup>10</sup> Disappointingly, this hydrogel did not perform well. In contrast, the permeability of monolithic open-pore polyurethane foams introduced slightly later was excellent.<sup>11,12</sup> However, less suitable chromatographic characteristics of these materials prevented their broader use in both liquid and gas chromatography. Thus, macroporous discs<sup>13,14</sup> and compressed soft polyacrylamide gels placed in a cartridge or column<sup>15</sup> represented the first successful demonstrations of media that exhibited no interstitial porosity. These elegant approaches have recently been described in detail in a series of excellent review articles.<sup>16–19</sup>

In the early 1990s, yet another category was developed.<sup>20</sup> These rigid macroporous organic polymer monoliths were formed by a very simple *in situ* “molding” process in which a liquid mixture of monomers and solvents was polymerized under carefully controlled conditions and immediately used within a closed tube or similar container. Many review articles describing various aspects of these materials have been published during the years since their inception.<sup>19,21–28</sup>

Porous inorganic materials, in general, and porous silica in particular, are very popular supports widely used in chromatography. Therefore, development of silica monoliths followed closely to that of the organic polymers.<sup>29–31</sup> Detailed accounts of these materials have also been published several times.<sup>32–35</sup> Separations using these monolithic separation media have also been treated theoretically.<sup>36–41</sup>

In contrast to columns, the microfabricated devices feature a network of microchannels etched in glass or imprinted in a polymer plate that are designed to enable much smaller sample volumes to be analyzed at an increased speed and permitting a large number of analysis to be performed simultaneously, thus increasing the overall throughput. Microfluidic analytical devices with open channel geometry are currently most frequently used to achieve the desired functions. Open channels are best suited for separation systems in which no interactions with functionalities located at the solid surface are required or are even undesirable, such as in electrophoresis.

In contrast, the mode of operation of a number of other modules in microfluidic devices, such as reactors, solid-phase extraction, and separation units require interactions of molecules in solution with functionalities attached to a solid support. Obviously, this support can itself be the channel wall but, in this case, the overall surface-to-volume ratio is very small. This ratio can be increased by filling the channel with a solid phase, and the monolithic materials represent one of the options to fill the channel with a suitable stationary phase.

## 47.2 PRACTICAL APPLICATIONS

### 47.2.1 REVERSED-PHASE HPLC

According to International Union of Pure and Applied Chemistry (IUPAC),<sup>42</sup> chromatography is a physical method of separation in which the components to be separated are distributed between two phases, one of which is stationary while the other moves in a definite direction. HPLC is then defined as “an analytical separation technique used to detect and quantitate analytes of interest in more or less complex mixtures and matrices” that uses “elevated pressures to force the liquid through the bed of the stationary phase.”<sup>43</sup> The bed is most often located in a column. Since almost four decades of its inception, HPLC technique has advanced and there is enormous literature available on this technique.

In contrast, very small activity can be observed in the field of HPLC on chip. The simplest approach to microfluidic HPLC devices that mimic typical chromatographic columns include channels packed with chromatographic beads.<sup>44–54</sup> However, an early attempt by Ocvirk et al.<sup>44</sup> to pack channel on a silicon microchip with beads was not very successful due to technical difficulties, and the 20-mm long microfluidic HPLC “column” generated only 200 theoretical plates (4000 plates/m).

Using a different approach, Oleschuk et al.<sup>55</sup> succeeded in packing octadecyl silica beads from a side channel into a specifically designed chamber of the microchip.

Although packing is a typical approach for the preparation of HPLC columns, filling channels with porous beads is difficult to accomplish due to the need of frits or other retaining structures and the difficulty associated with efficient packing of the channels. Therefore, for a long time, microfluidic separation modules packed with particles did not match the performance of their counterparts, such as standard packed columns. Only recently, Agilent Laboratories developed a microfluidic system for HPLC coupled with mass spectrometry (HPLC-MS). Although characteristics such as column efficiency are not shown, their separations appear acceptable.<sup>56</sup>

Another reason for the limited interest in HPLC-like separations on chip appears to be the complexity of plumbing since an external pump typical of standard HPLC instrumentation has to be included. The role of the chip then degrades to a capillary-like column and the advantages attributed to microfluidic devices vanish. In order to avoid attachment of the chip to a bulky mechanical pump, Penrose et al.<sup>57</sup> used centripetal force to propel the mobile phase through a bed of particles packed in a channel. Since no detector was added to the system, the readout was a scan of the bed after visualizing the bands in ultraviolet (UV) light.

An alternative option to packed channels is the use of monolithic materials, which may have many of the same benefits as packed beds, including high surface area and easily controlled surface chemistry. However, a distinct advantage of monoliths is the ability to prepare them easily and rapidly via polymerization of liquid precursors within the channels of the microdevice without the need for any retaining structures. Despite the popularity of monolithic capillary columns for separations of a variety of low and high molecular weight compounds in HPLC mode,<sup>19,26,58</sup> their first application in microfluidic chips dates back only to 2005.

Several modules had to be developed before a functional microfluidic HPLC system could be assembled. In a series of papers, the Sandia National Laboratory group demonstrated high-pressure connectors for introduction of liquids, fabrication of integrated polymer checking microvalve elements, on-chip high-pressure picoliter injector, and eventually a complete HPLC chip.<sup>59–62</sup>

Their plastic connectors linking the chip with the external pump via common capillary fittings were glued to the fluid access holes. Although this approach is not ideal for mass production due to the extensive skilled manual work needed to obtain reasonable yield of useful chips, the best units withstood pressures up to 8.5 MPa. Certainly, interconnects integrated into the top part of the chip represent a better solution to the problem,<sup>63</sup> but these would be very difficult to implement with glass chips.

The flow control elements or valves developed in Sandia were plugs of nonporous monolithic polymer prepared from fluorinated acrylates via UV-initiated polymerization directly in one of the channels. The reason for using the fluorinated monomers is to manage the surface energy, decrease their friction in channel, enable actuation at a low pressure, as well as to avoid both swelling and shrinking in solvents typically used in reversed-phase separations such as water and acetonitrile. The friction could be further decreased by modification of the valve channel with fluorinated alkylsilane.<sup>61</sup> However, the latter may be counterproductive in systems used for the separation of proteins and peptides because they tend to adsorb on highly hydrophobic surfaces.

The high-pressure picoliter injector also consists of a moving monolithic plug similar to that used for valving, thus significantly reduced in size.<sup>60</sup> The injection volume is controlled by pressure difference between sample and mobile phase channels and by time. For example, a 0.25 s long injection afforded a sample volume of 180 pL.

The fused-silica chip designed for the separation of peptides and proteins is shown in Figure 47.1.<sup>62</sup> It consists of a sample channel, an injector valve, a mobile phase channel, a separation channel accommodating the monolithic column, and a miniaturized fluorescence detector. The fluids are driven through the channels by syringe pumps. The 17-mm long monolithic column was prepared by *in situ* UV-initiated polymerization developed previously by our group.<sup>64,65</sup> A solution of monomers comprising stearyl acrylate, 1,6-hexanediol diacrylate, and tetrahydrofurfural

**FIGURE 47.1** Four-port valve allowing rapid sample changes. Sample is changed by flushing at low pressure when the sample waste port is open. Sample is injected by closing sample waste port and pressurizing the sample line. (Reprinted with permission from Reichmuth, D. S., et al., *Anal. Chem.*, 77, 2997, 2005. Copyright 2005 American Chemical Society.)

**FIGURE 47.2** Repeated isocratic HPLC separations of proteins on chip. (Reprinted with permission from Reichmuth, D. S., et al., *Anal. Chem.*, 77, 2997, 2005. Copyright 2005 American Chemical Society.) Conditions: lauryl methacrylate monolith; mobile phase 24% acetonitrile + 0.16% heptafluorobutyric acid in 5 mmol/L phosphate buffer (pH 2.0); Injections 6.4 nL, 750 ms, pressure 0.2 MPa. Peaks: free dye (a), insulin (b), antibiotin (c),  $\alpha$ -lactalbumin (d).

acrylate in a mixture of acetate buffer solution (pH 5.0) and methoxyethanol serving as porogens was polymerized using azobisisobutyronitrile (AIBN) as photoinitiator.

First, excellent control and repeatability of the injection volumes was confirmed with over 100 injections of a peptide mixture consisting of glycine-tyrosine, valine-tyrosine-valine, methionine enkephalin, leucine enkephalin, and angiotensin II. The overall relative standard deviation for peak area and retention time was 3.9% and 3.6%, respectively. Chromatographic performance of the chip in reversed-phase mode was then tested with a mixture of proteins (insulin, antibiotin, and  $\alpha$ -lactalbumin). Repeated separations of these compounds are shown in Figure 47.2.<sup>62</sup>

This relatively simple system demonstrates the potential of a microfluidic chip for separations in HPLC mode. It was certainly not ideally suited for the separations of more complex mixtures since it was only used in isocratic conditions and the several minutes long retention times are too long for

the desired high throughput systems. However, the column efficiency of 25,000 plates/m found for  $\alpha$ -lactalbumin using less-than-ideal conditions is remarkably good.

Moschou et al.<sup>66</sup> used the compact disc microfluidic platform that is spun to allow the centripetal force to achieve pumping of the mobile phase through the channel. They incorporated a poly(2-hydroxyethyl methacrylate-co-ethylene dimethacrylate-co-[2-(methacryloyloxy ethyl) trimethylammonium chloride) monolith in the channel of a poly(dimethylsiloxane) (PDMS) chip. The unusual feature of this preparation is the use of irradiation with microwaves in a common domestic microwave oven to initiate the polymerization reaction, which is then completed in only 4.5 min. This is a significantly shorter time compared to 20 h required to obtain monolith using thermally initiated polymerization of the same mixture. This monolith was then used for the purification of enhanced green fluorescent protein in ion-exchange mode.

Despite the high popularity of silica-based monoliths in HPLC, use of this chemistry in microfluidic chips is scarce. Ishida et al.<sup>67</sup> etched a 42-cm long, 400  $\mu\text{m}$  wide, and 30  $\mu\text{m}$  deep serpentine channel in glass substrate. In order to avoid the “race track” effect, the turns were tapered to a width of only 50  $\mu\text{m}$ . Four syringes were attached to the chip through glued outlet capillaries (Figure 47.3). The separation channel was filled by drawing the sol solution prepared by adding tetramethoxysilane

**FIGURE 47.3** Fabricated LC chip with a 45-cm long serpentine channel. (Reprinted with permission from Ishida, A., et al., *J. Chromatogr. A*, 1132, 90, 2006. Copyright 2004 Elsevier B.V.) (c) Chromatographic separation of catechin (1), epigallocatechin gallate (2) and epicatechin (3) on chips with tapered turns. Conditions: sample concentration, 1 mmol/L, mobile phase methanol–water (3:2, v/v), 0.02 mol/L phosphate buffer (pH 2.0), flow rate, 300 nL/min; applied potential, +400 mV versus Ag/AgCl.

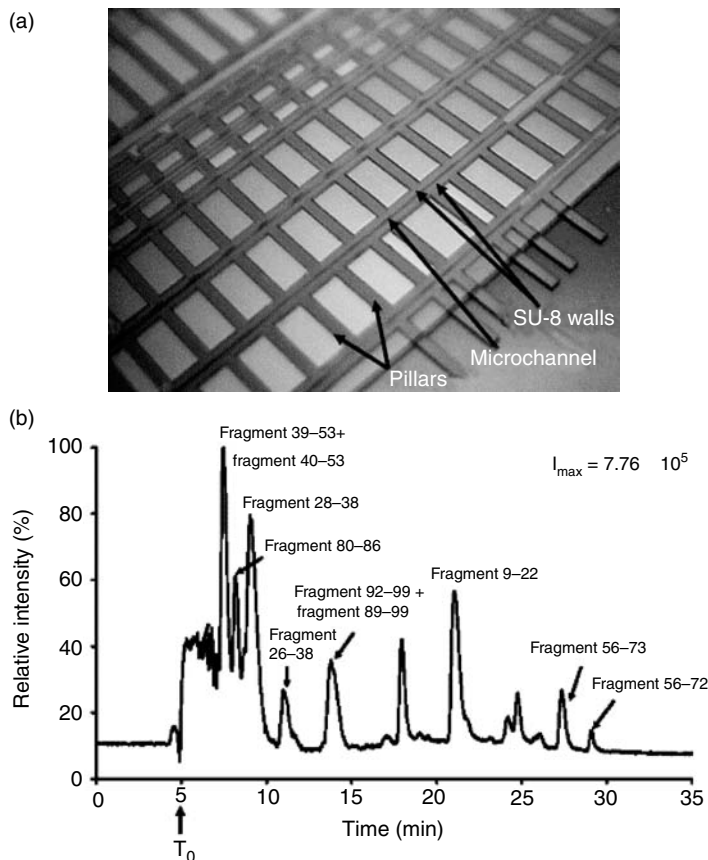

to poly(ethylene glycol) (PEG) containing urea and acetic acid and the contents heated to 40°C for 24 h. The generated gel was then brought to a temperature of 120°C for 3 h and after cooling, the resulting silica monolith was washed with water and methanol. The porous silica was dried at 60°C for 10 h, followed by heating at 200°C for 50 h. After cooling to the room temperature, pores within the monolith were modified by flushing it with a toluene solution of octadecyltrichlorosilane at 100°C for 12 h. As apparent from the description of the preparation, this process is significantly more complex than the simple photoinitiated polymerization affording organic polymer monoliths and indicates why these monoliths are more common stationary phases in microfluidic HPLC. Figure 47.3 shows separation of three catechins using the silica-based monolithic stationary phase and electrochemical detection. Clearly, with a smallest height equivalent to theoretical plate (HETP) of 60  $\mu\text{m}$  representing about 16,500 plates/m, this separation does not match that of typical monolithic silica columns prepared in capillary.

A variety of detectors have been developed that are useful for monitoring separations on chip. Most of the detectors are based on electrochemical and optical concepts.<sup>68</sup> For example, electrochemical detection is successful in detection of electroactive compound (*vide supra*).<sup>67</sup> The very popular laser-induced fluorescence (LIF) is sensitive enough to detect molecules containing a suitable chromophore. Since only a small number of compounds include this feature, most of them must be first modified with a fluorescent label. While this may not be difficult for certain type of molecules, labeling of proteins and peptides possessing a plurality of reactive groups is a problem since their separation may then also occur according to the number of attached labels. In addition, knowledge of the accurate molecular mass is required in fields such as proteomics, glycomics, metabonomics, and so forth. The optical and electrochemical detection methods do not provide this type of information. Therefore, several chip designs were developed that include both monolithic column and an interface that enable connection to mass spectrometer (MS).<sup>69,70</sup>

In one of the early implementations, the chip features shown in Figure 47.4 were fabricated on silicon wafer using SU-8-based multilayer technology.<sup>71</sup> The channels were then covered with a glass wafer. Standard fused-silica capillaries coated with polyimide were glued to the channel ends to enable connection with the nanoflow pump and injector at one end and the coupling to MS at the other end. This chip withstands an internal pressure of up to 5 MPa without visible delamination and no damage was observed after pumping different solvents such as water, acetonitrile, and acetic acid through the channel for several hours. The polymerization mixture consisting of lauryl methacrylate, ethylene dimethacrylate, cyclohexanol, ethylene glycol, and azobisisobutyronitrile (AIBN) was injected in the channel and irradiated through a mask to achieve photopolymerization only in the desired 22-mm-long part of the channel. This device afforded certain separations of peptides originating from digested cytochrome C as also shown in Figure 47.4.

In the following chapter, this group used a monolith in an improved chip design provided with a nib fabricated on the bottom silicon plate to enhance the nano-ESI interface.<sup>72</sup> In contrast to the previous system, less-hydrophobic butyl methacrylate instead of the lauryl derivative was used to prepare the monolith. No real separation of a peptide mixture was attempted and the performance of this system was only demonstrated with desalination of the peptide sample before MS analysis.

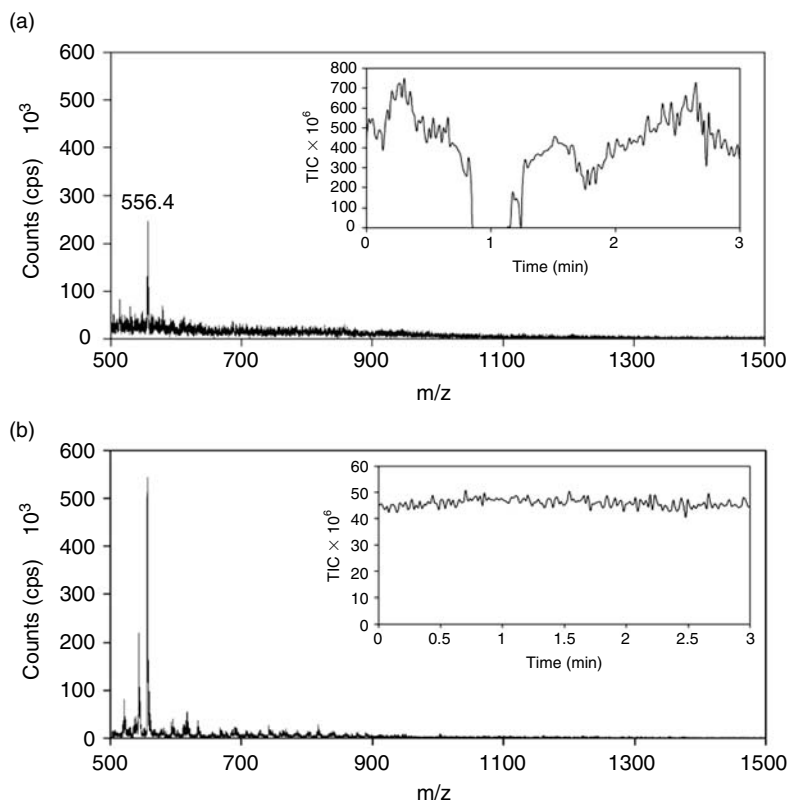

Oleschuk and coworkers<sup>73</sup> prepared monoliths in a glass chip with semicircular channel cross-section. They used slightly modified polymerization mixture developed by Peters et al.<sup>74</sup> consisting of butyl acrylate, ethylene dimethacrylate, 2-acrylamido-2-methyl-1-propanesulfonic acid, and photoinitiator benzoin methyl ether all dissolved in porogenic solvent comprising water, 1-propanol, and 1,4-butanediol. The device was made by patterning a plug of the monolith in the center of a doubled unit followed by dicing it in two parts to obtain chips with a monolith reaching to the channel exit. In contrast to open channel, implementation with the monolith inside afforded a stable electrospray at a wide range of flow rates (50–500 nL/min). The best results were obtained at lower flow rates of 50–100 nL/min. Figure 47.5 compares mass spectra of leucine enkephalin obtained from both open and monolithic formats, and demonstrates significantly impaired spray stability and sensitivity found for the open channel device. The positive effect of the monolith was ascribed to multiple Taylor

**FIGURE 47.4** Photograph of a microsystem fabricated via the multilayered structure route (top) and on-chip HPLC separation of cytochrome c digest using a lauryl methacrylate-based monolithic column (bottom). Conditions: sample concentration 800 fmol, mobile phase A, 5% acetonitrile in 0.1% aqueous formic acid, mobile phase B, 95% acetonitrile in 0.1% aqueous formic acid, gradient 5–50% B in A in 30 min, 50–95% B in A in 1 min, flow-rate 200 nL/min.

cones originating from numerous large pores at the face of the monolithic material that generated the mist. The multiple paths also minimized clogging and the hydrophobic nature of the monolith avoided droplet spreading at the emitter.

A 70-fold enhancement in stability of the spray and sensitivity of detection has also been demonstrated with plastic chips containing 5-mm long monolithic sprayer in the zero dead volume emitting tip.<sup>75</sup> The microfluidic devices were fabricated from three different polymeric substrates including poly(methyl methacrylate) (PMMA), cyclic olefin copolymer (COC), and PDMS. The channel surface had to be first modified by photografting to afford covalent attachment of the monolith to the channel walls.<sup>76,77</sup> The monolith was then patterned in the desired location via photopolymerization of a mixture consisting of lauryl acrylate, ethylene dimethacrylate, benzoin methyl ether, methanol, and 2-propanol. PDMS did not appear as a suitable substrate for the formation of monoliths, most likely due to its high permeability for oxygen,<sup>78</sup> which is a known inhibitor of free-radical polymerization reactions. PMMA was not ideal either since it tends to dissolve in the polymerization mixture, thus causing distortion of the channel shape.<sup>75</sup> In contrast, COC has an excellent UV transparency required for photoinitiation of the polymerization reaction within the chip; it does not dissolve in the polymerization mixture or in typical chromatographic solvents, and enables

**FIGURE 47.5** Representative mass spectrum of leucine-enkephalin obtained using chip with open channel emitter (a) and porous polymer monolith-assisted electrospray process from a microdevice at a constant infusion (b). (Reprinted with permission from Koerner, T. and Oleschuk, R. D., *Rapid Comm. Mass Spectr.*, 19, 3279, 2005. Copyright 2005 J. Wiley.) Conditions: peptide solution 1.0  $\mu\text{mol/L}$  in 50% aqueous acetonitrile with 0.5% acetic acid, flow rate of 100 nL/min, applied voltage of 3.5 and 3.0 kV, respectively.

*in situ* formation of excellent monoliths.<sup>63,79</sup> The hydrophobic monolith/emitter was also used for preconcentration and desalting of myoglobin. A 225 nL plug of the protein solution in ammonium acetate buffer containing 450 pmol of myoglobin was pumped through a 50-mm long poly(lauryl acrylate-co-ethylene dimethacrylate) monolith, the channel was then rinsed with water, and the protein released and sprayed using aqueous acetonitrile. This process afforded an excellent MS spectrum.<sup>75</sup>

Knapp and coworkers<sup>80</sup> approached the electrospraying from the COC chip containing a monolith differently. First, they used the channel opening on the edge of the device as the emitter. Similar to observations of Bedair and Oleschuk,<sup>75</sup> they also found hydrophobicity of the native COC insufficient to maintain stable electrospray ionization (ESI) from the channel opening on the edge. Therefore, they used radiofrequency (RF) plasma-assisted chemical vapor deposition (CVD) with octafluorocyclobutane to form a thin hydrophobic fluorocarbon layer around the channel exit. Unfortunately, this coating was quickly damaged by occasional corona discharge. The problem was then solved by adding a thin layer of perfluoroalkyl ether Krytox 1625 over the fluorocarbon-coated surface. The octafluorocyclobutane fluorocarbon covalently attached to the COC surface serves as an anchor for the perfluoroalkyl ether coating. This flexible layer has the ability to repair arcing damage and keep the hydrophobic surface around the edge exit. The high voltage for ESI was applied through the carbon ink line. Lifetime of the resulting microfluidic emitter was found to exceed 20 h. Despite all the success, the fabrication of the spray appears to be rather complex.

**FIGURE 47.6** Schematic diagram of the microfluidic device fabricated from cyclic olefin copolymer containing poly(ethylhexyl methacrylate-co-ethylene dimethacrylate) monolith (top) and chromatogram of tryptic digested bovine serum albumin in the reversed-phase mode. Conditions: digest sample 5 pmol/ $\mu\text{L}$ , mobile phase A 5% acetonitrile in 0.1% aqueous TFA, mobile phase B 70% acetonitrile in 0.1% aqueous TFA, gradient 0% B for 5 min, then from 0% to 70% B in 60 min, flow rate 300 nL/min.

To avoid formation of voids at the monolith–channel wall interface, the inert COC was photografted<sup>78</sup> with trimethylolpropane triacrylate to afford polymerizable double bonds enabling covalent anchoring of the monolith. The channel was then filled with a polymerization mixture consisting of ethylhexyl methacrylate, ethylene dimethacrylate, 1-decanol, and photoinitiator 2,2-dimethoxy-2-phenylacetophenone and polymerization initiated by UV light through a mask. The 55-mm long monolith having a cross-section of about  $50 \times 50 \mu\text{m}$  ended 3 mm before the exit, thus adding a postcolumn dead volume of only 7.5 nL.

The performance of the device was demonstrated with the separation of a tryptic digest of bovine serum albumin (BSA) in the reversed-phase mode using a gradient of acetonitrile in aqueous solution of trifluoroacetic acid as the mobile phase.<sup>80</sup> The separated peptides were detected by mass spectrometer. Figure 47.6 shows both the device and separation of a sample containing 5 pmol of peptides. Comparison with a database revealed an excellent amino acid sequence coverage of 70%.

Similar chip design was also used for the offline interface with matrix-assisted laser desorption/ionization time-of-flight mass spectrometry (MALDI-TOF-MS).<sup>81</sup> In contrast to inline ESI, MALDI provides for time flexibility. Separated compounds are collected on the plate and archived, thus enabling reanalyzing the sample later if so desired. Also, MS or MS/MS performance can be optimized independently in this implementation. An important part of the system is the noncontact electric field-driven deposition system mounted on an x,y,z stage, enabling computer-controlled deposition of sample spots across the plate.

The chip similar to that shown in Figure 47.6 included two parallel circular channels with a diameter of 100  $\mu\text{m}$ , of which both ends were provided with connecting capillaries, leaving 6-cm long

space for the monolithic column. The wall modification and preparation of the poly(ethylhexyl methacrylate-co-ethylene dimethacrylate) monolith was identical with that shown earlier.<sup>80</sup> The ultimate test of the performance of the system included separation of a digest of three proteins—BSA, myoglobin, and cytochrome c. The sequence coverage obtained using the microchip with two monolithic columns run in parallel is shown in Table 47.1 and compared with MALDI-MS analysis data obtained for nonfractionated sample. Clearly, the separation on chip containing monolith affords significantly better results.

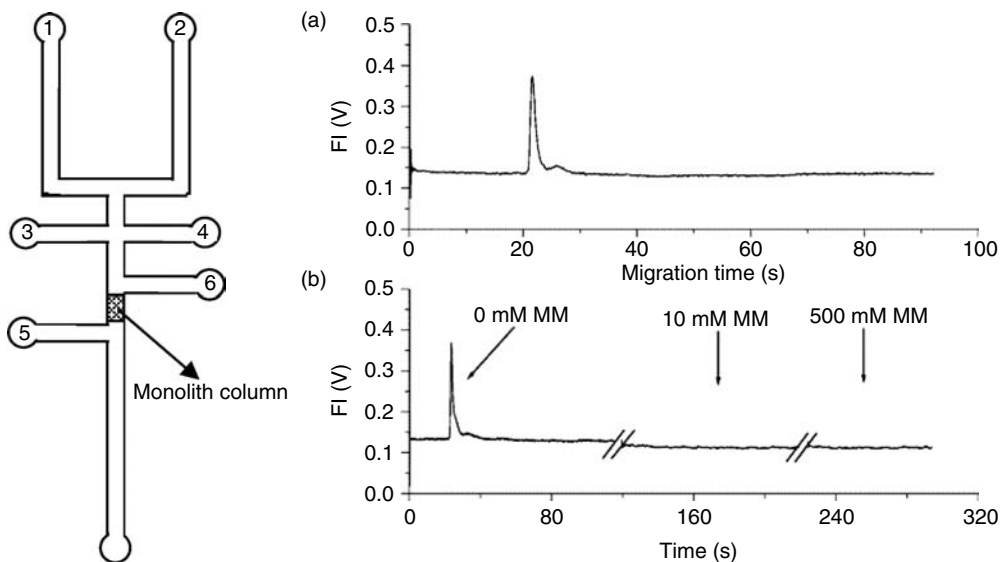

### 47.2.2 AFFINITY CHROMATOGRAPHY

This chromatographic mode represents a simple on-off technique. The compound of interest is fished-out from a more complex mixture via a very selective interaction with a ligand immobilized on solid support. Once the entire sample is processed through the column and followed by washing, the captured compound is released using a strong eluent.<sup>82</sup> Thanks to the simple binary separation mechanism, plate counts are not important and the development of devices mostly focuses on binding capacity and selectivity.

Li and Lee<sup>83</sup> used a very simple microfluidic glass chip containing two crossing channels. The length of the main separation channel was 2 cm. Using a mask-enabling irradiation of only a part of the channel, they prepared 2- and 10-mm long poly(glycidyl methacrylate-cotrimethylolpropane trimethacrylate) monoliths using photopolymerization procedure developed earlier.<sup>64</sup> They then reacted epoxy groups of the monolith with an excess of ethylenediamine in methanol by pumping this solution through the channel at a flow rate of 1.0  $\mu\text{L}/\text{min}$  for 10 min, followed by stopping the flow and letting the reaction continue for another 6 h at a temperature of 70°C. The last step was a reaction with a reactive dye, Cibacron-blue-3G-A, to afford specific ligands. The dye was attached to the solid support, after its solution in aqueous methanol was pumped through the monolith to fill completely the pores and left to react at 60°C for 3 h.

The function of the device containing 2-mm long monolith was first tested on capture of fluorescein isothiocyanate (FITC)-labeled lysozyme from its mixture with cytochrome c. The capture was monitored via an increase in fluorescence of the monolith. The ability of the monolith to selectively capture lysozyme from the mixture was validated by MALDI-TOF mass spectrometry. Since the Cibacron-blue-3G-A ligand has a strong affinity for albumins, the ultimate function was successfully demonstrated with capture of albumin from human cerebrospinal fluid.<sup>83</sup>

Lectins represent a group of affinitants that are very specific for interactions with sugars and were also used for the bioaffinity separations of glycoproteins in microfluidic chip.<sup>84</sup> First, 0.5-mm long monolith was prepared by UV-initiated photopolymerization in a vinylized glass chip using a mixture consisting of glycidyl methacrylate, ethylene dimethacrylate, cyclohexanol, dodecanol, and 2,2-dimethoxy-2-phenylacetophenone (photoinitiator). The movement of sample and other fluids

**FIGURE 47.7** Layout of the microfluidic chip including running buffer reservoir (1), eluent buffer reservoir (2), sample reservoir (3), sample waste reservoir (4), washing reservoirs (5,6) and waste reservoir (7) and electropherograms of human serum albumin detected above (a) and below the affinity monolith column with immobilized *Pisum sativum* agglutinin (b). (Reprinted with permission from Mao, X., et al., *Anal. Chem.*, 76, 6941, 2004. Copyright 2004 American Chemical Society.)

between the seven reservoirs located at the ends of seven channels comprising the chip shown in Figure 47.7 was achieved by voltage. The pores of the monolith were filled with a solution of lectin *Pisum sativum* agglutinin that was allowed to react for 16 h at 30°C. A solution of fluorescently labeled glycoproteins, turkey ovalbumin, chicken ovalbumin, and ovomucoid was then driven through the monolith. Only the proteins with terminal mannosyl residues or *N*-acetylchitobiose fucose structures were adsorbed while other glycoforms were washed off by the running buffer. The captured proteins were then released from the matrix in fractions according to their different affinity toward the immobilized lectin using a mobile phase with an increasing concentration of displacing sugar, methyl- $\alpha$ -D-mannopyranoside, and detected via LIF. For example, glycoproteins from egg white with different glycan structures were separated into fractions according to the strength of their affinity toward immobilized lectin (Figure 47.7). This study demonstrated that the microfluidic chip-based lectin affinity chromatography of glycoforms significantly reduces the analysis time. The whole analytical process could be completed in less than 6 min, whereas it needs at least 4 h using the traditional affinity chromatography.

So far, only a very limited number of reports on affinity chromatography on chip are available. Interestingly, all monoliths in these publications were prepared from the same pair of monomers, glycidyl methacrylate and ethylene dimethacrylate. The epoxide functionality of the former is being used for the attachment of ligands in affinity chromatography since the 1970s.<sup>85</sup> Although quite reliable, the direct reaction of nucleophilic groups of proteins with epoxides is slow and very long reaction times are required. This feature may not be desirable for immobilization of sensitive ligands. Alternative multistep immobilization approaches that include reaction with a diamine or hydrolysis of epoxide to diol, its oxidation to aldehyde using periodate, followed by fast immobilization of the ligand and stabilization of the imine via hydrogenation using a hydride are rather tedious.<sup>86</sup> Therefore, we introduced azlactone chemistry, originally advocated by 3M company,<sup>87</sup> in the field of monoliths.<sup>88</sup> This functionality reacts with proteins in a single step and significantly faster as demonstrated on the fabrication of enzymatic microreactor on chip for peptide mapping.<sup>89</sup>

### 47.2.3 SEPARATIONS IN ELECTROCHROMATOGRAPHIC MODE

#### 47.2.3.1 Concept of Electrochromatography

In contrast to mechanical pumping typical of HPLC discussed earlier, which relies on pumps with moving parts, electroosmotic flow (EOF) is generated within a stationary system by applying an electrostatic potential across the entire length of a device. The potential advantages of the flat flow profile generated by EOF in chromatography were recognized by Pretorius as early as in 1974.<sup>90</sup> Although the first electrochromatographic separations in packed capillary columns (CEC) were demonstrated at the beginning of 1980s,<sup>91</sup> serious technical difficulties resulted in limited interest, until a revival of interest in capillary electrochromatography (CEC) occurred in the mid 1990s arising from the search for new miniaturized separation methods with vastly enhanced efficiencies and peak capacities.

Although not completely correct, CEC is often presented as a hybrid method that combines the capillary column format and EOF typical of high-performance capillary electrophoresis (HPCE) with the use of a solid stationary phase and a separation mechanism based on specific interactions of solutes with a stationary phase characteristic of HPLC. Therefore, CEC is most commonly implemented by means typical of both HPLC (packed columns) and HPCE (electrophoretic instrumentation). To date, both columns and instrumentation developed specifically for CEC remain scarce.

CEC packing plays a dual role: in addition to providing sites for the required interactions as in HPLC, they must also be involved in EOF. This realization of the basic difference between HPLC and CEC has stimulated the development of both specific particulate packings having properties tuned for the needs of CEC as well as alternative column technologies.

The successful use of packed capillary columns in CEC separations has already been demonstrated in numerous papers and monographs.<sup>92–94</sup> The preparation of these columns includes two key steps: the fabrication of retaining frits within a capillary and the packing of small diameter particles into narrow-bore tubes. Both these steps require considerable experimental skills and experience in order to obtain stable columns with reproducible properties. Although packing is currently a well-established technique for the production of CEC columns, reproducibility of this procedure remains problematic.

Technical difficulties associated with packed columns have spurred the development of various alternative approaches. For example, Regnier's group developed systems with features microfabricated within the channel that does not fit the traditional definitions of either open channel or packed bed columns.<sup>95–101</sup> The microfabricated channels contain so-called collocated monolith support structures (COMOSS), shown in Figure 47.8, which are essentially an array of tightly packed posts. The size and shape of the posts, as well as the dimensions of the channels between them, can be varied as desired. Although the support structures are called directly fabricated "particles," the resulting column is referred to as "a bundle of interconnecting capillaries with frequent mixing nodes." COMOSS have numerous advantages, including the uniformity and regularity of the support particles, the high level of control over the channel dimensions and geometry, and the ability to control the extent of mixing in the column.<sup>100</sup>

Yet another broadly explored option is columns containing monolithic *in situ* prepared separation media adopted from a concept developed for HPLC columns.<sup>25,92,102</sup> As a result of their unique properties, monolithic materials have attracted considerable attention. Perhaps the most appealing aspect of the monolithic materials is their ease of preparation. The simple polymerization process performed directly within the confines of a capillary avoids the problems related to both frit formation and packing. In addition, columns of virtually any length and shape are easily accessible. The polymerization mixture may also be prepared using a wide variety of monomers, allowing a nearly unlimited choice of both matrix and surface chemistries. This flexibility enables the easy tailoring of both the interactions that are required for specific separation modes and the level of EOF generated by the support. Finally, the control that can be exerted over the polymerization process enables the

**FIGURE 47.8** SEM micrographs of a section of a diamond COMOSS column (a) and its extended hexagonal modifications with the extension lengths of 4.6 (b), 9.3 (c), and 24  $\mu\text{m}$  (d). (Reprinted with permission from Slentz, B. E., et al., *J. Sep. Sci.*, 25, 1011, 2002. Copyright 2007 Elsevier B.V.).

facile optimization of the porous properties of the monolith that directly affect the flow rate and chromatographic efficiency of the system.

Electrochromatography includes features of both electrophoresis and liquid chromatography. Therefore, electrochromatographic separations are achieved as a result of differences in both electrophoretic mobility (for ionized analytes) and specific interactions of solutes with the stationary phase. This combination of separation mechanisms enables efficient electrochromatographic separations of both ionizable and neutral compounds.

One of the major advantages of electrochromatography compared to HPLC is the ease with which it can be miniaturized to a microfluidic format and makes it most frequently used mode of separation in chips. The separation in electrochromatographic mode is achieved by simply applying an electric field across the channel. Since the fluid flow is driven by EOF, the separation device does not need to include mechanical pumps or valves.<sup>103</sup> In addition, the flat flow profile generated by EOF minimizes dispersion of analyte bands during their passage through the stationary phase and allows very high plate counts to be achieved. Since EOF is largely independent of channel or particle size, monolithic stationary phases with small pores can be used, thus facilitating solute mass transfer without generating the large pressure drops associated with classical pressure-driven HPLC. As a result, electrochromatography on chip is an attractive choice for “lab-on-a-chip” separations due to its excellent separation performance and relatively easy implementation. The topic of chip electrochromatography was summarized partly or completely in several very good review articles.<sup>104–113</sup> Our own recent review<sup>114</sup> also became the major source for writing this section.

### 47.2.3.2 Acrylamide-Based Monoliths

Despite a significant number of studies concerning capillary electrochromatography using monoliths in capillaries, the first monolithic material prepared in channel of a very simple chip was demonstrated by Hjertén's group only in 2000.<sup>115</sup> This first polymer-based monolithic stationary phase was prepared in 30.6-cm long and approximately 40- $\mu\text{m}$  wide and 20- $\mu\text{m}$  deep semicircular serpentine microchannels etched into quartz substrates and sealed with a "roof" formed by 4- $\mu\text{m}$  thick layer of silicon dioxide shown in Figure 47.9. Monolithic stationary phase for reversed-phase electrochromatography was obtained by polymerization of methacrylamide, isopropyl acrylamide, piperazine diacrylamide (crosslinker), and vinylsulfonic acid mixtures in an aqueous buffer solution using the common redox initiating system ammonium peroxosulfate/tetramethylethylenediamine (TEMED). In addition, similar polymerization mixtures were used to create polymer monoliths in straight channel shown in Figure 47.9 for pressure-driven anion-exchange liquid chromatography with the exception that isopropyl acrylamide and vinylsulfonic acid were used instead of diallyldimethylammonium chloride. Since polymerization commences once the initiator is added, channels have to be filled immediately after the mixture is prepared. Before formation of the polymer monolith, the channels were treated with [3-(methacryloyloxy)propyl] trimethoxysilane to provide them with pendant methacryloyl groups that are incorporated during polymerization into the growing polymer monolith, thus covalently attaching it to the channel walls.

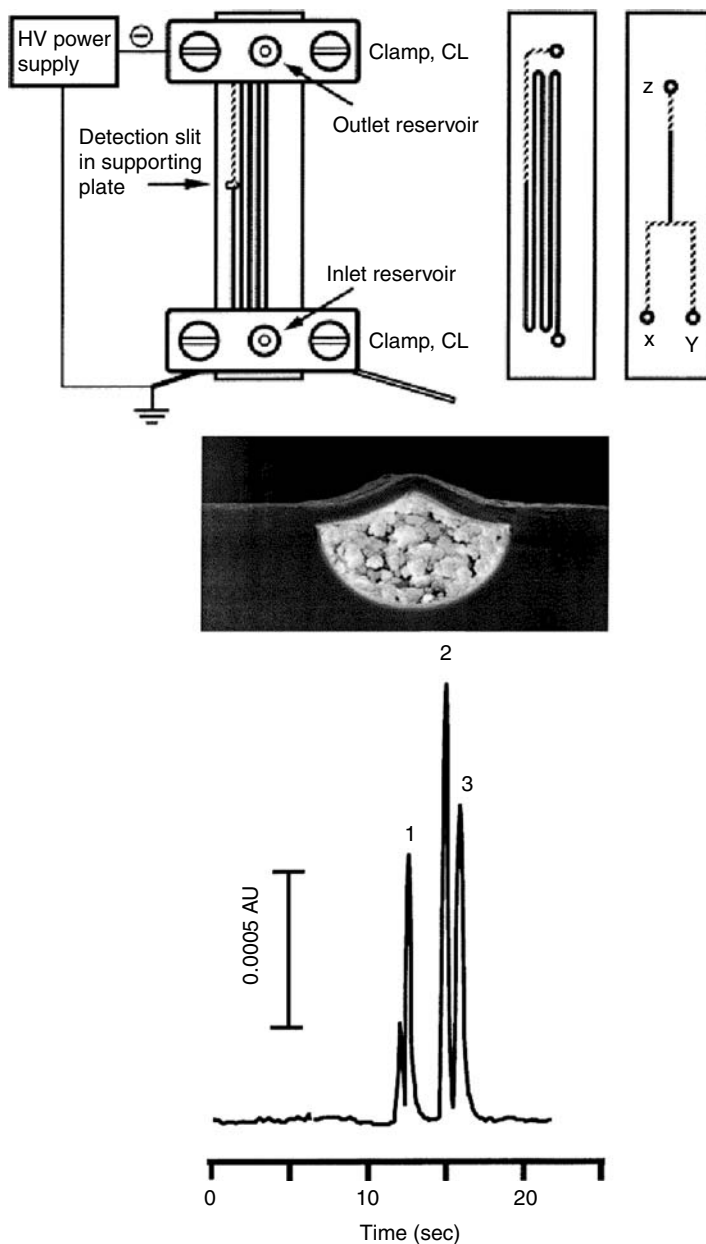

The location of the polymer bed could be controlled to a limited extent by using fluid plugs containing PEG, TEMED, and ammonium peroxodisulfate, but no monomers. These fluid plugs displaced the polymerization mixture to keep certain sections of the microchannel clear of monolith. The plugs also helped to create sharp ends to the monolith. The completed chips were attached to a special clamp apparatus for fluid interfacing and operated using a highly modified CE instrument capable of UV-detection.

The performance of the acrylamide-based monolithic stationary phase in the chip was compared to that in a fused-silica capillary containing monolith prepared from the same mixture. Not surprisingly, van Deemter plots were virtually identical for both devices since the channel etched in quartz, which did not have on-chip injection arms, closely resembled the capillary. Neutral alkyl phenones and positively charged antidepressants were separated in the serpentine channel in 18 and 9 min, respectively. A faster separation was demonstrated with a rapid separation of uracil, phenol, and benzyl alcohol in a Y-shaped channel (Figure 47.9) containing only a 1.8-cm long monolith. The separation was completed in less than 20 s, with all three peaks eluting within a 7 s window. A column efficiency calculated for unretained peak of uracil was 6300 plates, which represents 350,000 plates/m.

Overall, this implementation using the expensive and difficult-to-fabricate quartz microchips does not represent a significant advantage compared to typical CEC in much cheaper fused-silica capillaries placed in standard instruments. Also, carrying out experiments required laborious manual changing of contents of the inlet reservoir to achieve the sample injection.

Later, the same group developed what they call a hybrid microdevice as an alternative to quartz microchips.<sup>116</sup> This device consisted of a short, fused-silica capillary column containing a 2.8-cm long polymer gel prepared from acrylamide, 2-acrylamido-2-methyl-1-propanesulfonic acid (AMPS), and allyl- $\beta$ -cyclodextrin as crosslinker. This capillary was set in a groove on a polyvinyl chloride support plate that included sample reservoirs, electrodes, and a slit for "on-tube" UV-detection. In addition, a ball lens was mounted beneath the detection slit to focus the UV beam. Gel electrophoresis and electrochromatography were then performed in this system. For example, several alkyl phenones were separated in the electrochromatographic mode in less than 200 s. The suggested separation mechanism was related to interactions between the hydrophobic cavity of the  $\beta$ -cyclodextrin and the analytes. However, no direct evidence for this mechanism was presented.

Claimed advantages of this hybrid device compared to traditional microchips include lower cost in terms of materials and preparation, UV-detection with no need for fluorescent labels, the ability to

**FIGURE 47.9** Chip layout, cross-section of the monolith, and fast anion-exchange chromatography of uracil (1), phenol (2), and benzyl alcohol (3) using the Y-shaped chip format. (Reprinted with permission from Ericson, C., et al., *Anal. Chem.*, 72, 81, 2000. Copyright 2000 Elsevier B.V.) Conditions: straight monolithic column 18-mm long, mobile phase 5 mmol/L sodium phosphate buffer (pH 7.4) containing 15% acetonitrile, applied voltage, 2.4 kV (500 V/cm), EOF 2.1 mm/s, UV detection at 254 nm, electrokinetic injection 100 V for 2 s.

change the separation column by simply switching the capillary, and the ability to directly utilize the existing body of experience available for capillary separations. However, this approach is limited to very simple geometries and is less suitable for the more complex layouts typical of micro total analysis system ( $\mu$ TAS).

Szekely and Freitag<sup>117</sup> fabricated separation chips from glass with the channels sawed with a 70- $\mu\text{m}$  resinoid blade. While this approach only enables the fabrication of straight channels, it is much faster and less complex than methods based on photolithography and etching, and does not require work in the clean room. A multifunctional connection and support unit containing optical probes, reservoirs, as well as high-pressure and high-voltage connectors, constituted the interface to the macro world. To demonstrate their possible application in voltage-driven electrochromatography, a monolithic stationary phase was prepared using a mixture of piperazine diacrylamide, *N,N*-dimethylacrylamide, sodium vinyl sulfonate, and ammonium sulfate dissolved in phosphate buffer. The polymerization reaction was initiated by the addition of TEMED and ammonium persulfate dissolved in water. A charge-coupled device (CCD) camera serving as a fluorescence detector and a plug of fluorescein moving through the 52-mm long, 70- $\mu\text{m}$  deep, and 80  $\mu\text{m}$  wide semicircular channel driven by voltage demonstrated functionality of the chip.

Latter, they added another module to their system that allowed setting and maintaining the flow rate in microfluidic systems using EOF to drive the mobile phase.<sup>118</sup> The sensing principle is claimed to be compatible with any type of microanalytical device in which the mobile phase resides in a reservoir. The relatively simple unit consists of a light-emitting diode, fiber optics, and a photomultiplier. This sensor optically records the speed of sinking of the liquid level in the reservoirs. Readings are taken with a frequency of 1000 Hz allowing measurements of the liquid level in intervals less than 0.4 s. On the basis of these measurements, they could maintain a flow rate at a preset value via automatic adjustments in the field strength applied across the channel. The concept was again demonstrated on stabilized flow through an acrylamide-based monolith in the channel. Since the reservoir appears to be open, evaporation of the liquid can also occur. The observed flow rate would then be higher than the actual value.

Using this system, the same group also studied effects of electrochemical processes on the electrodes located in reservoirs of chips containing acrylamide-based monolith.<sup>119</sup> For example, the pH in the cathodic reservoir containing 50 mmol/L potassium chloride changed after 4 min at 4000 V from 7.58 to 8.49. Use of phosphate buffer pH 9.2 helped to stabilize the pH and the increase was only 0.21 pH units after 1 min. Surprisingly, these changes did not affect EOF generated by the ionizable functionalities of the monolith.

Zeng et al.<sup>120</sup> fabricated PDMS chips including two crossed channels using typical soft lithographic replication process. They advocated extended irradiation of the chip leading to formation of hydroxyl functionalities at the channel surface. Following modification with [3-(methacryloyloxy)propyl] trimethoxysilane, they drew in the separation channel a solution of acrylamide, methylenebisacrylamide, AMPS, allyl substituted  $\gamma$ -cyclodextrine ( $\gamma$ -CD), TEMED, and ammonium persulfate in borate buffer. The  $\gamma$ -CD moieties then enabled enantioseparation of labeled derivatives of amino acids. Although some separation in electrochromatographic mode could be observed, the chromatographic evaluation of results was very poor to make it worth of significant attention.

### 47.2.3.3 Acrylate- and Methacrylate-Based Monoliths

The early monolithic columns were prepared by thermally initiated polymerization. Although useful for larger scale columns, this technique is not ideally suited for the fabrication of monoliths within microfluidic devices. Therefore, in the late 1990s, we introduced polymerization initiated by irradiation with UV light, which is better suited for the preparation of monoliths in capillaries and microchips.<sup>64,121</sup> Later, we refined this approach to enable both preparation of the monolith and its *in situ* surface functionalization.<sup>77–79,122–126</sup> The significant advantage of photoinitiation is the ability to photolithographically define the size and position of the monolith using a mask through which the liquid polymerization mixture in the channel is irradiated. This process was demonstrated with the preparation of a variety of methacrylate-based monolithic porous polymer stationary phases. The typical polymerization mixtures contained monomers, initiator, and porogenic solvents.

**FIGURE 47.10** Chip filled with monolith connected to switch box and power. (Reprinted with permission from Fintschenko, Y., et al., *Fresenius' J. Anal. Chem.*, 371, 174, 2001. Copyright 2001 Springer Verlag.) (1) T injector, (2) offset T-injector. Chip dimensions:  $8.5 \times 2.0$  cm, channel cross section  $50 \mu\text{m}$  wide,  $25 \mu\text{m}$  deep, separation channel  $7.5$  cm, total length of monolith to separation window  $7$  cm. Reservoirs: B running buffer, W waste, S sample, SW sample waste. Injection and run voltages  $2$  kV.

For example, the early monomer mixtures contained crosslinker such as ethylene dimethacrylate and trimethylolpropane trimethacrylate, monovinyl monomers such as butyl methacrylate, and AMPS. The initiator was originally 2,2'-azobisisobutyronitrile. However, the use of aromatic phenone initiators later enabled significant acceleration of the polymerization process such that it was completed in several minutes as opposed to more than 12 h. A large number of various porogenic solvents was also tested.<sup>127</sup>

Microfluidic electrochromatography with polymer-based monolithic stationary phases prepared *in situ* by photoinitiation was again studied extensively in Sandia National Laboratories. Although the early studies primarily focused on the development of acrylate-based polymer monoliths in capillaries, initial test separations were also carried out in glass-/fused-silica microchips with a simple double-T cross layout (Figure 47.10).<sup>128–130</sup> Both positively and negatively charged monoliths were prepared. Positively charged monoliths were found to be useful for separations at low pH since they afforded high EOF and, at the same time, prevented undesired Coulombic interactions with positively charged compounds, such as amines. A typical polymerization mixture comprised crosslinker 1,3-butanediol diacrylate, butyl acrylate or combinations of butyl acrylate with lauryl acrylate, ionizable monomer (AMPS for negatively charged monolith or [2-(acryloyloxy)-ethyl] trimethylammonium methyl sulfate for positively charged monoliths), AIBN (photoinitiator), and adhesion promoter (z-6030, Dow Chemicals). The porogenic solvent contained ethanol, acetonitrile, and a phosphate buffer. The surface of channels in glass microchips was silanized using treatment with [3-(methacryloyloxy)propyl] trimethoxysilane.<sup>131</sup> The  $50\text{-}\mu\text{m}$  wide and  $25\text{-}\mu\text{m}$  deep microchannels were filled with the liquid polymerization mixture using capillary action and monoliths were prepared by exposure to UV light for 10–30 min. The ionized functionalities on the monolith and aqueous buffer present in the porogenic solvent enabled the use of EOF, rather than pressure-driven flow, to purge the unreacted components from the porous material after polymerization. Figure 47.11 demonstrates the separation of three bioactive peptides, fluorescently labeled with naphthalene-2,3-dicarboxaldehyde (NDA) using a 7-cm long monolithic stationary phase, affording efficiencies of 105–5800 plates

**FIGURE 47.11** Electrochromatographic separation of NDA-labeled papain inhibitor GGYR (1),  $\alpha$ -casein (fragment 90–95) RYLGYL (2), and Ile-angiotensin III, RVYIHPI (3) using negatively charged lauryl methacrylate-based monolithic stationary phase in a glass chip. (Reprinted with permission from Shediac, R., et al., *J. Chromatogr. A*, 925, 251, 2001. Copyright 2001 Elsevier B.V.) Conditions: mobile phase 35:65 acetonitrile–12.5 mmol/L phosphate buffer (pH 7.0), LIF detection at 413 nm, field strength 1.2 kV/cm, channel dimensions: 25- $\mu$ m deep, 50- $\mu$ m wide, separation channel length 8.0 cm; injection arms 1.0 cm each; length to detector 7.0 cm.

(1500–83,000 plates/m). The performance was limited by undesirable electrostatic interactions of the peptides with the stationary phase.<sup>129</sup>

The alkyl acrylate-based monoliths were also used for the separation of polycyclic aromatic hydrocarbons (PAHs). Good performance was demonstrated on the separation of three neutral PAHs with efficiencies of 8400–13,900 plates (140,000–231,000 plates/m).<sup>128</sup> In a different study, the number of PAH analytes was increased to 13.<sup>130</sup> In this work, the monolith-free window required for detection was created by decomposition of the monolith using the energy of a frequency-doubled argon ion laser, which was part of the LIF detector. The authors claim that irradiation for 10–20 min while electroosmotically pumping buffer solution through the device was sufficient to completely remove the monolith from the desired area. Chips containing polymer monolith in two different configurations were prepared and evaluated. In the first device, all the channels were completely filled with porous polymer monolith. The second then had the monolith located only in a specific area of the chip using polymerization initiated through a mask. This photopatterned monolith filled all but the injection arms of the device. Interestingly, its performance was poorer than that of the former, featuring efficiencies of 100,000–150,000 plates/m as opposed to 180,000–200,000 plates/m for the chip completely filled with monolith. Heterogeneous regions in the patterned polymer, specifically at the ends of the monolith, and/or zeta potential mismatch between the sections of the chip with and without monolith were blamed for the poorer performance. The latter could have introduced parabolic flow, which would have led to band broadening and decreased efficiency. In addition to comparing their separation performance, the operational limitations and the reproducibility of the two types of monolith devices were also investigated. For example, low resistance to flow in the device with open injection arms allowed running buffer to flow into the fluid reservoirs and dilute the sample during pinched separation runs. Similar problem was observed by Jacobson et al.<sup>132</sup> On the other hand,

**FIGURE 47.12** Reversed-phase electrochromatography of NDA-labeled peptides papain inhibitor (1), proctolin (2), opioid peptide ( $\alpha$ -casein fragment 90–95) (3), Ile-angiotensin III (4), angiotensin III (5), and GGG (6) in a microchip containing negatively charged lauryl acrylate monolith. (Reprinted with permission from Throckmorton, D. J., et al., *Anal. Chem.*, 74, 784, 2002. Copyright 2002 American Chemical Society.) Conditions: mobile phase 30:70, acetonitrile–25 mmol/L borate buffer (pH 8.2) containing 10 mmol/L octane sulfonate, LIF detection at 413 nm, field strength 770 V/cm (5 kV).

injection times as long as 5 min or more were required to ensure uniform sample injections in the devices with monolith-filled sample arms. This study also highlighted the importance of carefully sealing fluid reservoirs during chip operation. Using unsealed reservoirs, 95% reductions in signal peak heights were observed over the course of just five separations due to dissolved oxygen that quenched the fluorescence of the PAHs. In addition, variations in retention times were rather high, with deviations up to 20%. Thus, further work was needed to improve the overall performance of these chips.

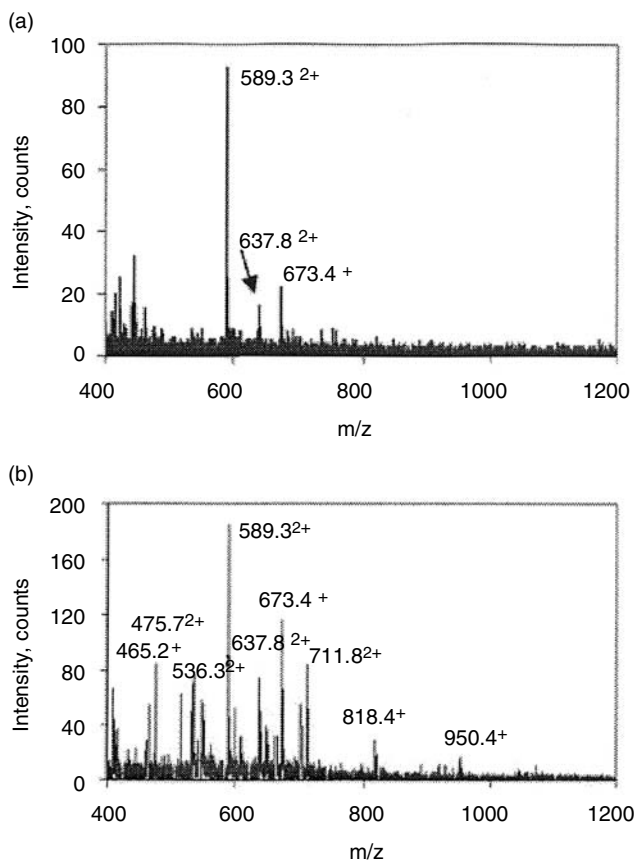

Microchips filled with acrylate-based polymer monolith were later used to separate bioactive peptides and amino acids.<sup>133</sup> Citing decreased performance due to zeta potential mismatch between open and monolith-filled channels, all the channels of the microchip were filled with monolith except for a small detection window. NDA-labeled peptides were separated with excellent efficiencies in fused-silica chips with channels either 25- $\mu$ m deep and 90- $\mu$ m wide or 40- $\mu$ m deep and 130- $\mu$ m wide. The mobile phase contained octane sulfonate, apparently acting as an ion-pairing agent for the charged peptides.<sup>134</sup> The effect of voltage on the peptide separation was evaluated in a range of 1–5 kV. The best performance occurred at 2 kV ( $\sim$ 300 V/cm), affording efficiencies of 6350–30,000 plates/chip (127,000–600,000 plates/m). However, nearly baseline resolution was achieved even at the highest field strengths (770 V/cm) and the separation was completed in impressive 45 s (Figure 47.12). In contrast to the previous report,<sup>130</sup> these new devices featured an improved reproducibility with relative standard deviation (RSD) values for the retention times of approximately 2%. Since glass-based microchips are costly, this report also describes a procedure for their recycling via thermal incineration of the monolith. However, our results with recycled glass chips did not match those obtained with the new chips.

Lazar et al.<sup>134</sup> have recently demonstrated the first example of interfacing chip electrochromatography with mass spectrometric detection. The glass microchip contained a methacrylate-based monolith as well as an integrated capillary tip for ESI. The straight 130- $\mu$ m wide and 50- $\mu$ m deep main channel of the chip contained a 5 to 6-cm long separation section that led directly to the ESI

**FIGURE 47.13** Schematic diagram of CEC system integrated on microchip: separation channel containing poly(glycidyl methacrylate-co-methyl methacrylate-co-ethylene dimethacrylate) monolith (1), double-T injector (2), ESI source (3), eluent reservoir (4), sample inlet reservoir (5), sample waste reservoir (6), eluent waste reservoir that houses the porous glass gate (7), side channel for flushing the monolith (8), and ESI emitter (9). M., et al., *Electrophoresis*, 24, 3655, 2003. Copyright 2003 Elsevier B.V.)

emitter as shown in Figure 47.13. A 5-mm long trench was etched into the cover plate before the chip was bonded to allow insertion of the emitter tip into the end of the separation channel. Further, the chip design included an additional fluid reservoir near the end of the separation channel. This reservoir contained a conductive, semipermeable glass disk, which allowed voltage to be applied to the fluid in the channel but prevented bulk fluid movement. With this design, electroosmotically driven fluid in the main channel was forced out through the ESI capillary tip. Similar to the Sandia approach,<sup>130,133</sup> all of the microchannels were completely filled with monolith to ensure uniform EOF throughout the chip. The monolithic stationary phase was prepared by photoinitiated polymerization of mixtures consisting of glycidyl methacrylate, methyl methacrylate, and ethylene dimethacrylate in the presence of formamide and 1-propanol as porogenic solvents and 2,2-dimethoxy-2-phenyl-acetophenone as the initiator. Subsequently, the monolith was incubated with *N*-ethylbutylamine overnight at 70°C. The amine reacted with the epoxy groups of glycidyl methacrylate on the monolith, forming tertiary amine functionalities and rendering the surface positively charged. This chemistry was chosen in order to minimize electrostatic interactions between the monolith and the positively charged peptides

**FIGURE 47.14** Time-of-flight mass spectra of peptides prepared via tryptic digestion of bovine hemoglobin. (Reprinted with permission from Lazar, I. M., et al., *Electrophoresis*, 24, 3655, 2003. Copyright 2003 Elsevier B.V.) (a) Peptides separated in the CEC system with monolithic column shown in Figure 47.13, (b) unseparated peptides detected in an infusion experiment.

of bovine hemoglobin tryptic digest. Although it would also be possible to separate mixtures of peptides on negatively charged monoliths such as those prepared by copolymerization of AMPS, this approach would require the addition of an ion-pairing agent in the mobile phase. This approach would be counterproductive since most ion-pairing agents are incompatible with ESI mass spectrometry.

The positively charged surface of the monolith drives the electroosmotic flow to run from cathode to anode. This EOF was opposite to the direction of electrophoretic migration of the analyzed peptides and increased the time they spent in the relatively short column. Separations of the peptide mixture using mass spectrometric detection afforded a sequence coverage of 70–80% and efficiencies of 3000–4000 plates. While the tryptic digest was not completely separated on the monolithic stationary phase, the mass spectra were greatly simplified compared to a spectrum of the original peptide mixture (Figure 47.14). In addition, multiplexed devices with 3–4 operating lines were also constructed.

Performing injections proved to be problematic for this system. While the positively charged monolith and “reversed” EOF improved separation performance, they also significantly enhanced electrophoretic discrimination during injection. In addition, despite the tuned chemistry, the analytes interacted with the amine functionalities and neutralized them, completely suppressing the EOF in the injection arms after multiple injections. This prevented long-term use of the device. Use of disposable, perhaps plastic, chips appears to be a simple solution to this problem.

#### 47.2.3.4 Silica-Based Monoliths

Monolithic silica is the most recently introduced class of stationary phases for electrochromatography on microchips. They benefit from their very high surface area, adjustable pore size, and controllable surface chemistry. Functionalities required for the separation in reversed-phase mode are typically incorporated onto the silica monolith by including an appropriate silicon alkoxide in the precursor mixture or by silanization of the surface after the monolith has been formed. Monolithic silica-based columns are generally known to exhibit superior performance in HPLC separations of small molecules, which is attributed to the presence of mesopores entailing large surface areas.<sup>135</sup>

Silica monoliths in capillaries are usually prepared via acid-catalyzed condensation of alkoxy-silanes followed by heat treatment.<sup>92</sup> Thus, the spatial definition of such a monolith is difficult.<sup>136–138</sup> This is why use of silica-based monoliths in chips is scarce. In one example, Zare and coworkers<sup>139,140</sup> at Stanford has developed a new method for the preparation of photopatternable sol-gel monoliths. They mixed a partially gelled solution of 3-methacryloxypropyl-trimethoxysilane (MPTMS) with a solution of photoinitiator in toluene and immediately filled the channels with this mixture via capillary action. Exposure to UV light through a photomask initiated a free-radical polymerization of the methacrylate vinyl groups of MPTMS. The resulting monolith is thus a hybrid of both silica and polymer monoliths. The electrochromatographic performance of a 4.7-cm long monolith prepared in this way in a glass chip with 35- $\mu\text{m}$  deep and 90- $\mu\text{m}$  wide channels was demonstrated with the separation of two neutral coumarin dyes shown in Figure 47.15. Although a baseline resolution was achieved, only modest efficiencies 280 and 940 plates (6000–20,000 plates/m) were found for the two peaks.

In another approach, Breadmore et al.<sup>141,142</sup> developed silica-based monolithic stationary phases suitable for microchip electrochromatography. They modified the procedure originally developed

**FIGURE 47.15** Electrochromatograms showing the separation of a mixture of Coumarin 314 (peak 1) and Coumarin 510 (peak 2). (Reprinted with permission from Morishima, K., et al., *J. Sep. Sci.*, 25, 1226, 2002. Copyright 2002 J. Wiley.) Conditions: sample concentration 0.6 mg/mL, mobile phase 1/3/6 (v/v/v) 50 mmol/L ammonium acetate (pH 6.5) (10%), water (30%), acetonitrile (60%), voltage 2.0 kV for (a) and 2.5 kV for (b), LIF detection at 420 nm, peaks detected on open channel adjacent to 4.7-cm long monolithic section (a), and on-column 1.2 cm from the top of the monolith (b).

by Tanaka and coworkers.<sup>143</sup> First, an unmodified silica monolith was formed by hydrolytic condensation of tetramethyl orthosilicate in the presence of PEG. This water-soluble polymer induced a phase separation during gelation, resulting in a monolith with well-controlled porous properties. Varying molecular weight of PEG significantly changed the resulting structure of the monolith and its chromatographic performance. The resulting monoliths were then functionalized using two different procedures. First, cationic polymer poly(diallyldimethylammonium chloride) (PDDAC) was dynamically adsorbed from its solution pumped through the monolith to make it suitable for anion-exchange electrochromatography.<sup>141</sup> To maintain the coating during separations, PDDAC was also included in the mobile phase. In the second approach, the silica monolith was coated with multiple, alternating layers of polymer electrolytes of opposite charges forming polyelectrolyte multilayer.<sup>142</sup> The cationic layers in the multilayer coating were made from PDDAC, while anionic layers consisted of either dextran sulfate or poly(styrene sulfate). This system afforded very stable and reproducible EOF. In addition, the multilayers could be used for multiple runs in ion-exchange and reversed-phase modes without the need for recoating. The use of coatings has several advantages over both modification with functional silanes and the use of functional silica precursors. For example, the silica monolith must be completely dried before modification by silanization. This drying process can lead to shrinkage or even cracking of the monolith. Next, although addition of functional alkoxysilanes to the monolith reaction mixture creates a functional monolith in a single step, the sol-gel process is more complex, and any attempt to adjust the composition of the monolith mixture may require reoptimization of the sol-gel process. With coatings, the monolith can be functionalized without the need for drying and, further, the monolith formulation is decoupled from the coating formulation. However, application of this approach has yet to be demonstrated in microchips.

### 47.3 CONCLUDING REMARKS

The field of chromatographic separations on chip using channels containing a stationary phase is still in its infancy; although significant effort has already been dedicated to development and application of a variety of stationary phases. Obviously, implementations involving monolithic separation media are likely to continue to grow. Their major advantage is the formation from liquid precursors that are easy to fill the channel and simple to polymerize *in situ*. The focus must also shift toward improving their separation performance. Current chips do not by far match selectivities and efficiencies of their older relatives—capillary columns.

In addition to serving as the stationary phases, monolithic materials are also finding numerous other applications in the microfluidic world.<sup>144</sup> Their use in on-chip solid-phase extraction and preconcentration,<sup>28</sup> as supports for immobilization of enzymes to form enzymatic microreactors for protein mapping,<sup>27</sup> static mixers,<sup>145</sup> and valves<sup>146,147</sup> represent just a few examples of modules in the microfluidic toolbox and further growth is inevitable.

However, to make the microfluidic devices affordable, it is imperative to switch from expensive chips made from glass or quartz to inexpensive, mass-produced plastic devices. Although a certain success with plastic devices has been demonstrated, it is clear that further development is needed.

Obviously, much remains to be done on the road leading to the creation of more complex analytical devices called lab-on-a-chip or total microanalytical systems ( $\mu$ -TAS) and the monoliths are expected to help to achieve this goal.

## 48.1 INTRODUCTION

Microdialysis is a generic sampling technique that can be used for the continuous monitoring of small molecules present in aqueous samples. It has found application in a number of areas such as *in vivo* monitoring, process analytical chemistry and environmental sampling. In microdialysis, sampling is accomplished through the diffusion of analyte molecules across a semipermeable membrane that is built into the probe. Sampling is achieved by pumping a solution through the probe that is similar in composition to that of the matrix being sampled. A concentration gradient of the analyte is generated between the perfusate and the surrounding medium, causing analytes to diffuse into the probe. They are then delivered by the syringe pump to a fraction collector or an appropriate analysis system. It is also possible to deliver compounds into the aqueous environment outside the probe by adding the compound of interest to the perfusate.

A generalized schematic illustrating a typical sampling and analysis setup is shown in Figure 48.1. Most commonly, dialysate samples are collected and analyzed offline using techniques such as liquid chromatography (LC) coupled to optical detection modes (UV, fluorescence), electrochemical detection or mass spectrometry (MS). Alternatively, online analysis can be performed by directly coupling the microdialysis probe to flow-through sensors or separation-based analytical systems. The most commonly used separation techniques for the analysis of such microdialysis samples are LC

**FIGURE 48.1** Typical microdialysis sampling and analysis setup.

and capillary electrophoresis (CE). These have been combined with electrochemical or fluorescence detection for near real-time monitoring applications.

More recently, microchip-based analytical systems have proven to be an attractive alternative for the analysis of small volume-limited samples. Microchip systems also enable faster separations, can be made portable, and are less expensive than conventional instrumentation. The integration of microdialysis sampling with microchip analysis systems has the potential for achieving very fast analysis times, thereby maximizing temporal resolution. This chapter will discuss the theoretical aspects of microdialysis sampling and considerations for the coupling of the sampling technique to microchip systems and will conclude with future directions of this technology.

## 48.2 BACKGROUND

Microdialysate samples have been analyzed using a variety of nonseparation-based analytical techniques including immunoassay, biosensors, and MS [1–4]. The main limitation to the use of these methods is that they are typically restricted to the measurement of a single analyte. For more complex samples, the detection of multiple substances is usually necessary. In this case, the dialysate sample is normally analyzed by conventional chromatographic or electrophoretic separation methods employing optical, electrochemical, or mass spectrometric modes of detection [5].

When developing an assay based on microdialysis sampling, several parameters must be taken into consideration. These include the concentration range of the analyte to be sampled, the temporal resolution desired, and the volume of sample that is available. Low flow rates generally yield a higher recovery of analyte but also generate much smaller samples per unit time. Electrophoresis-based methods require nanoliter (nL) to picoliter (pL) volumes of sample, which can lead to good temporal resolution but also exhibit reduced sensitivity for mass sensitive detectors. Larger volumes can be introduced with chromatographic separation methods but frequently at the expense of temporal resolution.

The direct coupling of microdialysis to separation systems yields a system that is capable of continuous monitoring of the analyte(s) of interest. Microdialysis sampling has been coupled online to conventional separation systems such as LC and CE [6–8]. As samples are protein-free, they can be delivered and injected directly into the analytical system. A major advantage of online analysis is that it obviates the need for the manipulation of small volume samples ( $<1 \mu\text{L}$ ) and thus reduces the chance for sample loss and contamination as well as improving temporal resolution. The interface that physically couples the microdialysis system to the separation system, however, can be challenging to implement. The tubing and connectors associated with such an interface can lead to an increase in dead volume in the system that may lead to a delayed response in online monitoring experiments as well as causing band broadening.

An important consideration for online coupling of microdialysis sampling and conventional LC separation is the time required for analysis and the relatively high sample volume requirements

(5–10  $\mu\text{L}$ ) that can limit temporal resolution. CE offers the advantage of small sample volumes requirements (nL), highly efficient separations, and fast analysis times. However, in the case of electrophoretic separation systems, it is necessary to isolate the microdialysis probe and sample body (e.g., an animal in animal sampling experiments) from the high field strengths used for separation. In addition, when electrochemical detection is used, care must be taken to isolate the potentiostat from the separation voltage to prevent grounding through the detector or animal.

The first reported online coupling of microdialysis with conventional CE-laser-induced fluorescence (LIF) was reported by Hogan et al. [8], in 1994. The system achieved separation of an antineoplastic agent and its major metabolite in less than 60 s. The overall temporal resolution was 90 s. This system utilized a 60 nL injection valve and a capillary-based interface for delivering the sample to the CE system. The interface between the microdialysis and electrophoresis systems could also be used to introduce derivatizing reagents for chemical labeling of biological analytes; these reagents are often needed for fluorescence and electrochemical detection [9]. Using a capillary-based system with very short capillaries, Kennedy's group has been able to perform extremely fast separations (12 s) of amino acid neurotransmitters [10]. It is anticipated that the advent of microchip technology will facilitate separations on the subsecond scale.

While the vast majority of microdialysis sampling to date has been achieved in conjunction with conventional systems, microdialysis has also been coupled online with biosensors and, more recently, to microchip-based separation devices. These devices can be fabricated using low cost materials and are amenable to mass production [11]. The smaller dimensions of microchip systems minimize sample and reagent volume requirements and allow placement of the analysis system closer to the aqueous sample or animal being sampled. Due to the planar nature of microchip devices, additional sample handling procedures such as preconcentration, mixing, extraction, or derivatization can also be carried out on the same platform [12–15]. Considerations for coupling microdialysis to microchip instrumentation systems will be discussed in Section 48.5.

### 48.3 THEORETICAL ASPECTS

Microdialysis sampling involves the recovery of low molecular weight analytes following their diffusion across a semipermeable membrane [16]. The membrane is housed in hollow tubing connected to an inlet and outlet. A solution similar in ionic strength to that of the sample matrix is perfused through the tubing, and the analytes recovered represent some fraction of the original analyte concentrations in the area sampled (Figure 48.2).

Analyte recovery is dependent on characteristics of the probe (length, pore size, chemical composition) and physicochemical properties of the sampled analyte(s) (coefficient of diffusion, hydrophobicity) as well as the rate of perfusion across the probe. The length of the probe is primarily correlated to the membrane surface area that is available for diffusion—a greater surface area facilitates higher sample recovery. The pore size of the semipermeable membrane determines the molecular weight cutoff and, hence, can be customized depending on application as well as the analyte(s) of interest. With regard to the perfusion fluid, lower flow rates can allow greater sample recoveries; however, longer perfusion times are needed if higher sample volumes ( $\mu\text{L}$ –mL) are required for analysis. An alternative strategy to improve analyte recovery involves the addition of chemical additives such as cyclodextrins or osmotic agents to the perfusate [17,18].

Microdialysis can achieve both sample recovery and cleanup before analysis. The pore size of the microdialysis membrane can be tailored for selective exclusion of macromolecules such as proteins and enzymes, thus producing cleaner samples with reduced possibility of enzymatic degradation of the sample.

Selection of a suitable microdialysis probe will be dictated by the target of interest and sample matrix being sampled. As far as the types of probe are concerned, probes for brain sampling are usually rigid and shorter in length (cannula probes) compared to probes for subcutaneous or organ

**FIGURE 48.2** Microdialysis sampling.

implantation (linear probes), which are typically longer and flexible [19]. It should be kept in mind that in the case of *in vivo* microdialysis experiments (e.g., brain, muscle) the probe samples only the extracellular environment, not the intracellular fluid. It also does not measure analyte that is protein bound. Once the microdialysis system has been optimized, attention must focus on the analysis of recovered samples.

#### 48.4 PRACTICAL APPLICATIONS

A distinct advantage of microdialysis is that it allows continuous sampling with no net fluid loss; as a result, it has been used most extensively for *in vivo* sampling. Sampling can be performed in awake, freely moving animals over several days with the animal acting as its own control. Microdialysis has been used for recovery of endogenous compounds such as amino acids, catecholamines, and peptides [20,21]. It has been applied extensively to the study of neurotransmitters [22], for pharmacokinetic modeling of drug substances [23], and for drug delivery [24]. Microdialysis has also been used to monitor blood gases [25]. As a generic sampling method, microdialysis has also found application in the areas of biological, environmental, and biofermentation monitoring [26,27].

Flow-through microchip systems incorporating an integrated membrane [28,29] or coupled to an external probe have been used for monitoring biomolecules such as glucose and lactate [30]. These systems incorporated electrochemical sensors for analyte detection. An online flow-through biosensor has been demonstrated for the *in vivo* determination of glucose, choline, and glutamate in a freely moving rat dosed with aspartate, an agonist of the N-methyl D-aspartate (NMDA) receptor [31]. An electrode array was used for discrimination of individual analytes.

Microdialysis sampling has also been coupled to separation-based microchip devices. External probes have been used in microchip electrophoresis for the monitoring of enzyme reactions [32] and have been applied to the *in vivo* analysis of glutamate in the striatum of an anesthetized rat [33]. Considerations for coupling microdialysis sampling to flow-through and separation-based microchip devices are similar and will now be discussed in more detail, with reference to specific examples from the literature.

## 48.5 METHOD DEVELOPMENT GUIDELINES

### 48.5.1 MICROCHIP FABRICATION

The substrate for the microfluidic device should be selected with consideration of the end application. Substrates used to fabricate the microchip device should not interact with target analytes, and must be compatible with the detection method employed (i.e., should not exhibit background fluorescence, BGF.). For the analysis of nonpolar compounds, it should be kept in mind that substrates such as poly(dimethyl)siloxane (PDMS) can adsorb hydrophobic analytes such as peptides and proteins. Plasma oxidation or treatment of the surface can sometimes be useful to minimize these interactions [34,35]. For perfusates containing organic solvents, compatibility with polymer substrates can also be an issue. Substrates to be used for the fabrication of electrophoresis-based separation devices should be capable of supporting a stable electroosmotic flow (EOF). The use of a low cost material and standard processing procedures can permit mass fabrication of devices.

One of the first demonstrations of coupling microdialysis to a flow-through miniaturized analysis system was reported by Steinkuhl et al. [36] for glucose monitoring. The system was designed and fabricated using a full wafer process and used glass and silicon substrates. Device components were small enough to be housed in a wearable device. The system was tested *in vitro* with human serum and standard solutions of glucose with a stability of 5% achieved over 5 days.

### 48.5.2 MICRODIALYSIS SAMPLING

#### 48.5.2.1 Choice of Membrane

Selection of the dialysis membrane will be dictated by the target analytes and sample matrix. There are several types of commercial probes available for biological monitoring applications. The most fundamental of these probe types are based on length and molecular weight cutoff. Accessories such as guide cannulae, tubing connectors, and so forth compatible with probe dimensions must also be selected. Both integrated membranes and external probes have been used in conjunction with microchip devices. When external probes and tubing are connected to microchip platforms, sample can be delivered directly to the microchip device. This has been demonstrated with both flow-through and separation-based devices. Dialysis membranes should be conditioned with perfusion fluid before sampling commences.

#### 48.5.2.2 Integrated Membranes

Interfacing microchip devices to the macro world is a challenging task [37]. Microdialysis may be coupled to microchip systems through integrated membranes built into the device or by coupling external probes to the device. The integration of membranes into microchip devices has recently been reviewed [38]. Dialysis membranes have been integrated into flow-through microchip devices by clamping or bonding between channel layers. Cellulose membranes have been sandwiched between two acrylic plates for blood monitoring (Figure 48.3) [28].

Another approach involved the use of a carbonate membrane bonded to SU8 channels with a glass layer used to seal the device [29]. The system used a stacked approach with a dialysis membrane sandwiched between an SU8 perfusion channel and a poly(dimethylsiloxane) flow channel (Figure 48.4). Bonding the membrane reduced the chance of leakage and resulted in a more robust device. A fluorescent dye and glucose solution were used for optical characterization of the system. A commercially available glucose sensor was used to determine the concentration of glucose in the dialysate. A recovery of 80% was obtained at flow rate of 1.5  $\mu\text{L}/\text{min}$ .

Dialysis membranes can also be fabricated *in situ* on microchip devices. This was achieved by Song et al. [14] who filled glass (fused silica) microchannels with monomer solutions and initiated polymerization by exposure to a UV laser. The membranes produced could be used between

**FIGURE 48.3** Schematic representation of fluidic device with integration of cellulose membrane. (Reproduced from Kurita, R., et al., *Biosens. Bioelectron.*, 21, 1649, 2006. With permission.)

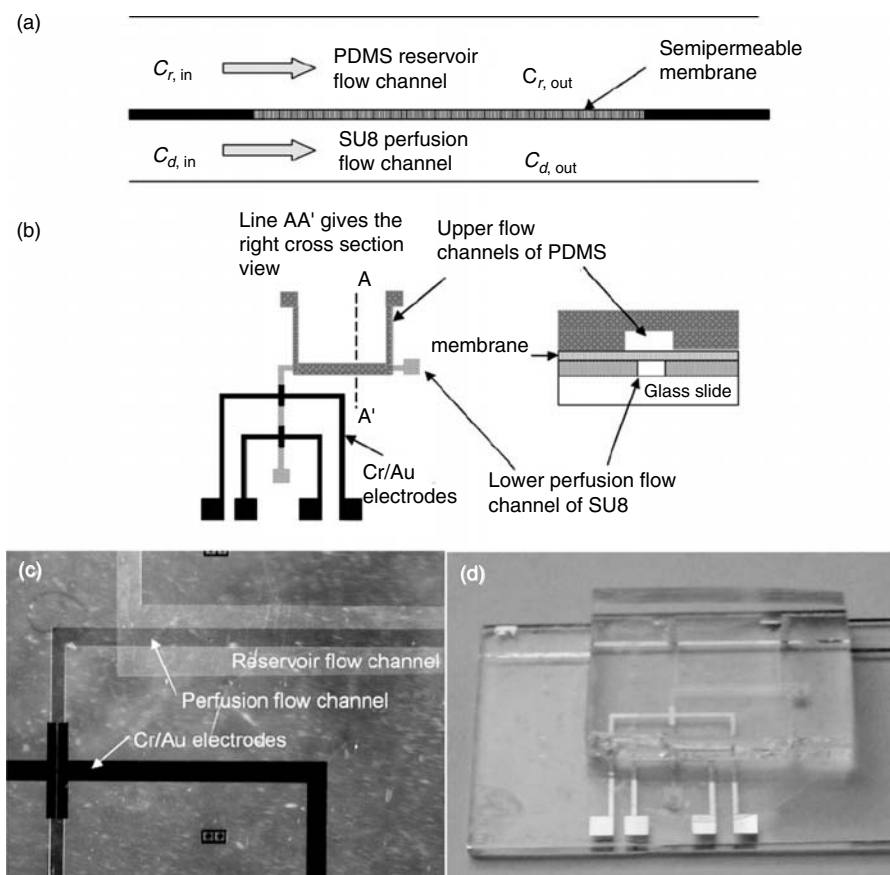

pH 2.7 and 9, and minimal protein adhesion was observed. The system was designed for desalting of protein samples. The advantage of using photopatterning is that the molecular weight cutoff of the membrane can be tailored to suit the application.

### 48.5.2.3 Interfacing to External Probes

For *in vivo* or *in vitro* monitoring, external probes can be used and implanted in tissue or a solution of interest. The microdialysis system is then interfaced to the microchip device for detection (flow-through systems) or separation of recovered analytes. Where possible, connectors should be fabricated as part of the device to minimize the number of external fittings required and associated dead volumes and band broadening. For interfaces attached using adhesives (e.g., epoxy quick dry), care must be taken to ensure that no material leaches into the device as this can lead to contamination and interferences in detection. A thorough characterization of the interface is necessary to ensure that there is no sample leakage, which can result in a variation in perfusion flow rates through the probe. When electrophoresis is used as the separation mechanism for *in vivo* monitoring applications, the interface between the microdialysis setup and the microchip may also need to be grounded to achieve isolation of the animal from the high voltage. Specific approaches to coupling external probes to separation-based devices will be discussed in Section 48.5.4.

### 48.5.3 DETECTION

Integration of a dialysis membrane or coupling to a microdialysis probe can help to exclude many of the larger molecules such as proteins that are typically responsible for fouling the sensor elements of microchip analysis systems. The nature of the analysis will dictate whether coupling to a flow-through or separation-based sensor must be achieved and the kind of detection elements to be employed (optical, electrochemical, etc.). One of the issues with microchip devices is the very small

**FIGURE 48.4** (a) Model of microdialysis system. Schematic of the mass transfer. (b) The schematic of stacked microdialysis system. The depth and width of PDMS channels are 30 and 1500  $\mu\text{m}$ . The depth and width of SU-8 channels are 15 and 400  $\mu\text{m}$ . (c) Electrodes SU-8 and PDMS channels under brightfield microscopy. (d) Photo of a complete device. (Reproduced from Hsieh, Y.-C. and Zahn, J. D., *Biosens. Bioelectron.*, 22, 2422–2428, 2007. With permission.)

volumes (nL–pL) of sample that are injected, which can impact the sensitivity of the analysis [39]. While miniaturized optical components and electrode materials can be integrated onto microchip platforms, sensitive off-chip detection systems (LIF; MS) may also be used.

If a single analyte is to be detected, a simple flow-through microdialysis/microchip system may suffice. If multianalyte determination is needed, a separation-based microchip device can allow resolution and detection of several analytes in a single sample (Section 48.5.4). In flow-through devices, the perfusate is directed to an array of sensors, which may be also be modified to allow detection of different analytes and improve detection sensitivity.

Detection of lactate in whole blood has been achieved using a miniaturized flow-through device with gold film working electrodes modified with lactate oxidase and a poly(vinylpyridine) mediator containing horseradish peroxidase. The analysis results were achieved in 2 min without the need for centrifugal separation or serum separation. A flow-through potentiometric sensor based on semipermeable dialysis tubing in a silicon device has also been described [40]. The system consisted of a microdialysis probe, a sensor array, and a calibration element. The *in vitro* sensor was able to detect a standard solution of potassium as part of an integrated microdialysis system. The sampling time was 60 s with a flow rate of 2  $\mu\text{L}/\text{min}$ .

Impedance electrodes have also been investigated as detectors for microchip microdialysis applications. An on-chip microdialysis system with inline sensing electrodes for impedance detection was developed [41]. Cr/Au electrodes were used to determine the electrical resistance of changes in the concentration of phosphate-buffered saline (PBS) solutions that were used to characterize the system. The system monitored concentration changes with a 210-s system response delay. The lag time was attributed to dead volume in the tubing between the syringe pumps and the microsystem.

#### 48.5.4 SEPARATION

There have only been a few reports of coupling microdialysis to microchip-based separation systems. Ideally, the microchip system should allow the injection of discrete sample plugs from a continuously flowing stream of dialysate without disturbing the separation element of the analysis. This allows maximal temporal resolution and limits the effect of perfusion flow rate on system performance.

The first reported coupling of microdialysis to a separation-based microchip device was achieved by Huynh et al. [32], who coupled an external commercially available probe to a glass microchip (Figure 48.5). The use of a glass microchip allowed generation of sufficient EOF to gate the sample stream away from the separation channel until an injection was required. This can be more difficult to achieve with polymer substrates such as poly(dimethylsiloxane) where the magnitude of EOF supported by the substrate is often considerably less than that of glass. The device was used to monitor the products formed during an enzyme assay in near real time. Laser-induced fluorescence detection was used, and device performance as a function of flow rate and applied voltage was characterized using a fluorescent dye. The resulting system was then used to monitor the progress of an enzyme reaction (Figure 48.6). Some optimization of the setup was needed to balance the perfusion flow rate with the requirements of the separation system. Using perfusion flow rates of  $1\ \mu\text{L/s}$ , a temporal resolution of 30 s was achieved with a system lag time of  $\sim 6.5$  min. This was attributed to dead volume due to the microchip and associated connectors that were added to the device following fabrication.

On-chip labeling of analytes may also be needed if fluorescence or electrochemical detection is employed. This has been demonstrated with flow-gated design using naphthalene 2,3-dicarboxaldehyde and 2-mercaptoethanol [33,42]. Labeling reagents were added to the buffer reservoir and on-column labeling was achieved (Figure 48.7). Using this approach, the

**FIGURE 48.5** Layout and schematic of microdialysis/microchip CE system. (Reproduced from Huynh, B. H., et al., *Anal. Chem.*, 76, 6440, 2004. With permission.)

**FIGURE 48.6** Near real-time monitoring of an enzyme reaction using microdialysis/microchip CE system. (Reproduced from Huynh, B. H., et al., *Anal. Chem.*, 76, 6440, 2004. With permission.)

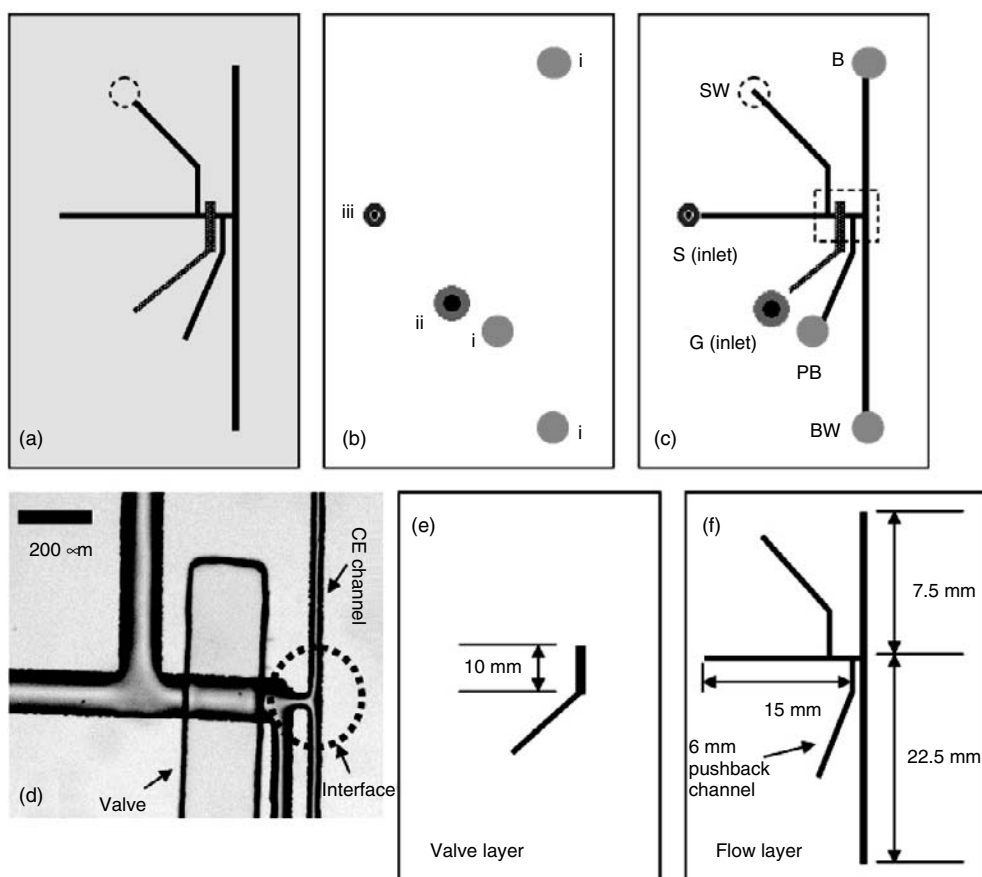

**FIGURE 48.7** (a) Schematic of microdialysis/microchip setup and (b) continuous separation of three-component mixture sampled through external microdialysis probe. (Reproduced from Huynh, B. H., et al., *J. Pharm. Biomed. Anal.*, 42, 529, 2006. With permission.)

microdialysis/microchip system can achieve a high degree of process integration with sample preparation, delivery, derivatization, separation, and detection all accomplished on the one platform. Multiple separations of a three-component mixture that was sampled through the external microdialysis probe and fluorescently labeled on-chip have been reported.

An alternative approach by Li et al. [43] examined the use of integrated polymer valves to achieve discrete injection of microdialysate samples for separation on chip. Polymer valves have been incorporated in microchip devices previously [44]; however, this was the first report of integrating these valves into an electrophoretic microchip system. While fabrication of microchips incorporating polymer valves is not trivial, the injector design allows discrete injection of microdialysate samples for separation on chip without the need for flow-gating. External pneumatic operation of a polymer valving channel causes it to expand and seal off the fluidic channel until an injection is required. The injector design reported by Li et al. was further optimized to include a push-back channel and avoid sample leakage following injection. The device was then coupled to an external microdialysis probe and used to monitor a recovery and separation of a fluorescein dye mixture (Figure 48.8). An injection frequency of 43 Hz was reported with a system lag time of only 14 s; this illustrates the potential of the system for applications requiring high temporal resolution.

The first application of a separation-based microchip/microdialysis system to the *in vivo* monitoring of a live animal has been reported [33]. The device design (Figure 48.9) incorporated a

**FIGURE 48.8** Assembled microchip with integrated polymer valves. (Reproduced from Li, M. W., et al., *Anal. Chem.*, 78, 1042, 2006. With permission.)

**FIGURE 48.9** Layout and schematic of microdialysis/microchip CE system for online monitoring of neurotransmitters. (Reproduced from Sandlin, Z. D., et al., *Anal. Chem.*, 77, 7702, 2005. With permission.)

**FIGURE 48.10** Typical electropherogram obtained *in vivo* from the rat striatum using microchip/microdialysis system indicates the peak for glutamate. (Reproduced from Sandlin, Z. D., et al., *Anal. Chem.*, 77, 7702, 2005. With permission.)

sample introduction channel for the dialysate, a precolumn reactor for derivatization, a flow-gated injector, and a separation channel. Laser-induced fluorescence detection was used. The device was applied to the analysis of glutamate following an infusion of the glutamate uptake inhibitor *L-trans*-pyrrolidine-2,4-dicarboxylic acid into the striatum of an anesthetized rat (Figure 48.10). Two microchip layouts were examined, with the second approach achieving separations of selected neurotransmitters within 60 s.

External microdialysis probes fabricated in-house were used in these experiments. Initial studies found that the addition of ethylenediamine tetraacetic acid (EDTA) to the derivatizing reagent was necessary to prevent divalent cations ( $\text{Mg}^{2+}$  and  $\text{Ca}^{2+}$ ) present in the cerebral spinal fluid from decreasing the EOF. Using the device, separations could be carried out at 1.8 min intervals; however, the effective temporal resolution was estimated to be between 2 and 4 min due to delay times attributed to the dead volume in the system. Increases in perfusion flow rates led to a decreased delay time but reduced recovery through the probe was observed.

### 48.5.5 INTEGRATED SYSTEM CONTROL

Control of discrete system elements, which allows added flexibility for sampling, is important to consider. An integrated computer-controlled system was demonstrated for a microdialysis probe coupled online to a flow-through system for lactate and glucose monitoring in serum samples [30]. The system comprised a microdialysis probe and a micromachined silicon stack along with a miniaturized flow cell and sensor array. The integrated system was computer controlled with a response time of 4 min.

### 48.5.6 VALIDATION

In most cases, the investigator should compare the results of the microchip analysis with those of an offline standard technique (CE; high-performance liquid chromatography, HPLC) for method validation. Control microdialysate samples must be collected, particularly for *in vivo* experiments that involve injection of a compound or drug. Such control samples can help identify or eliminate peaks from the microchip analysis. In many cases it is useful to incorporate an internal standard into the sampling process to correct for any changes in the recovery, reaction chemistry or with the on-chip injection process.

## 48.6 CONCLUDING REMARKS

Microdialysis is a well-established sampling technique that has found application in many areas, most notably in biological monitoring. Advances in fabrication technologies have led to the development of innovative microchip technologies suitable for real-world monitoring applications. Microdialysis/microchip systems offer several advantages, including lower costs, faster analysis for improved temporal resolution, and simplified connections and fittings for device fabrication and operation. While the performance of conventional bench-top systems is currently superior to that of the separation-based devices, initial reports clearly demonstrate the potential of coupling microdialysis to microchip platforms.

Future developments will see the optimization of device design and the investigation of alternative materials for microchip, electrode, and membrane fabrication. It is envisioned that further advances in fabrication and integration procedures will allow the development of implantable/wearable microdialysis/microchip systems for personal or on-animal monitoring. Integration of the separation-based systems with powerful detection techniques such as MS will further improve the detection capability of these systems for biological, pharmaceutical, and environmental monitoring.

## ACKNOWLEDGMENTS

This research was supported by research grants from the National Institutes of Health (R01 NS042929-04) and from the National Science Foundation (CHE-0111618). Support in the form of a predoctoral fellowship from the American Heart Association for Pradyot Nandi is also gratefully acknowledged. The authors would also like to thank Nancy Harmony for her assistance in the preparation of this manuscript.

## 49.1 INTRODUCTION

Explosive progress in the last decade in the field of genomics has generated new insight and an enormous amount of data concerning the codes and functions of different genes. Proteomics constitutes the huge corresponding effort to systematically unravel the functions of the different proteins encoded in the genome. Identification of proteins and studies of protein expression, interaction, and post-translational modifications (PMTs) are imperative for understanding biological systems. This has led to an increased interest in the development of microanalysis systems that allows proteins to be subjected to mass screening.

This chapter will briefly cover some aspects of microfluidic sample preparation techniques in the field of proteomics with a special focus on applications using matrix-assisted laser desorption

ionization-mass spectrometry (MALDI-MS) for the analysis readout. The reader is referred to Chapter 54 by Lazar as a complement to this chapter. Owing to the fact that the amount of available sample in protein analysis often is very limited, the use of microfluidic structures in combination with MALDI-MS has many great advantages, such as the ability to handle small amounts of sample, miniaturized sample handling that reduces sample losses, rapid digestion of proteins, effective solid-phase extraction (SPE) and easy automation.

## 49.2 BACKGROUND

### 49.2.1 MINIATURIZATION OF ANALYTICAL SYSTEMS

Miniaturization of analytical systems has been a long-standing priority and one of the first examples of pioneering work in chip-based miniaturization is the gas chromatograph developed by Terry et al. at Stanford in 1975.<sup>1</sup> In the late 1980s, the term micrototal analysis system ( $\mu$ TAS) was introduced by Michael Widmer and colleagues at Ciba Geigy in Switzerland, a concept followed up later in 1993 when chip-based capillary electrophoresis of amino acids was presented.<sup>2</sup> In the last decade, an ever increasing number of applications have been developed for microfluidic devices (e.g., in protein analysis).<sup>3–11</sup> genomic analysis,<sup>12–14</sup> forensic science,<sup>15</sup> environmental analysis,<sup>16</sup> cell handling,<sup>17–21</sup> clinical analysis,<sup>22–24</sup> combinatorial chemistry,<sup>25</sup> microreactors,<sup>26–28</sup> enzymatic assays,<sup>29–31</sup> and for fundamental science studies of microfluidics.<sup>32–34</sup>

The main driving force behind the increasing interest for miniaturization in proteomics is the need to integrate and automate analysis to facilitate increased speed and reduced costs per analysis. The benefits of miniaturization arise from the increased reaction kinetics in small volumes and the possibility to perform sample handling procedures at a high speed in micro-/nanoliter systems. Reduced dead volumes in integrated systems allow for increased system performance. Extreme surface-to-volume ratios ( $80000\text{ m}^{-1}$ ) compared to conventional microtiterplates ( $500\text{ m}^{-1}$ ) enables elution of samples in very small volumes<sup>4</sup> (e.g., after SPE). The art of microfluidics is utilizing the scaling laws for new effects and better performance. This is not always a straightforward process as the behavior of fluids at the microscale can be significantly different from generic behavior in macroscale. Factors such as surface tension and frictional forces give a liquid behavior governed by capillary forces, with a laminar flow as viscosity and not inertia dominates fluid behavior. Other aspects that can be used to advantage when constructing microfluidic systems are low thermal mass and efficient mass transport, for example, if a channel is reduced in width by a factor 10 the mean diffusion time for an analyte across the channel is reduced by a factor 100. All microfluidic structures inherently benefit from the lower sample and reagent consumption and the high degree of parallelity that can be achieved. For additional user-friendliness, microfluidic structures should be manufactured as disposables when it is possible.

### 49.2.2 PROTEOMICS

The idea of mapping all the human proteins was presented in 1982, with the human protein index suggested by Anderson and Anderson.<sup>35</sup> At that time, technology for this purpose was rather limited, but with time and technology development, more and more scientists became aware of the gains of such a project. The term proteome was introduced in 1994 by the Australian researchers, Keith Williams and Marc Wilkins, at the 1994 Siena meeting<sup>36</sup> (“2-D Electrophoresis: From Protein Maps to Genomes” September 5–7, 1994). The proteome is defined as the complete set of proteins from the information encoded in a genome that can be expressed and modified by a cell, tissue, or organism. The number of transcribed genes in the human genome is currently believed to be around 20,000–25,000, although this number is fiercely debated and might soon change. With regard to the number of PMTs, the 20,000–25,000 genes are estimated to give rise to approximately 1 million different protein molecules.

Protein technology is also inherently more complex than DNA-based technology. Not only is the basic alphabet bigger and more heterogeneous, genes can also be variously spliced<sup>37</sup> resulting in numerous different protein products from a single stretch of DNA. In addition, mRNA editing is relatively common, leading to modified messages and corresponding protein products.<sup>38</sup> There are also more than 200 different PMTs by which proteins can be modified after they have been synthesized. Proteins once synthesized can be cleaved, to eliminate signal sequences, transit or propeptides, and initiator methionines. There are examples of proteins that have been found to possess more than 1000 different isoforms.<sup>39</sup> The proteome analysis projects have no equivalent to the high-throughput sequencers, which have served the genome projects so well. Neither is it possible to amplify the proteins by any analog to the polymerase chain reaction (PCR) technique used for DNA amplification, leaving only the proteins isolated from the original sample available for analysis. While the genome is virtually static, at least in the case of DNA, the proteome continuously changes its state. In principle, therefore, an infinite number of proteomes can be assigned to a given genome. Adding to the complexity is also the huge dynamic range of the proteome;<sup>40</sup> on average, a human cell contains about 10,000 different proteins present at concentration ranges from  $10^1$  to  $10^{12}$ . Finding a specific low-abundance molecule in such a complex mixture is more difficult than having to seek a certain person out of the entire population of Earth.

The huge complexity of proteomic analysis makes it a technically challenging goal. The technologies required to separate large numbers of proteins, to identify them, and to study their modifications are by no means straightforward or homogenous,<sup>41–44</sup> but as proteomics research evolves so does the technology used in this field. Explosive progress the last decades in the fields of protein science, bioinformatics, and cell and molecular biology have resulted in an increased demand for development of instrumental technology that allows identification and detailed structural studies of proteins to be automatically performed at high speed and with a high sensitivity. Miniaturization can, with advantage, be implemented by applying microfabrication techniques. Although, it should be mentioned that a lot of miniaturization in the field of proteomics have been accomplished by using conventional means (e.g., using capillaries).

Despite the many advantages of miniaturization there are some concerns. For instance, if the speed of analysis is limited in a preceding or subsequent step, it is not necessarily a huge gain for the overall analysis time if the application of miniaturization allows for one rapid sample preparation step. In cases where the sample/analytes are not limited, it might not be necessary to use miniaturization to facilitate analysis. Another difficulty is that miniaturized sample preparation has the inherent characteristic that small sample volumes have to be used; while this has some advantages, it includes the disadvantage that fewer analyte molecules are available for detection. Consider a scenario where a sample containing an analyte at a concentration of 1 pM is to be analyzed with a miniaturized device that allows for loading of 1 nL sample. Disregarding any sample losses or dilution in the analysis device, there will be  $\sim 600$  molecules (1 zeptomole) available for detection. Although there are detection techniques that can facilitate single molecule detection,<sup>45–50</sup> this makes analysis more difficult than required if a more concentrated sample could be applied.

To counter the effect of small sample loads in miniaturized analytical systems, a huge number of methods for preconcentration of analytes have been deployed.<sup>51</sup> These include numerous “electrokinetic concentration” processes such as isotachopheresis,<sup>52,53</sup> field-amplified sample stacking,<sup>54</sup> and electrokinetic trapping.<sup>55,56</sup> Chromatographic SPE methods have shown to provide 1000-fold preconcentration before electrochromatography<sup>57,58</sup> and micellar electrokinetic chromatography (MEKC).<sup>59</sup> Membrane preconcentration have also been adapted to microfluidics with success.<sup>60–63</sup> A recently presented technique used an integrated nanofluidic filter to accomplish electrokinetic trapping<sup>64</sup> with concentration factors as high as  $10^6$ – $10^8$ . Examples of other techniques for concentration of analytes are liquid–liquid extraction,<sup>65–67</sup> microdialysis,<sup>68</sup> and immunoaffinity capture.<sup>69–71</sup>

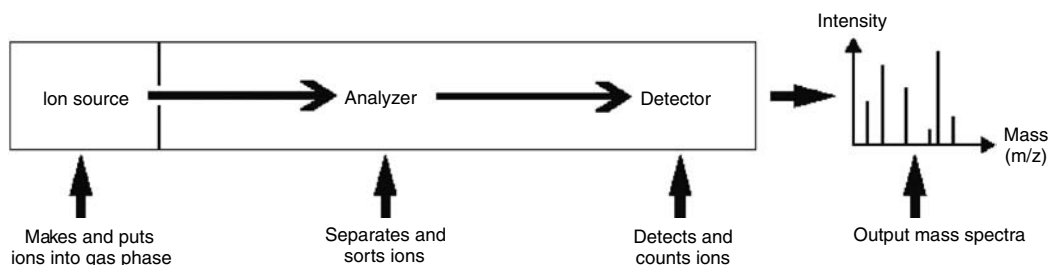

### 49.2.3 MASS SPECTROMETRY FOR ANALYSIS AND IDENTIFICATION OF PROTEINS

In the late 1980s, two technology breakthroughs in soft desorption/ionization of large biomolecules occurred with the introduction of electrospray ionization (ESI)<sup>72,73</sup> and laser desorption ionization.<sup>74,75</sup> These methods have paved the way for the intense use of MS for analysis of biomolecules that we see today, and were awarded with a Nobel prize in 2002. The generic mass spectrometer consists of an ion source, an analyzer and a detector (Figure 49.1). The mass spectra generated provide the mass of the analyzed molecule and in the case of a MS/MS experiment, the masses of the breakdown products of a selected analyte.

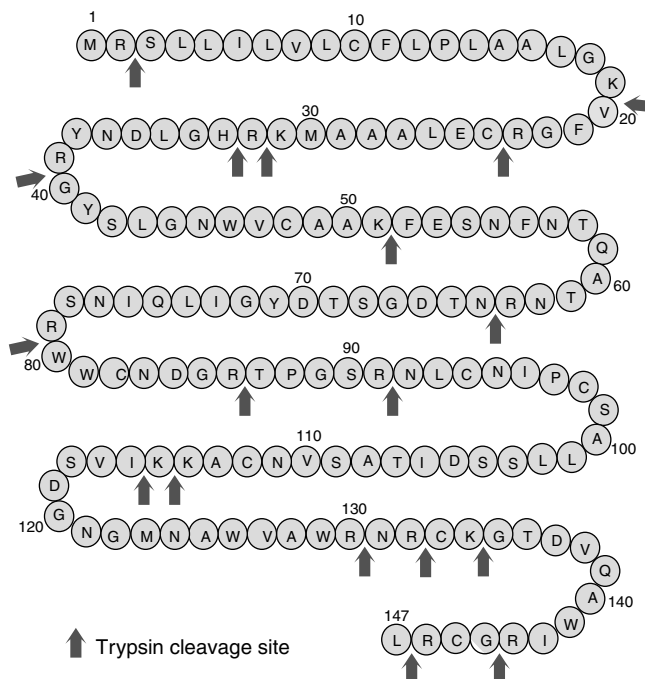

When the mass of a protein or peptide in a mass spectra does not immediately give the identity of the analyte, it was quickly understood that if a protein was cleaved in a predictable manner, the peptides generated from a given protein would form a fingerprint for the protein.<sup>76</sup> This protein fingerprint could then be compared to *in silico* patterns of protein sequences generated from databases. In 1993, this technique of peptide mass fingerprinting (PMF) was independently described by a number of groups.<sup>77–81</sup> The most commonly used proteolytic enzyme for generation of this fingerprint is trypsin, which cleaves specifically at the C-terminal end of arginine and lysine (Figure 49.2). Owing to its ease of use PMF analysis with MALDI-MS is still the most common way of identifying proteins separated by two-dimensional gel electrophoresis (2-DE).<sup>82</sup>

As an alternative to PMF, proteins can be identified by MS/MS of peptides generated from the proteins. This identification method was introduced in 1994 by Mathias Mann<sup>83</sup> (Sequence Tags) and John Yates<sup>84</sup> (cross-correlation). In an MS/MS experiment a certain ion is selected in MS mode to undergo fragmentation in the gas phase. Peptides fragment in a sequence-specific manner, yielding a MS/MS spectrum that reflects its amino acid composition. The fragmentation of the peptide is commonly brought about by collision-induced dissociation (CID), but many other forms of fragmentation can also be used, for example, PSD fragmentation with MALDI,<sup>85,86</sup> or Electron Capture Dissociation (ECD). The usefulness of ESI-MS/MS took a further leap with the sensitivity increasing and sample-saving nanospray. The ability to perform sensitive MS/MS analysis of peptides is the basis for the “shotgun”/multidimensional protein identification technology proteomics (MudPIT).

From the beginning, MALDI was commonly coupled with time-of-flight (TOF) analyzers and ESI with ion trap or quadrupole analyzers.<sup>87</sup> Modern mass spectrometers are evolving at a rapid pace and numerous different configurations exist on the market today. Both MALDI and ESI ion sources can be combined with a number of analyzers, for example, triple quadrupole (TQ), quadrupole TOF (Q-TOF), ion traps (IT), quadrupole ion traps (QIT), or Fourier transform ion-cyclotron resonance analyzers (FT-ICR). The new technologies in MS, such as linear ion traps,<sup>88</sup> orbitrap,<sup>89,90</sup> ion mobility,<sup>91,92</sup> MALDI TOF-TOF,<sup>93</sup> and FT-ICR-MS<sup>94,95</sup> provide ever-increasing sensitivity and speed of analysis. The fact is that MS has matured so that it is no longer the most limiting factor in

**FIGURE 49.1** Diagram of a generic mass spectrometer. Sample analytes are transposed to ions in the ion source and separated in the analyzer. The ions hit the detector and a mass spectra is recorded, where the intensity of the ions are plotted against their mass.

**FIGURE 49.2** Amino acid sequence of lysozyme and trypsin cleavage sites (carboxy terminal to lys and arg). The specificity of the trypsin digestion results in a “fingerprint” for the protein when analyzed by MS.

proteomics. The difficulties of analyzing low-abundance proteins are currently more limited by the sample preparation.

#### 49.2.4 SAMPLE PREPARATION FOR MALDI-MS

The laser desorption technique almost exclusively used today is the MALDI technique developed by Franz Hillenkamp and Michael Karas.<sup>74,96,97</sup> The sample is dispersed in a large excess of matrix material, which will strongly absorb the incident laser light. The matrix also serves to isolate sample molecules in a chemical environment that enhances the probability of ionization without fragmentation. Short pulses of laser light focused (10–200  $\mu\text{m}$  spot diameter) on the sample spot will cause the sample and matrix to volatilize. The analyte ions formed are then separated according to mass in the analyzer (commonly a TOF) and subsequently recorded as an electrical signal as they arrive at the detector.

The most important step in MALDI-MS, is finding the optimal matrix-sample preparation method.<sup>98</sup> The first reports in the field all use the conventional “dried-droplet” (DD) method,<sup>99</sup> where analyte and matrix solutions are premixed in a 1:1 ratio and subsequent deposition of approximately 1  $\mu\text{L}$  volumes onto a metal target; the spot is left to dry and crystallize within a few minutes. However, this method often leads to sample inhomogeneities, that is, the crystal formation originating from the rim of the droplet results in crystals of varying size and density. The final sample surface has spots with little or no crystals at some locations, while a dense crystal layer normally forms at the rim. Since several laser scans have to be averaged in order to obtain a mass spectrum with a good signal-to-noise ratio, there is a major interest in maximizing the shot-to-shot reproducibility. Both inhomogeneous analyte incorporation into the matrix crystal structure<sup>100</sup> and variation of the analyte/matrix ratio as a result of the crystallization process<sup>101</sup> are believed to contribute to the poor reproducibility. Improved reproducibility have been reported using crystal crushing,<sup>102</sup> spin-coated drying,<sup>103</sup>

stirring,<sup>104</sup> aerospray,<sup>105</sup> electrospray,<sup>106</sup> and recrystallization<sup>107</sup> sample preparation methods. The presence of microcrystals can cause significant enhancement in the crystal growth rate<sup>108</sup> and hence result in smaller crystal sizes. A method that has been shown to provide good reproducibility is fast evaporation method.<sup>99</sup> An approach that uses fast evaporation to produce microcrystals followed by a second layer of matrix to obtain a homogeneous crystal layer have been presented by Dai et al.<sup>109</sup> A similar approach to seed-layer method was developed in our group for high reproducibility and high-throughput purposes and automated by use of microdispensing.<sup>110</sup> It is also possible to first add the matrix to the MALDI target followed by subsequent addition of sample to the dried matrix. This is very conveniently facilitated by the thin-layer method where nitrocellulose is included into the matrix solution.<sup>111</sup> The thin-layer matrix a convenient solution for automated peptide analysis as the samples can be deposited directly onto a predeposited thin-layer matrix surface in nanovials. This method was later improved by Miliotis et al.<sup>112,113</sup> Recent developments in MALDI matrix-sample preparation are direct desorption/ionization on porous silicon,<sup>114</sup> carbon nanotube matrix,<sup>115</sup> and liquid ionic matrix.<sup>116,117</sup>

The optimal matrix-sample preparation is ultimately dependent on the MALDI instrument used and the nature of the sample. Thus, the optimal sample preparation for a certain application has to be deduced empirically.

#### 49.2.5 MICRODISPENSING TECHNIQUES FOR MALDI-MS SAMPLE PREPARATION

The most well known and successful application of microfluidics is inkjet printing.<sup>118</sup> Sample volumes in the nanoliter–picoliter range are very difficult to handle by conventional pipetting and in this context, droplet dispensers for sample handling are finding increased use in life science<sup>119</sup> and chemistry.<sup>120</sup> Therefore special tools need to be developed (Figure 49.3).

The development is fueled by rising demands for speed in high-throughput screening systems and the overall trend toward miniaturized analysis systems. The technology has evolved from the conventional inkjet printing technology, where droplets are generated from an enclosed volume of liquid. The use of droplet dispensers have been presented in a number of applications for biological sample handling,<sup>120–125</sup> for example, for sample introduction in CE,<sup>126</sup> fabrication of sensors,<sup>127</sup> and sample deposition in MALDI.<sup>128–130</sup> An example of a commercial dispenser for proteomics applications is the Chemical inkjet Printer (Chip) marketed by Shimadzu Corporation (Kyoto, Japan), as tool for on-membrane protein digestion.<sup>131,132</sup> The limitation of these dispensers is that they are of the single-ended type where the sample is either filled from a stationary reservoir or aspirated through the orifice of the dispenser.

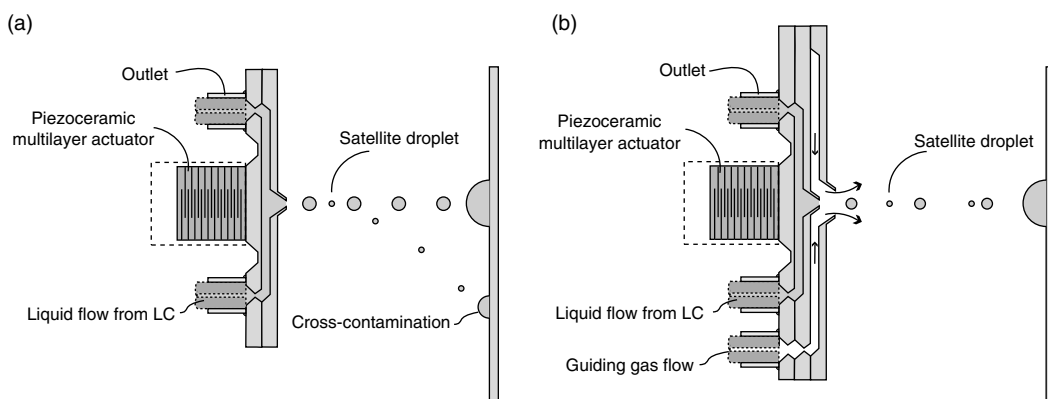

**FIGURE 49.3** Pictures illustrating the difficulties of liquid deposition in nanovials using conventional techniques (right pipetting and left capillary deposition). Nanovial dimensions are  $400 \times 400 \mu\text{m}$ .

To handle the many physically diverse sample solutions that are encountered in the field of proteomics, a piezo-actuated flow-through microdispenser developed within our group<sup>133</sup> has found many uses for depositing sample volumes ranging from 65 pL to over 300 nL. The dispensing principle is based on a piezo-ceramic element, which elongates when a voltage pulse is applied, thus creating a pressure pulse that results in droplet ejection at the orifice. A schematic cross-section of a dispenser structure is illustrated in Figure 49.4. A raised pyramid-shaped nozzle ensures stable droplet directivity and flow-through capability allows for online coupling to high-resolution liquid chromatography (LC), as have been implemented by Miliotis et al.<sup>112,113,134</sup>

During the years, a number of improvements of the piezoelectric microdispenser have been made in order to shrink internal volumes and obtain optimal operational characteristics. In addition, a number of new design solutions have been tested; an example is the compound microdispenser<sup>135</sup> that was developed to avoid crystal formation at the nozzle orifice, which will have an adverse effect, on the droplet formation. This compound dispenser, when adapted for gas-flow-guided dispensing (Figure 49.5) was also found to offer potential improvements for the situation where piezoelectric microdispensing was coupled to online LC separations.<sup>136</sup> Especially in situations where the composition of the liquid varies with time, as the changes in surface tension of the dispensed liquid could lead to decreased droplet stability, directionality (formation of satellite droplets that may have a different trajectory) and in the worst case disrupted dispensing.

**FIGURE 49.4** Schematic cross-section of a microdispenser. (Reproduced with permission from Miliotis, T., Kjellstrom, S., Nilsson, J., Laurell, T., Edholm, L. E., and Marko-Varga, G., *Journal of Mass Spectrometry*, 35, 369–377, 2000, copyright 2000, John Wiley & Sons.)

**FIGURE 49.5** Droplet ejection with satellite droplets from an ordinary flow-through dispenser (Figure 49.7a) and from a gas-flow guided dispenser (Figure 49.7b). The gas flow is achieved by adding a second nozzle side with a single inlet for gas to the dispenser depicted in Figure 49.4.

### 49.2.6 MICROSPOT TECHNIQUES FOR MALDI-MS SAMPLE PREPARATION

It is a well-known fact that a small spot size is beneficial to MALDI analysis.<sup>137,138</sup> As MALDI-MS desorbs/ionizes the analytes with a laser having a focal spot size of 50–200  $\mu\text{m}$ , it follows that the analyte density in the deposited sample spot is critical for the final sensitivity. To increase the sensitivity and reproducibility in MALDI-MS, different microspot preparation techniques have been developed. There are two main ways to accomplish a microspot. It can be done either by having a moiety on the target plate that confines the sample or by use of a specialized deposition of the sample. Examples of methods that can be applied to ensure a small spot are drop-on-demand dispensing,<sup>128,139–141</sup> hydrophilic anchor point on a hydrophobic target<sup>142</sup> or deposition on a hydrophobic target,<sup>143</sup> capillary deposition,<sup>144–147</sup> electrowetting-on-dielectric (EWOD)-based deposition,<sup>148</sup> wall-less sample preparation,<sup>149</sup> and electrospray deposition.<sup>150</sup>

### 49.2.7 SOLID-PHASE EXTRACTION AS SAMPLE PREPARATION BEFORE MALDI-MS

Despite the high sensitivity and the relatively high tolerance for contaminants of MALDI-MS, successful analysis often requires pure and concentrated analytes. One of the most robust and convenient techniques for sample clean up is SPE. A study of the literature will reveal numerous strategies that can be used to combine MALDI-MS with miniaturized SPE. They can be summarized as (i) micropipette tips packed with SPE media; (ii) microtiterplates with integrated SPE; (iii) MALDI target plates for on-target (on-probe) purification of samples and (iv) microfabricated on-chip-based SPE technologies. The micropipette tip-based SPE is probably the easiest to implement, the first examples used ordinary pipette tips packed with beads.<sup>151,152</sup> More recently, reports of similar SPE tips using monolith media<sup>153</sup> and pieces of SPE membranes<sup>154</sup> have been published. Currently, there are several suppliers of different microextraction tips, for example, ZipTip™ (Millipore Corporation, Billerica, MA, USA), SuproTip (The Nest Group, Inc, Southborough, MA, USA), Omix pipette tips (Varian, Inc. Paulo Alto, CA, USA), Eppendorf PerfectPure Tips (Eppendorf AG, Hamburg, Germany), and Agilent Cleanup C18 Pipette Tips (Agilent, Palo Alto, CA, USA). The advantage of the micropipette tip-based SPE is that it is easy to automate using ordinary pipette robotics and relatively inexpensive, with a cost per sample of 2\$–3\$. The drawbacks are that there are many sample transfers, where sample can be lost and the requirement of a low flow resistance (large pores) in the tips leads to a slow mass transfer of analyte to the SPE media and tip-to-tip variations. Thus, several aspiration dispensing cycles are needed and recovery (i.e., sensitivity) has been questioned for the ZipTips when small elution volumes are used.<sup>155,156</sup>

The microtiterplate-based technologies such as the ZipPlate (Millipore Corporation, Billerica, MA, USA) and the device presented by Nissum et al.<sup>157</sup> where the SPE media is integrated at the bottom of each well (300 nL in the case of ZipPlate) offers a more an elegant solution. Here, sample losses due to unnecessary sample transfers are minimized and this is claimed to result in higher sensitivities. Standard pipetting robotics can be used to perform most of the sample transfers and the sample can be eluted directly onto a MALDI-MS target placed under the device. Although, special adapters have to be made in order to facilitate the final elution onto the MALDI target. These devices are relatively new and there is a lack of published data on their performance, but the methodology is sound and as long as the cost per analysis is kept low the use of these type of devices can become as common as the tip-based approach.

On-target purification (SPE) has been accomplished by modifying the surface of the MALDI target to promote binding of the analytes and allowing contaminants to be washed away.<sup>158–160</sup> There are many examples of surfaces and strategies that can be used for on-target cleanup, as described in a review by Xu et al.<sup>161</sup> Examples of commercial on-target SPE technology are the protein chip used for SELDI analysis<sup>162</sup> (CIPHERGEN, Fremont, CA, USA) and MassPrep PROtarget (Waters, Milford, MA, USA). Just as the microtip and microtiterplate-based SPE standard robotics can be used, here the final elution step is avoided as elution is done by addition of the matrix solution to the

spot (i.e., the recovery should be 100% unless some of the analyte is lost during washing). Sample losses due to many sample transfers are potential drawbacks of SPE. It will also become important to avoid spreading of the sample spot when the matrix is added to the spot as sensitivity will suffer with increasing spot size. Limited capacity of a “planar” surface another concern that might be of less importance when the goal is purification/concentration of peptides from in-gel digest. But when the goal is biomarker discovery where the sample contains many different species of a broad concentration range, this capacity deficit becomes more of a concern.

The coupling of microfabricated on-chip SPE devices to MALDI-MS has previously been presented by our group.<sup>163–167</sup> Another approach to on-chip SPE—the microfluidic compact disk Gyro Lab MALDI SP1 (Gyros AB, Sweden)—has been presented and commercialized by Gyros AB, where centrifugal force is used to transport liquids for the purpose of SPE before MALDI-MS.<sup>168</sup> EWOD<sup>148</sup> and electrocapture<sup>55</sup> are techniques that can be used instead of SPE for purification and concentration before MALDI-MS.

### 49.2.8 SEPARATION TECHNIQUES INTERFACED TO MALDI-MS

Since its introduction in 1975 by Klose<sup>169</sup> and O’Farrell,<sup>170</sup> 2-DE has been the most commonly used protein separation technique.<sup>171</sup> A number of developments have extended the usefulness of 2-DE, such as narrow range immobilized pH gradients (IPGs),<sup>172</sup> and 2-D difference gel electrophoresis<sup>173</sup> (DIGE). High resolution and the ability to get a visual representation of the intact proteins and their isoforms are the advantages of 2-DE. Among the difficulties with 2-DE is the separation of membrane proteins, separation of alkaline proteins, and the difficulty of identifying low-abundance proteins from the separation. Owing to the offline nature of 2-DE (i.e., intact proteins in-gel), identification of the gel-separated proteins are with advantage done by MALDI-MS or MS/MS.

An increasingly popular approach in proteomics is to cleave (usually with a proteolytic enzyme) the proteins to peptides, which are separated by LC, followed by MS/MS protein identification of the peptides.<sup>174</sup> The separation is usually done by combining two or more orthogonal chromatographic steps such as a first step of chromatofocusing, size exclusion, ion exchange, hydrophobic interaction, or affinity, followed by a last step of reversed-phase LC, which has the best compatibility with MS. By using ESI MS/MS the separation is analyzed online and this is the most common method.<sup>175–177</sup> Alternatively, the separation is fractionated directly onto a MALDI target as discrete spots.<sup>112,113,134,178–180</sup> While multidimensional separations coupled to ESI MS (MS/MS) have a greater throughput compared to protein identification with MALDI-MS it is not clear that either technique has a clear advantage. Rather it seems that the two techniques are complementary.

Capillary electrophoresis has also been applied to separate peptides before MS analysis with very high separation efficiency and several review publications can be recommended.<sup>181–183</sup> LC is more commonly used in conventional proteomics than CE because of the rather limited capacity of CE. In microfluidics, CE is the most well-developed separation technique.<sup>184–187</sup>

Capillary electrochromatography<sup>188</sup> (CEC) where a stationary phase is introduced in the separation channel, is another option for on-chip separation of biomolecules. This has been achieved by using chemically derivatized walls,<sup>189,190</sup> packed beads in microchannels,<sup>57,191</sup> *in situ* polymerization to obtain monolithic stationary phases;<sup>58,192</sup> alternatively, molded collocated monolithic support structures (COMOSS) can be used to increase the surface-to-volume ratio.<sup>193,194</sup> Pressure-driven LC has been more rarely used in microfluidics; but in principle, many of the microstructures used for CEC or SPE could be applied to LC and coupled offline to MALDI-MS. The increased use of LC in proteomics is now starting to reflect in microfluidics<sup>195–197</sup> and Agilent (Agilent, Palo Alto, CA, USA) is currently marketing a high-performance liquid chromatography (HPLC) chip<sup>198</sup> that integrates trapping, separation column, and an ESI nozzle.

There are also numerous different integrated microfluidic systems published in the literature, but to describe all of them here would neither be possible nor do them justice. The coupling

of microfluidics to ESI MS has been extremely successful since the first examples were published<sup>199–201</sup> and the developments have been described in several reviews.<sup>202,203</sup>

Integrated microfluidic systems capable of protein digestion have been presented in many configurations,<sup>56,204–212</sup> and will continue to be a goal in the development of microfluidic proteomics technologies.

## 49.3 PRACTICAL APPLICATIONS

### 49.3.1 APPLICATION OF MICRODISPENSING AND NANOVALS FOR MALDI-MS SAMPLE PREPARATION

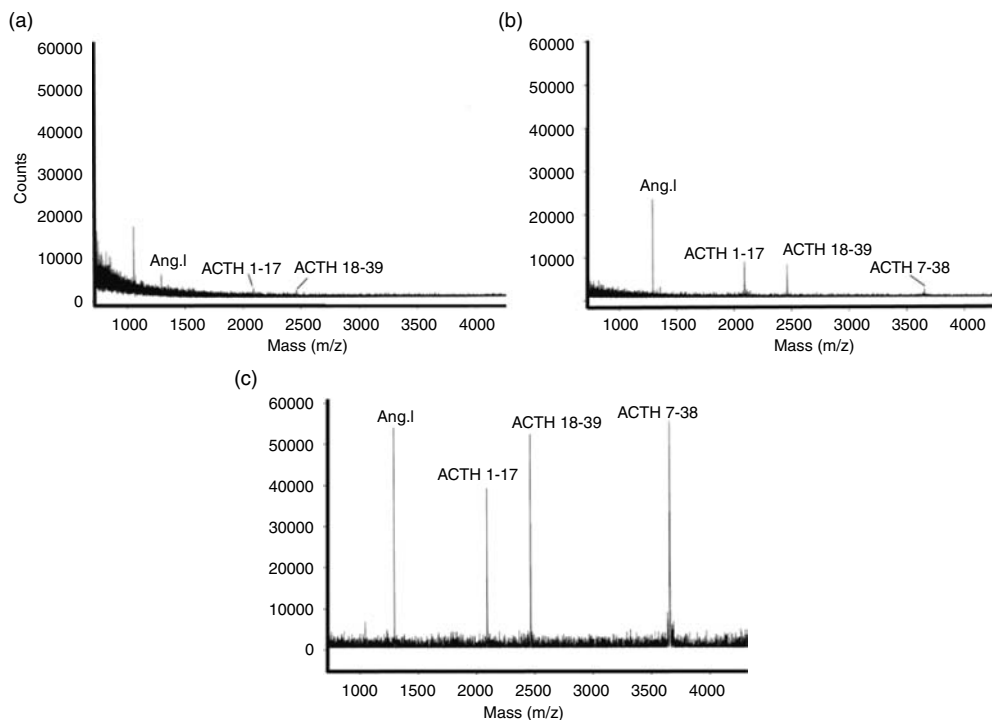

The use of microdispensing in combination with nanovals has a number of advantages, as it combines both a moiety and a deposition technique for achieving the MALDI microspot. The combination of microdispensing and micromachined silicon nanovals allows for enrichment of the analyte in the nanoval by making multiple depositions. This “spot-on-a-chip” enrichment (Figure 49.6) has been shown to provide a signal amplification of at least 10–50 times compared to ordinary sample preparations.<sup>213</sup> The linearity of the enrichment effect was demonstrated and the signal amplification technique was applied for analysis of relevant biological samples. The cytokine IL-8, involved in inflammatory responses, was not detectable with the standard dried-droplet sample preparation at a 100 nM concentration; but by using the “spot-on-a-chip” enrichment, the IL-8 peaks were evident in the MALDI-spectrum. Figure 49.7 illustrates the sensitivity gain provided by sample enrichment through microdispensing.

The use of nanovals to confine the sample spots to a size approximately matching that of the laser focal point is also a major advantage in the automation process since searching for high intensity locations (“hot-spots”) can be avoided.

The silicon nanoval MALDI target arrays used in our laboratory are usually recirculated because using them as disposables are considered too expensive. Therefore, an effort was made to manufacture low-cost polymeric high-density nanoval MALDI targets, which could be used as disposables and

**FIGURE 49.6** The “spot-on-a-chip” platform: (a) the piezo-actuated microdispenser (b) heated high-density MALDI-target plate, and (c) automated MALDI-TOF MS. **FIGURE 49.8** Pictures of high-density polymeric nanovial MALDI target plates. (Reproduced with permission from Ekstrom, S., Nilsson, J., Helldin, G., Laurell, T., and Marko-Varga, G., *Electrophoresis*, 22, 3984–3992, 2001, copyright 2001, John Wiley & Sons.)

allow for archiving of samples<sup>214,215</sup> (Figure 49.8). These disposable high-density MALDI target plate were made either from polymethylmethacrylate (PMMA) and polycarbonate (PC) using precision micromilling and cold embossing to produce nanovials with 0.3–0.5 mm diameter (Figure 49.8). The polymeric high-density nanovial MALDI target plates was found to provide similar performance

as silicon nanovial arrays and an extension of the in-vial chemistry that facilitates identification of phosphorylated peptides was applied in these nanovial arrays.

### 49.3.2 MINIATURIZED ENZYMATIC DIGESTION OF PROTEINS FOR MALDI-MS

Owing to the complex nature of proteins and the fact that MS has a lower limit-of-detection (LOD) for peptides than for proteins, most protein identifications are made from tryptic peptides. This imposes a limitation as trypsin proteolysis is concentration dependent, that is, there has to be enough protein available in the sample for effective proteolytic digestion to take place.<sup>216</sup> Similar to most other proteases, trypsin has Michaelis-Menten constants,  $K_m$  in the low  $\mu\text{M}$  range. So the problem of insufficient digestion becomes apparent when trying to digest low nM concentrations of protein. It should be noted that low nM concentrations is to be considered relatively high in the field of proteomics. It is well known that identification of proteins from 2-DE is limited by this, where spots containing <100 fmol of protein are very difficult to identify. This also affects the gel-free proteomics approaches (shotgun) where the proteins are present in largely varying amounts and here the repeatability of the digestion also becomes important.<sup>217</sup> Some methods of solving the problems of insufficient digestion are scaling-up/concentrating the protein sample, the introduction of a more effective way of cleaving protein to peptides (preferably in a specific manner), or performing the digestion in a smaller volume. Scaling-up the sample is the earliest method, but this is not always possible with limited samples. While the proteomics community is waiting for a more effective digestion protocol to be invented, the only remaining solution is to shrink the volumes while increasing protein concentration. By performing the digestion in a concentrated low microliter or better nanoliter volume, the enzyme kinetics becomes more favorable as the enzyme substrate ratio allows operation at favorable  $K_m$ .

In the late 1990s, a number of microfluidic structures have been developed at our department (Electrical Measurements, Lund Institute of Technology; Lund University, Sweden) including the porous silicon immobilized enzyme reactor (IMER) and the piezoelectric dispenser. The optimal porosity for IMER and the manufacturing procedure for this porous layer had been determined for glucose monitoring systems in our earlier work. It was anticipated that flow-through digestion of proteins could be facilitated by immobilizing trypsin in the IMER. Initial applications of piezoelectric dispensing for MALDI-MS sample deposition had been very promising.<sup>140,218</sup> The sensitivity gain obtained by confining the MALDI spots in small area spots had been demonstrated in the literature,<sup>137</sup> and nanovials<sup>138,139</sup> seemed a particularly convenient method of confining the MALDI sample spot. With the aforementioned technologies at hand, it was decided to investigate the possibility of creating a proteomics workstation. This effort resulted in an integrated microanalytical platform for automated identification of proteins. The silicon micromachined analytical tools, (i.e.,  $\mu$ -chip IMER, piezoelectric microdispenser, and high-density nanovial target plates, are the corner stones in the system (Figure 49.9). The  $\mu$ -chip IMER provided online enzymatic digestion of protein samples within 1–3 min and the microdispenser enabled subsequent online picoliter sample preparation in a high-density format. Interfaced to automated MALDI-TOF MS, this system provided a highly efficient platform that could analyze 100 protein samples in 3.5 h.

The trypsin  $\mu$ -chip IMER was later improved, with respect to porosity and geometry, to allow for 12 s digestion of  $\beta$ -casein in a study by Bengtsson et al.<sup>219</sup> An excellent review on the subject of immobilized enzyme reactors and their integration to other analytical devices have been written by Massolini et al.<sup>220</sup>

### 49.3.3 IN-NANOVIAL CHEMISTRY

The integrated microanalytical platform for automated identification of proteins described earlier was found lacking sensitivity when samples containing <500 nM were to be digested. There were also concerns about the possibility of cross-contamination arising from the flow-through

**FIGURE 49.9** The integrated analysis system presented in its different parts: automated sample pretreatment and injection; microchip IMER, photo insert shows a SEM picture of the lamella structure with the porous layer; the microdispenser used to deposit sample into microvials; shallow nanovials ( $300 \times 300 \times 20 \mu\text{m}$ ) on the MALDI-target plate; and automated MALDI-TOF MS analysis. (Reproduced with permission from Ekström, S., Önnérjörd, P., Bengtsson, M., Nilsson, J., Laurell, T., Marko-Varga, G., *Anal. Chem.*, 72, 286–293, 2000, copyright 2000 American Chemical Society.)

IMER methodology. This was addressed by performing the digestion directly in the nanovials,<sup>221</sup> thus excluding the IMER for enzymatic digestion. The in-vial digestion protocol is described in Figure 49.10. The in-vial chemistry allowed for a high degree of sample preconcentration, of low volume samples (1.8–8 nL digestion volume) for reduced sample loss; improved Michaelis-Menten kinetics and enhanced sensitivity allowed enzymatic digestion of proteins in concentrations (low nM), which is normally difficult to process. The in-vial digestion technology was later improved by the use of porosified nanovial arrays allowing for improved and faster digestion.<sup>222</sup>

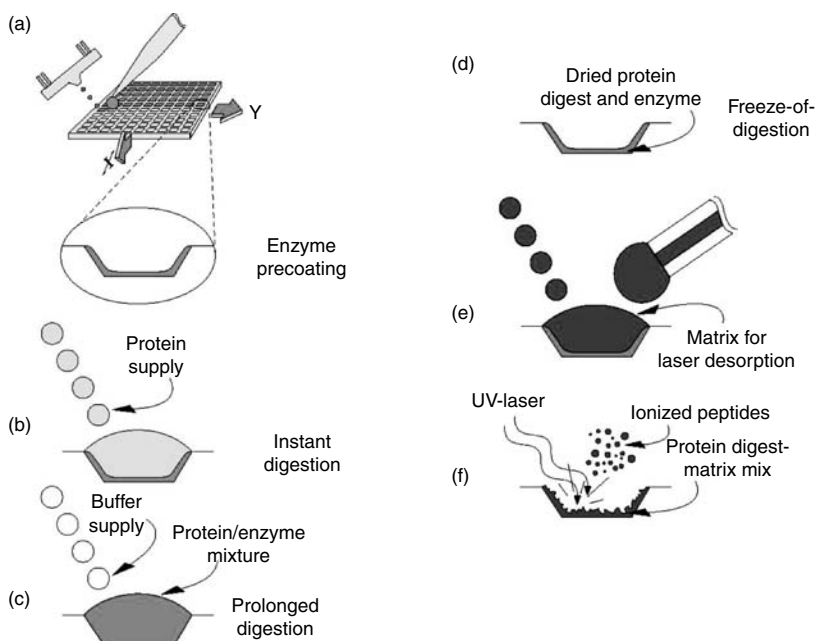

#### 49.3.4 IN-VIAL IDENTIFICATION OF POST-TRANSLATIONAL MODIFICATIONS

Proteomic analysis of PMTs is of paramount interest as these are used to modulate the activity of most eukaryote proteins.<sup>223</sup> The PMTs can serve as molecular switches for enzyme activation, signaling processes, and subcellular localization. There are over 200 different PMTs that can be encountered. Examples of important PMTs are phosphorylation,<sup>224,225</sup> glycosylation,<sup>226–229</sup> and ubiquitination.<sup>230</sup> Microfluidic structures can be applied to facilitate identification of these highly important PMTs. By adapting the sample preparation method developed for in-vial digestion, phosphorylated peptides can be identified. This was accomplished by first depositing the sample in two adjacent nanovials and subsequently treated one of the samples with the enzyme alkaline phosphatase; phosphopeptides treated in this manner will show a mass shift of  $-80 \text{ Da}$ . The in-vial chemistry and dispensing allowed detection of phosphopeptides at low fmol amounts (Figure 49.11). Miniaturized phosphopeptide analysis has also been demonstrated using compact disk (CD)-based microfluidics with immobilized metal affinity capture and alkaline phosphatase treatment.<sup>231</sup>

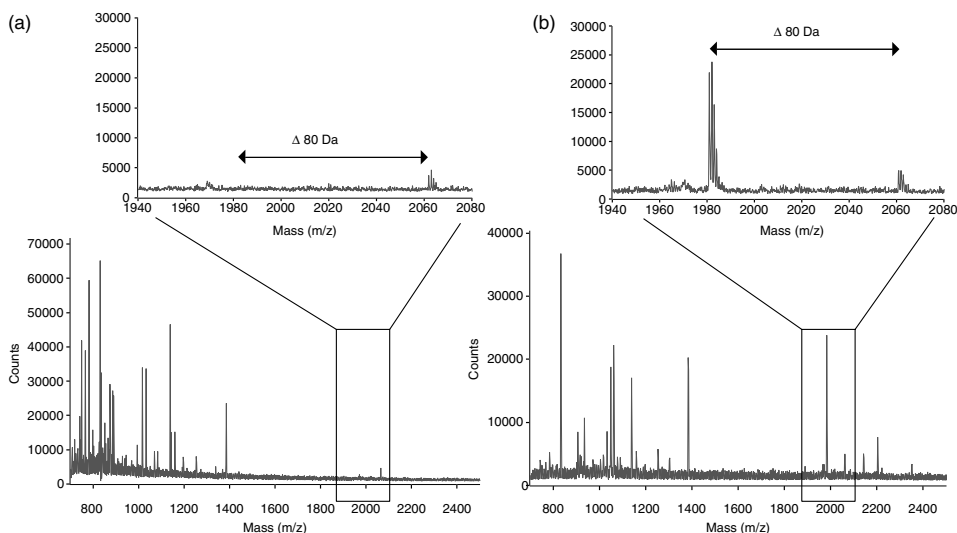

#### 49.3.5 MICROFABRICATED PROTEIN ARRAYS FOR MALDI-MS ANALYSIS

Microarray-based proteomics, where antibodies or other molecules that have been arrayed onto a surface to selectively capture proteins, has been presented and covered in a number of reviews.<sup>232–235</sup>

**FIGURE 49.10** Step-by-step illustration of the in-vial digestion protocol. (a) Enzyme pre-coating of the nanovial array by dispenser or pipette. (b) Dispensing of protein sample— instant digestion begins. (c) Dispensing of digestion buffer or water— prolonged digestion. (d) Digestion stops when let to dry— freeze-of-digestion. (e) MALDI-matrix deposition by dispensing (i) left or GELoader-tip (ii) capillary-and-pump (iii) right. (f) MALDI-TOF MS analysis. (Reproduced with permission from Ericsson, D., Ekstrom, S., Nilsson, J., Bergquist, J., Marko-Varga, G., and Laurell, T., *Proteomics*, 1, 1072–1081, 2001, copyright 2001, John Wiley & Sons.)

**FIGURE 49.11** In-vial dephosphorylation of  $\beta$ -casein. (a) Mass spectra obtained from the untreated  $\beta$ -casein and (b) mass spectra obtained from a nanovial containing  $<10$  fmol  $\beta$ -casein after microdispensing of alkaline phosphatase (0.1 unit/ $\mu$ L) in 50 nM  $\text{NH}_4\text{HCO}_3$ , pH 7, 8 at 6 Hz for 60 s (corresponding to 36 nL alkaline phosphatase). During this treatment the entire target plate was heated to  $40^\circ\text{C}$ . The deposited enzyme was then allowed to dry for 5 min followed by microdispensing of 10 nL matrix. The marked peak in (b) shows the dephosphorylated peptide that is generated by the loss of a phosphate group from the marked peak in (a) by the enzymatic treatment. (Reproduced with permission from Ekstrom, S., Nilsson, J., Helldin, G., Laurell, T., and Marko-Varga, G., *Electrophoresis*, 22, 3984–3992, 2001, copyright 2001, John Wiley & Sons.)

**FIGURE 49.12** Mass spectra generated using a micro chip coated with a scFv antibody fragment (CT-17) specific for cholera toxin. The chip was first allowed to react with a protein mixture before being washed. Mass spectroscopy spectra were performed before (a) and after washing (b). (Reproduced with permission from Borrebaeck, C. A. K., Ekstrom, S., Hager, A. C. M., Nilsson, J., Laurell, T., and Marko-Varga, G., *Biotechniques*, 30, 1126, 2001, copyright 2001, Eaton Publishing.)

The MALDI-MS “spot-on-a-chip” sample preparation platform has been applied to protein array experiments, by microdispensing of a recombinant single-chain variable fragment (scFv) antibody specific for cholera toxin onto a nitrocellulose-coated nanovial array chip<sup>236</sup> (Figure 49.12). This concept has later been considerably expanded by use of porous silicon as an arraying substrate by Ressine et al.<sup>237–239</sup> The implementation of microfluidic array-based antibody assays to MALDI-MS has a huge potential both as a biomarker discovery tool and for in-depth investigation of the biological mechanisms of known antigens.

#### 49.3.6 APPLICATION OF SOLID-PHASE EXTRACTION SAMPLE PREPARATION BEFORE MALDI-MS

To make any MALDI microspot technique (e.g., the “spot-on-a-chip” method) to work optimal, the sample has to be devoid of contaminants. Purification and enrichment of proteins and peptides is conveniently performed by SPE. Previously, standard commercial SPE options for miniaturized SPE<sup>240</sup> or tips packed with beads<sup>151,152</sup> were used for purification and enrichment before the “spot-on-a-chip” sample preparation. These methods lacked the desired sensitivity, reproducibility and integration possibilities for large scale proteome analysis. To enable integrated sensitive, high-throughput SPE, a silicon microfabricated extraction chip (SMEC) was developed. The manufacturing and investigation of this silicon microextraction chip for sample cleanup and trace enrichment of peptides was investigated using both standard samples and samples derived from 2-DE separations.<sup>164</sup> The SMEC structure used a weir structure to trap reversed-phase chromatography media (Poros™ R2 beads) that facilitated a flow-injection-based methodology for sample purification/enrichment of contaminated and dilute samples before the MALDI-MS analysis (Figure 49.13).

The SMEC design was also optimized with regard to microfluidic properties by replacing the weir with a grid structure, in another publication (not included in this thesis) by Bergkvist et al.<sup>163</sup> This improved design (Figures 49.14 and 49.15) was evaluated both numerically and experimentally.

The intended use of the SMEC chip was to enable SPE followed, by “spot-on-a-chip” sample preparation and integration with microdispensing. Despite considerable efforts to realize this, it could not be implemented satisfactorily. The problems were inherent in the microfluidic design. The pressure-driven flow-injection-based methodology for SPE (Figure 49.13) was negatively affected by air-bubble formation, due to the high back-pressure across the bead-trapping structure. These air bubbles made integration with the microdispenser awkward, since they were trapped in the microdispenser and provided a compliance that absorbed the pressure pulse generated by

**FIGURE 49.13** The instrumental setup used for the SMEC sample cleanup/enrichment. (Reproduced with permission from Ekstrom, S., Malmstrom, J., Wallman, L., Lofgren, M., Nilsson, J., Laurell, T., and Marko-Varga, G., *Proteomics*, 2, 413–421, 2002, copyright 2002, John Wiley & Sons.)

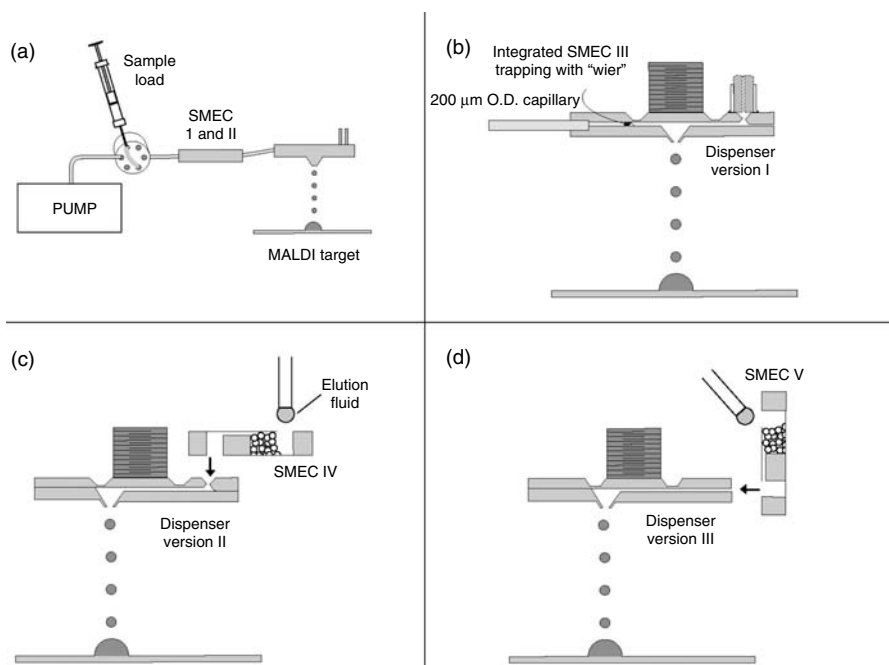

**FIGURE 49.14** Schematic drawings of the (a) weir-SMEC and (b) the improved grid-SMEC structures. (Reproduced with permission from Bergkvist, J., Ekstrom, S., Wallman, L., Lofgren, M., Marko-Varga, G., Nilsson, J., and Laurell, T., *Proteomics*, 2, 422–429, 2002, copyright 2002, John Wiley & Sons.)

the piezo-actuation (Figure 49.16a). This could be minimized by degassing all solutions used in the system. A microdispenser with integrated SPE bead trapping was manufactured and tested (Figure 49.16b) but long-term operation was still a problem. Furthermore, aspects of carryover from the solid-phase bed were not readily solved in such a setup and repeated use would inherently alter the binding capacity and flow resistance of the packed bed with time. If the microextraction

**FIGURE 49.15** SEM photograph of the improved grid-SMEC structure. (Reproduced with permission from Bergkvist, J., Ekstrom, S., Wallman, L., Lofgren, M., Marko-Varga, G., Nilsson, J., and Laurell, T., *Proteomics*, 2, 422–429, 2002, copyright 2002, John Wiley & Sons.)

**FIGURE 49.16** Schematic pictures of some different designs that were investigated in the study, (a) and (b) used the FIA methodology that later was abandoned. The first generation of the modular capillary filling SPE system (c) having the fluid inlet on the top of the dispenser had problems with capillary filling being erratic and the second generation (d) having the inlet on the side of the dispenser chip, in the central pin.

chip has to be exchanged for each sample in a FIA setup, automation efficiency is severely affected and the fluidic operations are also inherently time consuming.

A more attractive approach would be to enable a parallel mode operation, while avoiding pressure-driven flow. To accomplish this, it was decided to develop a modular capillary force-driven system. This was not a straightforward task and a number of designs (shown in Figure 49.16) had to be manufactured and tested before arriving at the design presented (Figure 49.16d).

**FIGURE 49.17** Process steps in preparing microextraction array. (Reproduced with permission from Wallman, L., Ekstrom, S., Magnusson, M., Bolmsjo, G., Olsson, M., Nilsson, J., Marko-Varga, G., Laurell, T., *Measurement Science & Technology*, 17(12), 3147–3153, 2006, copyright 2006 Iop Publishing.)

**FIGURE 49.18** Operational setup of the final microsystem. The dispenser is docked to one outlet of the extraction array and elution fluid is applied at the SMEC inlet. The eluted analyte is subsequently dispensed onto the MALDI target. The total time for one cycle (one position) was less than 1 min. (Reproduced with permission from Wallman, L., Ekstrom, S., Marko-Varga, G., Laurell, T., and Nilsson, J., *Electrophoresis*, 25, 3778–3787, 2004, copyright 2004, John Wiley & Sons.)

The final design presented shown in Figure 49.16d was a solid-phase microextraction system that performed the sample enrichment and cleanup with the packed microbead bed in an array chip format, offline, and using low pressure to aspirate the sample as well as the washing fluid through the chip (Figure 49.17).

The SPE array chip is then transferred to a robotic station where displacement of the sample from the solid phase is performed by adding a droplet of elution fluid to the extraction chip inlet, which

subsequently is drawn by capillary forces through the packed bed to the chip outlet. A newly designed microdispenser with a capillary inlet is docked to the microextraction chip outlet, whereby capillary forces pull the eluted sample automatically into the dispenser. The elution front contains the enriched sample, which thus can be transferred by microspotting onto a MALDI target (Figure 49.18). This system avoided the drawbacks of the flow-injection-based methodology and in an evaluation study, it outperformed two commercially available SPE techniques.<sup>166</sup>

The modular capillary force-driven system resulted in an automated workstation for SPE before MALDI-MS analysis. While miniaturization has the prerequisites for optimizing the SPE process and provides the desired parallelization and sensitivity, it can often lead to quite complicated design solutions that are expensive produce, and requires specialized robotics for sample delivery/transfers since interfacing the microworld to the macroworld is not a trivial task in the laboratory. As an alternative to the modular capillary force-driven SPE system, a less complex solution was developed. The least complex solution would be to integrate the SPE with the MALDI target. Solutions for on-target SPE have been presented in literature and are commercially available. Other options are the microtiterplate-based SPE as presented by Nissum et al.<sup>157</sup> and the ZipPlate. On the basis of this knowledge and our previous efforts, it followed that a miniaturized device that incorporated the vacuum-driven flow-through approach of the microtiterplate SPE devices with a minimum of sample transfers and the final elution as a small analyte spot on the same device would have great potential for SPE before MALDI-MS. The first design of such a device utilized a sieve structure for the bead trapping. These initial experiments showed huge promise, but the eluted MALDI spot became large ( $>2$  mm); elution was difficult to control and beads were not securely trapped. Therefore a new design comprising of a single outlet that retained the beads either due to the beads being larger than the outlet or by the key-stone effect.<sup>241</sup> This device was named Integrated Selective Enrichment (ISET). The ISET serves as both a sample treatment device and MALDI-MS target, and contains an

**FIGURE 49.19** Workflow when using the ISET, (a) sample, (b) wash, and (c) elution is drawn through the media by a applying a vacuum underneath the ISET. After elution, the analytes forms a spot (0.5–1 mm) on the analysis zone surrounding the outlet. After elution the ISET is turned up side down and the analyte positions are subjected to analysis (d). (Reproduced with permission from Ekstrom, S., Wallman, L., Hok, D., Marko-Varga, G., and Laurell, T., *Journal Proteome Research*, 5, 1071–1081, 2006, copyright 2006, American Chemical Society.)

array of 96 perforated nanovials, which can be filled with approximately 40 nL of reversed-phase beads. The workflow for ISET sample preparation is described in Figure 49.19. Liquid transport is achieved by placing the ISET in a vacuum fixture. Samples can then be loaded either by incubating the beads in the sample solution and subsequently transfer the beads to the perforated nanovials or the sample solutions can be drawn through array positions prefilled with beads. After capture, contaminants are removed by drawing a washing solution through each position; in the case of SPE, the final elution can then be performed with acetonitrile solution including the matrix. MALDI spot sizes of  $\sim 500 \mu\text{m}$  are achieved by control of the elution volume and the applied vacuum. The spot size can be further reduced, with improved sensitivity, by making the analysis zone on the ISET hydrophobic. The ISET sample preparation minimizes the number of sample transfers and the total surface area available for undesired adsorption of the analytes in order to provide high-sensitivity analysis.

Examples of ISET sample preparation protocols used for SPE are given below.

#### **Protocol for Transfer of Analytes while Being Bound to Beads**

1.  $1 \mu\text{L}$  of a suspension of Poros R2 beads in 50% ACN/0.1%TFA was added to the sample (acidified with TFA) while stored in an external container (e.g., a microtiterplate). The analytes (peptides) were allowed to bind for at least 30 min.
2. The beads, with the captured analytes, were transferred to the ISET by aspiration of  $5 \mu\text{L}$  sample/beads from the bottom of the sample container and loaded into the perforated nanovials under maximum vacuum ( $-600$  to  $-800$  mbar as measured at the gauge).
3. Wash with  $2 \times 3 \mu\text{L}$ , 0.1% TFA, under maximum vacuum, followed by removing the ISET from the vacuum fixture and rinsing the entire backside with Milli-Q water (i.e. ultrapure water) (MQ).
4. Elution of the analytes onto the backside of the ISET with  $2 \times 0.3 \mu\text{L}$ , 50% ACN/0.1%TFA containing 1 mg/mL of cyano-4-hydroxy-cinnamic acid and ACTH 18–39/ $\mu\text{L}$  (internal calibrant). The elution was done at a lower vacuum (approximately  $-100$  mbar).

#### **Protocol for ISET Sample Preparation with Prefilled Beads**

1. Each perforated nanovial was filled with approximately 40 nL Poros R2 beads in 50% ACN/0.1%TFA, at maximum vacuum.
2.  $5 \mu\text{L}$  of acidified sample was applied to each position and drawn through the bead volume by applying maximum vacuum.
3. Wash with  $2 \times 3 \mu\text{L}$ , 0.1% TFA, under maximum vacuum, followed by removing the ISET from the vacuum fixture and rinsing the entire backside with MQ.
4. Elution of the analytes onto the backside of the ISET with  $2 \times 0.3 \mu\text{L}$ , 50% ACN/0.1%TFA containing 1 mg/ml of cyano-4-hydroxy-cinnamic acid and ACTH 18–39/ $\mu\text{L}$  (internal calibrant). The elution was done at a lower vacuum (approximately  $-100$  mbar).

The ISET technology has been successfully applied for characterization of proteins coisolated by affinity chromatography of prostate-specific antigen (PSA) from human seminal fluid<sup>165</sup> and subjected to a more thorough study of the performance, when used for SPE of peptide samples, including a favorable performance comparison with some of the commercially available SPE techniques.<sup>167</sup> The main advantage of the ISET platform is the generic microfluidic approach to sample cleanup and enrichment in a high-throughput format with a very high performance. In addition, the platform is a very cost-effective alternative to existing sample preparation strategies. The ISET platform can be used to address several needs in the field of MS, based on life science research and circumvents many of the problems associated with miniaturized SPE, as the uncomplicated design minimizes sample transfers and makes custom robotics unnecessary.

## 49.4 CONCLUSIONS

When introduced the word proteomics was used to describe the ambitious goal of cataloging the proteins in different organisms. Today there are many more meanings and the field of proteomics has been differentiated considerably, with subdivisions such for, structural proteomics, clinical proteomics, and so forth.

In addition to the proteomics techniques described here, which by no account can be claimed to be representing all the flavors of proteomics, there are numerous others. Examples of novel technologies that are highly interesting but not mentioned earlier is protein–protein interaction analysis by the yeast two-hybrid system,<sup>242,243</sup> and tandem affinity purification (TAP).<sup>244</sup> Currently strong emerging field of proteomics is clinical proteomics and biomarker analysis (*Journal of Proteome Research*, Special Biomarker Issue, Vol. 4: August 2005), where the goal is to discovery proteins with medical relevance and their pathophysiological implications. An interesting MALDI-MS technique for biomarker discovery is the tissue imaging methodology developed by Caprioli and coworkers.<sup>245</sup>

Despite the fact that mRNA and protein expression have been shown to differ from predicted values,<sup>246</sup> it is also foreseeable that the information about the proteome obtainable from the transcriptome, that is, by looking at the mRNA present via cDNA microarray analysis, will be expanded as systems biology matures.<sup>247</sup>

The sheer amount of methodologies in the field of proteomics can be grasped by the fact that a topic search using the search words such as “proteomics or proteome or proteomic” in the Web of Science® database returns 12081 publications (*search done 2005-10-27*). The huge amount of publications does by no means imply that there is no room for improvement. The application of microfluidics to proteomics analysis is still in its infancy and as the detection technologies becomes even more sensitive the ability to handle minute sample amounts will become paramount for continued progress.

The development of new technology and methodology in both proteomics and microfluidics, as well as an increased merging of the two fields, guarantees that the future holds bright promise for new routes. This will lead to improved bioanalytical performance and pave the way to better understanding of biological processes and disease pathogenesis.

## 50.1 INTRODUCTION

The capillary format has proven to be ideal for separations requiring an applied electric field. The micrometer-dimensioned capillary cores facilitate the analysis of smaller, nanoliter-sized samples, which in turn means higher separation resolution and much shorter separation times. Reduction of column diameters means a commensurate reduction in detection volumes, however, making detection of low analyte concentrations even more challenging as numbers of analyte species available for detection are decreased. Sample preconcentration methods are thus required to compress more analytes into smaller volumes to improve detection limits.

This report gives an overview of the sample preconcentration techniques which have to date been implemented in microfluidic devices. Some of these techniques originate from the conventional capillary electrophoresis (CE) and high performance liquid chromatography (HPLC) world and are quite recognizable despite incorporation into a miniaturized format. Other techniques are brand new, having been enabled by the access to micro- and nanofluidics that new fabrication technologies provide us. Interestingly, recent reviews that appeared while this chapter was in preparation categorize available on-chip preconcentration methods in much the same manner as we do, in terms of electrokinetic

preconcentration, surface extraction, and similar nanofilter and membrane approaches,<sup>1,2</sup> The reader is advised to consult these and other papers for more comprehensive overviews of what has appeared in the literature over the past few years. We have opted to focus more on describing the mechanisms underlying various methods, and how these methods have been realized practically in terms of device. This chapter does not, however, provide an in-depth “how-to” instruction manual for implementing these techniques in microfluidic devices. However, we hope that the information given here will be enough for the reader to be able to decide what approach may be best suited to his or her problem.

## 50.2 ELECTROKINETIC PRECONCENTRATION TECHNIQUES

Fortunately, applied electric fields can be very effectively exploited not only for separation but also for on-line sample preconcentration in capillaries, as evidenced by a number of well-established electrokinetic preconcentration techniques for CE (see, for instance, Chapters 13 and 19 of this book for more details).

The microfluidic chip format may not directly resemble the capillary format, but certainly the microchannels that make up microfluidic networks have inner dimensions that are comparable to capillaries. Electric fields can thus be used just as effectively in microchips to perform CE and similar types of separations. Generation of EOF has also proven to be the most popular mechanism to date by which fluids are moved through microchannels. On the flip side, detection of low concentrations in small volumes is as great or an even greater issue in chips. As a result, sample preconcentration methods for electrokinetically driven microdevices have received significant attention in the past few years. The transfer of existing electrokinetic preconcentration techniques to the microchip format is an obvious approach, given the similarity in system inner dimensions and the fact that CE had already been successfully realized in chips. In addition, some new approaches have been developed in the last decade, enabled by micro- and nanotechnologies. This section will investigate further how a number of these techniques have been implemented in a microfluidic format.

### 50.2.1 FIELD-AMPLIFIED SAMPLE STACKING (FASS)

Field-amplified sample stacking (FASS) is a preconcentration technique which is commonly used in CE. The technique was first mentioned by Mikkers et al.<sup>3</sup> in 1979 and has been intensively studied by Burgi and Chien et al.<sup>4–6</sup> In 1995, Jacobson and Ramsey<sup>7</sup> reported the first FASS experiment on a microchip.

To achieve a preconcentration of the sample with FASS, the sample is diluted in a buffer which has a much lower conductivity ( $\sigma$ ) than the surrounding run buffer used for the separation. In FASS, the high- and low-conductivity buffers differ only in concentration (which is related to the ionic strength and thus the conductivity), to overcome problems due to unwanted electrodispersion, which could occur when two buffers with different chemical compositions are introduced.

The introduction of a low-conductivity sample plug into higher-conductivity run buffer results in the local variation of the applied electric field, with a higher electric field in the sample segment than in run buffer segments. The relationship between the electric field and the conductivity is given by

$$E = \frac{I}{A\sigma} \quad (50.1)$$

where  $I$  is the electric current running through the channel,  $A$  is the channel cross-sectional area, and  $\sigma$  is the conductivity of the buffer. Since the current running through any given section of the

**FIGURE 50.1** (a, b) Schematic view of on-chip FASS and (c) the general chip layout used for FASS. (a) Anionic and cationic sample ions are introduced into the injection region (b) and on application of an electric field along the separation channel, sample ions exit the low-conductivity region and enter the high-conductivity region.

microchannel will be the same, a decrease of  $\sigma$  in a certain segment will result in a larger electrical field in that segment in relation to the rest of the system.

The FASS stacking phenomenon is schematically shown in Figure 50.1a and b, in a sample plug that has been formed at a double-T injector. Since the electrophoretic velocity of charged molecular species is proportional to the applied electrical field (see Chapter 1), species migrate faster in higher applied electric fields. In the amplified electric field within the sample plug, both cations and anions migrate with increased velocity, the former toward the negative electrode and the latter toward the positive electrode (see Figure 50.1b). When the ions encounter a sudden drop in electric field strength at the sample-run buffer boundaries, their electrophoretic velocity decreases sharply and they are focused into narrow zones at the boundaries of the sample plug. These zones subsequently migrate into the surrounding run buffer and are separated by CE (not shown). As Figure 50.1b shows, an initial separation of cations from anions is achieved in the stacking process.

There are several different strategies for realizing sample stacking on microfluidic devices. The simplest involves the injection of a sample dissolved in low-conductivity buffer into a high-conductivity buffer stream, employing either volume-defined injection<sup>8–12</sup> or gated injection.<sup>7,13</sup> A commonly used channel geometry for volume-defined injection is shown in Figure 50.1c. Known as a “double-T” injector device,<sup>14</sup> the injection loop that defines the volume to be analyzed is the channel located between the sample and sample-waste reservoirs, labeled “injection channel” in this figure. The injection channel is filled with sample diluted in a buffer with low conductivity by applying an electric field between the sample and sample-waste reservoirs. The analytes are focused and separated in the separation channel by applying a potential between the buffer and buffer-waste reservoirs. A number of different variations of this type of injection geometry have been employed for FASS on chip.<sup>8–10,12</sup> Gated injection is carried out in so-called “cross layouts,” at the intersection of two channels laid out in the form of a cross. The volume of sample injected is defined by the amount of time the sample is allowed to enter the separation channel.<sup>7</sup>

**FIGURE 50.2** Comparison of microchip CE of two fluorescently labeled amino acids (10  $\mu\text{M}$  Ser and Gly) with ( $\gamma > 1$ ) and without ( $\gamma = 1$ ) sample stacking. Separation conditions: separation length, 7.5 cm; electric field, 460 V/cm; run buffer, 32 mM carbonate at pH 9.6. (From Lichtenberg, J., et al., *Electrophoresis*, 22, 258, 2001. With permission.)

**FIGURE 50.3** Signal gain (peak height) as a function of relative conductivity for a high-conductivity (32 mM carbonate, pH 9.6) and medium-conductivity (100 mM Tris/20 mM boric acid, pH 9.1) buffer. Analyte: glycine. Experimental conditions as in Figure 50.2. (From Lichtenberg, J., et al., *Electrophoresis*, 22, 258, 2001. With permission.)

Ideally, the stacking effect is only due to the conductivity differences between the sample and run buffers. This means that the relative conductivity is the most important factor for FASS. The relative conductivity ( $\gamma$ ) is given by

$$\gamma = \frac{c_r}{c_s} = \frac{\sigma_r}{\sigma_s} = \frac{E_s}{E_r} \quad (50.2)$$

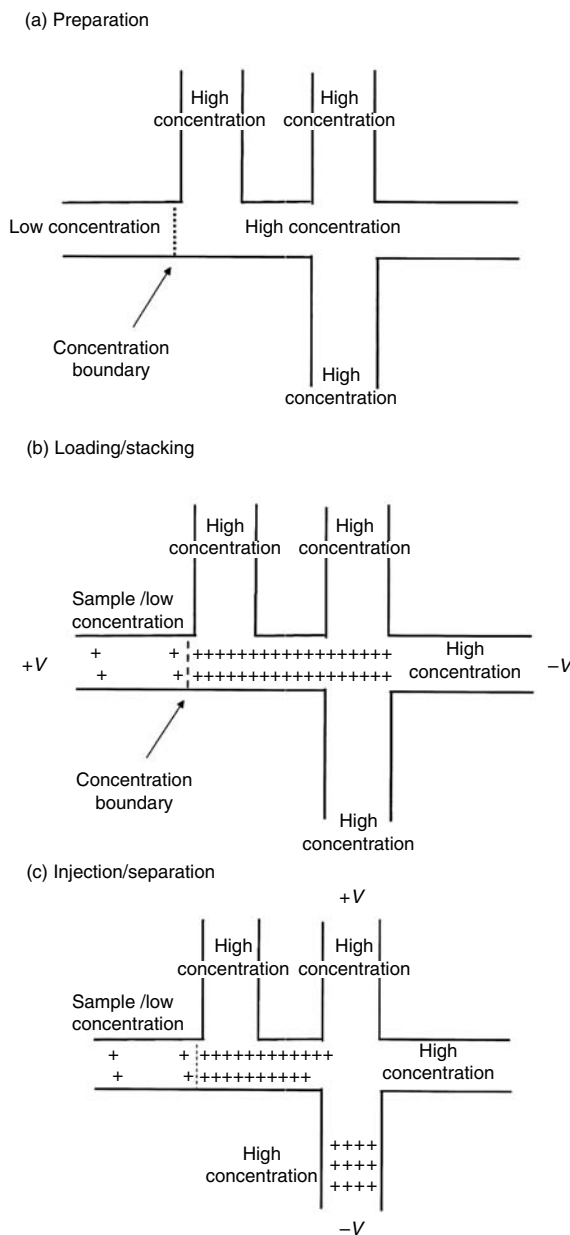

**FIGURE 50.4** Schematic of FASS on a microchip demonstrated by Yang and Chien.<sup>16</sup>

where  $c_r$  and  $c_s$  are the buffer concentrations for the run buffer and the sample buffer, respectively.  $\sigma_r$  and  $\sigma_s$  are the conductivities of the two buffers and  $E_s$  and  $E_r$  are the electric field strengths in the two buffers. According to the theory, the peak height of the analytes should increase by a factor  $\gamma$  and the peak width should decrease by a factor  $\gamma$ . Unfortunately, this is not fully true, as Figures 50.2 and 50.3 show. The rate at which peak height increases as a function of  $\gamma$  is relatively constant up to  $\gamma = 10$  or so, in accordance with other reports.<sup>7,13</sup> However, for  $\gamma$  greater than 10, this rate decreases steadily, until it levels off at values of  $\gamma$  of 400 or so in this case.<sup>8</sup> This is a result of the generation of additional flow effects when conductivity differences are large, due to the electroosmotic flow (EOF) in the sample buffer being higher than in the run buffer. Due to this mismatch of EOFs, a backpressure will be generated in the channel as the sample plug attempts to displace the slower moving buffer both in front and behind it. The appearance of this backpressure results in dispersion of the stacked zone, and a loss of peak height as a result.<sup>4,15</sup> This means there is a trade-off between the optimum relative conductivity and the appearance of peak broadening. The effect of relative conductivity on the signal gain is discussed by Lichtenberg et al.<sup>8</sup> for FASS on a microchip, and by Burgi and Chien<sup>5</sup> for FASS in conventional CE.

Yang and Chien<sup>16</sup> have reported FASS on a microchip with a 100-fold increase in signal concentration. In the described experiment, the walls of the channels were coated with an acrylamide polymer layer to eliminate EOF. This coating minimizes the problems associated with the mismatch of EOF and results in a concentration boundary, which is stationary except for dispersion caused by diffusion. An optimized chip layout used by Yang and Chien for static sample stacking is given in Figure 50.4. The steps required to achieve stacking are depicted in Figure 50.5. Interesting in this example is that flow control in the channels is accomplished by controlling the pressures rather than the voltages applied at all the reservoirs, using an instrument especially designed for this purpose. Yang and Chien demonstrated a 100-fold increase in signal at a theoretical relative conductivity of 200. Yang and Chien provide a thorough “how-to” description of the conditions used for their experiments and details of chip operation in Reference 16.

The stacking approaches described up to this point are all based on the preconcentration of analytes in relatively small volumes of sample. For trace analysis applications, such small samples often will not contain enough analyte molecules for detection, even after stacking. Several researchers have, therefore, explored how to introduce and stack larger samples in microfluidic devices. Lichtenberg et al.<sup>8</sup> reported a field-amplified stacking method with a long channel for large-volume stacking. A schematic layout of the chip along with a depiction of its operation are shown in Figure 50.6.

**FIGURE 50.5** Operation of FASS device in which EOF has been eliminated through deposition of a polymer coating onto microchannel walls. In Step (a), a concentration boundary is formed between high- and low-conductivity solutions by filling the various channels with the appropriate solutions. In Step (b), a voltage is applied in the horizontal direction to load sample from the left. Stacking occurs at the concentration boundary, as shown. In Step (c), a voltage is applied along the vertical (separation) channel. A well-defined portion of the stacked sample plug is injected in the downward direction and separated. (From Yang et al., *J. Chromatog. A*, 924, 155, 2001. With permission.)

**FIGURE 50.6** Schematic diagram of a chip layout with a long preconcentration (“stacking”) side channel (7.5 cm) used by Lichtenberg et al.<sup>8</sup> The operation of the device is also outlined in this figure. All flows were controlled electrokinetically. In this particular example, anions are stacked at the stacking buffer-sample boundary, as this boundary is pushed back toward the injection intersection. (From Lichtenberg et al., *Electrophoresis*, 22, 258, 2001. With permission.)

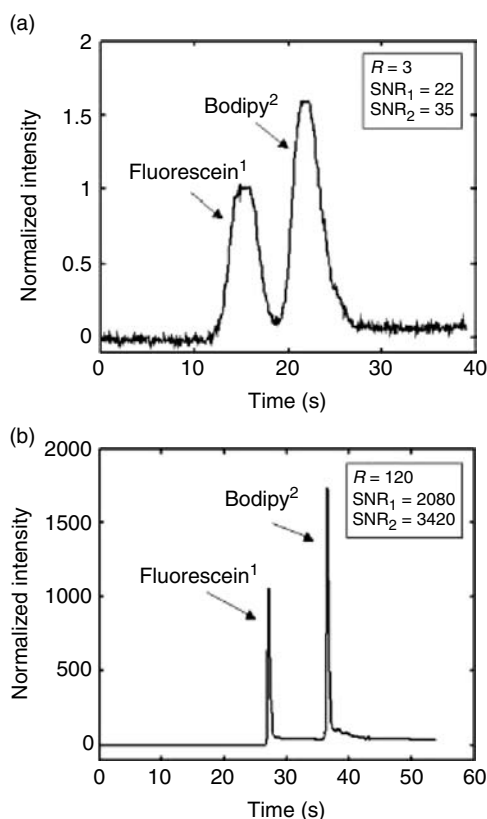

By applying a voltage between the sample inlet and the stacking waste, the long stacking channel is filled with sample diluted in a low-conductivity buffer. When the channel is filled with sample, the electric field is reversed, and a potential difference is applied between the stacking buffer and the sample waste. The high-conductivity stacking buffer ensures that the anions are concentrated in the stacking channel. With this setup, a much higher sample volume can be injected, so more analytes can be focused and a higher sensitivity achieved. The focused sample plug is brought into the injection channel and, by applying a voltage between the buffer and the buffer waste, injected into the separation channel.

One possible limitation with this setup is that only cations or anions can be injected into the separation channel. However, this could also be an advantage if only one of the two is of interest. With this particular chip, a 65-fold increase in sample concentration can be obtained with an injection plug length of 7.5 cm. The effect of injection plug length on sensitivity is also reported by Burgi et al.<sup>5</sup> for FASS in conventional CE and by Beard et al.<sup>11</sup> for FASS on chip.

In the examples discussed earlier, conductivity gradients between sample and run buffers are established through use of electrokinetic flows to bring the different solutions into contact with one another for subsequent stacking. In addition to the adverse pressure-driven flow (PF) effects that can arise, dispersion of the stacked zones can also be caused by electrokinetic flow instabilities that occur in electrokinetically driven flow systems with high-conductivity gradients. Excessive dispersion at buffer–buffer interfaces can result. To overcome this problem, Jung et al.<sup>12</sup> recently reported a new chip layout incorporating a porous polymer plug between buffers of differing conductivity. The layout of the chip is shown in Figure 50.7. The high flow resistance of the plug allows the introduction

**FIGURE 50.7** Schematic view of the chip layout that is used by Jung et al. [12]. The porous plug is made by photopolymerization of methacrylates and has a median pore diameter of about 4.6  $\mu\text{m}$ . Length of the plug, 500  $\mu\text{m}$ .

**FIGURE 50.8** Electropherograms of fluorescein and BODIPY separations. (a) Electropherogram of analytes in a CE separation and detection performed without stacking: conductivity ratio,  $\gamma$ , of unity. (b) Stacked CE electropherogram for a conductivity ratio,  $\gamma$ , of 1290. The differences in electromigration times are due to the effects of FASS. The signal increase is 1100-fold for the stacked case, and resolution increases from 3 to 120. (From Jung et al., *Electrophoresis*, 24, 3476, 2003. With permission.)

of the required buffers on either side of the plug using syringe pumps without any mixing, while electrical contact is maintained between the different solutions. In this way, a conductivity gradient may be established without the use of electrical fields and the attendant dispersion at the buffer–buffer interface. Volume-defined injection of sample in a low-conductivity buffer can then be performed electrokinetically, with subsequent stacking and separation in the horizontal separation channel.

Furthermore, sample dispersion during the FASS-CE process is reduced by coating microchannel walls with methylcellulose to suppress EOF. The preconcentration factors attainable using this approach are excellent, with a concentration increase of 1100-fold reported for two fluorescent dyes (Figure 50.8).

Field-amplified sample injection (FASI) is a variation of FASS which can lead to very high-sensitivity enhancements on the order of several thousand in conventional CE.<sup>17</sup> To perform FASI of anionic analytes, a plug of very low-conductivity solution such as water is introduced between the run buffer and the sample, which is injected last at the capillary inlet. The application of a reversed polarity voltage (EOF toward inlet) then results in sample anions rapidly migrating through the water to stack at the buffer interface, while water is pumped out of the capillary at the inlet. Subsequent reversal of the polarity allows the stacked analytes to be carried down the capillary and separated, to be detected near the outlet. FASI has recently been successfully implemented in microfluidic devices by Gong et al.<sup>17</sup> and Shiddiky et al.<sup>18</sup> The former group managed signal gains between 90 and 160 for fluorescent dyes using a very simple cross layout. The latter group combined a FASI step (signal enhancement of about 1000) with a preceding FASS step (signal enhancement of 5) to obtain a total gain of 5200 for detection of trace phenolics by micellar electrokinetic chromatography (MEKC).

Field-amplified stacking methods are only applicable to charged species. However, stacking of neutral species is possible if a micelle-containing run buffer is employed. Termed *sweeping*, this involves the injection of an analyte zone into a column of separation buffer containing a pseudo-stationary phase (micelles). On application of the electric field, the micelles are swept through the analyte zone, collecting analyte as they go, and resulting in a unique focusing effect. Charged species can also be preconcentrated in this way. When first described,<sup>19</sup> preconcentration factors of several thousand-fold were achieved. In a recent variation of sweeping, sensitivity increases approaching 1,000,000-fold have been reported.<sup>20</sup>

A few examples of sweeping implemented on microchips have appeared in the literature. One approach, reported by the Landers and coworkers<sup>21,22</sup> for both capillaries and microchips, involves the addition of salt (e.g., NaCl) to the sample matrix to increase its conductivity to levels 2–3 times higher than the run buffer. The latter typically contains negatively charged micelles of sodium dodecyl sulphate (SDS) or sodium cholate. The result is a substantial drop in electric field strength at the sample plug-run buffer interfaces, and a field amplification effect analogous to FASS. In this case, it is the negatively charged micelles, with electrophoretic mobilities counter to the EOF that stack at the cathodic interface of the sample plug and the buffer. Analyte is collected and preconcentrated by the micelles as it is electroosmotically driven through this interfacial zone. The micelle zone is also effectively “locked” in place up against the higher concentration chloride, until this latter zone has diffused sufficiently to let cholate anions enter. Hence, a sharp interface is maintained for analyte stacking, which makes this type of stacking very attractive for electrokinetic injection of the sample. This technique lends itself very well to chip-based separation, with 20-fold peak height improvement being observed for an 80-s injection of a solution containing 67 nM BODIPY (Figure 50.9).<sup>21</sup> Sera et al.<sup>23</sup> have also reported increased sensitivity for the detection of fluorescent dyes using a sweeping technique, with signal gains of 90-fold for rhodamine B and 1500-fold for cresyl fast violet. More recently, Kitagawa et al.<sup>24</sup> reported the combination of sweeping with very sensitive thermal lens microscopy to achieve increases in sensitivity on the order of  $10^5$  to  $10^6$ .

### 50.2.2 ISOTACHOPHORESIS (ITP)

Isotachopheresis (ITP) was, like FASS, originally developed for CE, but it relies on zero EOF. ITP is a quantitative analytical separation technique in its own right, with a wide range of applications. It has also been successfully applied in conjunction with CE for both sample preconcentration and removal of highly abundant charged species, by coupling the ITP and CE columns. The first

**FIGURE 50.9** Electrokinetic stacking injection on a microchip. Sample: 67 nM BODIPY (a neutral fluorescent dye) in 150 mM NaCl. Run buffer: 80 mM sodium cholate, 10% ethanol, 5 mM tetraborate, pH 9. Sample was first injected by applying an electric field of 183 V/cm between the sample reservoir (S) and the outlet (O) for various periods of time as indicated in the figure. Separation was then carried out by applying 366 V/cm between the inlet (I) and outlet (O). An 80-s injection of 134 nM BODIPY in run buffer is included to show nonstacking injection. (From Palmer et al., *Anal. Chem.*, 73, 725, 2001. With permission.)

microfluidic device for ITP separation was reported by Walker et al.,<sup>25</sup> who demonstrated separation of the herbicides paraquat and diquat at submicromolar levels using Raman spectroscopic detection.

ITP extends the stacking concept of FASS to ternary buffer systems. In ITP, the sample is injected between a leading buffer (LE) and a terminating buffer (TE). The mobility of ions in the LE is larger than the mobility of the fastest electrolyte present in the sample, and the mobility of the ions in the TE is lower than the mobility of the slowest electrolyte present in the sample. Owing to the different buffer electrolyte mobilities, a mobility gradient is established between the two buffers. Applying a voltage results in separation of the different electrolytes in the sample between the LE and the TE in order of descending mobilities. Owing to a self-focusing mechanism governed by the Kohlrausch regulation function,<sup>26,27</sup> sharp analyte zones are achieved. This mechanism is based on the fact that ions diffusing out of an analyte zone are always recaptured due to the different field strengths in the neighboring zones. To illustrate this, consider an analyte ion that diffuses out of the front end of an analyte zone. It experiences a sudden drop of the electric field strength as the higher mobility ions in the neighboring zone provide less resistance to current flow. The escaped ion, therefore, slows down and is quickly reabsorbed into its particular analyte zone. The same reasoning is also valid for the back end of the analyte zone. The zone following the analyte zone contains lower-mobility ions, resulting in a higher electric field. Analyte ions diffusing into this zone will exhibit increased velocity back toward their own zone. The focusing effect in ITP for negatively charged analytes is schematically shown in Figure 50.10.

To perform ITP in the conventional format, three different solutions must be introduced sequentially into a fused-silica capillary, making ITP a technique that requires specialized instrumentation and expertise. Researchers have also successfully constructed coupled-column arrangements with capillaries to combine ITP and CE, but again, the attachment of capillaries to one another with

**FIGURE 50.10** Schematic of an isotachopheresis sample stacking process for negatively charged analytes. The sample is introduced between the terminating electrolyte and the leading electrolyte ( $t_0$ ). By applying a potential difference over the sample, the analytes start to migrate through the sample plug ( $t_1$ ). At a certain point ( $t_2$ ), small zones containing analytes with different electrophoretic mobilities have formed.

minimum dead volumes to form a robust network is not trivial. In contrast, the interconnected, branched microchannel networks of microfluidic devices are easily fabricated using microtechnologies, making this an attractive alternative for facilitated implementation of ITP and ITP-CE systems. While the first example of on-chip ITP employed only a single serpentine microchannel of uniform cross-section,<sup>25</sup> later examples that appeared starting in 2000 boasted more sophisticated designs. Kaniansky et al.,<sup>28</sup> Grass et al.,<sup>29</sup> and Bodor et al.<sup>30,31</sup> realized ITP on-chip with two coupled separation columns with on-chip conductivity detectors. An example of one of these devices is shown in Figure 50.11, along with an isotachopherogram of a sample containing 14 different anions. With this chip, it was also possible to extract a sample fraction containing focused low-concentration analytes from the ITP zone system and electrophoretically transfer them to the second column for separation by CE. In the process, high-concentration matrix constituents were left behind in the ITP region. This makes the technique very amenable for trace analysis in complex mixtures, where analytes present in high concentration would otherwise mask analytes present in low concentration.

The preconcentration factors or gains in signal that can be achieved with on-chip ITP can be quite spectacular, as will be discussed later. For a model ITP system, which consists of leading electrolyte ion ( $LE^-$ ), analyte ion ( $S^-$ ), trailing electrolyte ion ( $TE^-$ ), and a common leading counterion ( $LC^+$ ), an expression for the concentration adjustment between two zones in ITP can be derived as<sup>32,33</sup>

$$C_{S,final} = C_{LE} \frac{v_S (v_{LE} + v_{LC})}{v_{LE} (v_S + v_{LC})} \quad (50.3)$$

where  $C_{S,final}$  is the adjusted sample concentration and  $v$  is the linear velocity. From the derived equation, it can be seen that sample concentration,  $C_{S,final}$ , is proportional to the concentration of leading electrolyte. This effect was investigated by Jeong et al.,<sup>32</sup> who demonstrated a threefold improvement of the peak height when increasing the leading electrolyte concentration from 100 to 250 mM. The resolution between analytes for the experiment described by Jeong et al.<sup>34</sup> was reduced, however. The peak height increases with increasing LE concentration, but the time needed for efficient stacking also increases.

Jeong et al.<sup>32</sup> described an improvement in signal of 500-fold, using ITP as a stacking method to preconcentrate simple fluorescein electrolytes using 250 mM NaCl as leading electrolyte.

**FIGURE 50.11** (a) Schematic diagram of the PMMA ITP microchip used by Kaniansky et al.<sup>28</sup> and described in Reference 29. Chip dimensions: 2 cm × 7 cm. TE: terminating buffer reservoir (10  $\mu$ L); SL1: large sample loop (15  $\mu$ L); SL2: small sample loop (1.2  $\mu$ L); SC1: pre-separation column (1.2  $\mu$ L); SC2: analytical column (1.2  $\mu$ L); BF: bifurcation block; LE1, LE2: leading buffer reservoirs (15  $\mu$ L); D1: conductivity detector 1; D2: conductivity detector 2 (both these detectors consist of integrated thin-film Pt electrodes). There are a number of points in the system, indicated by vertical lines in the diagram, at which the different solutions required can be introduced to the various sample loops and separation channels using syringes or syringe pumps. (From Grass et al., *Sens. Act. B.*, 72, 249, 2001. With permission.) (b) An isotachopherogram for the separation of a 14-component model mixture of anions using concentration-cascade ITP. After an initial separation in SC1, the components were introduced to SC2 for a second ITP separation under different conditions, using D2 to monitor the separation. The injected sample contained the anions at 200  $\mu$ mol/L concentrations. Zone assignments: (LE) leading anion (chloride); (1) chlorate; (2) methanesulfonate; (3) dichloroacetate; (4) phosphate; (5) citrate; (6) isocitrate; (7) glucuronate; (8)  $\beta$ -bromopropionate; (9) succinate; (10) glutarate; (11) acetate; (12) suberate; (13) propionate; (14) valerate; (TE) terminating anion (capronate). (From Kaniansky et al., *Anal. Chem.*, 72, 3596, 2000. With permission.)

Wainright et al.<sup>35</sup> also showed a decrease in the limit of detection by a factor of 400 for samples containing fluorescent molecules having a range of electrophoretic mobilities. The chip designs used in these examples are similar to that in Figure 50.11a. In contrast, Jung et al.<sup>33</sup> demonstrated a million-fold increase in sample concentration using ITP performed in a simple cross layout of microchannels made in glass. The operation of this device, which also includes CE separation of the concentrated analytes, is shown in Figure 50.12. Figure 50.13 compares a CE separation of 100 nM concentrations of two fluorescent dyes with an ITP-CE separation of the same dyes but at 1 pM concentrations. The concentration increase and signal increase for Alexa Fluor 488 (first peak) are  $6.4 \times 10^4$  and  $4.5 \times 10^5$ , respectively. The best performance in this particular study was obtained for

**FIGURE 50.12** (a) Schematic of ITP/CE assay protocol. Configurations of co-ions are also shown at each step. (a) The upper and lower reservoirs are filled with LE, and the left reservoir is filled with a mixture of TE and sample. TE/LE boundary is formed by applying vacuum at the lower reservoir. White arrows show the direction of PF. (b) ITP stacking is initiated by applying high voltage and ground at the right and left reservoirs, respectively. The black arrow denotes the direction of electric field. (c) The field is switched toward the upper reservoir to inject LE ions behind the sample and initiate CE. ITP stacking continues until LE ions overtake the TE and sample ions. (d) Separation of samples occurs further downstream where sample ions electromigrate in nearly homogeneous LE electrolyte. (From Jung et al., *Anal. Chem.*, 78, 2319, 2006. With permission.)

an initial fluorescent dye concentration of 100 fM, for which a concentration increase of 2 million was observed, with a signal-to-noise ratio greater than 11. The same researchers later developed a high-sensitivity detection system in conjunction with this microfluidic ITP-CE approach, which allowed the detection of two fluorescent dyes in a sample having an initial concentration of 100 aM ( $10^{-18}$  M). With detected concentrations on the order of 15–20 pM, the concentration increase achieved by ITP was  $2.1 \times 10^5$  fold.<sup>36</sup>

Isotachopheresis as a sample preconcentration method is very useful for concentrating analytes in biological samples. A similar approach as described by Jeong et al.<sup>37</sup> was used for capillary gel electrophoresis of DNA fragments on microchips. Preconcentration of double-stranded DNA fragments based on isotachopheresis with a zone electrophoretic separation step has also been reported by Wainright et al.<sup>38</sup> HCl-imidazole buffer was used as leading electrolyte and HEPES-imidazole buffer as terminating buffer. An increase in detection sensitivity of 40-fold compared to standard chip zone electrophoresis was observed. The advantage of isotachopheresis, in contrast to field-amplified stacking, is the option of analyzing samples with a high salt concentration. However, it is not possible

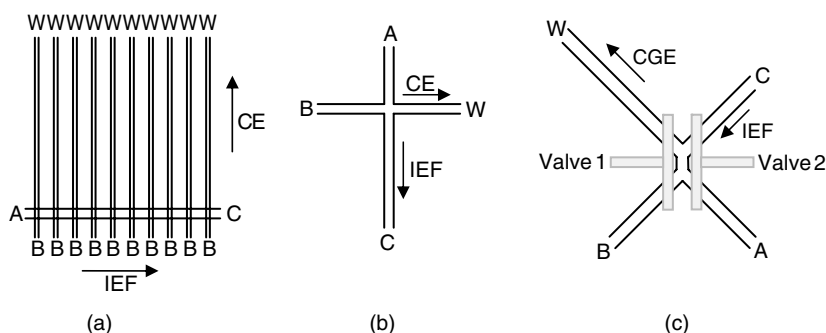

**FIGURE 50.13** Comparison of ITP/CE and CE separations of two fluorescent dyes Alexa Fluor 488 (first peak) and BODIPY (second peak). Inset electropherogram shows separation (with no stacking) of 100 nM initial concentrations of Alexa Fluor 488 and BODIPY. 5 mM HEPES was used as a background electrolyte and the applied electric field was 280 V/cm. For ITP/CE mode (main plot), initial concentrations of Alexa Fluor 488 and BODIPY were both 1 pM in 5 mM HEPES (i.e., diluted by a factor of  $1 \times 10^5$ ). Here, LE was 1 M NaCl and the nominal applied field was 220 V/cm. The concentration increase and signal increase for Alexa Fluor 488 (first peak) are  $6.4 \times 10^4$  and  $4.5 \times 10^5$ , respectively. (Reprinted from Jung et al., *Anal. Chem.*, 78, 2319, 2006. With permission.)

to concentrate anions and cations in the same run, and it is not possible to concentrate neutral species in their native form.

### 50.2.3 ISOELECTRIC FOCUSING (IEF)

One of the ways in which amphoteric molecules differ from one another is their isoelectric point (pI), the pH at which overall molecular charge is zero. In isoelectric focusing (IEF), a pH gradient is generated in a channel or capillary in either gel or free-solution form, and sample analytes are driven through this gradient by an applied electric field. The anode is located at the acidic end of the gradient and the cathode at the basic end. In most cases, the pH ranges from 3 to 10, a range that is established by filling the channel with an acidic compound (so-called anolyte) and a basic compound (so-called catholyte). Application of an electric field results in the formation of different buffer regions in the system. The analytes will travel through the capillary and become focused at the location in the gradient where the pH equals their pI. A molecule with a net positive charge, for example, will migrate in the increasingly basic gradient and gradually become less charged, until the point where the local pH corresponds to the pI of the molecule. At this point, the overall molecular charge is zero, and the molecule will cease to migrate in the applied electric field.<sup>39</sup> Since the majority of biological samples are amphoteric molecules, IEF is suitable for stacking many types of biological analytes. Chapter 19 in this book provides an excellent discussion on IEF in capillary systems.

IEF is the conventional method for protein separation in two-dimensional (2D) polyacrylamide gel electrophoresis and is considered one of the most powerful techniques available for separating proteins. However, IEF in gels is a time-consuming technique. Hjertén and Zhu,<sup>40</sup> therefore, adapted IEF to fused-silica capillaries, so-called capillary IEF (cIEF), to minimize analysis times. No gels are used in cIEF; instead, the capillary is filled with ampholytes in free solution to create the pH gradient. This technique is also called liquid-phase IEF. Additional advantages of cIEF are the potential for system automation and the possibility of on-line detection.

**FIGURE 50.14** Different chip designs for IEF coupled to CE. The chip with gel-filled microchannel used by Chen et al.<sup>45</sup> (a), the chip used by Herr et al.<sup>46</sup> (b), and the chip used by Wang et al.<sup>47</sup> (c). The first dimension (IEF) extends from reservoir A (analyte) to reservoir C (catholyte) and the second dimension from reservoir B (buffer) to reservoir W (waste).

Conventional IEF and cIEF are generally known as analytical separation techniques. However, IEF can also be used as a stacking or preconcentration technique, particularly when coupled to SDS-gel electrophoresis for protein analysis. Two-dimensional gel electrophoresis (2D-GE) has become one of the workhorses for the rapidly growing field of proteomics. The use of IEF as the first dimension provides typical preconcentration factors of between 50 and 100, in addition to excellent separation resolution.<sup>41</sup> The miniaturization and integration of 2D protein separations into microfluidic devices has attracted much attention recently, as such platforms would provide a significant reduction in analysis times. Column switching is also achieved much more easily in these devices. However, the goal of 2D-GE has proven to be elusive, due in part to the need for multiple separation media, which must be localized in different regions of a device.

There are a few early examples of IEF performed in microfluidic devices, including IEF of green fluorescent protein (GFP) in a plastic microchannel,<sup>42</sup> continuous concentration of bacteria in a microfluidic flow cell,<sup>43</sup> and microchannel IEF for protein separation and the study of protein–protein interactions.<sup>44</sup> However, the first published example of preconcentration of protein mixtures with IEF in gel-filled microchannels coupled to SDS-gel electrophoresis was reported more recently, by Chen et al. in 2002.<sup>45</sup> The device, formed in the elastomer, poly(dimethylsiloxane) (PDMS), consisted of several layers, containing both in-plane and vertical microchannels to form a 3D microfluidic system. A schematic diagram of the system layout is shown in Figure 50.14a. As this figure shows, IEF is carried out in a single channel first, to form a series of focused, separated zones. These zones are then transferred simultaneously to an array of microchannels, which are positioned in another level of the device and perpendicular to the IEF channel. A series of vertical holes ensures analyte transfer from one level to the next. Each zone then undergoes further separation by SDS-GE in an individual channel. In this example, the IEF gel was embedded by applying vacuum to one end of the PDMS microchannel to draw gel solution from a reservoir at the other end. Unfortunately, no factors for sample enhancement were given.

The device by Chen et al. required performing the IEF separation in one PDMS device first, then disassembling this to remove the enclosed IEF channel for reassembly in a second PDMS device also containing the microchannels for SDS-GE. Li et al.<sup>41</sup> reported a simpler device for 2D-GE having a layout again like that shown in Figure 50.14a, but formed by imprinting a single network of microchannels into a polycarbonate (PC) layer. This layer was sealed by a second PC layer into which a series of holes had been made to align with the microchannels. One of the main challenges with this device was controlling the local composition of media in the IEF and SDS-GE channels, which needed to be different for these two operations. The absence of integrated valves to close off one channel system from the other meant that it became more difficult to introduce a medium into one system without affecting the other. Two approaches were found to resolve this issue, however.

**FIGURE 50.15** Fluorescent images of on-chip 2D separation of five model proteins using multiple separation media. (a) Non-native IEF with focusing order of (i) actin; (ii) bovine serum albumin, ovalbumin, and trypsin inhibitor; and (iii) parvalbumin from left to right; (b) electrokinetic transfer of focused proteins; (c) SDS-gel electrophoresis. (From Li et al., *Anal. Chem.*, 76, 742, 2004. With permission.)

One involved simply using the same gel medium for both separations so that the entire chip was filled initially with the same gel and solution phase. The IEF solution was replaced after separation by flushing the SDS-GE channels with the SDS-containing buffer required for this separation. The second approach involved filling the entire chip with gel medium, followed by introduction of IEF solution medium into the IEF channel, thereby replacing the gel in this region. Figure 50.15 shows the layout of channels in the PC chip on the left. The images on the right show images of IEF focusing (panel A), electrokinetic transfer of proteins (panel B), followed by SDS-GE separation of the transferred proteins (panel C).

Herr et al.<sup>46</sup> reported the coupling of liquid-phase IEF with free-solution CE in an acrylic device using a simple cross layout of microchannels. The IEF channel was filled with a liquid pH gradient, by filling the buffer reservoir of the cathode with sodium hydroxide (pH 10) and the buffer reservoir of the anode with phosphoric acid (pH 3). The sample components were separated by their isoelectric points in the IEF channel and were mobilized to an intersection by EOF, where fluidic volumes were electrokinetically sampled into the CE channel. With this chip, an increase in sample concentration of 70-fold was obtained in a separation time of less than 1 min. A schematic view of the chip is given in Figure 50.14b. Images showing IEF of proteins and the intermittent sampling of the resulting zones for CE separation in the second dimension are shown in Figure 50.16.

A third approach for coupling IEF with capillary gel electrophoresis has been reported by Wang et al.<sup>47</sup> and is given in Figure 50.14c. Microfluidic valves based on a thin deformable PDMS membrane and pneumatic actuation<sup>48</sup> were integrated into this device. These valves could be operated in such a way as to physically separate the two separation systems and prevent mixing between the different buffers used. The sample was first focused in the IEF channel. When the analyte of interest entered the transfer region, both valves were closed in order to trap the analytes. After opening valve 1, the trapped analytes were guided into and separated in the gel electrophoresis channel. With the two valves, very controllable flows were obtained. The advent of integrated valving has meant new options for researchers developing microfluidic applications in which procedures that are incompatible from a solution or medium point-of-view must be coupled with one another.

**FIGURE 50.16** CCD images during species sampling. (a) Species are focused by IEF in the first dimension (dark bands in horizontal channel). Simultaneously, the bands are mobilized by EOF toward the catholyte reservoir (not visible on the right). (b) Once a fluid volume of interest,  $n$ , reaches the microchannel intersection, all applied potentials are switched to floating. (c) High voltage is then applied at the upper reservoir while the lower reservoir is grounded. This initiates protein separation in the second dimension by CE. (d) On completion of the CE separation, IEF/EOF is reinitiated causing sample species to refocus and the next fluidic volume ( $n - 1$ ) to migrate to the intersection. (From Herr et al., *Anal. Chem.*, 75, 1180, 2003. With permission.)

**FIGURE 50.17** Schematic representation of the concentration of ionic species in temperature gradient focusing.<sup>49</sup>

## 50.2.4 TEMPERATURE GRADIENT FOCUSING (TGF)

Temperature gradient focusing (TGF) is a relatively new technique for the concentration and separation of ionic species in microchannels or capillaries (Figure 50.17). The first TGF on chip was reported by Ross and Locascio in 2002.<sup>49</sup> In TGF, one end of the channel is heated while the other end is cooled, resulting in a temperature difference along the channel.

Since the conductivity of a buffer is temperature-dependent, a conductivity gradient is established in the channel due to the temperature difference. The relationship between the conductivity and the temperature can be written as

$$\sigma(T) = \frac{\eta(20)\sigma_0}{\eta(T)f(T)} \quad (50.4)$$

where  $T$  is the temperature,  $\sigma_0$  is the conductivity at  $T = 20^\circ\text{C}$ ,  $\eta(20)$  is the viscosity at  $T = 20^\circ\text{C}$ ,  $\eta(T)$  is the temperature-dependent viscosity, and  $f(T)$  is a function that accounts for all other potential temperature-dependent factors besides viscosity that could affect conductivity, such as ionic strength.  $f(T)$  is normalized to  $f(20) = 1$ .

Because the conductivity is related to the electric field (see Equation 50.1), the electric field is also temperature-dependent. Using Equations 50.1 and 50.4, the electric field dependence on the temperature can be written as

$$E(T) = \frac{I\eta(T)f(T)}{A\sigma_0\eta(20)} \equiv E_0 \frac{\eta(T)f(T)}{\eta(20)} \quad (50.5)$$

where  $E_0$  is the electric field at  $T = 20^\circ\text{C}$ .

The electrophoretic mobility of a charged analyte is also dependent on viscosity, which is dependent on temperature, as given in Equation 50.6. The relationship between the viscosity and the temperature is given by

$$\mu_{\text{EP}}(T) = \frac{\eta(20)\mu_{\text{EP},0}}{\eta(T)f_{\text{EP}}(T)} \quad (50.6)$$

where  $\mu_{\text{EP},0}$  is the electrophoretic mobility at  $T = 20^\circ\text{C}$ , and  $f_{\text{EP}}(T)$  is a function that accounts for all other temperature-dependent factors besides viscosity that affect mobility.  $f_{\text{EP}}(T)$  is normalized so that  $f_{\text{EP}}(20) = 1$ .

Combining Equations 50.5 and 50.6 results in the velocity of an analyte ( $v_{\text{EP}}$ ):

$$v_{\text{EP}}(T) = E_0\mu_{\text{EP},0} \cdot \frac{f(T)}{f_{\text{EP}}(T)} \quad (50.7)$$

According to Walden's rule, the conductivity is inversely proportional to the viscosity. This means that the temperature dependence of the electric field and electrophoretic mobility tend to cancel each other out (see Equation 50.7), except for buffers where  $f(T)/f_{\text{EP}}(T)$  is not constant. Most buffers and analytes have constant  $f_{\text{EP}}(T)$ , so buffers with a temperature-dependent  $f(T)$  have to be chosen to achieve a velocity gradient.

Ross and Locascio showed that buffers made from Tris and boric acid have a temperature-dependent  $f(T)$ , due to the ionic strength being temperature dependent. This means that an electrophoretic velocity gradient can be achieved in the channel when a temperature gradient is applied. Concentration of the analytes is achieved by balancing the electrophoretic mobility of analytes ( $\mu_{\text{EP}}$ ) against a bulk flow of buffer solution ( $\mu_{\text{Buf}}$ ), which is shown in Figure 50.17. The average bulk mobility of the buffer can be driven by using an applied pressure gradient, electroosmosis, or a combination of the two.

The analytes will focus at point ( $\mu_T$ ), where the sum of the electrophoretic mobility of the analyte ( $\mu_{\text{EP}}$ ) and the bulk mobility of the buffer ( $\mu_{\text{Buf}}$ ) equals zero:

$$\mu_T = \mu_{\text{EP}} + \mu_{\text{Buf}} = 0 \quad (50.8)$$

Achieving high-resolution separation in CE requires long channels or capillaries. In contrast, equivalent resolution can be achieved with TGF with much shorter microchannels (a few millimeters). For this reason, TGF is very suitable for integration into microfluidics.

Ross and Locascio<sup>49</sup> reported the first microfluidic device for temperature gradient focusing. They used the Tris/borate buffer due to the non-constant  $f(T)$ . Copper blocks were used at the ends of the microchannels to realize the temperature gradient. With this setup, a 10,000-fold increase in

analyte concentration was achieved after 100 min of focusing for a carboxylic acid solution. After 1 min, the degree in focusing ranged from 2- to 100-fold, depending on the analyte mobility, applied voltage, and temperature gradient.

Ross and Locascio also demonstrated a more elegant way to apply a temperature gradient within a microchannel, namely a gradient generated by internal Joule heating. This means that the applied electric field, which drives the focusing, also generates the temperature gradient. Change in resistance within the channel is a result of changing the dimensions of the channel so that the diameter of the channel at one end is smaller than at the other end.<sup>50</sup> The resistance of the fluid ( $R$ ) is given by

$$R = \frac{\rho L}{A} \quad (50.9)$$

where  $\rho$  is the solution density,  $L$ , the length of the column, and  $A$  the cross-sectional area. It can be concluded from Equation 50.9 that when the cross-sectional area of the channel increases (increasing channel diameter), the resistance of the fluid decreases. The resistance is related to the heat liberated, according to Joule's law:

$$Q = I^2 R t \quad (50.10)$$

where  $Q$  is the amount of heat liberated,  $I$  is the current,  $R$  is the resistance, and  $t$  is the time. Equations 50.9 and 50.10 show that when the cross-sectional area of the channel decreases, the resistance increases and the heat liberated also increases. This increase in resistance is due to the increase in current density. A schematic view of the chip used by Ross and Locascio is shown in Figure 50.18.

The analytes are focused in the temperature gradient. With this chip (only 1.7 cm long), a 300-fold increase in concentration was obtained for a carboxylic acid solution.

Balss et al.<sup>51</sup> reported the concentration of enantiomers with TGF using two copper blocks for the temperature gradient. The concentration of small molecules, including fluorescent dyes, DNA, proteins, particles, and whole cells has also been demonstrated using the TGF technique.<sup>49,51,52</sup> Balss et al.<sup>53</sup> combined TGF with MEKC to obtain so-called micellar affinity gradient focusing (MAGF) for focusing neutral analytes. Although the hydrophobic interiors of the micelles interact with neutral analytes by partitioning, micelles are charged, which means they can be focused in the temperature gradient based on their electrophoretic mobility.

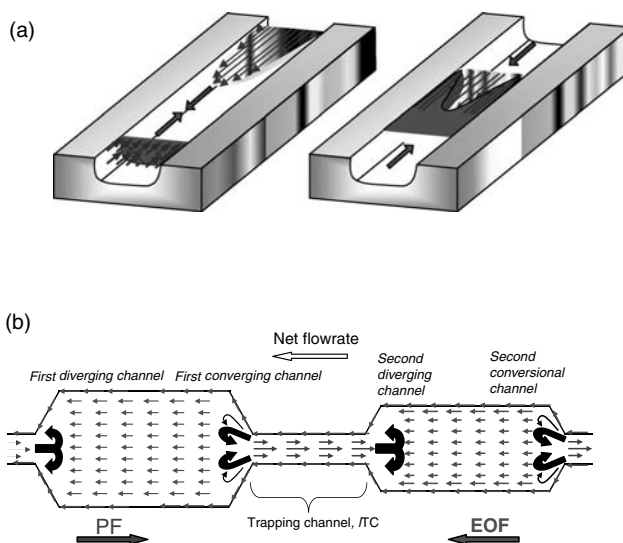

### 50.2.5 FLOW-INDUCED ELECTROKINETIC TRAPPING (FIET)

The use of recirculating flows for the preconcentration of samples in microfluidic devices is, like TGF and nanofluidic filtering (see later), a relatively new approach (early 2000s). The technique, which has been termed flow-induced electrokinetic trapping (FIET), involves the concentration and

**FIGURE 50.18** Schematic view of the chip used for TGF generated by internal Joule heating. (Adapted from Ross et al., *Anal. Chem.*, 74, 2556, 2002.)

**FIGURE 50.19** (a) Schematic showing how bidirectional flow is generated in a microchannel. (b) Schematic diagram of a FIET device. (From Lettieri et al., *Lab Chip*., 3, 34, 2003. With permission.)

manipulation of particles using fluid flows only. Electrophoretic migration of charged particulate species is species-dependent, dictated by the species' electrophoretic mobility,  $\mu_{ep,part}$ , which is a direct function of its electrostatic surface properties. If a charged particle is to be captured and accumulated in an applied electric field, conditions that result in a zero net force being applied on the particle need to be established. In FIET, this is accomplished by applying counteracting EOF and PF in a microchannel. The technique relies on the different flow profiles exhibited by EOF and PF (Figure 50.19a).

The microchannel geometry used is easily made by microfabrication and consists of a narrow channel ( $<100\ \mu\text{m}$ ), which opens up into two tapered elements at either end (Figure 50.19b). When EOF and PF co-exist, the resulting velocity profile is simply the sum of the velocity profiles for the two flows (Figure 50.19a).<sup>54–56</sup> The observed ratio of flows required for trapping is such that bidirectional flow is established in the narrow channel segment. PF prevails down the channel core in one direction with EOF along the channel walls in the other. The tapered elements are thus described as being either diverging (PF exits the narrow channel) or converging (PF enters the narrow channel). The geometry of the diverging and converging elements results in the establishment of well-defined electric field and pressure gradients in these regions. The flow velocity gradients thus created are manifested as recirculating flow patterns. Particles within the microfluidic device are drawn toward these gradients and are caught in the rotating flows, resulting in the formation of concentrated particle zones. Although each zone of trapped particles is stationary, the particles themselves continue to follow rotating streamlines. A number of different types of 1- and 2- $\mu\text{m}$  polymer microspheres have been successfully captured in this device, as shown in Figure 50.20.

A couple of features about FIET are worth noting. First, as alluded to earlier, the conditions of electric field  $E$  and pressure under which a particle is trapped are dictated by its electrophoretic velocity. In other words, FIET can be tuned to the  $\mu_{ep,part}$  of the particle of interest. Second, while bidirectional flow exists over a range of electric field strengths at any given applied pressure, there is only one value of electric field strength at which total net flow is equal to zero. Thus, particles can be trapped under conditions of nonzero net flow. This makes the FIET system unique, as it allows concentration of particles in a stationary zone under conditions of net flow. This offers the possibility to process the trapped particles through perfusion with different reagents, and to flush away untrapped species.

**FIGURE 50.20** These photos show trapping of Protein-A coated fluorescent polymer microspheres (1  $\mu\text{m}$ ) at diverging channel elements. Boundary conditions are the same for both diverging channels, that is, an average electric field of  $E = 200 \text{ V/cm}$  and  $\text{PD} = 7 \text{ mbar}$  (7 cm of buffer).

**FIGURE 50.21** Schematic of a device layout used by Lettieri et al.<sup>57–59</sup> and an exploded view of the microfluidic vortices when the overall velocity is close to zero.

A schematic view of one of the devices used by Lettieri et al.<sup>57–59</sup> for the recirculating flow is shown in Figure 50.21. In this particular embodiment, the beads are introduced into the system from the lower right reservoir by applying a pressure difference using a narrow column of buffer solution several centimeters high. A voltage is applied between the buffer reservoir at the top and the one at the bottom, resulting in an EOF. When the overall velocity of the beads is close to zero, the beads are trapped in the small central channel and are subjected to recirculation. Lettieri et al. demonstrated the potential of FIET for bead-based assays by perfusing trapped negatively charged streptavidin-coated beads with a solution containing fluorescein-labeled biotin and monitoring the development of a fluorescent signal within the bead cluster.

Lettieri et al.<sup>58,60</sup> also demonstrated the recirculation and concentration of double-stranded  $\lambda$ DNA in a trapping channel. The device used for the experiment was similar to the one presented in Figure 50.21. This means that DNA can be extracted and concentrated using the FIET principle, extending the applicability of this technique to biological “particles”. This type of approach could be a nice alternative for many microfluidic applications now requiring solid-phase extraction (SPE). Because trapping occurs in free solution, there is no need for a SPE step of any kind. This simplifies the transfer of material from the FIET component to a subsequent unit operation in a microfluidic device, as it obviates the need to remove material from a surface. FIET is just one example of how

**FIGURE 50.22** Schematic representation of the device used for preconcentration by Astorga-Wells. (Adapted from Astorga-Wells et al., *Anal. Chem.*, 76, 2425, 2004.)

the unique flow properties at the micro- and nanometer scale can be exploited to perform certain sample handling operations in completely new ways.

Astorga-Wells et al.<sup>61,62</sup> demonstrated a similar trapping principle for the preconcentration of peptides and proteins for conventional liquid-based separation systems. A schematic representation of the microfluidic device used for the preconcentration is given in Figure 50.22.

Since poly(etheretherketone) PEEK tubing is used (wall is not charged), no EOF is obtained. The proteins and peptides were introduced into the PEEK tubing by PF. When a voltage was applied over the PEEK tubing, the charged species having an electrophoretic velocity higher than the velocity of the flow will be retained. Neutral species and species with a lower electrophoretic velocity will not be retained. By decreasing the applied voltage over the tubing, the charged species are eluted out of the PEEK tubing depending on their electrophoretic velocity. The device described by Astorga-Wells is not yet implemented on a microchip, but could easily be done.

Other examples of the use of gradients of counteracting electroosmotic and pressure-driven forces to preconcentrate small molecules have been reported. Hori et al.<sup>63</sup> demonstrated this principle of analyte concentration in a conventional flow system in 1993, concentrating small molecules and DNA by factors of 10 to 47. Ista et al.<sup>64</sup> recently demonstrated this approach in a microfluidic device for small molecules.

### 50.3 SOLID-PHASE EXTRACTION (SPE)

In pressure-driven chromatography, the technique most used for sample concentration is solid-phase extraction (SPE). The first experimental applications of SPE were reported five decades ago in conjunction with the first attempts to perform trace analysis of organic compounds in water.<sup>65</sup> The number of citations for the term “SPE in pharmaceutical chemistry” has increased tremendously since the late 1980s.<sup>65</sup>

SPE is an extraction method that uses a solid phase and a liquid phase to isolate and preconcentrate analytes of interest from a solution. The technique is based on partitioning of the analyte between the liquid phase and the extraction material (solid phase), with the mechanism of interaction depending on the extraction material. SPE is very popular, not only because it concentrates the sample, but can also be used to remove the analyte from interfering molecules if the interfering molecules do not show interactions with the SPE material. Chapter 27 of this book is devoted to SPE and its cousin, solid-phase microextraction.

There are three possibilities for the implementation of SPE in microfluidic devices, namely, (1) to fill a channel with particles that serve as the extraction material, (2) coat the channel wall with the extraction material, and (3) fill a channel with a polymeric rod (monolithic phase) extraction material.

### 50.3.1 PARTICLES

While approaches such as FIET may replace the way we perform extraction and preconcentration in the future, it is clear that the general availability of a large number of optimized extraction phases will ensure that SPE is not abandoned any time soon in microfluidics. However, using particulate phases requires developing good protocols for packing them into microchannels. Irregular packing can occur when small microchannels are packed with particles having diameters not much less than the channels themselves. SPE particles are often quite small, about 3–5  $\mu\text{m}$  in diameter. However, if they are packed into a channel having a depth of only 20  $\mu\text{m}$ , it is clear that not more than four particles fit across the channel. Voids in the packing formed particularly at the wall can result in bandbroadening during elution.

Particles also need to be retained locally in a microchannel, particularly if the on-chip SPE process is to be coupled with a separation directly in the device. This generally requires that some kind of porous physical barrier or frit be formed in a microchannel, often a nontrivial process. Ramsey and Collins<sup>66</sup> reported the fabrication of methacrylate frits in microchip devices made of glass. The channel was filled with a polymer solution containing a monomer, cross-linker, photoinitiator, and an EOF promoter. Polymerization was achieved by a photopolymerization process started on exposure of the polymer solution to ultraviolet (UV) radiation. To polymerize only a small part of the channel, two pieces of black electrical tape were used to mask the channel except for a small slit ( $\sim 200$   $\mu\text{m}$  wide). After polymerization, the device was flushed thoroughly, and the channel was packed by pressure with octadecyl-derivatized silica beads. The formation of silicate frits in microchannels to aid in the generation of EOF for better flow control in glass-based microreactors has been described by Christensen et al.<sup>67</sup> and Skelton et al.<sup>68</sup> The main problem generally in fabricating frits for retaining packing material is the poor reproducibility, an issue that several authors have discussed.<sup>69–71</sup>

Oleschuk et al.<sup>72,73</sup> showed that it is possible to create a structure within the microchip to retain the particles by using differential etching instead of frits. Two photomasks were used to create the device shown in Figure 50.23. The first was used to perform a shallow etch of the tops of the weirs (walls over which solution enters the chamber) and the second to etch the channels. The space between the top of the weirs and the cover plate was only 1  $\mu\text{m}$ , which is less than the diameter of the individual particles (1.5–4  $\mu\text{m}$ ). This means the particles were unable to cross the weir. The particles were introduced into the chamber using an additional channel. In Figure 50.23, a cross-section of the packed chamber and the channel layout with the bead introduction channel are shown. To achieve a uniformly packed chamber, particle slurry was introduced by applying a high voltage between the bead introduction channel and the sample inlet and outlet. The EOF obtained transferred the neutral

**FIGURE 50.23** (a) Schematic view of cross-section of packed chamber without the need for frits and (b) top view of channel layout used by Oleschuk et al. (From Oleschuk et al., *Anal. Chem.*, 72, 585, 2000. With permission.)

**FIGURE 50.24** Images of packing the chamber (a) at an initial stage and (b) after it is completely filled with beads. (From Oleschuk et al., *Anal. Chem.*, 72, 585, 2000. With permission.)

particles to the chamber. The bead introduction channel is hook-shaped at the chamber entrance. This results in uniform chamber packing and keeps the particles in the chamber after packing. It also minimizes backflow into the bead introduction channel.

An advantage of the chip described by Oleschuk et al.<sup>72</sup> is the possibility to remove the beads packed in the chamber and replace them with other beads having a different partitioning mechanism. If the chamber is not tightly packed, the beads can be removed and repacked just by reversing the voltages between the sample inlet and outlet channels and the bead introduction channel. The two images in Figure 50.24 show how the chamber is packed electrokinetically. With this chip, a concentration enhancement of up to 500-fold is observed for the nonpolar fluorescent dye, BODIPY.

Another way to pack channels with particles without using frits is to make use of the so-called “keystone effect.” Lord et al.<sup>74</sup> showed that tapering conventional capillaries to an inner diameter of approximately 10  $\mu\text{m}$  was sufficient to trap particles of 3  $\mu\text{m}$ . Mayer et al.<sup>75</sup> also used the “keystone effect” to pack capillaries for capillary electrochromatography (CEC). Introducing particles toward the taper by applying a pressure on the inlet and vacuum on the outlet reservoir results in an increase in density of the particles at the taper. Due to this density increase, the particles aggregate without requiring a physical barrier or filter. The first particles that are aggregated act as the “keystones,” blocking the other particles and allowing the packed section to grow. Ceriotti et al.<sup>76</sup> adapted the “keystone effect” to microfluidic devices for CEC applications. The “keystone effect” and the channel dimensions used by Ceriotti et al. are shown in Figure 50.25.

Surprisingly, the C18 packings made by Ceriotti et al. remained in place when solvent was flushed through them, even though there was no taper or frit at the end of the microchannel to retain the packing. It was surmised that a heat treatment was sufficient to stabilize the packing. This treatment consisted of filling the channel with water and placing the chip in an oven overnight at 115°C. Due to this heating, the outer surface of the particles is believed to dissolve in water, forming a saturated solution of polysilicic acids, which redeposits as silica between the particles on cooling. This interparticle bonding was proposed by Adam et al.<sup>77</sup>

**FIGURE 50.25** Schematic view of the “keystone effect.” (From Ceriotti et al., *Anal. Chem.*, 74, 639, 2002. With permission.)

The concentration of the particles in the suspension is critical. At high concentrations, the particles aggregate before the tapered column and at low concentrations the particle density at the tapered column is too low, resulting in particles entering the injection channel (the channel with an internal diameter of 16  $\mu\text{m}$ ).

There have been no articles published to date reporting the use of the “keystone effect” for packing channels for sample preconcentration, although this should be possible.

The first commercially available chip with sample enrichment column for the analysis of biological samples has been available since early 2005 from Agilent Technologies (Palo Alto, California, USA). The chip integrates an HPLC column, sample enrichment column, and nanoelectrospray tip. The sample and mobile phase are introduced with an external nanopump. The enrichment column and analytical column are packed using a modified version of the method described by Smith and Evans.<sup>78</sup> The particles (5  $\mu\text{m}$ ) are kept in the trap column by closing it with a frit at one end. There are five microchannels with an internal diameter smaller than the particle size at the other end, which also act as a frit. With this setup, it is possible to elute the analytes from the packing material by using a backward flush method. More details about the chip layout and the working of the chip are extensively described in References 79–81.

### 50.3.2 WALL COATING

Kutter et al.<sup>82</sup> reported a microfluidic device made of glass with C18-coated channels. The channels of the chip were modified using octadecyltrimethoxysilane in dried toluene at room temperature.<sup>83</sup> The trimethoxysilane reacts with the silanol groups of the glass resulting in covalently bonded octadecyltrimethoxysilane on the wall of the channel. An 80-fold increase in concentration was obtained for a coumarin dye. In Figure 50.26, an example is given of the preconcentration of an 8.7 nM coumarin dye C460, which was preconcentrated for 160 s. A borate buffer with 15% acetonitrile was used for sample loading and a borate buffer with 60% acetonitrile was used for elution.

The chip described by Kutter et al. has limited sample trapping capacity. The phase ratio of the stationary phase bonded to the inner wall is low, and not all of the sample may be extracted using

**FIGURE 50.26** Chromatograms of (1) 160-s injection with concentration and (2) 1-s injection without concentration. (From Kutter et al., *J. Microcol. Sep.*, 12, 93, 2000. With permission.)

this type of approach. Despite their high surface-to-volume ratios, the available surface area for extraction can be significantly increased in microchannels through packing with microspheres.

### 50.3.3 POLYMERS

To increase the surface-to-volume ratio in the preconcentration channel without the need for particles, the channel can be filled with a polymeric rod. These are formed by *in situ* polymerization, during which the polymer material also reacts with the wall of the channel. As a result, no frits are needed to hold the material in place. Columns filled with a polymeric rod, so-called monolithic columns, were originally developed for conventional liquid chromatography. They are made by sol-gel technology,<sup>84</sup> which enables the formation of a highly porous material containing macropores and mesopores in its structure.<sup>85</sup> The use of a monolithic phase circumvents the problems encountered when packing a column with particles.

The polymerization of monolithic material in-chip has been described by several authors. In most cases, the monolithic phases were prepared by photoinitiated polymerization<sup>86</sup> of methacrylate mixtures introduced to the microchannels. Once the microchannels are filled with polymer solution, the surface of the chip is covered with a mask having an open window to expose a specific part of the channel to UV light. The microchip is then covered with some kind of foil or tape, except for the open window, and after illuminating the chip with UV light, the polymerization reaction starts. The advantage of using photoinitiated polymerization is that the polymerized plug can be localized to any desired location on chip. The dimensions of the plug or rod can also be precisely defined.

The feasibility of synthesizing monolithic material in PDMS,<sup>87</sup> glass,<sup>88,89</sup> and polymeric substrates<sup>90,91</sup> has been shown. However, PDMS is not so suited for the analysis of nonpolar analytes. The analytes are absorbed onto and into the PDMS, which results in poor recovery and low enrichment. Without surface modification, PDMS is only suited for polar samples such as genomic DNA.<sup>87,92</sup> In Figure 50.27, a SEM image of monolithic material inside a Zeonor polymer microchannel is shown.<sup>90</sup>

Yu et al. described the integration of ion-exchange and hydrophobic concentrators based on a methacrylate-based monolithic phase in a chip made of glass.<sup>88</sup> With this device, they were able to concentrate a hydrophobic tetrapeptide, Coumarin 519, and green fluorescent protein (GFP) by a factor of 1000.

**FIGURE 50.27** SEM images showing a cross-section of monolithic material inside a Zeonor polymer chip described by Tan et al. (From Tan et al., *Anal. Chem.*, 75, 5504, 2003. With permission.)

The extraction efficiency for nucleic acids using monolithic silica material in microfluidic devices is not nearly as good as what can be achieved using silica beads.<sup>93</sup> However, with monolithic material, better repeatabilities are obtained. For these reasons, Karwa et al.<sup>87</sup> and Wolfe et al.<sup>93</sup> combined the two materials. Both groups used a sol-gel to immobilize silica beads in a channel. This approach has already proven its usefulness in CEC.<sup>94</sup> The channel is packed by a two-step process, where the particles are first introduced into the channel and then held in place with a polymeric phase. This packing technique provided excellent efficiency, repeatability, and stability. In fact, Wolfe et al. found that the extraction efficiency for a  $\lambda$ DNA sample improved to a value of about 70%, compared to 57% for silica beads alone, and 20–30% for the sol-gel matrices tested. Due to the presence of the particles in the column, matrix cracking caused by internal pressure differences within the pores of the sol-gel matrix is reduced.

#### 50.4 LIQUID-LIQUID EXTRACTION (LLE)

Liquid-liquid extraction (LLE) is among the oldest sample extraction and preconcentration techniques available in analytical chemistry. LLE is a method whereby two immiscible phases, generally an organic solvent and an aqueous solution, are brought into contact in order to extract one or more analytes from one phase into the other. If the receiving phase has a smaller volume than the donor phase, preconcentration can be effected. The separation mechanism is, like SPE, based on partitioning. At equilibrium, the partition coefficient of analyte  $i$  ( $K_i$ ) in a two-phase system is given by

$$K_i = \frac{C_{i,\text{organic\_phase}}}{C_{i,\text{sample}}} \quad (50.11)$$

where  $C_{i,\text{organic\_phase}}$  is the concentration of extracted analyte in the extraction solvent and  $C_{i,\text{sample}}$  the concentration of analyte in the sample at equilibrium. The use of microfluidic devices is attractive for LLE, since the contact area between phases can be enlarged to facilitate a more rapid equilibrium of analyte partitioning between phases.

Tokeshi et al.<sup>95</sup> reported the first two-phase microextraction system on a microchip in 2000. An Fe(II)-complex was extracted from an aqueous solution into a chloroform solution with a simple Y-shaped chip (see Figure 50.28). The solvents were introduced with two syringe pumps, and a parallel two-layer flow was formed in the microchannel because the surface tension and frictional forces are much stronger than that due to the specific gravity. The extraction of Fe(II)-complex from aqueous

**FIGURE 50.28** Y-shaped chip used by the Kitamori group for micro-LLE.<sup>95–98,101</sup>

**FIGURE 50.29** Chip with recess used for micro-LLE by Chen et al.<sup>102</sup>

solution took place where the two-layer flow was formed. Later on, Kitamori and coworkers showed more applications for their chip<sup>96–99</sup> and they have even modified the chip to create a three-layer flow system.<sup>100,101</sup> However, these devices were not intended to be used specifically for sample extraction and purification, but to study the molecular transport of analytes through an organic membrane. In this section, we will briefly focus on the implementation of LLE in microchips specifically for sample enrichment. Readers are referred to Chapter 36, which details the efforts made by Kitamori and coworkers to incorporate LLE into microfluidic devices for different purposes.

Chen et al.<sup>102,103</sup> realized a chip for LLE employing a stationary organic solvent and flowing aqueous sample. The chip was Y-shaped, similar to the chip used by Kitamori and coworkers, but the solvents were introduced by differential hydrostatic pressure created by varying liquid levels in the reservoirs. The chip, made of glass, was first filled with an organic solvent by filling the organic solvent reservoir and keeping the other reservoirs empty. Then the sample reservoir was filled with aqueous sample, which produced a flow of this solution through the channel. The organic solvent was rinsed out of the sample solvent channel, but remained in the organic solvent channel due to the pressure introduced by the organic solvent volume in the reservoir. This resulted in a stable interface between the aqueous and organic phases at the exit of the organic solvent inlet channel (see Figure 50.29, left half of structure). The sample, butyl-rhodamine B (BRB) was extracted at this point from the aqueous solvent into the organic solvent.<sup>103</sup> A preconcentration factor of 40 was obtained and the relative standard deviation was only 2.7% for this method.

More effective for LLE proved to be the introduction of a single microrecess in the channel wall for organic solvent trapping.<sup>102</sup> This ensured that droplets of organic solvent could be trapped and

held in place as aqueous solution flowed past.<sup>102</sup> Different recess geometries were studied, and the chip with the recess that resulted in the best preconcentration factor is depicted in Figure 50.29.

The chip works the same as the chip that was used for BRB extraction.<sup>103</sup> It was first filled with an organic solvent, which filled the recess, and then with aqueous solution. The organic solvent was rinsed out of the sample solvent channel by the aqueous solution, but stayed in the recess where the extraction then took place. After the extraction, the organic solvent with analytes trapped in the recess was flushed out of the chip by passing acetone through the solvent channel. An enrichment factor of about 5000 was achieved in a recess of  $\sim 750$  nL, but at the expense of a very long extraction time of 50 min. In a much smaller recess ( $\sim 140$  pL), an enrichment factor of 250 was achieved within 5 min. This enrichment factor was not only achieved by extraction of the analytes from the aqueous solvent into the organic solvent, but was also due to dissolution of organic solvent in the flowing aqueous sample. During the extraction, a part of the stagnant organic solvent dissolved into the aqueous solvent, resulting in a decrease in organic solvent volume and higher enrichment factors. This chip was, unfortunately, not coupled to a separation channel.

Cai et al.<sup>104</sup> recently published an example of LLE on-chip based on the principle of wetting-film extraction. Wetting-film extraction was introduced by Ruzicka, Christian, and coworkers in 1996.<sup>105</sup> The technique is based on the film-forming characteristics of an organic solvent on hydrophobic walls. In conventional wetting-film extraction, Teflon tubing is used as the support for the wetting film. An organic solvent is passed through a tubing or channel, and due to the hydrophobic wall, a uniform organic film is formed on the wall. When passing an aqueous sample through the tubing or channel, the hydrophobic analytes will extract from the aqueous liquid into the organic liquid. The extracted analytes are then eluted with an organic liquid.

Cai et al. used a polymeric chip (polycarbonate), because the native surface is an excellent support for creating organic-wetting films. The organic liquid and the aqueous sample were sequentially injected using a gravity pump. Butanol was used as the organic wetting film and as eluting solvent, and BRB diluted in sodium hydroxide was used as sample (pH 13.0). An enrichment factor of 24 was obtained. With this chip, an RSD of only 1.5% was obtained for eleven BRB injections at 10  $\mu$ M.

## 50.5 NANOPOROUS MEMBRANES AND FILTERS

### 50.5.1 MEMBRANE FILTRATION

The first membrane filtration was done by Dr. Sourirajan in 1960 in his laboratory at UCLA ([http://www.gewater.com/library/tp/698\\_Membranes\\_the.jsp](http://www.gewater.com/library/tp/698_Membranes_the.jsp)). Since then, many scientists have been developing new membranes that can specifically separate particles from solution or other particles in solution.<sup>106</sup> Membranes are semipermeable barriers which are used to separate analytes based on their size, making membrane filtration a size-exclusion technique. Membranes have pores with specific size ranges, and molecules and particles having diameters that are bigger than the membrane pores cannot pass. In contrast, molecules and particles with smaller diameters can pass through the membrane.

With membrane filtration techniques, analytes can be concentrated on the membranes if the molecular diameter is bigger than that of the pores of the membrane. Analytes are dissolved in a buffer containing ions that are smaller than the pores of the membrane. The buffer ions pass through the membrane, and the analytes with sizes bigger than the membrane pores are concentrated at the membrane. In theory, the degree of concentration is only limited by the ratio of the initial sample volume to the surface of the membrane, and the solubility limit of the samples.

The first microfluidic chip with a porous membrane for the preconcentration of a biological sample was presented by Khandurina et al. in 1999.<sup>107</sup> In this experiment, they demonstrated preconcentration of DNA samples. The channels were etched into a glass substrate and bonded to a cover plate using a silicate solution as an adhesive. The chip layout used in this experiment is presented in Figure 50.30.

**FIGURE 50.30** (a) Schematic of the chip layout used by Khandurina et al.<sup>107</sup> (b) Schematic cross-sectional view through the preconcentrator.

As can be seen in Figure 50.30, the preconcentration channel and the sample channel are not directly connected to each other, but are separated by a distance of about 3–5  $\mu\text{m}$  (see Figure 50.30b). Electrical contact between the two separated channels is maintained through the porous, semipermeable silicate membrane. The DNA sample is loaded by applying a voltage between the sample inlet and the preconcentrator reservoirs. The buffer ions pass through the silicate membrane, but the large DNA molecules accumulate at the preconcentrator due to their hindered transport through the membrane. After preconcentration, the voltage is applied between the buffer and buffer waste, and the DNA molecules are injected onto the separation column.

With this chip, DNA can be concentrated by a factor of up to two orders of magnitude. Khandurina et al.<sup>108</sup> also reported an integrated system for polymerase chain reaction (PCR)-based analysis on a microchip with this preconcentration technique. The chip layout was similar to that depicted in Figure 50.30, with an additional Peltier thermoelectric element integrated for the DNA amplification. With this chip, a 25-fold preconcentration of the DNA sample due to the semipermeable silicate membrane was observed.

Footo et al.<sup>109</sup> recently published an article where they have used the same chip as described by Khandurina et al.<sup>107</sup> for the preconcentration of proteins. However, they observed distortions of peak shape and loss of resolution for some sample components. This could be due to slow desorption of sample from the membrane surface or changes in buffer composition in the injection channel and adjoining portions of the separation channel during preconcentration. To overcome these problems, they changed the chip layout, as shown in Figure 50.31.

The samples used in this experiment were fluorescein-labeled proteins. The sample was concentrated by applying a voltage between the sample inlet and the preconcentrator reservoirs. The proteins were first accumulated at the preconcentrator. After concentration, the sample was loaded into the injector region by applying a voltage between the sample-inlet and the sample-waste reservoirs, and injected by applying a voltage between the buffer and buffer-waste reservoirs. With this chip, good peak shapes were obtained, as seen in Figure 50.32. Peak resolutions improved as a function of concentration time up to the 8-min point, after which time resolution started

**FIGURE 50.31** Schematic of chip layout used by Foote et al.<sup>109</sup> for side channel preconcentration.

to deteriorate again. Although these effects were not fully understood, it appeared to be due to time-dependent changes in the sample buffer. However, the stacking was more complete at longer preconcentration times. At 8 min concentration time, a maximum signal enhancement of a factor of approximately 600 was obtained. As Figure 50.33 shows, the rate at which peak height increases for a protein grows as a function of concentration time. This is most likely due to the fact that there was a delay between application of the loading potential and the arrival of the sample proteins at the preconcentrator. Proteins had to migrate through gel-filled channels in order to get to this element.

Another approach to use the membrane filtration technique in microchips is to integrate the membrane into the separation channel, as Song et al.<sup>110</sup> and Hatch et al.<sup>111</sup> have demonstrated. The chip layout used by Song et al. is given in Figure 50.34a.

Song et al.<sup>110</sup> used a zwitterionic polymer membrane (molecular weight cutoff <5700), which was integrated by using photoinitiated polymerization. The sample was loaded onto the bottom left part of the membrane by applying a voltage between the sample and sample waste. By applying a voltage between the buffer and buffer waste, the concentrated sample could be removed from the membrane again, separated, and detected. Song et al. showed a concentration increase by two orders of magnitude for both BSA and phosphorylase *b* with a 100-s concentration time (see Figure 50.35).

Hatch et al.<sup>111</sup> have also integrated a membrane (polyacrylamide) into the injection channel by photopolymerization. With this chip, a concentration increase of over 100-fold was observed for four disease biomarkers (IL-6, IL-1 $\beta$ , TNF $\alpha$ , and CRP) in saliva.

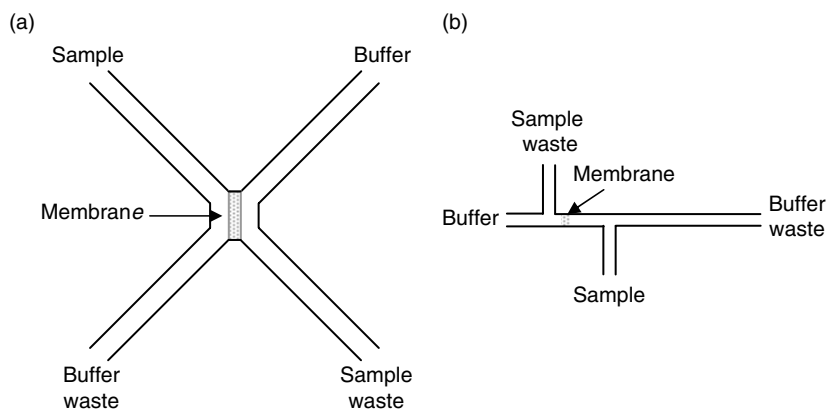

Membrane filtration is an effective technique for the preconcentration of biological macromolecules like proteins and DNA. However, relatively low enrichment factors are obtained compared to LLE, SPE, and TGF. Concentration enrichments with a factor of about 100 were shown for both proteins and DNA molecules by several groups. A problem that has to be taken into account is the probable adsorption of the macromolecules on the membrane surface. This could result in tailing in the injection channel and/or in a low recovery of the molecules. Another issue that has to be taken into account is the good probability that concentration increase is not a linear function of time, as observed by Khandurina et al.<sup>107</sup> and Foote et al.<sup>109</sup>

**FIGURE 50.32** CGE separations of fluorescent high-molecular-weight protein standards following pre-concentration in the sample channel. Starting with the top electropherogram, pre-concentration times were 0, 1, 2, 4, 6, and 8 min. Peak numbers: (1) trypsin inhibitor, (2) carbonic anhydrase, (3) alcohol dehydrogenase, (4) bovine serum albumin, (5)  $\beta$ -galactosidase, and (7) myosin. (From Foote et al., *Anal. Chem.*, 77, 57, 2005. With permission.)

**FIGURE 50.35** Linear increase in the concentration of both BSA and phosphorylase *b* with the voltage-time product. The curve is linear for over two orders of magnitude increase in concentration factor. (From Song et al., *Anal. Chem.*, 76, 4589, 2004. With permission.)

### 50.5.2 NANOFIUIDIC FILTERS

Nanofluidic filtering is based on an electrokinetic trapping mechanism enabled by recent advances in nanochannel fabrication. A nanofluidic filter consists of two microfluidic channels bridged by buffer-filled nanochannels which act like an ion-selective membrane. The technique is a relatively new technique which has a demonstrated potential for sample enrichment. A schematic chip layout of a nanofluidic filter is given in Figure 50.36.

The substrate most often used for making nanofluidic filter chips is glass. Glass surfaces are negatively charged, due to the presence of deprotonated silanol groups. Positively charged counterions from the buffer form an electrical double-layer at this surface. When the ionic strength of the buffer is decreased, the thickness of the double-layer is increased because the square root of the buffer concentration is inversely proportional to the diffuse double-layer thickness. With buffer

**FIGURE 50.36** Schematic chip layout of a nanofluidic filter.

concentrations of  $10^{-2}$ – $10^{-6}$  M, double layers in the range of 3–300 nm are obtained.<sup>112</sup> This means that when the diameter of the nanochannel is small enough and buffer concentration is low enough, a double-layer overlap can occur in the nanochannel. The cation concentration ( $A^+$ ) will be greater than the anion concentration ( $B^-$ ) in the nanochannel, due to the slight excess of cations present in the electrical double-layer. In other words,

$$[A^+] = \alpha \cdot [B^-] \quad (50.12)$$

where  $\alpha$  is greater than 1. In the case of a positively charged nanochannel wall, a negatively charged double layer is established and the anion concentration will exceed that of the cations in the nanochannel upon double-layer overlap. In this situation,  $\alpha$  is less than 1.

A difference in the bulk conductivity of the micro- and nanochannels results from the double-layer overlap, even if they are filled with the same buffer. At low buffer concentrations, the interface conductivity (at the nanochannel) starts to dominate over the conductivity of the buffer ions. This results in a current being carried by different ratios of cations to anions in a nanochannel compared to a microchannel. Assuming that  $A^+$  and  $B^-$  have equal concentrations in the microchannel, the relationship between the ion fluxes in the microchannel ( $J_m^A$ ) and nanochannel ( $J_n^A$ ) for the cations can be described as<sup>112</sup>

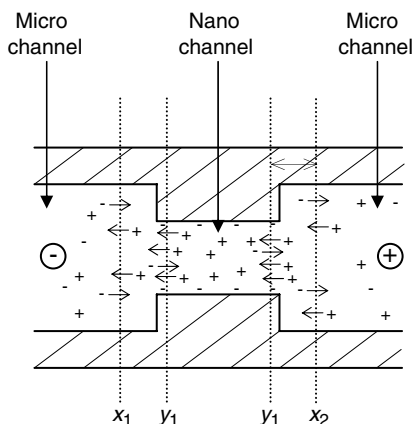

$$J_m^A = \left( \frac{\mu_A + \mu_B/\alpha}{\mu_A + \mu_B} \right) \cdot J_n^A \quad (50.13)$$

where  $\mu_A$  is the electrophoretic mobility of the cations and  $\mu_B$  the electrophoretic mobility of the anions. When the nanochannel is negatively charged,  $\alpha$  is greater than one (see Equation 50.12). This means,  $J_m^A < J_n^A$ .

The microchannel takes away cations on the cathode side of the nanochannel and the nanochannel provides cations. However, because  $J_m^A < J_n^A$ , an enrichment of cations is obtained at the cathode side of the nanochannel. On the anode side of the nanochannel, the opposite is observed and a decrease in cations is obtained, so-called ion-depletion. The ion fluxes for anions ( $B$ ) can be described as<sup>112</sup>

$$J_m^B = \left( \frac{\mu_B + \alpha \cdot \mu_A}{\mu_A + \mu_B} \right) \cdot J_n^B \quad (50.14)$$

The wall of the nanochannel is negatively charged, thus  $\alpha > 1$ , which results in  $J_m^B < J_n^B$ . The microchannel provides anions on the cathode side of the nanochannel and the nanochannel takes away anions at the cathode side. Again, because  $J_m^B < J_n^B$ , an enrichment of anions as well as cations is observed at the cathode side. A depletion of anions occurs on the anode side of the nanochannel. This means that on the cathode side of the nanochannel, enrichment of cations and anions is obtained, while on the anode side, a depletion of cations and anions results.

**FIGURE 50.37** Schematic representation of the ion-enrichment and ion-depletion effect. (From Pu et al., *Nano Letters*, 4, 1099, 2004. With permission.)

**FIGURE 50.38** The chip with nanofluidic filter, which is used by Petersen and Ramsey (From Petersen, N. J. and Ramsey, J. M., in *Micro Total Analysis Systems ( $\mu$  TAS)*, Boston, 2005, pp. 1252–1254.)

When the wall of the nanochannel is positively charged, the double-layer overlap in the nanochannel is due to the negatively charged buffer ions, and  $\alpha < 1$ . In this case, the enrichment of ions is obtained on the anode side and depletion on the cathode side. This ion-enrichment and depletion effect is schematically shown in Figure 50.37, where  $\mu_A = \mu_B$  and  $\alpha = 3$ .

Figure 50.37 has four cross-sectional planes,  $x_1$ ,  $y_1$ ,  $y_2$ , and  $x_2$ , respectively. The two  $x$ -cross-sectional planes represent the current passing through the microchannels and the two  $y$ -planes represent the current through the nanochannel.  $x_1$  and  $y_1$  are at the cathode end and  $x_2$  and  $y_2$  are at the anode end. At both  $x$ -planes, where no double-layer overlap exists, the current is carried by two cations and two anions. At both  $y$ -planes, where the interface conductivity starts to dominate the bulk conductivity, the current is carried by three cations and one anion. This results in an ion-enrichment at the cathode side and an ion-depletion at the anode side for both cations and anions.

Pu et al.<sup>112</sup> demonstrated this ion-enrichment or ion-depletion effect for a solution containing either negatively charged fluorescein or positively charged rhodamine-6G. Both species were enriched at the cathode end and depleted at the anode end of the nanochannels. Unfortunately, no enrichment factors were given.

Petersen and Ramsey<sup>113</sup> demonstrated a signal enhancement of a factor 100 within 3 min for ionic analytes. The chip layout that was used is given in Figure 50.38, while an experiment showing the concentration of a positively charged fluorescent dye is shown in the fluorescence image of Figure 50.39.

**FIGURE 50.39** Concentration of the positively charged rhodamine-6G at a micro–nanochannel junction. All channels and reservoirs were initially filled with 5  $\mu\text{M}$  rhodamine-6G solution. (a) Potential applied through the microchannel and (b) potential applied between nanochannels (positively biased) and right-hand microchannel (negatively biased). (From Petersen, N. J., et al., in *Micro Total Analysis Systems ( $\mu\text{TAS}$ )*, Boston, 2005, 1252. With permission.)

Wang et al.<sup>114</sup> demonstrated the use of a nanofluidic filter for the preconcentration of biological samples. They demonstrated a concentration enrichment factor of  $10^6$ – $10^7$  for GFP within 1 h with the chip, which is schematically shown in Figure 50.36. The filter collects sample molecules from a relatively large volume (few  $\mu\text{L}$ ) and concentrates them into small volumes (pL–nL). Much higher enrichment factors are obtained compared to small analytes. This is probably due to electrostatic exclusion of the proteins from the nanochannel, resulting in a concentration effect before the nanochannel interface. Buffer ions, on the other hand, can pass through the nanochannel.<sup>115</sup> This means the whole sample gets concentrated before the nanofluidic filter. Wang et al.<sup>114,116,117</sup> also demonstrated the enrichment of peptides with a factor of  $10^7$ .

The use of nanofluidic filters in microchips for the preconcentration of peptides and proteins is one of the best chip-based preconcentrators reported so far. Small ion samples could also be concentrated with this nanofluidic filter. The integration of the nanochannel is very easy, because it does not need special buffers or any physical barriers for sample enrichment. Long times are required, however, to achieve high enrichment factors (30 min to 1 h).

## 50.6 CONCLUSIONS

Microfluidics is a rapidly growing discipline being driven by new technological applications in the medical, material, and chemical sciences, to name but a few. There are a number of advantages when using microfluidics technology, including dramatically reduced analysis times and reagent/sample consumption, and the potential for engineering high-throughput systems and systems for cell-based analysis. However, system miniaturization also implies reduced detection volumes, which in turn often results in poor detection sensitivity. A built-in preconcentration technique that compresses the analytes of interest into a smaller volume is often desirable.

The preconcentration techniques that have to date been most used in microfluidic devices have been presented in the preceding pages. Most of the techniques were originally developed for conventional CE or liquid chromatography and have (more or less simply) been adapted to microchips. FASS, ITP, and IEF are examples of these types of techniques. A few new techniques have been developed for the preconcentration of samples on microfluidic devices. TGF and nanofluidic filtering are both examples of techniques that have been developed solely for microfluidic chips. High enrichment factors can be achieved with both techniques, on the order of 10,000 and 1,000,000, respectively. Table 50.1 summarizes the top performers in each device category with respect to preconcentration factor and time.

**TABLE 50.1**  
**Different Preconcentration Techniques with Their Preconcentration Factors**

Reference	12	33	46	49	72	102	110	114

Analyte	BODIPY Fluorescein	Alexa Fluor 488	Recombinant GFP	Carboxylic acid solution	BODIPY 493/503	BRB	BSA Phosphorylase <i>b</i>	GFP
Technique	FASS	ITP	IEF	TGF	SPE	LLE	Membranes	Nanofluidic filter

It is worth noting that in the studies described in this chapter, only fluorescent dyes or simple, fluorescently labeled biological molecules have been analyzed for the most part. Few real physiological or biological samples were actually tested. To investigate the suitability of these preconcentration techniques, they must ultimately be applied to the biological sample matrices that are of actual interest in proteomics, genomics, and the other life sciences. Thus, some interesting challenges remain for researchers in this area, despite the significant advances that have been made to date.

## 51.1 INTRODUCTION

For many years, miniaturization has been used to improve separation performance in chemical analysis. Since first demonstrated over 25 years ago,<sup>1,2</sup> capillary electrophoresis (CE) has been found to offer many advantages compared to slab gel electrophoresis, and CE has become a powerful technique for the analysis of complex biological samples due to its high efficiency and ease of automation.<sup>3</sup>

The potential for using silicon-based technologies to fabricate microdevices for chemical analysis was initially demonstrated in 1979 by Terry et al.<sup>4</sup> Over a decade later, the concept of integrated microfluidic devices, or micrototal analysis systems ( $\mu$ TAS), was presented by Manz et al.<sup>5</sup> Chip-based analytical systems offer many advantages over their conventional, larger-size counterparts. Separations in microchips are particularly attractive due to rapid analysis times, parallel runs, high sample throughput, ability to manipulate ultra-small volumes, and potential for integration of sample processing steps in series with separation.<sup>6</sup> Because of its relative simplicity, CE was first demonstrated in a microfabricated format in 1992.<sup>7</sup> Today, microchip electrophoresis ( $\mu$ CE) has become a well-developed technique with numerous analysis applications reported for DNA,<sup>8,9</sup> proteins,<sup>10,11</sup> cells,<sup>12</sup> small molecules,<sup>13,14</sup> explosives,<sup>15</sup> and environmental contaminants,<sup>16</sup> among others.

Microfluidic analysis devices were initially fabricated almost exclusively in glass and silicon, using micromachining techniques such as photolithography and wet chemical etching.<sup>4,17–19</sup> Glass substrates have been implemented widely due to their favorable optical properties, well-known surface chemistry, and established fabrication techniques. However, the construction of glass microchips requires a well-equipped cleanroom and the use of hazardous chemicals such as hydrofluoric acid. In most cases, the bonding step is performed at high temperatures ( $>600^{\circ}\text{C}$ ) for several hours, making the process slow and impractical for mass production of microdevices.<sup>20</sup> Silicon microfabrication uses almost the same technology and surface chemistry as glass; however, crystalline silicon is brittle and must be handled with care. In addition, silicon is opaque to visible and ultraviolet (UV) light and thus, cannot be used with laser-induced fluorescence (LIF) detection.

These problems with glass and silicon microdevices have led to growing interest in using polymer-based substrates. Indeed, plastic microchips should overcome several limitations of their glass and silicon counterparts, since plastics are easier to manufacture and handle, enabling the development of lower cost and more rugged microfluidic devices.<sup>21</sup> Moreover, polymeric materials possess a broad range of physical and chemical properties, which should enable compatibility with many biological and chemical reagents and assays.<sup>22</sup> A variety of polymers have been used to fabricate microfluidic devices, including poly(methyl methacrylate) (PMMA),<sup>23,24</sup> poly(dimethylsiloxane) (PDMS),<sup>25,26</sup> polycarbonate (PC),<sup>27</sup> polyimide (PI),<sup>28</sup> cyclic olefin copolymer (COC),<sup>29</sup> polystyrene,<sup>30</sup> and polyethylene terephthalate (PET).<sup>31</sup> Finally, polymer manufacturing methods, such as hot embossing<sup>32,33</sup> and injection molding,<sup>34</sup> offer great potential for the mass production of low-cost platforms containing complex microfluidic patterns.

Polymer microchips are expected to contribute strongly in biological analysis in the postgenome era, especially in the field of proteomics.<sup>35,36</sup> Considerable research has already focused on separations, the use of new materials, and transferring conventional analysis methods to a microchip platform, but more work remains to be done to enable the exploitation of the full potential of plastic microdevices. In particular, the use of conventional device-bonding techniques has limited the broad application of polymer microchips.

Thermal bonding is a widely used approach for sealing microfluidic patterns made in polymer substrates.<sup>21–23,27,37–40</sup> The standard thermal bonding method involves heating a patterned substrate and cover layer to near the glass transition temperature of the material.<sup>23,37</sup> Other reported approaches have used heated weights,<sup>41</sup> or bonding in boiling water.<sup>42</sup> These methods are used because they are easy to implement and allow the formation of microchannels with a surface entirely composed of the same material. However, applying elevated temperatures to a microchip can be incompatible with some biological analyses. Moreover, since bonding takes place near the glass transition temperature of the material and under applied pressure, the microstructures can be distorted readily during this step. This issue is especially problematic for small channel dimensions or low-aspect-ratio microchannels, and can affect the yield and reproducibility of device fabrication. In addition, thermal bonding does not provide sufficient device robustness for introducing viscous sieving solutions into polymeric microchips. Therefore, the development of new technologies to

enclose polymer microfluidic systems (without using heat) should broaden the range of applications of plastic microchips.

Several studies have been performed to develop alternate sealing methods for plastic microdevices. Thermal lamination<sup>34</sup> is one approach for enclosing microfluidic channels, but this technique leads to channels whose walls are composed of different materials, which results in inhomogeneities in zeta potential and band broadening.<sup>43</sup> Bonding of microchips using an intermediate adhesive layer is easy to implement;<sup>44–47</sup> however, this approach is limited by a high incidence of channel blockage. In addition, the difference in surface composition between the substrate and adhesive has a negative effect on separation efficiency.<sup>44,48</sup> Lai et al.<sup>49</sup> developed a resin–gas injection bonding method, in which blank and patterned substrates were held together, and a monomer solution that filled the gap between the two pieces was cured using UV radiation. This technique allows for surface modification and bonding to be performed simultaneously; however, the monolayer inside the channel must be uniform and stable to prevent irregular electroosmotic flow. Moreover, this method is only applicable to UV-transparent polymers. Chemical bond formation at contact surfaces has been used to seal plastic microdevices;<sup>50–54</sup> however, this approach requires surface modification before bonding<sup>52</sup> or the use of intermediates such as catalysts and initiators.<sup>53,54</sup>

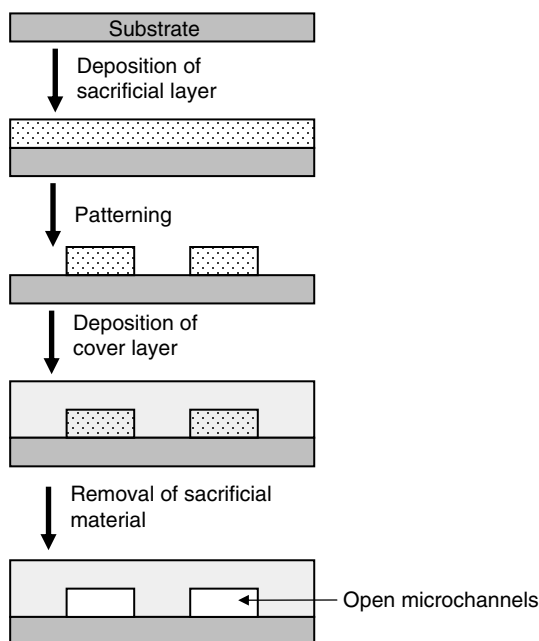

Solvent bonding is an attractive alternative to conventional thermal bonding.<sup>52,55–58</sup> Briefly, polymeric surfaces to be bonded are exposed to an organic solvent, which partially dissolves the polymer at the surface. When two solvent-wetted polymer pieces are brought together under applied pressure, the polymer chains in both surfaces can interdiffuse and entangle, forming a high-strength bond.<sup>59–61</sup> In principle, solvent bonding of polymer substrates should produce robustly enclosed microchannels due to the strong molecular interaction between the surfaces. However, the use of this technique has been limited due to the ease with which microchannels can be blocked by dissolved polymer, or swelling or softening of the substrate.

Several papers have reported solvent-assisted bonding of polymer microdevices at room temperature.<sup>55–58</sup> Liu et al.<sup>62</sup> demonstrated the solvent bonding of PC devices, but at an elevated temperature of approximately 200°C. Recently, Shah et al.<sup>58</sup> reported the enclosure of polymer microfluidic devices by inducing a flow of solvent through a microfabricated channel via capillary action. This approach was simple to implement, but the bond strength of the microdevices was low (80 psi), which would limit applications that require viscous gels or chromatographic stationary phases to be pumped into microchannels under pressure. Therefore, the development of fabrication protocols that more fully realize the advantages of solvent bonding is warranted.

This chapter describes the theory, methodology, and application of a microfabrication process that uses phase-changing sacrificial layers (PCSLs) as intermediates to protect microchannel features during bonding or hydrogel polymerization. We focus on key process details associated with the fabrication of microchips, and the application of PCSL-formed microfluidic devices in CE separations and other electric field-based analysis methods. Finally, we provide a brief overview of potential future trends and applications of PCSL fabrication methods in microfluidics.

## 51.2 BACKGROUND AND THEORY

In the past 15 years, the use of microfluidic devices for chemical analysis has increased tremendously. Indeed, a broad range of chromatographic and electrophoretic separation methods have been implemented in microchips.<sup>63</sup> However, for widespread utilization of microfabricated devices in analysis applications, particularly in the field of proteomics, further efforts are needed to develop simple fabrication techniques that achieve functional integration of multiple tasks in a single device.<sup>64</sup> In this section, we describe the fabrication of microdevices using sacrificial materials and discuss some of the advantages of this approach over conventional microfabrication methods.

**FIGURE 51.1** Schematic diagram of the general processing steps involved in the fabrication of microchannel structures using sacrificial materials.

### 51.2.1 SACRIFICIAL MATERIALS

Microfabrication using sacrificial layers is well developed in the field of microelectromechanical systems. Reports include the fabrication of micro- and nanomechanical components,<sup>65</sup> electroosmotic micropumps in silicon and glass substrates,<sup>66</sup> and nano-<sup>67</sup> or microchannels<sup>68,69</sup> with potential applications in biology.<sup>70</sup> Unlike bonding protocols, in which a cover plate is affixed to a patterned substrate to seal microchannels, sacrificial layer methods can obviate the bonding step, making this approach very attractive.<sup>71,72</sup>

Figure 51.1 provides a general overview of the process for making microfluidic systems using sacrificial materials. Briefly, a sacrificial layer is deposited on a substrate by spin coating, vapor deposition, or some other method. Then, using photolithography, the sacrificial material is patterned and serves as a temporary “placeholder,” which defines the channel geometry. After deposition of a top layer, the sacrificial material is removed, leaving behind open tubular features between the substrate and the cover layer.<sup>71</sup>

There are a variety of materials that can be used as sacrificial cores. Inorganic sacrificial materials include  $\text{SiO}_2$ <sup>73</sup> and metals such as aluminum,<sup>74</sup> titanium,<sup>75</sup> and nickel.<sup>76</sup> Polymers such as PI,<sup>77</sup> PMMA,<sup>65</sup> PC,<sup>68</sup> and photoresist<sup>78</sup> have also been used as sacrificial materials. After deposition of the cover film, removal of the sacrificial layer can be achieved by dissolution,<sup>79</sup> etching,<sup>66,74,80</sup> or thermal degradation.<sup>81,82</sup> These removal methods each have benefits and drawbacks; selection of the optimal approach is specific to particular combinations of substrate, sacrificial layer, and cover film.<sup>73,83</sup> Recently, Whitesides and coworkers<sup>84</sup> implemented a fabrication method using water-soluble sacrificial cores. Poly(acrylic acid) and dextran proved to be effective sacrificial layers that could be dissolved in water or aqueous NaCl, for making metallic microstructures by nickel electrodeposition.

Importantly, microfabrication using sacrificial cores is a versatile technique. First, there are no limitations in the size or flatness of the channel substrate, since no bonding is involved.<sup>81</sup> Second, the choice of sacrificial material can influence the geometry of the resulting microchannels; for example,

Peeni et al.<sup>74</sup> used aluminum/photoresist, SU-8, and aluminum to obtain semicircular, rectangular, and trapezoidal geometries, respectively. In addition, even though glass<sup>66,74</sup> and silicon<sup>85,86</sup> are the two most common substrates for microfabrication using sacrificial layers, the surface properties of microfluidic vias can be adapted to specific applications by depositing selected materials beneath and on top of the sacrificial layer. Moreover, sacrificial approaches facilitate the formation of three-dimensional fluidic systems through sequential deposition of layers.<sup>67,87</sup> Finally, the fabrication of microchannels *in situ* should enable the integration of fluidic and electronic components in microdevices.

## 51.2.2 SACRIFICIAL LAYER FABRICATED MICROFLUIDIC DEVICES

### 51.2.2.1 Silica and Glass Materials

Sacrificial etching methods have been used widely in the microelectronics industry for years; however, only a few examples of separations in sacrificially formed microfluidic systems have been demonstrated. Craighead and coworkers<sup>88</sup> used thin-film deposition and wet chemical etching to define approximately 100-nm-dimension nanochannels, which were used to measure the electrophoretic mobilities of two different lengths of DNA. More recently, the same group fabricated submicrometer-dimension fluidic channels for the analysis of less than 100 fg of DNA.<sup>80</sup> Hawkins and coworkers fabricated a microdevice using thin-film techniques, and used it to perform single-molecule detection.<sup>89</sup> Woolley and coworkers have shown CE separations of fluorescently labeled amino acids in a 9-mm-long microchannel fabricated by thin-film deposition of silicon dioxide over a photoresist/aluminum sacrificial layer.<sup>74</sup> Subsequent optimization also enabled peptide separations to be carried out in these devices.<sup>90</sup> These studies demonstrate the potential for performing separations in microdevices fabricated using sacrificial layer techniques, but further work remains.

Despite the successful construction of microchips using sacrificial layer methods, several issues must still be addressed with the fabrication process and the resulting devices. First, fabrication requires cleanroom facilities, costly instrumentation for thin-film deposition and patterning, and expertise to use such equipment, all of which make this approach inaccessible to some researchers. In addition, there are several constraints on the types of substrates, sacrificial layers, and overlayers that can be used.<sup>68,85</sup> For example, the sacrificial material must produce a high quality and uniform film of several micrometers thickness.<sup>73</sup> In addition, the sacrificial layer must adhere well to the substrate and not react with the covering film. Ideally, the sacrificial layer will be removed completely, leaving a smooth inner surface in the microchannel. Moreover, neither the substrate nor the cover layer must be affected during the sacrificial layer removal step.<sup>68</sup> Unfortunately, the removal of the sacrificial material can take hours to days, which limits the mass production of microchips by this method. Solubility can be a concern, especially when a polymer is used as the cover layer with a photoresist-based sacrificial material. In this case, the solvent present in the coating polymer solution can attack the sacrificial photoresist and compromise microchannel integrity.<sup>68</sup> Similarly, if a thermally decomposable polymer is used as a sacrificial layer, complete decomposition should occur in a narrow temperature range, which must be compatible with the other materials and components on the substrate.<sup>91</sup>

Structural strength is another important consideration in the fabrication of microchannels for fluid handling. In the sacrificial layer fabrication approach, microchannels are generated by deposition of a thin film on top of a patterned material, and the resulting structures are generally weaker than those made by standard bonding methods. Hubbard et al.<sup>83</sup> investigated possible causes of channel wall failure during fabrication with an aluminum sacrificial layer and silicon dioxide overcoating. Elevated internal pressure from gas generated during the etching of aluminum was found to be the main cause of microchannel wall failure during fabrication. A finite element model showed that channel width and film thickness were the most critical parameters to optimize in avoiding device failure.

In summary, sacrificial fabrication of microfluidic devices in glass and silicon overcomes some limitations of conventional manufacturing methods. Important benefits include the ability to fabricate nanometer- to several micrometer-dimension structures and the elimination of a bonding step. Nevertheless, several problems with sacrificial fabrication have limited the implementation of this technique in making microfluidic devices. First, the fabrication protocols are not generally easy to implement and require sophisticated instrumentation. Second, device materials are limited to glass and silicon, the substrates most compatible with the manufacturing methods. Finally, fabrication yield and reproducibility still need improvement. Thus, further work is essential to develop sacrificial fabrication techniques.

### 51.2.2.2 Polymeric Materials

We have been interested in applying sacrificial layer methods for making polymer microfluidic systems. We were inspired by work that utilized the solid–liquid phase change of waxes at their melting point, to form actuators such as valves in fluidic microchips.<sup>92–95</sup> This phase transition offers a promising approach for filling (as a liquid) and protecting (as a solid) microchannels during device processing steps.

In brief, PCSL microfabrication involves heating a solid sacrificial material to a temperature above its melting point and using it to fill a microchannel imprinted in a polymeric substrate. After cooling, the sacrificial material solidifies and protects the microchannel from solvent and dissolved polymer during bonding. Next, solvent is spread on top of the PCSL-protected channels, and a polymeric cover layer containing access reservoirs is aligned and held in contact with the imprinted substrate until a robust bond is obtained, resulting in enclosed PCSL-filled channels. Finally, the device is heated above the melting temperature of the sacrificial material, and vacuum is applied to remove the melted PCSL, creating open microchannels. Indeed, a paraffin wax PCSL was recently used to construct microfluidic devices; the combination of PCSLs and solvent bonding enabled polymer microchips to be fabricated and evaluated in  $\mu$ CE analysis of amino acids and peptides.<sup>96</sup>

PCSL microfabrication is an attractive alternative for making robustly enclosed microchannels by solvent bonding, while protecting microchannel integrity using a sacrificial material. This technique does not require sophisticated thin-film deposition instrumentation and should be easy to implement by microfluidics researchers. In the next section, we provide guidelines for the fabrication of polymer microfluidic systems using PCSLs.

## 51.3 FABRICATION TECHNIQUES AND METHOD DEVELOPMENT

Because of the many advantages of polymer microchips, there is a tremendous need for alternative fabrication processes to allow the realization of their full potential.<sup>64,97</sup> Thus, this section describes the steps to follow to make polymer microdevices using PCSL and solvent-bonding techniques. Because of its good optical properties and well-known patterning procedures, PMMA is used frequently for the fabrication of microfluidic chips.<sup>23,24,34</sup> As a result, the PCSL microfabrication method will be detailed for PMMA microchip fabrication. However, constructing microdevices from different polymers using the PCSL method should be straightforward, if the appropriate combination of substrate, sacrificial material, and solvent are selected. The basic fabrication procedure includes (a) template fabrication, (b) microchannel imprinting, (c) filling channels with PCSL, (d) microdevice bonding, (e) sacrificial layer removal, and (f) microchip evaluation. A schematic overview of the fabrication process is shown in Figure 51.2.

### 51.3.1 TEMPLATE FABRICATION

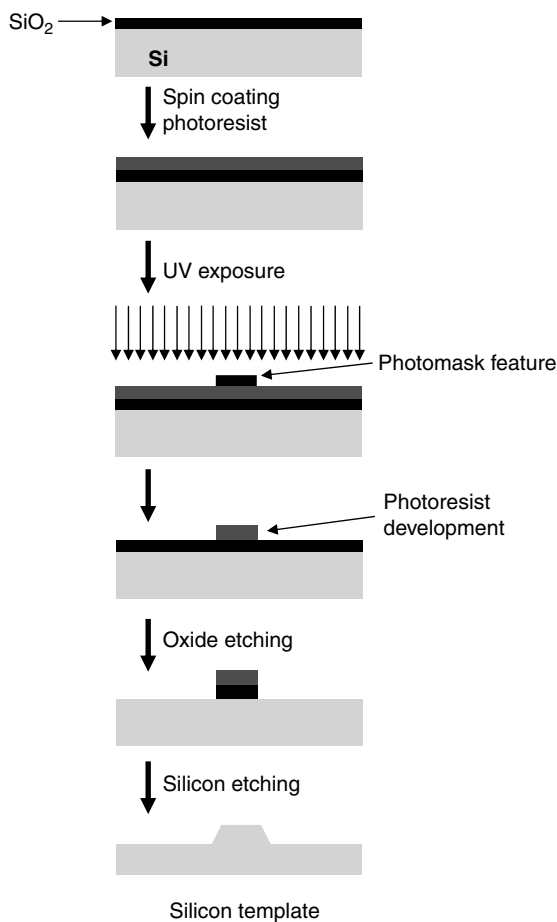

Polymer microfluidic systems for chemical analysis are normally fabricated by transferring a patterned microstructure from a template to a substrate.<sup>23</sup> Micromachined silicon templates are often

**FIGURE 51.2** Fabrication of microchannels in a polymer substrate using PCSLs and solvent bonding (additional details are in the text).

used; these are created by standard photolithographic and etching methods.<sup>42</sup> Figure 51.3 briefly summarizes the steps to transfer a pattern from a computer-designed mask to a silicon wafer. The process starts with a silicon substrate that has an  $\text{SiO}_2$  layer formed on the surface. Next, a photosensitive material (photoresist) is spin coated on the wafer, forming a film whose thickness depends on the spin speed and time. Excess solvent in the photoresist is removed by heating the wafer, leaving a solid photosensitive material on the surface, which is then exposed to UV radiation through a patterning mask. The UV light induces a chemical reaction in the photoresist, altering its solubility in a developer solution. After the photoresist pattern is developed, the wafer is subjected to solution- or gas-phase etching to remove the  $\text{SiO}_2$  from the areas not protected by the hardened photoresist. Finally, wet chemical or gas-phase etching is used to generate the elevated features, which should be identical to the mask pattern.

**FIGURE 51.3** Schematic of the photolithography process to transfer a pattern to a silicon wafer, forming a template for microchannel imprinting.

Although the silicon micromachining process is well developed, extensive use of costly clean-room instrumentation is required. Thus, alternative and simpler template construction approaches are being pursued. One such method utilizes SU-8, an epoxy-based negative photoresist, which has excellent chemical resistance and mechanical properties. Patterned SU-8 is being applied increasingly in making microstructures for templates in microchip production.<sup>98–100</sup>

### 51.3.2 MICROCHANNEL IMPRINTING

Using a procedure reported by Locascio and coworkers,<sup>23</sup> elevated features in a Si template can be imprinted into PMMA substrates to form microchannels (see Figure 51.2a through c). Briefly, the silicon template and polymer substrate are sandwiched between glass slides (Figure 51.2b), using two 2'' C-clamps to apply pressure. It is important to use flat and clean substrates to hold the polymer and template together, and to apply pressure evenly to avoid breaking the template. The pieces are heated to 110°C, which is above the glass transition temperature of PMMA. After 10 min, the assembly is removed, the C-clamps are tightened 1/8 turn, and the pieces are returned to the oven. The clamp tightening procedure is repeated two more times for a total imprinting duration of 30 min. This process results in the embedding of the template features into the PMMA (Figure 51.2b). After removal from the oven, the imprinted PMMA (Figure 51.2c) is cooled to room temperature.

### 51.3.3 FILLING MICROCHANNELS WITH PCSL

Before solvent bonding, the microchannels must be filled with PCSL. Some practical considerations for selecting a material for a sacrificial layer are (1) it should have a lower melting point than the substrate itself; (2) it must be resistant to the bonding solvent; (3) it should not react with the polymer substrate; (4) it should form a smooth surface after solidification; and (5) it must be easy to remove from the microchannel after bonding.

The following is a short overview of the process for depositing a PCSL into imprinted features. A PMMA piece having imprinted microchannels (formed as described earlier) is sealed reversibly to an approximately 1-mm-thick PDMS film, which has small holes that correspond to the channel ends. This temporarily enclosed PMMA-PDMS structure is placed on a hotplate at 85°C, heated paraffin wax is added to all but one of the channel access holes in the PDMS film, and vacuum is applied at the unfilled opening, causing liquid PCSL to fill the entire microchannel network (Figure 51.2d). Cooling the assembly to room temperature produces a solid PCSL, protecting the microchannels as indicated in Figure 51.2e.

Occasionally, some PCSL solidifies outside the microchannel region, and this excess wax needs to be removed for proper bonding. We have devised two solutions to the issue of PCSL deposition outside of channels. First, if the paraffin wax PCSL is left in contact with PDMS for 1–2 h, the PCSL outside the channels dissolves into the PDMS.<sup>96</sup> A second solution is to add the liquid paraffin wax to the device without applying vacuum; in this case, the PCSL enters the microchannels by capillary action, and a more uniform filling is observed. Once well-defined microchannels loaded with solid sacrificial material are obtained, the PDMS film is removed carefully, and the PCSL-filled device is ready for bonding.

### 51.3.4 MICRODEVICE BONDING

To form enclosed microchannels, the PCSL-protected PMMA piece must be bonded to a cover plate having channel access holes. To this end, solvent is added on top of the imprinted substrate (Figure 51.2f), a polymer top piece is aligned with the PCSL-protected microstructure, and applied pressure for approximately 2 min completes microdevice bonding (Figure 51.2g). The solvent bonding step must be performed sufficiently quickly so that the solvent does not evaporate or dissolve the substrate extensively, which could affect channel integrity. In practice, we found that bringing the two PMMA pieces together at an angle allowed air bubbles to escape from the side, leading to higher-quality microdevice bonding. Finally, it is important for the cover PMMA piece to be about the same size as the imprinted substrate.

The amount of solvent added also affects the quality of the bonded devices. Sufficient solvent must be added to cover the entire PCSL-protected surface, without leaving bubbles or unwetted areas. On the other hand, if an excess of solvent is applied, it flows outside the bonding interface and can compromise the optical quality of the surface of the resulting device. To overcome this problem, PDMS films can be placed on the nonbonding sides of the PMMA, to keep the solvent from damaging the microchip exterior surfaces. Using masking tape to protect the PMMA surfaces has also proven to be successful. Experimentally, we found that a 2 × 4 cm PMMA substrate with an approximately 3-cm-long separation channel could be completely bonded with as little as 35  $\mu\text{L}$  of acetonitrile.<sup>96</sup>

### 51.3.5 SACRIFICIAL LAYER REMOVAL

The final step in PCSL fabrication of microfluidic systems is removal of the sacrificial material to yield clean, smooth microchannel inner surfaces. Paraffin wax PCSL is removed by heating the microdevice to 85°C and applying vacuum to a reservoir in the PMMA cover piece to aspirate the liquid PCSL (Figure 51.2h). Nonpolar organic solvents such as hexane or cyclohexane can be used subsequently to dissolve and remove residual sacrificial material from inside the channel. With

PMMA microdevices, complete removal of the PCSL (Figure 51.2i) is verified by an absence of air bubbles in the channels on filling with water.

### 51.3.6 MICROCHIP EVALUATION

Several aspects of the microchips can be characterized after bonding is completed. For instance, the microchannel shape can be indicative of the effectiveness of the sacrificial material in protecting the microchannel during solvent bonding. Edge-on photomicrographs allow measurement of the cross-sectional area of features, both before and after bonding. As an example, Figure 51.4 shows cross-sectional views of a microchannel at several stages of the fabrication process. As is visible in Figure 51.4b, the paraffin wax PCSL appears to undergo a small amount of shrinkage on solidification. Importantly, this minor shrinkage does not compromise microchannel usefulness, even with structures having depths as small as  $7\ \mu\text{m}$ .<sup>96</sup>

Another important parameter to evaluate in PCSL-fabricated microchips is the bond strength. Several techniques have been reported to determine the bonding strength of microfluidic chips; for example, by measuring the tensile force in pulling pieces apart<sup>101</sup> or by evaluating the shear force at the bonding interface of chips.<sup>102</sup> These methods normally use epoxy to attach a device to an external force; thus, the bond strength determination may be limited by the strength of the epoxy rather than the microchip itself. We have devised an approach for determining the maximum internal pressure that can be sustained in PCSL solvent-bonded devices. We take an appropriately threaded PMMA piece (which can be connected to a  $\text{N}_2$  cylinder via 1/16-in copper tubing) and bond it to a second PMMA substrate utilizing the same conditions (solvent, applied pressure, and time) as for microchips. Once this assembly is connected to a gas cylinder, the applied pressure can be increased until either the

**FIGURE 51.4** Edge-on photomicrographs of channel cross-sections at different fabrication stages. (a) Imprinted channel. (b) Imprinted channel filled with PCSL. (c) Bonded device after PCSL removal. (Reprinted from Kelly, R. T., et al., *Anal. Chem.*, 77, 3536, 2005. Copyright 2005. With permission from American Chemical Society.)

device fails or the maximum cylinder value ( $\sim 2200$  psi) is reached. Using this approach, we found that PMMA bonded using acetonitrile and our conditions was stable to at least 2200 psi internal pressure.<sup>96</sup> To more precisely measure the bond strength, one could appropriately connect PMMA substrates to a high-pressure liquid chromatography pump and measure the maximum pressure obtained. As with all high-pressure device failure determination methods, it is necessary to take proper safety precautions to avoid injury from PMMA projectiles that may be produced when failure occurs.

## 51.4 PRACTICAL APPLICATIONS

### 51.4.1 MICROCHIP CAPILLARY ELECTROPHORESIS

Capillary electrophoresis in polymer microfluidic devices was first demonstrated 10 years ago, in both PDMS<sup>26</sup> and PMMA.<sup>23</sup> The analysis of amino acids and peptides by  $\mu$ CE is also well established.<sup>42,96,103,104</sup> The operational parameters for injection and separation in  $\mu$ CE are presented in Figure 51.5.<sup>105</sup> First, the microchannels are filled with buffer solution, ensuring that the channels are bubble free. Sample solution is pipetted into the sample reservoir (SR), and a potential is applied to the injection reservoir (IR) for a short duration, while keeping the other three reservoirs grounded to load sample. To separate the small sample plug loaded into the injector, the voltage configuration is switched so a potential that is several fold higher than the injection voltage is applied to the waste reservoir (WR), the buffer reservoir (BR) is kept at ground, and the SR and IR are held at the injection voltage. Detection of separated analytes takes place in the separation channel near the WR. Owing to its high sensitivity and ability to probe small volumes, LIF is the most commonly used detection method in  $\mu$ CE. However, LIF requires that many analytes be labeled fluorescently before analysis, for example, using reagents such as fluorescein isothiocyanate (FITC).<sup>106</sup> In this section, we describe the application of PCSL-formed PMMA microchips to the  $\mu$ CE analysis of amino acids and peptides.

#### 51.4.1.1 Amino Acid and Peptide Analysis

The PCSL techniques described in Section 51.3 were used to fabricate PMMA microchips for  $\mu$ CE analysis. The microchannel lengths from the injection intersection to the BR, SR, and IR were 0.5 cm, and the distance from the injection intersection to the WR was 2.5 cm (see Figure 51.5). The channels had a trapezoidal cross-section and were 40- $\mu$ m wide at the base and 30- $\mu$ m deep (see Figure 51.4).<sup>96</sup> Before analysis, the microchannels were filled with 10 mM carbonate buffer

**FIGURE 51.5** Schematic representation of the injection and separation steps in  $\mu$ CE (additional details are in the text).

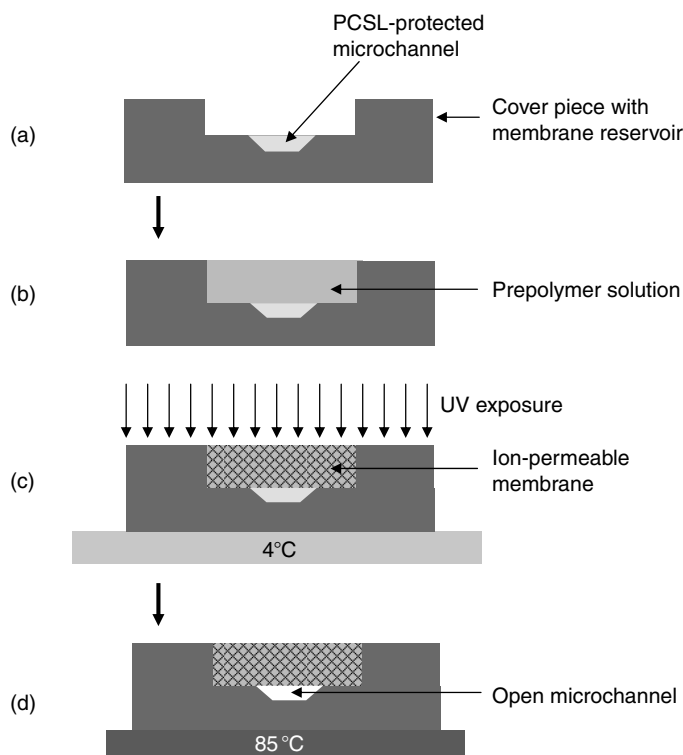

**FIGURE 51.6** Separation of FITC-labeled amino acids (75 nM) in 10 mM carbonate buffer, pH 9.2. The injection voltage was +800 V, and the separation voltage was +3.0 kV. (Reprinted from Kelly, R. T., et al., *Anal. Chem.*, 77, 3536, 2005. Copyright 2005. With permission from American Chemical Society.)

**FIGURE 51.7** Separation of 110 nM FITC-labeled peptides;  $\mu$ CE separation conditions were the same as in Figure 51.6. (Reprinted from Kelly, R. T., et al., *Anal. Chem.*, 77, 3536, 2005. Copyright 2005. With permission from American Chemical Society.)

(pH 9.2), containing 0.5% (w/v) hydroxypropyl cellulose (HPC) to minimize electroosmotic flow and prevent analyte adsorption.<sup>107</sup> Buffer solution was pipetted from the SR, and approximately 10  $\mu$ L of sample solution (amino acid or peptide) was added.

Figure 51.6 shows an electropherogram of four FITC-labeled amino acids separated in a PCSL-formed solvent-bonded microchip. Importantly, these PCSL-fabricated microdevices are able to withstand applied electric fields of at least 1500 V/cm, which is the highest reported field strength for  $\mu$ CE in polymeric devices. The use of high electric fields provided separation efficiencies of over 40,000 theoretical plates, which are comparable to values obtained in glass microchips.<sup>104,108</sup> Figure 51.7 shows an electropherogram of seven FITC-labeled peptides separated in a PMMA microchip constructed using solvent bonding with PCSLs. The separation efficiency in the analysis of FITC-labeled peptides was similar to that for the analysis of amino acids. The ability to carry out high-performance  $\mu$ CE of peptides indicates that PCSL-formed devices have potential for proteomic analysis. In addition, PCSL-fabricated microchips were used to perform more than 300  $\mu$ CE runs over a 3-month period with no degradation of separation performance. These results demonstrate the excellent potential for using PCSL solvent bonding in the fabrication of robust, low-cost microchips for high quality and rapid electrophoretic analysis of biomolecules.

**FIGURE 51.8** Schematic diagram of using PCSLs to interface microfluidics with ion-permeable membranes. (a) A PCSL-protected microchannel substrate is bonded to a PMMA cover piece having a membrane reservoir. (b) Prepolymer solution is poured into the membrane reservoir. (c) An ion-permeable hydrogel is photopolymerized. (d) The PCSL is melted and removed from the channel. (Adapted from Kelly, R. T., et al., *Anal. Chem.*, 78, 2565, 2006. Copyright 2006. ## 51.4.2 PCSLS FOR INTEGRATING MEMBRANES WITH MICROFLUIDICS

### 51.4.2.1 Fabrication

PCSLs offer a straightforward approach for incorporating additional components *in situ* during the fabrication of microchips. For example, Figure 51.8 shows a fabrication scheme for integrating an ion-permeable membrane with a microfabricated channel using PCSLs.<sup>109</sup> First, a PCSL-protected microchannel substrate is bonded to a PMMA cover piece having one or more reservoirs for membrane formation (Figure 51.8a). Next, prepolymer solution is poured into the membrane reservoir and UV polymerized while maintaining the whole assembly at 4°C to avoid melting the PCSL (Figure 51.8b,c). Finally, the microchip is heated to allow facile removal of the liquefied PCSL, leaving a membrane-integrated microchannel in the device (Figure 51.8d). In addition to the characteristics noted in Section 51.3.3, PCSLs for the integration of membranes with microchannels must not react with or dissolve in either the membrane monomer solution or the polymerized hydrogel.

### 51.4.2.2 Application to Electric Field Gradient Focusing

Electric field gradient focusing (EFGF) is an equilibrium-gradient separation method,<sup>110</sup> in which analytes are focused at different equilibrium positions in an electric field gradient.<sup>111,112</sup> In EFGF, the electrophoretic motion of charged molecules in an electric field gradient in a column is opposed by hydrodynamic flow. The result is that each analyte will focus (stop) at an equilibrium position

where the electrophoretic and laminar flow velocities are opposite and equal. The principle of EFGF has been studied theoretically and experimentally.<sup>111–115</sup>

Perhaps the simplest way to do EFGF is to interface an open column of constant cross-sectional area with a semipermeable membrane of changing cross-sectional area.<sup>116</sup> The ion-permeable membrane allows free flow of small buffer ions, but proteins are constrained to the open column, and the changing cross-sectional area of the semipermeable copolymer creates an electric field gradient. Interfacing an open column with an ion-permeable membrane is challenging using conventional methods,<sup>116</sup> but is a task that is ideally suited for PCSL fabrication.

Woolley and coworkers<sup>109</sup> have fabricated EFGF microchips using the PCSL approach. In these devices, the membrane reservoir was a shaped region (for generating an electric field gradient) in the PMMA cover piece, and the open channel in the patterned substrate was protected with PCSL during membrane polymerization. The performance of PCSL-fabricated EFGF microchips was compared to that in capillary-based EFGF devices by analyzing two natively fluorescent proteins, R-phycoerythrin (R-PE) and green fluorescent protein (GFP), in both systems. The results indicated a fourfold reduction in peak width and a threefold improvement in resolution for PCSL-fabricated EFGF systems compared to capillary devices. Moreover, resolution for the analysis of peptides in microchip EFGF devices was comparable to that in  $\mu$ CE, but sample was concentrated 150-fold in the EFGF system.

Using PCSLs to integrate microfabricated channels with ion-permeable membranes improves EFGF experiments. The smaller cross-sectional channel dimensions in the microchip EFGF devices reduce band width and improve the resolution of protein peaks. Importantly, the fabrication protocols are flexible and easy to adapt as needed for different device designs.

#### 51.4.2.3 Application to Protein Preconcentration

The same PCSL fabrication protocols for interfacing microfluidics and membranes in EFGF can also be used for on-chip protein preconcentration and separation.<sup>109,117</sup> A PCSL-filled microchannel imprinted in PMMA was affixed to a cover plate containing a membrane reservoir, and hydrogel was polymerized as described earlier.<sup>109</sup> To concentrate protein samples at the membrane, a voltage was applied between the sample and membrane reservoirs. Concentration factors as high as 10,000-fold for a model protein (R-PE) were observed.<sup>109</sup> Preconcentrated proteins were separated electrophoretically by applying a potential between the membrane reservoir and the reservoir at the end of the channel. A protein mixture containing R-PE and GFP has been concentrated and separated electrophoretically in a membrane-integrated device.<sup>117</sup> These experiments verify the power of the PCSL approach in making microchips for integrated sample enrichment and separation.

### 51.5 CONCLUDING REMARKS AND FUTURE TRENDS

In this chapter, we have presented phase-changing sacrificial layers as enabling tools for making a variety of microfluidic devices in polymers. Several successful uses of PCSLs in biological analysis are discussed herein, which should motivate the pursuit of new developments and applications of this emerging approach.

In the future, we anticipate the generalization of PCSL fabrication methods to polymers in addition to PMMA. Table 51.1 summarizes the key considerations for the substrate, sacrificial material, and solvent in PCSL fabrication.<sup>118</sup> We have recently obtained promising results in extending the PCSL technique to other polymeric substrates, including PC, PET, and COC.<sup>118</sup>

In addition to the possibility of using PCSLs to construct microfluidics in various polymeric materials, this approach could also facilitate the implementation of new analysis techniques in a microchip format. For example, applications that require high pressures, such as for loading viscous sieving polymers for DNA separation or for packing small-diameter-particle stationary phases for

**TABLE 51.1**  
**PCSL Solvent Bonding Method Development Considerations**

	<b>Requirements</b>
Substrate	Easily imprinted with template Inexpensive Seals to elastomer
Sacrificial material	Does not interfere with chemical analysis Transitions from solid to liquid near room temperature Does not interact with polymer/elastomer Appropriate viscosity Forms smooth, even channels
Solvent	Solubility differs from substrate Dissolves substrate but not sacrificial layer Appropriate rate for dissolving substrate

**FIGURE 51.9** Layout of a multilayer microdevice for parallel, simultaneous analysis of a single sample in three channels.

chromatography, may become feasible in PCSL-fabricated polymer microchips, because of their high-pressure stability.

### 51.5.1 FABRICATION OF MULTILAYER MICROFLUIDIC ARRAYS

Interestingly, most research efforts with polymer microfluidic structures have focused on applying the same planar two-dimensional layouts of glass microchips in plastic devices. However, multilayer microstructures, wherein multiple channels can cross over one another without contamination, would significantly increase the operational flexibility in miniaturized analysis. Multilayer microfluidics have been fabricated in glass,<sup>119</sup> PDMS,<sup>120,121</sup> and PDMS/glass hybrid microchips.<sup>122</sup> However, this design has not been implemented in easy-to-fabricate thermoplastic (rigid) polymers. Importantly, thermal bonding is problematic in the fabrication of multilayer structures, because the heat and pressure often deform the surface, making it difficult to bond subsequent layers; moreover, microchannels can be constricted or blocked as a result of repeated heating steps. In contrast, PCSL fabrication protocols are simple and straightforward to implement, which would be advantageous for making multilayer polymer microchips. Indeed, using PCSL microfabrication, multiple substrates can be bonded together successfully, without affecting the previous layers.

Important new applications could be developed in multilayer polymer microfluidic systems. For example, multiple replicate analyses of a sample in a single reservoir could be performed in parallel on a single device. Figure 51.9 shows a schematic diagram of a multilayer microdevice with channels

crossing over each other. This device could be used to separate a sample in three microchannels using a single input, which would allow parallel, replicate analyses of the same specimen. Additional designs could be formed with parallel channels having different surface properties or separation media, to implement orthogonal separation mechanisms. Such layouts could then be used in parallel analysis of the same sample under different conditions. Finally, multilayer structures with crossing channels would facilitate the integration of end-column fluorescent or other labeling techniques in  $\mu$ CE.

## ACKNOWLEDGMENTS

The authors are grateful to the National Institutes of Health (EB006124) for providing financial support to complete this work. We thank Dr. Ryan T. Kelly for training and useful tips on the fabrication of PCSL microdevices, and Bridget Peeni, Tao Pan, Weichun Yang, and Dr. Xiuhua Sun for helpful discussions.

## 52.1 INTRODUCTION

Microchip capillary electrophoresis (MCE), like conventional capillary electrophoresis (CE) and most other chemical separation techniques, is heavily dependent on surface chemistry. This connection is obvious for techniques that use a stationary phase but is also apparent for separation modes like zone electrophoresis where the separation is based on the mobility of the ions. An important component of zone electrophoresis is the electroosmotic flow (EOF), which is a surface-derived phenomenon. Furthermore, the degree of surface hydrophobicity can cause adsorption resulting in band broadening. As a result of the significance of the surface chemistry, it is important to develop an understanding of methods that provide control of surface chemistry in MCE. This problem is more

pronounced in MCE than in CE because a wide range of substrate materials are used. The goal of this chapter is to first introduce the reader to the substrate materials and the associated fabrication methods that are common to MCE. Next, general methods for modifying the surface chemistry of different substrate materials are provided. This is not meant to be an all-inclusive listing of methods but instead to provide the reader with general guidelines for controlling the all important surface chemistry of electrophoresis microchips through selection of the substrate material and/or modification of the surface. Finally, a brief summary of surface characterization methods is described, which permit evaluation of different surface modification methods.

## 52.2 SUBSTRATE MATERIALS

Since the initial report on MCE, a wide range of materials have been used to produce microchips [1]. Early on, all microchips were made from glass or similar materials (quartz, fused silica, etc.) because these materials have very good optical clarity, have well-established fabrication methods, and are chemically similar to the fused silica used with conventional CE. Soon other materials were explored for use with MCE in a search for lower cost substrates, providing a broader range of chemical properties including but not limited to flexibility, the ability to make microchips from multiple materials, and control of surface chemistry through differences in bulk material. In addition, some materials, polymers in particular, are amenable to parallel batch fabrication methods that can reduce the cost of the production in addition to the cost of the materials. Here a summary of each of the major materials used in MCE is provided, along with a description of the fabrication methods appropriate for each type of material.

### 52.2.1 SILICON-BASED MATERIALS

Silicon oxide materials, glass, quartz, and fused silica are arguably the most common substrates used for MCE and will be referred to here as glass for simplicity. Many reasons exist for the use of glass. First, glass is generally chemically stable. Common organic solvents ranging in polarity from methanol to hexanes are completely compatible with the material. Furthermore, aqueous buffers with most pH ranges (2–13) can be used with glass microchips as long as there is no covalent modification to the surface. Second, glass has good optical transmission through a broad range of wavelengths from the UV to the visible. Optical transmission is important for detection whether it is simple absorbance or the more sensitive laser-induced fluorescence (LIF). Third, a large number of fabrication methods preexisted the development of MCE as a result of the need to process silicon-based materials in the integrated circuit industry. These methods can be largely adapted to MCE fabrication. Finally, the material is rigid, making it easy to handle and integrate with external connections to pumps, and so forth. Glass is not without limitations, with fabrication methodology being the primary one. Channels are etched with either caustic hydrogen fluoride (HF) or expensive reaction ion etchers. In both cases, the channel dimensions and shapes are limited. Bonding requires high temperature furnaces, careful temperature programming, and long times (24 h) compared to the polymeric materials in use today. Finally, all of these processes must be repeated for each device produced and must be done in a clean room environment. This adds to the cost of commercially produced microchips and/or limits the availability of this technique to those with access to advanced microfabrication facilities. In the end, it is up to the user to decide whether the advantages of glass devices outweigh the disadvantages.

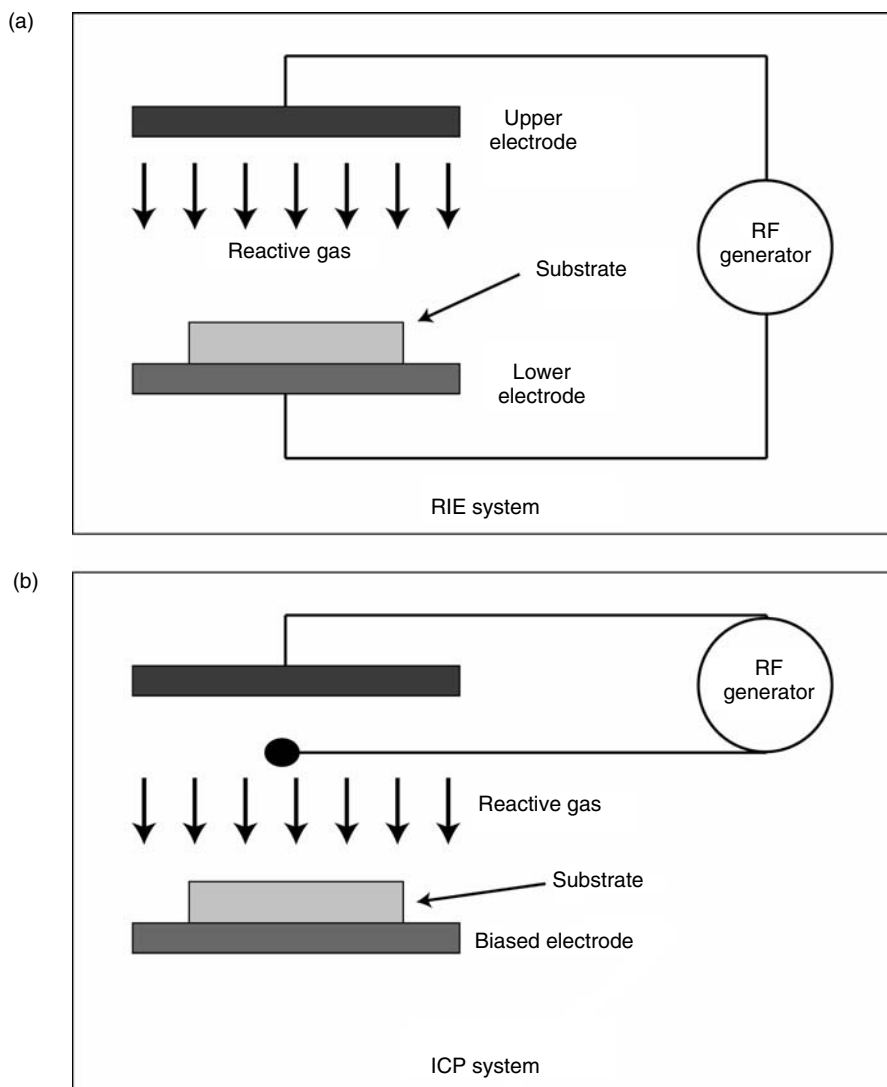

Figure 52.1 shows the general approach for creation of electrophoresis devices using a glass substrate. The main steps are etching, which define the channel dimensions and shape, and bonding, which adds the fourth wall to the channel to create a sealed capillary. Each of these steps can be accomplished in multiple ways, and therefore careful consideration is needed, particularly for etching.

**FIGURE 52.1** Schematic showing the fabrication process for glass microchips. The process begins with a blank glass plate. A masking layer (typically a metal plus photoresist) is deposited on top of the glass. The masking layer is patterned using UV light and the exposed metal removed. The underlying glass is etched using a caustic solution to the appropriate depth. The remaining photoresist and metal are removed and the patterned glass substrate is sealed to a second piece of unpatterned glass containing predrilled access holes using thermal methods.

### 52.2.1.1 Etching

Two general types of etching are used to create glass microchips, wet and dry. Wet etching is by far the most common because it does not require very expensive and complicated reactive ion etching (RIE) instrumentation. Dry etching, on the other hand, can provide better control over channel geometry and aspect ratios as well as give deeper channels. Which method is selected is often dictated by the availability of instrumentation and/or the specific application. For both fabrication methods, the glass is first covered with a thin layer of metal and photoresist. The metal is removed from the surface in the areas where etching will occur using a series of standard photolithography and metal etching steps. Finally, the exposed glass is etched to form three sides of the capillary. For wet etching, the most common etchants are based on HF [either concentrated HF or buffered oxide etch (BOE) that is a mixture of  $\text{NH}_4\text{F}$  and HF]. Wet etching (Figure 52.1) results in a hemicylindrical shape of the channel because etching occurs in all directions (isotropic). This etching mode limits, the aspect ratio of wet-etched glass microchips is limited and most channels are relatively shallow (10–30  $\mu\text{m}$ ). In many cases, this is acceptable; however, there are cases where deeper, narrower channels are needed [2]. In the latter case, a dry etching technique that is anisotropic or directional is needed to provide higher aspect ratios. Two dry etching methods, RIE and inductively coupled plasma (ICP) etching, are common in this application (Figure 52.2). Powder blasting has also been used in a limited number of cases, but generally results in rough channel surfaces owing to the etching mechanism. For both RIE and ICP, a cloud of reactive gases (plasma) is generated at reduced pressure using an RF generator and these gases react with the surface. The incoming gas composition can control the selectivity of the etch. For example,  $\text{CF}_4$  can etch Si quickly but leave metals relatively untouched. As a result, metal films are traditionally used as etch masks for both processes. In RIE, the substrate to be etched sits on top of one of the electrodes and the gas is driven to the surface, causing reactions that remove surface material (Figure 52.2a). In ICP a plasma is generated using RF frequency, but this reactions occurs above the substrate. The substrate is biased to a potential that causes the reactive gas species to be accelerated toward and react with the surface. Both etching methods provide directional control of etching. As the reactive gases bombard the surface, they react with the first surface they

**FIGURE 52.2** Schematic drawing of both reactive ion etching (RIE) and inductively coupled plasma (ICP) etching systems. In both cases, RF radiation is used to induce a plasma that is subsequently driven to the surface as a result of the charges on the gases coupled to a potential bias on an electrode underneath the substrate.

come to. Because they are being driven down, perpendicular to the surface, directional etching is achieved with minimal undercutting. In general, ICP etching is preferred for very small features, but RIE is the more common of the two instruments.

### 52.2.1.2 Bonding

After the channels are etched in a single piece of glass, the patterned substrate must be bonded to a second piece of glass to form the fourth side of the channel. For glass microchips, most bonding is done at elevated temperatures requiring the use of a second piece of glass that has the same thermal expansion coefficient as the etched substrate. After this consideration, bonding is relatively straightforward. Access holes are first drilled in the unpatterned substrate to allow solution to be added to

the capillaries. The two substrates are aligned and clamped together after copious washing to remove all particulate contamination. The assembly is subsequently placed in a programmable furnace and brought to a temperature above its glass transition temperature ( $T_g$ ), usually 600°C–1100°C. At this point, the two glass pieces fuse to form a single integrated device. After sufficient fusion time, the microchips are cooled slowly to room temperature over a period of several hours to prevent cracking due to thermal stress. On the whole, the bonding process can take up to 24 h to complete.

In addition to thermal bonding, several other bonding methods have been reported. The second most common technique is anodic bonding. In anodic bonding, the two substrates are again clamped together after copious washing, but are placed this time between two metal electrodes. The temperature is elevated (400°C) and a high DC voltage (>1 kV) is applied between the two electrodes. Bonding is achieved because sodium ions at the interface of one piece of glass migrate away from the surface, making it highly reactive with the silicon in the second substrate. One of the problems with both thermal and anodic bonding is the harsh conditions required to achieve the desired microchip. Alternative methods have been investigated, which are not as harsh. One good example of this is a photocurable epoxy method developed by the Landers group [3]. In this method, photocurable epoxy is added to special channels that line the microchip. The microchip is exposed to intense UV radiation to cross-link the epoxy, creating a stable bonded microchip.

## 52.2.2 POLYMERS

While glass has many benefits for MCE, it is not without its problems, as discussed above. As a result, many investigators have turned to polymers as substitute substrate materials because they are cheaper, easier to fabricate, and have a wide range of surface properties [4]. The first polymeric material used was poly(dimethylsiloxane) or PDMS [5]. After the initial landmark report, many other polymers were demonstrated for use with MCE, including poly(methyl methacrylate) (PMMA), poly(carbonate) (PC), polyester (PE), Teflon, and Parylene C. The monomeric repeat unit for the three most common polymers, PDMS, PMMA, and a typical PC are shown in Figure 52.3. Each material has different properties that make selection application dependent. In general, the three major considerations in selecting a polymer are (1) glass transition temperature of the material, which dictates fabrication methods, (2) the optical transparency and background fluorescence, and (3) the surface chemistry presented by the base material. The following sections describe the fabrication of polymer microchips in detail and are divided by the general methods used for fabrication.

### 52.2.2.1 Poly(methyl methacrylate) and Poly(carbonate)

Two of the more common polymeric materials for MCE are PMMA and PC. Both of these materials are rigid, have good optical transparency, and can be easily fabricated using one of two methods, hot embossing or injection molding. The general process for both fabrication methods is outlined in Figure 52.4. Hot embossing is the most commonly employed method because it does not require an expensive injection molding machine. Injection molding, however, arguably produces better devices. In both cases, the mold is a critical element and can be made through one of several

**FIGURE 52.3** Comparison of the chemical structures for poly(dimethylsiloxane) (PDMS, left), poly(methyl methacrylate) (PMMA, center), and a typical polycarbonate (PC, right).

**FIGURE 52.4** Comparison of hot embossing (top pathway) and injection molding (bottom pathway) approaches for the fabrication of PMMA or PC microfluidic devices.

different processes. The most common is to generate a mold using single crystal silicon wafers for the template. These molds are easy to make, but are fragile and typically last for 10 molding cycles or less. As a result, other methods have been used to generate metallic molds, usually made from nickel, which are extremely robust and can be used to produce thousands of microchips [6]. Metal molds are normally produced by fabricating an inverse master by normal photolithography. Ni or a similar metal is subsequently electrodeposited on top of this structure after applying an initial metallic seed layer for conductivity. After electrodeposition, the photoresist is released from the metal leaving the completed mold.

#### 52.2.2.2 Poly(dimethylsiloxane)

In 1994, Effenhauser's group reported the use of a commercially available elastomer Sylgard 184 for production of electrophoresis microchips [5] and was followed shortly by a similar application from Whitesides group [7]. Sylgard 184 is a composite material that contains primarily cross-linked PDMS. PDMS rapidly gained favor for production of MCE devices because it is very inexpensive, has good optical clarity into the low UV wavelength range, has very low background fluorescence compared to many polymers, is chemically stable to common aqueous and polar organic solvents, is gas permeable, and is generally biologically compatible. Finally, and arguably most importantly, PDMS uses a simple cast-and-cure molding process to produce complicated microfluidic channels. The molds can be created using a number of methods that varies in complexity from mechanical milling to RIE. The most common method, however, is the use of an epoxy-based photoresist (SU-8). In this fabrication method, a wafer is coated with SU-8, exposed to UV light through a simple transparency, and then developed to remove unexposed material. The remaining photoresist forms the mold upon appropriate curing and can last for upward of a thousand replications if appropriate care is taken. PDMS has been sealed to PDMS, glass, and many other plastics to complete the final microchip with great success. Furthermore, both permanent and reversible seals are possible, depending on the material used for the fourth side of channel and the pretreatment procedures. While PDMS is an attractive material, it has a significant disadvantage for MCE. PDMS is hydrophobic and has been widely used in a noncrosslinked version as a stationary phase in gas chromatography. For MCE, the hydrophobicity causes significant adsorption and therefore, peak tailing. This surface can be rendered hydrophilic for a short period of time using either plasma oxidation or treatment with strong base; however, this treatment is short-lived (often < 30 min) owing to the diffusion of linear oligomers to the channel surface. A second problem caused by the diffusion of the oligomer to the surface is generation of nonuniform EOF. Nonuniform flow creates significant band broadening as

well, making PDMS, one of the least attractive materials, which has been used in MCE laboratories, with respect to separation efficiency. Strategies to overcome this problem are addressed in the next section of this chapter.

### 52.2.2.3 Other Materials

While PC, PMMA, and PDMS are by far the most common polymeric materials used for MCE, several other materials have been used with varying degrees of success. In general, new materials are tested in an effort to combine the fabrication ease of PDMS with the surface and material properties of PMMA, PC, or even glass. This list is also not complete as reports of new materials are published on a regular basis in appropriate journals. Three of the more common examples are thermoset polyester (TPE) [8], parylene C [9], and SU-8 [10]. TPE devices are made from a simple polyester monomer but use a combination of thermal and photo-initiated cross-linking to produce devices from simple molds. The fabrication is akin to that used for PDMS, but produce a rigid polymer microdevice with better surface characteristics. Parylene C is a polymer that is more common to the microelectronics industry and has only recently been used for MCE. Parylene C is deposited using a simple vapor deposition method and forms thin, pinhole-free surfaces. Furthermore, its surface properties are similar to Teflon and therefore it holds significant interest for applications requiring low EOF. Finally, several researchers have reported the use of SU-8 photoresist for creation of microchannels. SU-8 is attractive because devices with a great variation in aspect ratio can be created using very simple photolithography. The devices are also mechanically stable because the base material is an epoxy. The major limitation to SU-8 devices lies in the inability to create microchips that have a uniform surface charge throughout the channel. In current versions of this device, the top and bottom are normally made of glass, while the side walls are the photoresist. The nonuniform zeta potential causes differential flow and therefore band broadening.

### 52.2.2.4 Summary

MCE devices have been made from a wide variety of materials with greatly varying properties. Selection of an appropriate material is best determined by the specific needs related to detection, cost, available microfabrication facilities, and required separation resolution. In many cases, however, the base material does not provide appropriate chemical properties for the desired application. For this reason, a number of methods for surface modification have been developed to provide chemical control of electrophoresis.

## 52.3 SURFACE MODIFICATION

Chemically modified surfaces play an important role in many different industries and applications ranging from medical diagnostics and *in vivo* devices to microelectronics. CE has long used chemical modification to control the surface properties of capillaries used for a variety of applications [11]. For example, modern CE-based DNA separations require that the surface charge and therefore the EOF be minimized or eliminated to generate high-resolution separations. In general, there are three methods for surface modification in MCE: covalent, adsorbed, and dynamic coatings. Covalent modification strategies generate new chemical bonds on the surface to change the chemistry, while adsorbed coatings use either electrostatic or hydrophobic interactions to adsorb a polymer onto the surface. Dynamic coatings are different in that the coating agent is in the running buffer and in contact with the surface at all times. A portion of the molecules adsorb to the surface in a dynamic equilibrium to define the chemistry. Surfactants are the most common species for dynamic coatings. In the following sections, a detailed description of the different types of coatings and how they are used is presented.

**FIGURE 52.5** General reaction schematic for silanizing surfaces. In this example, the silanizing agent is 3-aminopropyltriethoxysilane (APTES) that ultimately presents a primary amine to the surface. Most silanizing agents contain the same triethoxy or trimethoxysilane functional group with a different terminal chain. The terminal chain can be varied to give unique surface properties.

### 52.3.1 COVALENT METHODS

Covalent coatings come in two general types, those based on silane chemistry and those based on polymer grafting methods. Silane chemistries are among the oldest and best known coatings for electrophoresis and can be adapted almost directly from conventional CE to MCE for glass microchips. Silanization can also be performed on PDMS since it contains some free  $\text{SiO}_2$  functionality. The general schematic for silane modification is shown in Figure 52.5. Generating a silane-coated surface is a relatively time-intensive process, requiring that the surface first be activated with successive washings with NaOH and then HCl, followed by drying at elevated temperature to dehydrate the capillary wall. The reactive silane is added to the capillary and allowed to react for an extended period of time to ensure complete coverage. Silane chemistry is attractive because it is relatively simple and can modify the surface with a wide range of potential functional groups ranging from neutral polymers for reduced EOF to cationic amine coatings for reversed flow applications such as the analysis of anions [12]. Silane chemistry can also be used to deposit a base layer on the surface to eventually grow additional polymer layers for either electrochromatography or to further control flow. Silane chemistry is not without its problems. The most significant concern is the pH stability. Si–O bonds are hydrolyzed at low pH (<3) and moderately to strong alkaline pH (>8) removes the coating from the surface. While this pH range is quite useful for modern liquid chromatography, it excludes an important pH range and group of buffers commonly used with CE. As a result, many groups have focused on adsorbed and dynamic coatings for high pH applications of MCE using glass microchips.

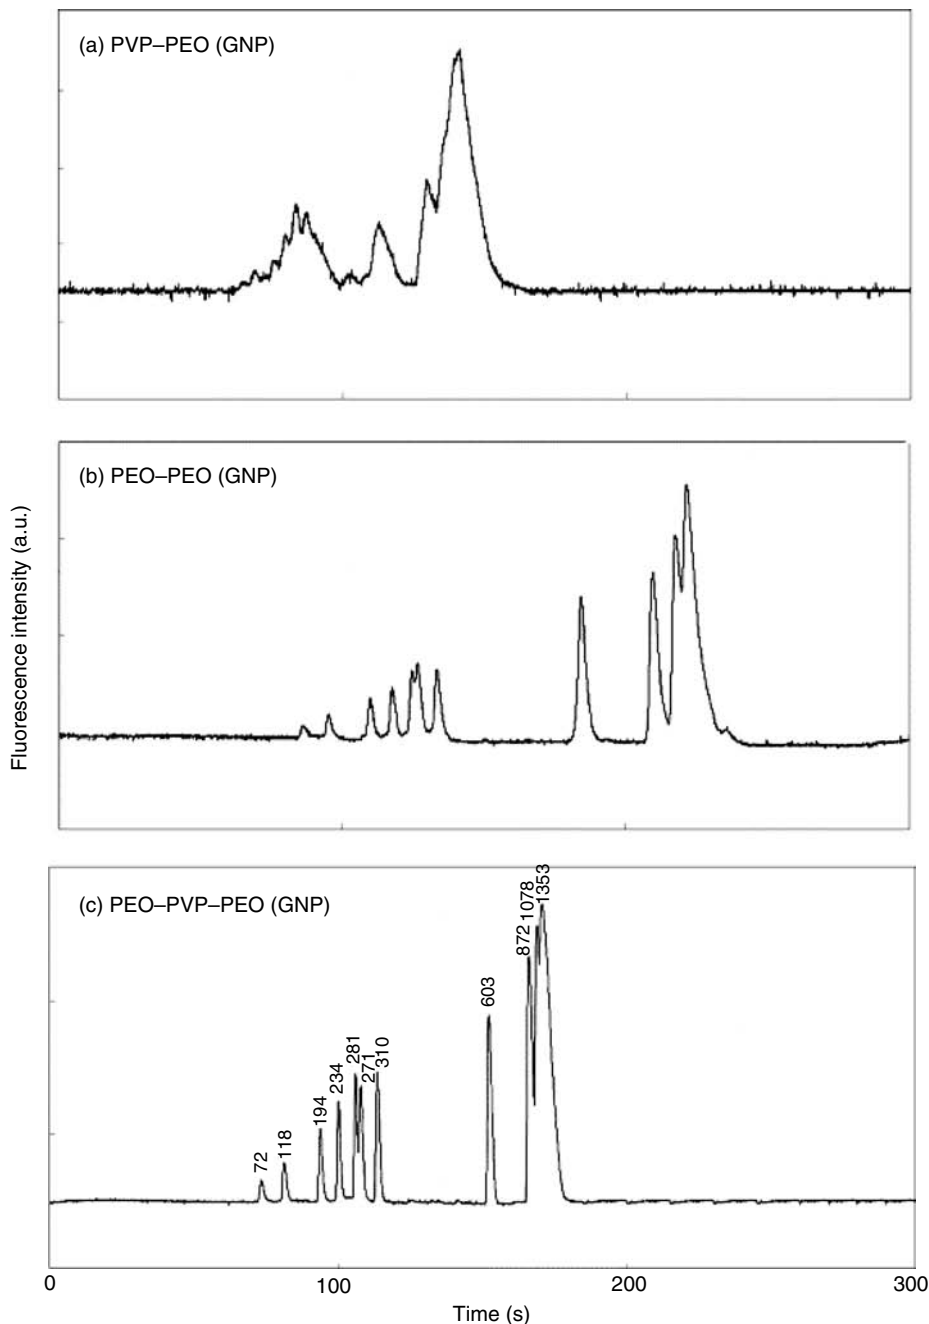

Silanization chemistry works well for silicon-based microchips; however, as mentioned above, there has been a significant shift to the use of polymeric substrate materials in an effort to reduce cost and fabrication complexity. Multiple methods have been used for modifying polymers, including plasma chemistry and surface grafting. Plasma modification is the most common approach and has been applied to many different substrates. Plasmas can be further defined as depositing plasmas or activating plasmas. In depositing plasmas, a thin film is deposited on the surface, typically before the devices are sealed together. Plasma chemistry holds significant, but as of yet, largely unrealized potential because a wide range of monomers can be used to deposit films with a vast array of chemical properties. Activating plasmas tend to be more destructive and work by breaking bonds of the surface generating ionizable functional groups. The most common example of this is the treatment of PDMS with oxygen or air plasmas to generate a hydrophilic surface [7]. Polymer grafting can also be used to modify microchip surfaces. Multiple methods involving UV surface activation have been reported. In one approach, the channel was filled with a solution containing the monomer units, a photoinitiator, and a chain terminator. Upon exposure to UV light, polymer formation was initiated on the surface and continued until the device was removed from the light [13]. In a similar approach, channels were pretreated with the photoinitiator and then dried. The monomer solution was subsequently introduced to the channel and exposed to UV light [14]. Additional methods exist for modification of PMMA and PC. For example, Henry et al. [15] generated a reactive mixture using ethylene or propylenediamine mixed with *n*-butyl lithium to covalently modify PMMA with a primary amine functionality. An alternative approach to generating an anionic surface used a combination of UV radiation and O<sub>3</sub> to convert methoxy groups to carboxylic acids on the surface of PMMA devices [16]. This approach has the advantage of being simple and easy to scale to large numbers of devices. In summary, many methods can be applied to the modification of polymer surfaces for MCE. The choice of the best approach is generally determined by the specific substrate material and desired application.

### 52.3.2 ADSORBED COATINGS

The second major form of coatings in MCE is adsorbed coatings. Adsorbed coatings adhere to the surface through either electrostatic or hydrophobic interactions, are simple to deposit, and can be achieved using a wide range of both neutral and ionic polymers. While adsorbed coatings do not have the same bond strength of a covalently attached film, they are generally stable for at least one day and can be easily regenerated. The major advantage of adsorbed coatings over covalent surface modification strategies, particularly for glass microchips, is the pH sensitivity. Many adsorbed coatings are stable from pH 2 to 13 and even provide a constant EOF in that range. Finally, unlike dynamic coatings, adsorbed coatings do not require any special additives in the run buffer to maintain the surface modification chemistry, allowing the use of a broader range of separation chemistries.

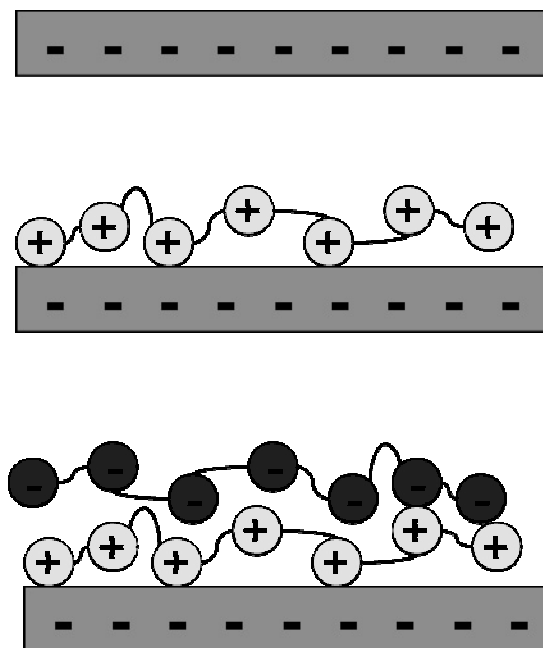

Of the many types of polymers used for adsorbed coatings, neutral polymers are the most common, particularly for the separation of DNA in fragment and sequencing applications. Neutral polymers chemisorb to the surface, and therefore their hydrophobicity and hydrophilicity are important. Hydrophobic polymers tend to adsorb the strongest to the surface of most chip materials, while hydrophilic polymers are the best for reducing the interaction of proteins with the capillary walls. A reasonable compromise can be found with a number of polymers, including hydroxypropylmethylcellulose (HPMC), hydroxyethylcellulose (HEC), poly(vinyl alcohol) (PVA), and poly(*N,N*-dimethylacrylamide) (PDMA). Another polymer that is particularly attractive for applications requiring a reduced EOF is poly(ethylene oxide) (PEO). Figure 52.6 shows a series of electropherograms collected using PEO and multilayer PEO-poly(vinyl pyrrolidone) (PVP) coatings for the separation of DNA fragments from  $\Phi$ X174 [17]. This data shows the difference that coating, including multilayer coating strategies, can have on the ability to resolve different DNA fragments.

**FIGURE 52.6** Comparison of the separation of 10  $\mu\text{g/mL}$   $\Phi\text{X}$  174 RF DNA-*Hae*III digest using PMMA chips with three different coatings, using the neutral polymers, PEO and PVP along with gold nanoparticles (GNP) [17].

The second most common type of polymer coatings uses polyelectrolytes. Polyelectrolytes are well known to form somewhat ordered polymer films of varying thickness when deposited on charged surfaces using the simple layer-by-layer deposition method [18]. A schematic drawing of the resulting structures is shown in Figure 52.7. These structures, referred to as polyelectrolyte multilayers (PEMs), can vary in thickness from 1 to 100 nm and exhibit a wide range of chemical properties. They are

**FIGURE 52.7** Schematic drawing showing the buildup of polyelectrolyte layers by the layer-by-layer deposition method in the generation of a polyelectrolyte multilayer structure.

deposited as alternating layers of cationic and anionic polymer. PEMs overcompensate for surface charge by forming a series of loop and tail structures on the surface. The result is that each subsequent PEM layer reverses the surface charge. The number of layers used can range from one or two up to 80–100, depending on the application. Thinner layers are typically used in CE applications, because the films form a chromatographic stationary phase, and thick stationary phases often lead to band broadening. PEM coatings are most commonly used when flow reversal is needed because they provide a relatively simple long-lived coating for this application. A second application of PEMs is to reduce the pH dependence on EOF. Coatings consisting of a strong polyelectrolyte (i.e., one that bears a permanent charge such as poly(styrene sulfonic acid) can give essentially pH-independent EOF because the functional group is charged throughout normal operating pH range. This is a useful characteristic in MCE to improve the reproducibility of separations. Finally, PEM coatings can be used to improve the separation efficiency in MCE separations, particularly for polymer microchips. Polymer microchips are well known to have lower separation efficiency than glass microchips. There are two general causes of this poor performance, use of dissimilar materials, and/or poor surface chemistry. In the case of dissimilar materials where the channel is made from one material and the top and/or bottom is made from a different material, two different  $\zeta$  potentials are present and thus two different EOFs. In this case, PEM coatings provide a uniform  $\zeta$  potential and therefore less band broadening. The other case is more difficult. Band broadening in MCE microchips made from the same material can be caused by one of two features, either micro-heterogeneity of the surface charge or inherent hydrophobicity of the material. In either case, coating the channel surface with a PEM can reduce the impact of these problems and improve separation efficiency dramatically.

In general, adsorbed coatings work well for applications requiring reduced EOF. Furthermore, they are attractive because a wide variety of chemistries exist and their deposition is very simple. On the negative side, however, adsorbed coatings have a finite lifetime requiring recoating more frequently than covalent systems.

### 52.3.3 DYNAMIC COATINGS

The last surface modification strategy for microfluidic devices uses dynamic coatings that are normally composed of surfactants. This process is given its name because the coating material is present in the running buffer and therefore is in a dynamic equilibrium between the capillary surface and the bulk solution. Dynamic coatings are not permanent and are in fact removed by replacing the running buffer with a solution that does not contain the surfactant. There are two molecular categories of surfactants used in dynamic coatings, polymeric and small molecules. Low molecular weight surfactants are the most common, with the compounds shown in Figure 52.8 being the most common. For glass microchips, the surfactants are normally cationic and form a simple bilayer structure that serves two roles. First, the anionic surface is replaced with the cationic surfactant, resulting in reversed EOF. Dynamic coatings using cationic surfactants are arguably the simplest and most common approach to flow reversal in MCE. Second, the bilayer phase can act as a weak stationary phase for electrochromatography. The interactions of surfactants with polymer microchips are different than with glass because of the porosity and difference in surface chemistry of those devices [19,20]. For polymers, both anionic and cationic surfactants have been found to be of use. Cationic surfactants reverse the flow through bilayer formation as noted above. Anionic surfactants, most notably sodium dodecyl sulfate (SDS), can form a tail down monolayer on the surface of some polymers resulting in an increased surface charge and EOF. Support for this binding motif also comes from studies of surfactants that have similar head groups but different tail groups. It was found that surfactants with more hydrophobic tails could remain on the surface much longer than surfactants with shorter tails.

The second group of surfactants that can be used in dynamic coatings are polymeric surfactants. The most common polymers include PEO, poly(ethylene glycol) (PEG), poly(propylene oxide)

**FIGURE 52.8** Three most common ionic surfactants used for coating microfluidic devices. From left to right: sodium dodecyl sulfate (SDS), cetyltrimethyl ammonium bromide (CTAB), and tetradecyltrimethyl ammonium bromide (TTAB).

(PPO), and co- and tri-block variations of these structures. Polymeric surfactants interact with the surface in very different ways than low molecular weight surfactants. In most cases, it is believed that the hydrophobic moiety of the surfactant binds to the surface, exposing the hydrophilic portion to the run buffer. Polymeric surfactants have the advantage in that they can form effective coatings at low concentrations; however, they are typically not as stable as their low molecular weight counterparts.

## 52.4 SURFACE CHARACTERIZATION METHODS

Finally, it is important to acquaint readers, particularly those more familiar with electrophoretic separations than materials characterization, with techniques that can be used to characterize different substrate materials and coatings. The direct analysis of the interior of capillaries is challenging so most of the methods discussed below are measured on a comparable flat surface. While it can be debated whether this approach is reasonable for traditional fused silica capillaries, the analogy between a flat surface of the material and the surface of the capillary in a microchip device is quite reasonable. The characterization methods that will be discussed here range from measurements of EOF to analysis of surface chemistry using X-ray spectroscopy techniques, with an emphasis on both how the measurement techniques are applied to materials used for electrophoresis and on how the results can be used to improve separation performance.

### 52.4.1 PHYSICAL CHARACTERIZATION

#### 52.4.1.1 Electroosmotic Flow

One of the most important measures of the channel surface chemistry comes from measuring the EOF. EOF is dependent on a number of factors, including surface charge. Furthermore, it is relatively trivial to measure the EOF through one of a number of methods. As a result, EOF measurements provide a convenient method to characterize coatings generated *in situ*. For permanent and adsorbed coatings this is important, but more so for dynamic coatings that are not stable on a surface in the absence of surfactant in the run buffer. EOF measurement provides three valuable pieces of information. First, it provides a measure of the overall surface charge,  $\zeta$ . Increasing, decreasing, or reversing the surface charge is a common goal of surface modification in MCE. Second, EOF measurements can provide a measure of the coating stability. EOF measurements made on a run-to-run basis are important for dynamic coatings, while EOF measurements made over hours to days are important for determining the stability and even presence of more permanent adsorbed or covalent coatings. Third, measuring EOF as a function of pH can determine acceptable ranges of operation, for a given application.

There are two common methods for measuring EOF as well as a host of additional more difficult, but arguably more useful, methods. The two most common methods are the current monitoring method [21] and the neutral marker method. In the current monitoring method, two different concentrations (ionic strengths) of the same buffer are prepared. The capillary and one reservoir are filled with one buffer and the second reservoir is filled with the second buffer. Voltage is applied to drive the buffer in the second reservoir through the capillary while the separation current is being measured. The current will gradually change as the new buffer replaces the old. The time required to reach a constant current is then used to determine the EOF rate. Alternatively, normal electrophoresis can be performed using a compound that is neutral. The migration time of the neutral compound can be used to determine the EOF. It should be noted that this technique does not work with micellar electrokinetic chromatography owing to partitioning of neutral analytes into charged micelles.

In addition to these two established methods for measuring EOF, several other methods have been published, which are worth mentioning. The first method, periodic flow monitoring, uses a

**FIGURE 52.9** Images of EOF through various microchannels and capillaries. (a) Acrylic microchannel at 266 V/cm. (b) PDMS microchannel at 248 V/cm. (c) Hybrid acrylic/PDMS microchannel 245 V/cm. (d) Fused-silica capillary at 250 V/cm. In each case, the first image was taken at the time of the UV laser pulse, and the time step between images was 50 ms. Each image is 300  $\mu\text{m}$  by 80  $\mu\text{m}$  [23].

two-spot laser system for periodic photobleaching [22]. This approach allows for measurement of the EOF in near real time during separation experiments and can provide dynamic information on flow during separations. A second method for characterizing EOF was reported by Ross et al. [23]. In this method, the buffer contains a caged fluorescent dye. Caged dyes remain nonfluorescent until hit with a high-intensity laser. Subsequent to this exposure, the dyes become fluorescent and can provide important information on relative EOF in a given channel cross-section. Figure 52.9 shows an image taken from this initial report by Ross et al. showing how EOF dispersion varies with capillary material. The difference in peak width, going from pure to hybrid materials, is significant, and results in a significant reduction in separation efficiency.

#### 52.4.1.2 Contact Angle

A second important measure of coating chemistry is the contact angle. Contact angle measures the relative hydrophobicity/hydrophilicity of a surface and is measured with a simple apparatus known as a goniometer. A simple schematic is shown in Figure 52.10 to provide an idea of how the measurement is achieved and what it means. The contact angle is always measured at the point where all three phases (liquid droplet, solid surface, gas) meet. The lower the contact angle, the more hydrophilic is

**FIGURE 52.10** Simple schematic showing how a contact angle is measured using a goniometer.

the surface in question and the larger the contact angle, the more hydrophobic. For example, clean unmodified glass surfaces commonly have contact angles of  $<20^\circ$ , while hydrophobic surfaces like unmodified PDMS can have contact angles  $>100^\circ$ . Different surface treatments can dramatically change the contact angle. For example, treatment of PDMS with a simple oxygen plasma reduces the contact angle to  $<60^\circ$  for a short period of time. Contact angle measurements are most useful in MCE for following the conversion of a hydrophobic surface to a hydrophilic one and vice versa. Contact angle measurements should be taken with care, however, as contaminated surfaces can cause inaccurate results.

### 52.4.1.3 Atomic Force Microscopy

One final physical technique that has been applied to the characterization of MCE materials and coatings is atomic force microscopy (AFM). AFM allows one to profile changes in surface morphology that occur with surface modification. AFM in MCE is most commonly used with polymeric coatings and not with molecular coatings because of the initial surface roughness. Most MCE surfaces are not atomically flat, a requirement for atomic resolution in AFM [24]. The main benefit of using AFM imaging in MCE is to measure surface roughness. Significant surface roughness can cause band broadening and a concomitant loss of separation efficiency.

## 52.4.2 CHEMICAL CHARACTERIZATION

### 52.4.2.1 X-Ray Photoelectron Spectroscopy

A final chemical characterization technique that is very useful in MCE is x-ray photoelectron spectroscopy (XPS). XPS measures the energy of photoelectrons emitted from the atom as they undergo excitation and decay as a result of exposure to x-ray radiation. The energy is referred to as the binding energy (BE). Furthermore, because the photoelectrons have to leave the surface, the technique is limited to the measurement of only the outermost layers ( $<10$  nm) of the surface, making it very specific for coatings. XPS can be used for characterization of elemental composition of the surface but arguably its most important use is in the discrimination of specific chemical bonds on a surface. For example, in Figure 52.11, an XPS spectrum for a PDMS surface is shown. The first spectrum is a global scan showing the presence of C, O, and Si as expected. The second spectrum is a high resolution scan of the C1s region. Peak-fitting routines are used to define three different peaks within this system, each corresponding to a different form of carbon. For example, the dominate peak at 284.7 eV is from carbon that is part of the siloxane backbone. The other two peaks come from different forms of carbon that are caused by either the cross-linking process or adsorption of contaminants from the surface. XPS is also a quantitative tool. The peak areas are proportional to the amount of each material present on the surface. This type of information is extremely valuable in defining the chemical content of the surface and has been used with both silicon and polymer-based microchips and coatings.

**FIGURE 52.11** (a) Low resolution XPS scan of an untreated PDMS surface. (b) High resolution scan of the C1s region of PDMS showing the presence of at least three forms of C with siloxane C being the most dominate.

## 52.5 SUMMARY

MCE is rapidly growing in importance in modern chemical analysis. As this growth continues, there will be a continuing need to develop cheap, reliable microchip devices for a broad range of applications. Important in this development is the control of the surface chemistry of microfluidic devices. Many approaches can be taken to accomplish this goal, from selecting appropriate substrate materials to modifying existing materials with one from a wide range of coatings. With the number of options available in this area, finding a starting point may seem overwhelming. Given this consideration, the following advice can be given. Start by selecting a microchip material that is readily available. For some scientists with access to clean room facilities, HF etching baths, and furnaces, glass is the best option. For others without access to these kinds of resources, PDMS or one of the other polymers may be the best starting point. The second option to consider is the need for and type of surface modification strategy. Dynamic coatings are the simplest, but may not be compatible with the desired application. Adsorbed coatings are more stable but may not give the desired properties such as removal of surface charge. The main consideration here is the specific application. As is commonly the case, all decisions made regarding coatings and substrate should be made while considering the end application.

## 53.1 INTRODUCTION

The development of microfabricated devices for analytical applications has been pioneered by Manz, Harrison, Widmer, Jacobson, and Ramsey in the early 1990s.<sup>1–9</sup> Since then, significant efforts have been invested to advance the theoretical foundations and the application areas of microfluidics. Under the generic name of “Lab-on-a-Chip” (LOC) or “Micrototal Analysis Systems” ( $\mu$ TAS),

microfabricated devices have emerged as powerful and reliable analysis platforms. Key application areas include DNA sequencing/sizing, polymerase chain reaction (PCR) amplification, SNPs Single Nucleotide Polymorphism scoring, one- and two-dimensional (1D/2D) separations, sample dispensing, immunoassays, proteomics, biomedical applications/diagnostics, and biodefense.<sup>10–20</sup> In parallel to microfluidics, mass spectrometry (MS) has evolved into an irreplaceable detection tool for qualitative and quantitative explorations of biological samples. The implementation of novel MS detection strategies on microfluidic chips represents a powerful and attractive alternative to conventional optical detection systems. However, the design of effective interfaces between microfabricated devices and MS instrumentation is not a straightforward process. This chapter is aimed at documenting the challenges and accomplishments related to interfacing microfluidic systems to MS detection, with emphasis on microfluidic capillary electrophoresis (CE) chips. Theoretical considerations are reviewed, and practical aspects of chip-MS interface design, performance, and limitations are described. Relevant applications that demonstrate the power of microfluidic-MS strategies for bioanalytical applications are discussed.

## 53.2 BACKGROUND

The implementation of the “LOC” concept for bioanalytical and biomedical applications was supported by quality characteristics that are unique to microfabricated devices. Miniaturization enables the development of distinct instrument configurations and novel analytical principles that can significantly reduce analysis times. The miniature format reduces adsorption-related sample losses on the instrumentation surface and is thus ideal for processing small sample amounts. Microfluidic handling operations can be performed accurately, in an automated fashion, and thus facilitate the generation of high-quality data. Microfabrication enables analytical process integration and multiplexing, and consequently high-speed/high-throughput sample analysis. In addition, large-scale parallelization results in the fabrication of inexpensive and disposable platforms that prevent sample contamination and carryover. Ultimately, the microdomain environment enables the emergence of unique physical events. For example, as the size of a device decreases, the surface-to-volume ratio increases; thus, phenomena that are dependent on the largest power of the critical dimension lose their significance, while phenomena that are less dependent on size become prevalent.<sup>21</sup> Consequently, surface-driven phenomena are dominating in the microscale world. The use of electroosmotic flow (EOF) for fluidic propulsion on the chip represents a relevant example as it can be effectively generated only in micrometer-sized channels. Major landmarks that demonstrate the power of microfluidic CE platforms include the ability to handle sample volumes as small as 1–10 pL,<sup>4,7</sup> the capability to perform sample manipulations (injection, separation, labeling, and detection) within a few seconds,<sup>8</sup> or ultra high-speed separations within < 1 ms,<sup>22</sup> and the ability to perform high-throughput experiments on multiplexed devices that comprise as many as 384–768 processing lanes.<sup>23,24</sup> For example, the experiment performed by Emrich et al.,<sup>23</sup> that is, DNA sequencing on microfluidic substrates incorporating 384 CE processing lanes that enabled simultaneous genotyping within 325 s, represents a remarkable example of a high-performance microfluidic application that simultaneously demonstrates complexity, speed, and throughput.

Microfluidic platforms comprise a variety of functional elements that perform operations such as pumping, valving, dispensing, labeling, mixing, separation, and detection. Fluidic propulsion is most commonly accomplished by using electrically and pressure-driven forces, especially when sample separations are performed.<sup>13,14</sup> Microchip devices are typically fabricated in glass, quartz, silicon, or polymeric substrates (poly(dimethylsiloxane), PDMS; poly(methylmethacrylate), PMMA; polyimide; polystyrene; polycarbonate; cellulose acetate; poly(ethyleneterephthalate); etc.). The functionality of the chip, the physical and chemical surface properties, the ease of fabrication, and the price are some of the dominant factors that determine the choice of a particular material for chip fabrication.

Microfluidic devices that use electrical fields for fluidic propulsion perform successfully for a variety of electrically driven separations, and thus, present unique opportunities to the analytical and biomedical community. The availability of a broad range of microfluidic functional elements, materials, and processes facilitated the miniaturization of most types of electrically driven separations that use optical and electrochemical detection systems: CE,<sup>3–8</sup> capillary electrochromatography (CEC),<sup>9,25–32</sup> micellar electrokinetic chromatography (MEKC),<sup>33,34</sup> isoelectric focusing (IEF),<sup>35–51</sup> isotachopheresis (ITP),<sup>52–55</sup> and capillary gel electrophoresis (CGE).<sup>56–59</sup> Moreover, a variety of microfluidic 2D separations have been developed, as well, such as MEKC-CE,<sup>60,61</sup> CEC-CE,<sup>62</sup> sodium dodecyl sulfate (SDS)-CGE/MEKC,<sup>63</sup> CGE/temperature gradient gel electrophoresis (TGGE),<sup>64</sup> IEF-CGE,<sup>65,66</sup> and ITP-zone electrophoresis.<sup>67</sup> The recent advent of bioanalytical processes implemented on the chip underline a clear demand for advancing MS detection for high-throughput microfluidic applications. MS combines the benefits of specificity, sensitivity, and resolving power that ultimately result in unambiguous detection capabilities for trace level components. Alternatively, the magnitude of most large-scale proteomics experiments underscore the need for multiplexed and low-cost devices that are capable of fast, sensitive, and reliable analysis. Overall, the data acquired with microfabricated MS devices demonstrate sensitivity, throughput, flexibility, and the great potential of these chips for bioanalytical applications. This chapter is aimed at providing the reader with an update on the status of microfluidic devices with MS detection, particularly on microfluidic CE-MS devices.

### 53.3 THEORETICAL CONSIDERATIONS FOR DESIGNING MICROCHIP-MASS SPECTROMETRY INTERFACES

#### 53.3.1 CAPILLARY ELECTROPHORESIS RELATED CONSIDERATIONS

**Chip Design.** Essentially, all theoretical aspects that affect the performance of conventional CE separation techniques also must be considered in the design of microfluidic CE experiments. The chip-MS interface facilitates the removal of the sample from the chip for detection and must be configured adequately to not alter the separation performance. This can be a challenging task, especially for fast CE separations. Typical CE microchips comprise 2–20 cm long  $\times$  10–20  $\mu\text{m}$  deep separation channels that operate at field strength of  $\sim$ 300–2000 V/cm. Sample separation can be accomplished within a few seconds or even milliseconds. Two main factors enable the capability to perform high-speed, high-resolution separations on the chip. First, the microfabricated layout enables designs that facilitate the injection of extremely short sample plugs, an essential requirement for high-efficiency CE separations ( $\sigma_{\text{inj}}^2 = l_{\text{inj}}^2/12$ , where  $\sigma$  represents the contribution of the injection process to peak variance and  $l$  represents the injection plug length). Thus, the injection plug length (20–100  $\mu\text{m}$ ) can be easily maintained at  $< 0.1$ – $0.2\%$ <sup>68</sup> of the separation channel length (2–20 cm). Second, the chip itself acts as a good heat sink because of its large mass, and therefore enables the application of high electric field strengths, efficient dissipation of Joule heat, and the generation of a large number of plate counts ( $N = \mu V/2D$ , where  $N$  is the number of theoretical plates,  $\mu$  is the electrophoretic mobility,  $V$  is the voltage, and  $D$  is the diffusion coefficient). For example, for a glass microfluidic chip that comprises a 20  $\mu\text{m}$  deep  $\times$  25 mm long separation channel, the peak width (s) and volume (nL) of an analyte eluting after 20 s can be anywhere in the range of  $\sim$ 0.3–1 s and 0.3–1 nL, respectively, if efficiencies of 100,000 to 10,000 plates/chip are desired (see theoretical considerations in Reference 68). Consequently, to minimize the detector contribution to peak variance and maintain losses in separation efficiency below 5–10%, the microchip-MS interface related dead volumes should be in the low picoliter volume range (30–100 pL).

**Electrical Field Strength.** The electrical field strength within each microchannel must be set properly to ensure that the EOFs are balanced in the entire microfluidic network. Channel depths and widths should be maintained small to minimize the effect of undesired parabolic flow profiles

that could result due to potential nonuniform EOF in the chip channels. An unbalanced EOF during injection can significantly broaden the initial sample peak width and deteriorate efficiency.

**CE Buffer Systems and Channel Coatings.** The solution pH and the buffer additives that are used to improve the CE performance, alter the analyte mobility, modify the EOF, reduce analyte-chip interactions, or increase sample solubility must be selected carefully to maintain compatibility with the MS ionization source (see also Section 53.3.2). Ultimately, the choice of a buffer system represents a compromise: (1) To increase the performance, on one hand, CE separations are typically carried out in high-concentration buffers systems (10–200 mM), or surface derivatizations are performed to either alter the EOFs or to suppress the analyte adsorption. To enable MS detection, on the other hand, low concentration (< 20 mM), volatile buffer systems that are compatible with commonly used MS ion sources are preferred. However, such buffer systems can compromise the separation performance. (2) Microfluidic applications are preferentially performed in homogeneous, high pH buffer compositions that promote large EOFs and enable reproducible fluidic manipulations. Not all CE separations, however, can be performed at high pH. (3) Electrospray ion sources operate in a stable manner only in the presence of organic modifiers in the eluent (minimum 10–20%, v/v, CH<sub>3</sub>OH or CH<sub>3</sub>CN). The addition of organic components to the CE eluents will result in a decrease of EOF. (4) High concentration, nonvolatile detergents and polymeric additives such as the ones used in MEKC, IEF, and ITP separations quickly contaminate the MS ion source and reduce the sensitivity, or even completely suppress the analyte signal. The presence of these additives in the CE eluent considerably limits the practical implementation of these separation techniques with MS detection. (5) Microchip channel coatings must be stable under given experimental conditions and should not bleed out from the channel to generate background ions in the mass spectrometer. Unstable coatings will also affect the EOF magnitude and potentially the stability of the spray. Coating lifetime can represent an issue if the chips are intended for prolonged use but is less of a concern in the case of disposable chips.

**CEC Considerations.** Complex sample-eluent-stationary phase interactions within a CEC microdevice create additional challenges that interfere with the injection and detection process.<sup>32</sup> The CEC stationary phase must generate EOF and provide for analyte retention. Thus, both charged and hydrophobic moieties must be incorporated in its structure. The charge on the stationary phase (+/–) and the eluent pH will affect the direction of the EOF, the migration of the analytes, and the ionization efficiency. The analyte will interact with the stationary phase through electrostatic and hydrophobic interactions, and its migration through the separation channel will be determined by its electrophoretic mobility and the direction of the EOF. These factors must all be considered and carefully balanced to create optimal conditions for sample separation, for analyte ionization, and for stable EOF generation in the direction of the MS detector.

### 53.3.2 MASS SPECTROMETRY DETECTION RELATED CONSIDERATIONS

**Analyzer.** The most common mass analyzers used in bioanalysis include ion trap (IT), time-of-flight (TOF), quadrupole (Q), Fourier transform ion cyclotron resonance (FTICR), and hybrid Q-TOF and IT-FTICR instruments. A specific mass analyzer should be chosen according to the sensitivity, mass accuracy, resolution, dynamic range, and data acquisition speed that satisfy the needs of a particular application. Most analyzers today are sensitive enough to enable the detection of low fmol or sub-fmol amounts of sample. Certain applications, such as proteomics, necessitate high mass accuracy, high-resolution characteristics such as displayed by the TOFMS and FTICR-MS detectors, to enable reliable sample identification in complex mixtures. The mass accuracy and resolution of TOF analyzers are in the 5–10 ppm and 10,000–30,000 range, and of the FTICR analyzers in the <1–3 ppm and 100,000–1,000,000 range, respectively. The TOF analyzers present particular advantages for high-speed separations, such as the ones produced on a microfluidic chip, due to the nonscanning characteristics that enable a fast data acquisition process (data generation/storage

at  $> 10$  full mass spectra/s). Ion trap instruments that are capable of accumulating ions over prolonged times enable sensitive analysis and  $MS^n$  explorations. Quantitation over a broad concentration range can be most reliably accomplished with analyzers that use detectors with a large dynamic range. Slow, scanning mass spectrometers such as the quadrupole instruments provide good performance for large dynamic range quantitation.<sup>69–71</sup>

**Ion Sources/Chip-MS Interfaces/Ionization Efficiency.** Electrospray ionization (ESI), matrix-assisted laser desorption ionization (MALDI), and atmospheric pressure chemical ionization (APCI) are the most commonly used ionization sources in bioanalysis and have also been implemented on the chip. ESI is a method used to bring ions from the liquid phase to the gas phase (at atmospheric pressure) by a series of processes that involve production of charged droplets at the tip of an ESI capillary, shrinkage of the charged droplets by solvent evaporation and repeated multiple disintegrations, and production of gas-phase ions from very small and highly charged droplets. ESI is a soft ionization method that results in single- and multiple-charged ions by attaching or removing cations ( $H^+$ ,  $Na^+$ ,  $K^+$ , or  $NH_4^+$ , etc.) to and from the analyte molecules. MALDI is an ionization method that involves mixing the sample solution with a volatile matrix (sample/matrix 1:1000), deposition on a target plate, irradiation with a laser pulse, sublimation/expansion of the sample/matrix in the gas phase, and sample ionization by gas-phase proton transfer with the photoionized matrix molecules in the expanding plume. Note that it is the MALDI matrix that absorbs energy at the wavelength of the laser and then transfers it to the analyte molecules. Thus, this process results in a soft ionization mechanism that maintains the analyte molecules intact. APCI produces ions through collisions between the molecules to be analyzed and ionic species already existent in the source (reagent gas) through a variety of mechanisms: proton transfer, hydride abstraction, adduct formation, charge transfer, and so forth.

The chip-MS interface must (1) facilitate efficient sample ionization and transfer from the liquid into the gas phase, (2) ensure that the contribution of the detection process to the peak variance is minimal, and (3) enable easy accommodation of the chip within the mass spectrometer ion source. ESI has found widespread utility especially for the ionization of large biological molecules, as multiple charging brings the analyte  $m/z$  ratios in the affordable range of most mass spectrometers. Stable and efficient electrospray generation is determined by a number of factors such as sample related parameters (buffer composition, ionic strength, eluent pH, surface tension, viscosity, dielectric strength, and flow rate), ESI emitter size (5–100  $\mu\text{m}$  i.d./10–300  $\mu\text{m}$  o.d.), distance between the ESI emitter and a counter electrode (3–20 mm), and voltage applied to the ESI tip ( $\sim 700$ –3000 V).

Low concentration ( $< 20$  mM), volatile buffer systems (ammonium bicarbonate or ammonia for high pH and ammonium acetate, acetic acid, or formic acid for low pH separations) in aqueous-organic ( $H_2O$ – $CH_3OH$ ,  $H_2O$ – $CH_3CN$ ) eluents of low viscosity and low surface tension are generally recommended for CE-MS applications. The CE eluent pH will affect not only the EOF magnitude and the electrophoretic mobility of the analytes during separation but also the sample protonation/deprotonation equilibria and the ESI efficiency. For example, low pH values will favor the generation of positive ions in the liquid and gas phase, and multiple ion charging. However, the relationship between the concentration of ions present in the solution and those observed in the gas phase is not always straightforward; components with large gas-phase basicity will tend to dominate in the gas phase. Moreover, as there is a competition among ions to occupy the surface of the electrosprayed droplets, in aqueous solutions, the most hydrophobic ions will be likely enriched on the surface of the droplet and will generate more intense signals.

Nano- and micro-ESI sources that operate in the  $\sim 50$ –300 nL/min flow range are an ideal match for typical EOF values generated on the chip (i.e.,  $< 300$ –400 nL/min). The dead volumes associated with nano-ESI sources are minimal. In addition, nano-ESI sources have reasonable tolerance toward buffer composition and concentration, and facilitate sensitive analysis of trace level components (even of unseparated mixtures). Moreover, due to low analyte consumption characteristics, nano-ESI analysis enables extended infusion-MS investigations, increased signal averaging capabilities,

and thus the generation of improved quality spectra. However, when high-concentration buffer systems are needed for a CE separation, liquid sheath or liquid junction ESI sources must be used. CE eluent dilution with the liquid sheath or liquid junction solution will inherently result in lower signal intensities, increased dead volumes and band broadening, and ultimately in worse detection limits (10–100 times deterioration is possible).

When the insertion of fine ESI capillary emitters in the chip is contemplated, an important factor to consider is that the small i.d. emitter may act as a flow restrictor on the CE channel, and will result in pressure build-up at the channel terminus. This pressure will generate a laminar backflow through the CE channel that will counteract the EOF. Depending on the microfluidic channel dimensions, and on the length and i.d. of the ESI emitter, the EOF could be suppressed to a level where stable electrospray operation cannot be anymore achieved. For example, a 20  $\mu\text{m}$  i.d.  $\times$   $\sim$ 10 mm long ESI emitter was capable of suppressing the EOF generated in a 20  $\mu\text{m}$  deep microchip channel to  $\sim$ 25–40% of its original value.<sup>32</sup>

In parallel with ESI, MALDI has also become a widely used ionization technique for the analysis of biological samples. It is considered a high-throughput MS approach that enables fast, sequential screening of peptide or protein samples deposited into spots on a MALDI plate. In particular, the technique has gained widespread acceptance for the fast analysis of 2D-gel separated protein tryptic digests. As MALDI-MS analysis is performed offline, after the separation has completed, the major concerns related to chip-MALDI-MS interfacing focus on the preservation of separation efficiency during the sample deposition process on a MALDI target plate. While conventional MALDI-MS is performed under high vacuum using TOF analyzers, the recent development of atmospheric/subatmospheric pressure ion sources has enabled the implementation of MALDI sources on a variety of mass analyzers that perform low-energy collision-induced dissociation (CID) for analyte fragmentation and structure elucidation, such as the ion trap and quadrupole. Moreover, recently developed MALDI-TOF/TOF instruments enable analyte fragmentation under high-energy conditions, and the generation of more complex structural information. Thus, the successful merger of a high-throughput analytical sample processing platform, such as a microfluidic chip, and a high-throughput detection strategy, such as a MALDI-MS, will clearly benefit a variety of applications.

**Detection Limits.** The detection limit of a mass spectrometer is affected by various parameters that include sample complexity, sample ionization efficiency, type of ion source, chip-MS interface design, type of analyzer, scanning or nonscanning operation, data acquisition conditions, speed of analysis, and so forth. The mass spectrometer is a mass sensitive detector that responds to the amount of sample that is reaching the detector. Mass spectra can be summed or averaged over prolonged times to generate a mass spectrum with an acceptable signal/noise (S/N) ratio. The detection limit of a mass spectrometer, per se, can be in the low amol, or even zmol range. For example, the detection of 300–500 zmol of gramicidin S from a 100 nM solution, during an acquisition time of 10 ms with a TOFMS detector, was demonstrated in a chip-MS infusion experiment.<sup>72</sup> A scanning instrument such as an ion trap would have generated similar results in a larger time frame (i.e., 100  $\text{ms}^{-1}$  s). From lower concentration solutions, a similar quality spectrum could have been generated by both instruments by prolonged mass spectral averaging.

For practical purposes, it is useful to discuss the detection limit taking into consideration the necessary time to acquire a full mass spectrum. Thus, using a simple nano-ESI infusion experimental setup, detection limits in the range of 10–100 amol of sample delivered to a mass spectrometer during a 1 s acquisition time window, which is sufficient for most instruments to acquire a full mass spectrum, should be relatively easily attainable on a well-tuned instrument. In the context of high-speed separations and microfluidic CE experiments, a 1 s time window is also commensurate with typical peak widths. This is, however, an ideal scenario. One must always distinguish between the amount of sample that is consumed to produce a mass spectrum at a certain S/N ratio, and the amount of sample that is injected into a separation column and that elutes in a few seconds wide peak.

As a result, for the analysis of real world samples that involve the separation of complex mixtures, the possible generation of broad peaks, and the use of different data acquisition conditions, detection limits can be orders of magnitudes worse, i.e., 10–1000 fmol of sample must be loaded on the separation column.

Depending on the objectives of the analysis, the mass spectrometer will be operated in various modes of data acquisition such as MS, tandem MS or MS/MS, selected ion monitoring (SIM), multiple reaction monitoring (MRM), full-scan or limited mass range, data dependent, and so forth. SIM/MRM conditions will improve the detection limits, while data-dependent MS/MS acquisitions will worsen them. The data acquisition/storage speed and the number of averaged spectrum are all factors that will ultimately affect the detection limits.

**Dynamic Range/Quantitation.** The dynamic range is the ratio of the largest to the smallest detectable signal by a mass spectrometer. The dynamic range of a mass spectrometer can reach values as high as  $10^5$ – $10^6$ , however, the concept is much more complicated. The dynamic range depends on several factors such as the type of the mass spectrometer, the detecting elements (electron multiplier, multichannel plate, and analog versus time-to-digital signal processing), the dynamic range of the ESI source, and so forth. For intraspectrum measurements, the MS dynamic range can reach values of  $\sim 10^4$ . For interspectrum/overall analysis, slow scanning mass spectrometers such as the quadrupole instruments that utilize electron multipliers and slow, but high dynamic range (16–20 bit) analog-to-digital converters (ADC) provide good performance for quantitation, that is, have a dynamic range of  $\sim 10^6$ .<sup>69–71</sup> On the other hand, fast, nonscanning TOFMS instruments that utilize electron multipliers or multichannel plates, and high sampling rate, but low dynamic range (8 bit) ADCs or time-to-digital converters, have a low dynamic range and thus require extended spectral summing to improve it.

**Speed of Analysis/Data Acquisition/Quantitation.** The operational conditions of a microchip-CE system result in fast separations that can be completed within several seconds, and peak widths that can be much less than 1 s. For qualitative purposes, the acquisition of one high-quality mass spectrum per peak could be sufficient for reliable sample identification. However, for quantitative purposes, the number of data acquisition points (i.e., mass spectra) per peak should be  $>10$ . Fast, nonscanning TOFMS instruments are particularly useful for such separations. TOF systems that generate 5,000–10,000 spectra/s and store 100–10 spectra/s have the capability to interrogate a narrow peak a sufficient number of times (i.e., 10–20 times) to enable accurate quantitation. In addition, TOF systems record all ions at all times (no loss of information), and enable massive data summing/averaging to improve the detection limits. Tandem MS investigations remain, however, a challenge. Ultimately, for fast separations and complex mixtures, there will be a trade between the data acquisition speed and the achievable detection limits. One should aim for the highest possible separation efficiency that can be sampled appropriately by an MS detector.

**Quantitation/Sample Complexity.** Complex samples such as cellular extracts and plasma contain proteins that span over abundance ranges of  $\sim 10^9$ – $10^{10}$ , a much broader range than the typical dynamic range of a mass spectrometer. Low abundant components are generally not detected in such mixtures. In addition, data-dependent acquisition methods will select the most intense peaks in a spectrum for tandem MS investigations and will contribute even more to the loss of low abundant components. Selecting data acquisition parameters that increase the acquisition speed of the mass spectrometer, without significantly compromising spectral quality, could benefit such types of analyses. Prefractionation, affinity enrichment, and removal of the most abundant species are just a few strategies that could help improve the quantitation of such samples.

**High-throughput Analysis in the Context of MS Detection.** Microfabricated devices are ideal analytical platforms for enabling multiplexed sample processing and high-throughput analysis. Nevertheless, it could be argued that these benefits are not fully exploitable in the context of sequential MS detection. The use of fully integrated and possibly disposable platforms will reduce, however, the

entire sample preparation time and effort. On the long run, MALDI-MS, which is already regarded as a high-throughput MS detection approach, and miniaturized and multiplexed mass spectrometers that are currently under development will represent a good match for multiplexed microfabricated devices. Ultimately, it is envisioned that parallelization and large-scale integration will result in the fabrication of inexpensive, disposable platforms that will be easily interfaced to a variety of mass spectrometers.

## 53.4 MICROCHIP-MASS SPECTROMETER INTERFACES

Microfabricated devices have been interfaced to a variety of mass spectrometers, and a number of bioanalytical applications have been demonstrated.<sup>73–82</sup> Microfluidic platforms typically include the following sample processing steps: infusion, cleanup, preconcentration, digestion, separation, and detection. However, in the context of MS detection, the efforts focused on developing adequate microchip-MS interfaces that enable effective sample ionization from the chip. Since tandem MS capabilities were available until recently only with ESI mass spectrometers, initially, microfluidic ESI sources were developed. Later, technologies that enabled high-throughput laser desorption ionization strategies, in particular MALDI-MS, have been also pursued.

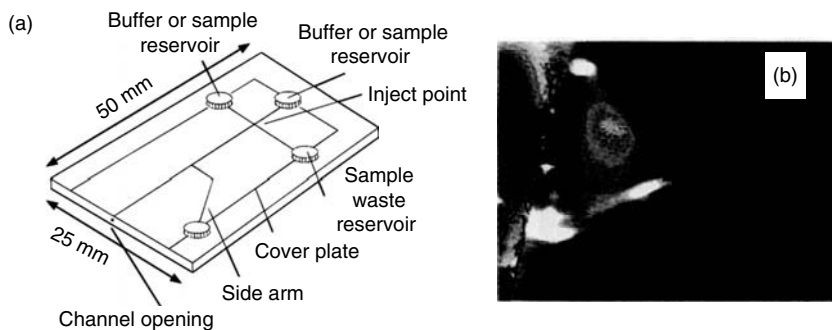

### 53.4.1 ELECTROSPRAY IONIZATION INTERFACES

Electrospray ionization from microfluidic devices can be generated directly from the chip surface, from capillary emitters inserted in the chip, or from microfabricated emitters. Liquid sheath, liquid junction, and nano-ESI sources have been implemented on glass, polymeric, or silicon substrates.

A common challenge associated with all microfluidic-MS chips that rely on electrically driven fluidic manipulations is related to the fact that fluidic flows (i.e., EOFs) follow the direction of the electrical potential gradients. In the case of CE/CEC separations, this flow is oriented toward the electrode placed at the separation channel terminus. Thus, the design of the microchip-MS interface must include a functional element that will effectively suppress the eluent flow to the terminal electrode, and will provide for an effective strategy for redirecting the fluid flow to the ESI emitter. This can be a particularly demanding task in the case of CE/CEC microfluidic chips that require very low dead-volume interfaces to not compromise separation efficiency. Several strategies have been used to stabilize the ESI fluid flows: (1) the chip was pressurized by connecting a N<sub>2</sub> cylinder or syringe pump to the sample infusion channel; (2) an external capillary EOF pumping system or a subatmospheric ESI source were connected to the chip to pull the eluent through the CE separation channel; (3) a miniaturized pneumatic nebulizer was fabricated as an integral part of the chip; (4) the ESI emitter was coated with gold and served as a terminal electrode for CE closure and for simultaneous ESI generation; (5) on-chip electroosmotic, electrochemical, and piezo-actuated pumping systems were used to pressurize the fluids on the chip; (6) coated microfluidic channels and porous glass membranes (gates) have been used to suppress the EOF in the direction of the terminal electrode and redirect it to the ESI tip; and (7) the nanospray process itself was used to draw a small fluid flow through the chip. The efforts invested in the development of these microfluidic chip-MS interfaces are reviewed in the following sections of this manuscript.

#### 53.4.1.1 Electrospray Ionization from the Chip Edge

The first attempts to generate ESI from the chip were performed by electro spraying the sample solution directly from the channel terminus at the chip edge (Figure 53.1a).<sup>83–85</sup> Two major, somewhat interrelated, problems were associated with this approach, that is, the electrospray Taylor cone-related dead volumes and the spray instability. Ramsey and Ramsey<sup>85</sup> have estimated that the volume of the Taylor cone at the chip edge is  $\sim 12$  nL, that is, much broader than are the typical CE peak volumes. The flat edge was not ideal for the establishment of a strong electrical field even if

**FIGURE 53.1** Electrospray generation from the chip flat edge. (a) Diagram of a microfluidic chip with a coated side arm for EOF reversal. (b) Taylor cone and electro spray generated at the channel opening at 3 kV applied between the microchip and a target electrode. (Reprinted from Ramsey, R.S., Ramsey, J.M., *Anal. Chem.*, 69, 1174–1178, 1997. Copyright 1997. With permission from American Chemical Society.)

**FIGURE 53.2** Microfabricated device with an integrated pneumatic nebulizer. (Reprinted from Zhang, B., et al., *Anal. Chem.*, 71, 3258–3264, 1999. Copyright 1999. With permission from American Chemical Society.)

very large voltages ( $>3000$  V) were applied to the chip, and thus did not facilitate stable and efficient spray generation but rather the build up of a fairly large liquid bubble (Figure 53.1b). Treating the chip surface around the channel exit with a hydrophobic silanizing solution,<sup>83</sup> or using microchips fabricated from polymeric, dielectric, nonwetting materials,<sup>86–88</sup> represent potential solutions that could minimize the growth and spread of the liquid at the channel terminus, minimize dead volumes, and improve spray stability and detection limits. As an alternative, polytetrafluorethylene hydrophobic membranes (50  $\mu\text{m}$  thick, 70% porosity, 0.22  $\mu\text{m}$  average pore size) were used to thermally “seal” the open channels (120  $\mu\text{m} \times 80 \mu\text{m} \times 30 \mu\text{m}$ ) of a polycarbonate chip, and to generate stable spray through the fine membrane pores with minimal lateral dispersion of the Taylor cone.<sup>89</sup>

Samples were typically infused through such devices either by using external syringe pumping<sup>83</sup> or on-chip electroosmotic pumping.<sup>85</sup> In the latter case, the EOF in the main channel was redirected to the chip edge for ESI generation by coating the side-arm channel with a linear polyacrylamide solution for EOF reversal.<sup>85</sup> Alternatively, miniaturized pneumatic nebulizers were integrated on the chip to enable sample infusion and/or CE separations with MS detection (Figure 53.2).<sup>90,91</sup> Common applications of these microfluidic-MS designs included infusion experiments performed from single and multiple channel devices. Relatively good quality mass spectra were produced by infusing 0.1–10  $\mu\text{M}$  peptide/protein solutions.

**FIGURE 53.3** A microchip-MS interface with a nebulizer that includes an aerodynamic focusing chamber for directing the ESI plume into the mass spectrometer sampling orifice. (Reprinted from Grym, J., et al., *Lab Chip*, 6, 1306–1314, 2006. Copyright 2006. With permission from The Royal Society of Chemistry.)

Recently, a more complex, aerodynamic interface was designed to enable electrospray generation from channel openings at the edge of a polycarbonate multichannel compact disk chip (Figure 53.3).<sup>92</sup> The ion source of an ESI mass spectrometer was fitted with an adapter that assisted the formation and transport of the electrosprayed plume from the microchip device. Electrospray was generated by applying a voltage between the sample wells on the chip and the entrance of the adapter. The flow through the chip ( $\sim 350$  nL/min) and the spray were stabilized by air suction provided by a pump connected to the adapter. The interface was tested with 1–20  $\mu$ M solutions of peptides and proteins.

### 53.4.1.2 Electrospray Generation from Capillary Emitters Inserted in the Chip (Sheathless Nano- or Microelectrospray)

Stable and efficient ESI, and thus sensitive MS detection, is most easily accomplished from very sharp emitters ( $2\text{--}10$   $\mu\text{m}$  i.d.  $\times$   $5\text{--}20$   $\mu\text{m}$  o.d.) fabricated from pulled fused-silica capillaries, that operate at an optimum flow rate of  $20\text{--}50$  nL/min and relatively low ESI on-set voltage ( $800\text{--}1800$  V). These are the typical nano-ESI emitters that enable the much desired amol and zmol detection limits. To achieve similar performance, such emitters have been inserted in the chip either through the edge of the chip, directly in the channel terminus,<sup>93–102</sup> or perpendicular to the chip, through an orifice that was communicating with one of the channels on the chip.<sup>72,103</sup> Flow generation and stabilization in these chips was accomplished by various approaches.

Similar to the flat edge designs, simple chips with capillary emitters were used for infusion experiments and their operation relied on external  $\text{N}_2$  pressurization<sup>104</sup> or syringe pumping.<sup>102,105</sup> An external EOF pumping approach, implemented by Figeys et al.,<sup>106–109</sup> used an amino-propyl silane activated fused-silica capillary transfer line inserted in the chip for fluidic propulsion. The capillary acted as an external electroosmotic pump to draw the eluent through the chip and transport it to a conventional electrospray source (Figure 53.4). The voltage applied to the capillary terminus that was placed in the ion source was used to promote EOF between the chip and the MS source, and to initiate the ESI process. This approach was demonstrated for infusion experiments and peptide fingerprinting from 3 to 300 nM solutions using single and multichannel devices.

Successful interfacing of microchip-CE to MS was also accomplished by inserting gold (or other conductive material) coated emitters in the chip to simultaneously serve as a CE terminal electrode and an ESI electrode. The ESI emitter actually acted as an extension of the CE separation channel (Figure 53.5).<sup>93</sup> These chips comprised a side channel placed close to the CE channel terminus to enable the infusion (with a syringe pump) of an MS calibrant or CE buffer dilution solution. Gold-coating lifetime and need for a fine fluid flow balance between the chip-EOF and syringe-infused flow are two possible concerns related to this approach. One solution to combining

**FIGURE 53.4** Diagram of a microfabricated device for MS infusion with an inserted capillary that acts as an electroosmotic pump and transfer line between the chip and ESI interface. (Reprinted from Figeys, D., et al., *Anal. Chem.*, 69, 3153–3160, 1997. Copyright 1997. With permission from American Chemical Society.)

**FIGURE 53.5** Schematic diagram of a microchip configuration for CE separation and MS analysis using a disposable nano-ESI capillary emitter. (Reproduced from Li, J., et al., *Anal. Chem.*, 72, 599–609, 2000. Copyright 2000. With permission from American Chemical Society.)

electrokinetic and hydrodynamic flow streams effectively was provided by Razunguzwa et al.,<sup>110</sup>—a hydrodynamic flow restrictor (a multichannel functional element) with increased hydraulic resistance was introduced between the CE channel terminus and the side channel intersection to prevent hydrodynamic backflow through the CE channel. Provided, however, there is sufficient EOF generated in the chip and that the CE buffer is electro-sprayable, no dilution solution must be provided to the CE system.<sup>111</sup>

A few alternative strategies have been used to achieve standalone operation of the microchip-ESI interface without external gas or fluid flows supplied to the chip. In the case of microchips equipped with fine nanospray emitters (5 μm i.d.), the electro-spray process generated at the emitter tip was capable of sustaining a small, but stable, flow through the microfluidic channel (~20–30 nL/min).<sup>72</sup> Full mass spectra acquired with a TOFMS at 50–100 spectra/s storage rates enabled the detection of <500 zmol amounts of peptides and proteins from 100 nM solutions. On-chip electroosmotic pumping for EOF generation and ESI stabilization was accomplished in the context of CE and CEC devices by connecting an auxiliary side channel to the main channel via an electrically permeable glass membrane (Figure 53.6).<sup>32,97</sup> The glass membrane had the purpose of enabling the transfer of ions for maintaining CE electrical continuity, but impeding the bulk EOF leakage from the CE channel into the reservoir. Using a similar glass membrane design, a multichannel electroosmotic

**FIGURE 53.6** Electrically permeable glass membranes (porous glass gates). (a) Integrated on the chip, prepared by placing two channels in close proximity to each other (i.e., at  $\sim 10\text{--}20\ \mu\text{m}$  apart). (Reprinted from Lazar, I.M., et al., *J. Chromatogr. A*, 892, 195–201, 2000. Copyright 2000. With permission from Elsevier.) (b) Exterior to the chip, prepared from a porous ( $\sim 4\ \text{nm}$  pore size) glass disc (4 mm diameter  $\times$  0.8 mm thick). (Reprinted from Lazar, I.M., et al., *Electrophoresis*, 24, 3655–3662, 2003. Copyright 2003. With permission from Wiley-VCH.)

pumping system was used to infuse sample or to deliver flow to an on-chip liquid chromatography (LC) system.<sup>112,113</sup> These pumping systems enabled the delivery of 50–400 nL/min flow to the ESI emitter. Alternatively, for similar purposes, the glass membrane was fabricated by etching through one of the chip substrates until generating a  $\sim 50\ \mu\text{m}$  thick membrane.<sup>114</sup>

To maintain the separation efficiency and ensure maximum ionization efficiency, the EOF in the CE channel must closely match the optimum electrospray flow of a given ESI emitter. In addition, to minimize dead volumes, the ESI emitters must be precisely aligned with the CE separation channel—a task that can be easily accomplished by etching both chip substrates to provide for a capillary guiding channel.<sup>32,90,97</sup> Somewhat more difficult, but equally effective, channel guides can be drilled in the chip to match the ESI emitter o.d.<sup>95</sup>

### 53.4.1.3 Liquid Sheath or Liquid Junction ESI Interfaces

Microfluidic chips with inserted ESI emitters were also used in conjunction with liquid sheath and liquid junction interfaces. In one approach, the spraying capillary was inserted in a liquid sheath interface external to chip.<sup>94</sup> Alternatively, a chip-inserted capillary and an auxiliary channel connected to the CE channel terminus were used in a liquid junction interface setup.<sup>96</sup> The mass spectrometer pumping system itself was utilized to vacuum the ESI source and the chip, and to draw fluid flow through the microfluidic system and the chip-MS transfer line. The liquid junction was either an integral part (Figure 53.7)<sup>96</sup> or was external to the chip.<sup>90</sup> The chip-integrated liquid junction comprised a removable electrospray tip inserted in the subatmospheric electrospray interface.<sup>96</sup> By adjusting the pressure in the MS interface, adequate mixing of the CE buffer with the liquid junction solution, and stable sample delivery were accomplished.

Wachs and Deng<sup>115–117</sup> have demonstrated a free-standing liquid junction interface that enabled ESI from the flat edge of a CE microchip. An external pump was used to deliver a suitable solution to the liquid junction element (2–6  $\mu\text{L}/\text{min}$ ) for collecting and transporting the CE effluent through a pneumatically assisted electrospray needle (Figure 53.8). While liquid sheath and liquid junction interfaces will clearly benefit the implementation of microfluidic CE-MS separations that need high concentration and possibly nonvolatile buffer systems, the large dilution volumes that are added through the interface can significantly deteriorate the detection limits and will necessitate additional means for effective nebulization of the effluent flows.

### 53.4.1.4 Microfabricated ESI Emitters

As efficient ESI generation from the flat chip surface is difficult to accomplish and the insertion of capillary emitters in the chip is often an impractical process, the fabrication of chip-integrated

**FIGURE 53.7** Microfluidic device with an integrated liquid junction interface and a subatmospheric ESI source for high-performance CE-MS analysis. (Reprinted from Zhang, B., et al., *Anal. Chem.*, 72, 1015–1022, 2000. Copyright 2000. With permission from American Chemical Society.)

**FIGURE 53.8** Schematic diagram of a chip-based CE/MS apparatus with an expanded view of a microliquid junction interface coupled to the exit of the microfluidic channel. emitters was actively pursued in the past few years. Complete device integration is highly desirable as it will enable batch generation of multiplexed architectures and improved detection quality and reproducibility. The fabrication of ESI emitters integral to the chip is, however, not a trivial task. A variety of microfabrication techniques have been used to create ESI emitters in polymeric and silicon substrates. Unfortunately, these techniques are less amenable for the generation of high-aspect ratio structures in silica or glass. ESI tips from glass were, however, occasionally fabricated by mechanical machining.<sup>114,118</sup>

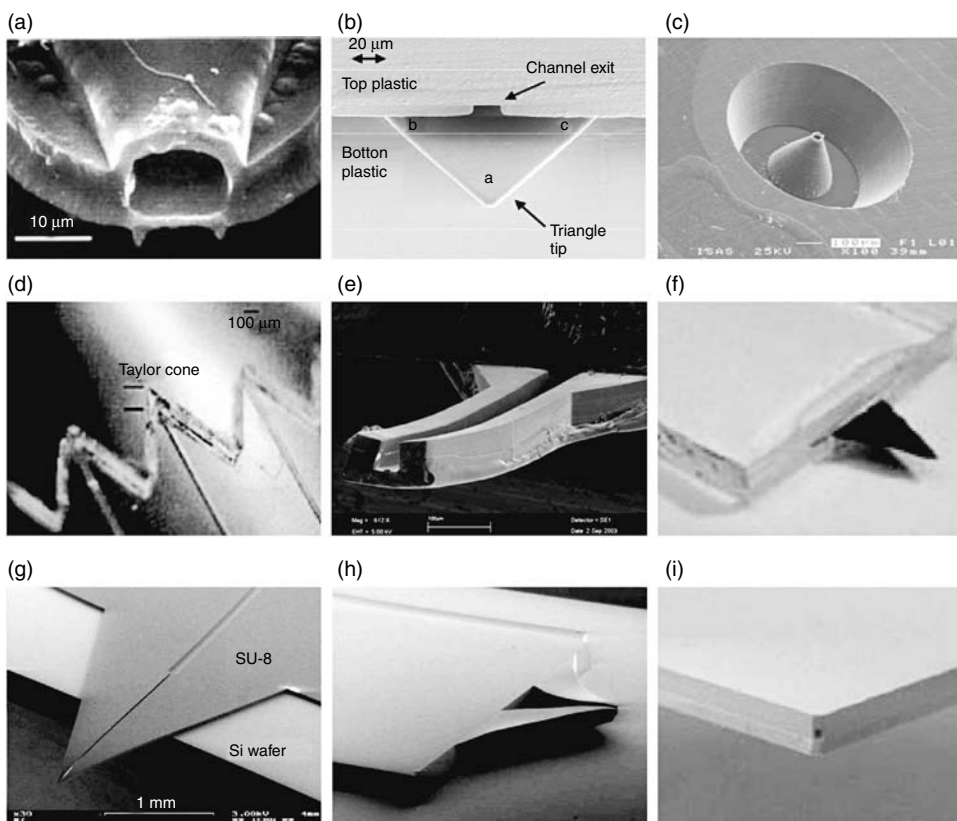

**FIGURE 53.9** Silicon-based microfabricated ESI emitters. (a) Silicon emitter fabricated by deep reactive ion etching (10–15  $\mu\text{m}$  orifice diameter). (Reprinted from Schultz, G.A., et al., *Anal. Chem.*, 72, 4058–4063, 2000. Copyright 2000. With permission from American Chemical Society.) (b) Silicon dioxide emitter fabricated by DRIE and oxidation of silicon (10–18  $\mu\text{m}$  diameter orifice). (Reprinted from Griss, P., et al., *J. Micromech. Microeng.*, 12, 682–687, 2002. (c) Polysilicon emitter fabricated by low-pressure chemical vapor deposition, pattern transfer, reactive ion and sacrificial layer etching (1.8  $\mu\text{m}$   $\times$  2  $\mu\text{m}$  and 2.5  $\mu\text{m}$   $\times$  5  $\mu\text{m}$  slot). (Reprinted from Arscott, S., et al., *Sens. Actuat. B*, 106, 741–749, 2005. Copyright 2005. With permission from Elsevier.)

**Silicon-Based Emitters.** Deep reactive ion etching (DRIE) techniques were used to fabricate silicon ESI nozzles (10  $\mu\text{m}$  i.d., 50  $\mu\text{m}$  depth) with a performance similar to nano-ESI emitters (Figure 53.9a).<sup>119</sup> Later, multiplexed configurations (400 spraying nozzles) on planar silicon wafers were fabricated, as well. The detection of proteins from 10 nM solutions infused at flow rates of 100 nL/min and drugs and metabolites spiked at 2.5 ng/mL in human plasma was demonstrated with these silicon emitters.<sup>119,120</sup> Syringe pumps or high-performance liquid chromatography (HPLC) systems were typically used to infuse the sample through these silicon chips. Alternatively, arrays of tapered SiO<sub>2</sub> needles were prepared by batch silicon etching techniques and oxidation (Figure 53.9b).<sup>121,122</sup> Polysilicon-based emitters were fabricated from two planar, triangular, free-standing cantilevers, by using a combination of low-pressure chemical vapor deposition, pattern transfer, reactive ion etching and sacrificial layer etching (Figure 53.9c).<sup>123</sup> The polysilicon emitters extended 800  $\mu\text{m}$  beyond the edge of the silicon substrate, comprised slot dimensions of 1.8  $\mu\text{m}$   $\times$  2  $\mu\text{m}$  or 2.5  $\mu\text{m}$   $\times$  5  $\mu\text{m}$ , and enabled MS detection from 1  $\mu\text{M}$  peptide solutions by simply applying a small electrospray voltage (700 V) through the rear side of the silicon wafer. The very fine emitter enabled standalone operation with no need for external assistance for spray stabilization.

**Polymeric Emitters.** A variety of technologies have been pursued to fabricate polymeric ESI emitters and integrate them within polymeric, glass or silicon microfluidic chips. Overall, polymeric microdevices can be more easily and cost-effectively fabricated and thus represent attractive analysis platforms for commercialization purposes. An initial demonstration of polymeric ESI emitters was performed by fabricating hollow needle structures from parylene polymer layers deposited on a silicon substrate (tapered ESI tips with 5  $\times$  10  $\mu\text{m}$  rectangular openings that extend 1 mm beyond the edge of the chip substrate) (Figure 53.10a).<sup>124</sup> Peptide samples (9  $\mu\text{M}$ ) were infused by N<sub>2</sub> pressurization at low 35–77 nL/min flow rates. These emitters were later integrated within a microfluidic device that incorporated a LC system driven by on-chip electrochemical pumps.<sup>125,126</sup> Parylene ESI emitters were also fabricated by incorporating a 5  $\mu\text{m}$  thick parylene C film between the substrate and cover plate of a chip prepared by embossing Zeonor 1020R polymer. The parylene film was prepared by lithography and etching into a triangular shape for effective ESI generation (Figure 53.10b).<sup>127</sup> Alternatively, adjustable-gap ESI emitters were fabricated from two triangular-shaped tips mounted in close proximity to each other on a PMMA substrate.<sup>128</sup> The tips were cut out from a 36  $\mu\text{m}$  thick poly(ethyleneterephthalate) film and were hydrophilized by plasma deposition of SiO<sub>2</sub>. The gap between the ESI tips was adjustable between 1 and 36  $\mu\text{m}$ , to allow for sample solution pumping at 75–470 nL/min and detection of standard peptides from 0.1  $\mu\text{M}$  solutions.

Polyimide, triangular-shaped ESI emitters prepared by lithography, chemical/plasma etching, lamination bonding, or knife-cutting techniques, were fabricated as an extension of chips made of

**FIGURE 53.10** Polymer-based microfabricated ESI emitters. (a) Parylene emitter fabricated by lithography and wet and plasma etching techniques ( $5\ \mu\text{m} \times 10\ \mu\text{m}$  opening). copper-coated polyimide printed circuit boards.<sup>129–131</sup> Experiments carried out with these chips relied on the flow that was induced by applying 1600–1800 V between the device and the mass spectrometer and enabled detection limits in the low 40 nM concentration range. Polyimide microfluidic chips that comprise sample enrichment modules, LC channels, and ESI emitters are presently commercialized devices (www.agilent.com) for HPLC applications.<sup>131–133</sup> When connected to

bench-top LC pumping systems, these chips enable the separation and detection of sub-fmol amounts of protein digests.

Electrospray emitters were also fabricated from polycarbonate substrates by laser ablation;<sup>134</sup> from PMMA by injection molding,<sup>135</sup> atmospheric molding,<sup>136</sup> micromilling (Figure 53.10c),<sup>137</sup> and mechanical cutting;<sup>138</sup> from PDMS by casting (Figure 53.10d through 53.10f);<sup>139–146</sup> and from SU-8 epoxy resin by photolithography and dicing (Figure 53.10g through 53.10i).<sup>147–152</sup> Some of the polycarbonate, PMMA, and PDMS emitters were further processed by hand polishing, machine milling, or trimming,<sup>135,139–142</sup> while other emitters were coated with gold particles or graphite powder to render them electrically conductive for ESI generation.<sup>135,145,146</sup> Recently, polymeric chips with pointed tips, comprising a microfluidic channel filled at its terminus with a photopatterned porous polymeric monolith prepared from lauryl acrylate-coethylene dimethacrylate, were fabricated. The multiple path, hydrophobic, porous polymer monolithic (PPM) emitter prevented the Taylor cone from spreading at the channel terminus, and thus provided a very stable spray.<sup>153,154</sup>

The ESI-MS performance of most of these microfabricated emitters was tested by performing infusion experiments with 0.1–10  $\mu\text{M}$  peptide/protein solutions. Syringe pumping or  $\text{N}_2$  pressurization was used to induce fluid flow through the chips at  $\sim 1$ –20  $\mu\text{L}/\text{min}$ , or at  $< 100$   $\text{nL}/\text{min}$  in the case of sharp emitters. Some of the sharper emitter enabled electrospray-driven fluid delivery without external pressurization or electroosmotic pumping.<sup>72,123</sup> The ESI voltage was typically applied to the chip reservoirs, to the gold-coated nano-ESI capillary emitters inserted in the chip, to the interconnecting standard stainless steel unions placed before or after the chip, to the liquid junction or liquid sheath interface, or, interestingly, to the chip material itself that was fabricated from conductive glassy-carbon substrates.<sup>101</sup> Most often, good quality mass spectra were generated from 1  $\mu\text{M}$  concentration samples. Background ions from polymeric contaminants were only seldom reported. However, the fabrication of such emitters, and most importantly their integration within microfluidic chips that perform complex sample processing, continues to remain a challenge and relevant applications have not yet been demonstrated.

### 53.4.2 MATRIX-ASSISTED LASER DESORPTION IONIZATION INTERFACES

The development of microfluidic devices with MALDI-MS detection has focused on interfaces that enable off-chip or on-chip MALDI-MS analysis and the microfabrication of silicon/polymeric MALDI target plates.

#### 53.4.2.1 Off-Chip MALDI-MS Detection for Microfluidic Sample Processing

Off-chip sample collection for MALDI-MS detection was essentially accomplished by syringe pumping for sample elution and deposition from the chip onto a standard MALDI target plate, by piezo-actuated sample dispensing from the chip onto the target plate,<sup>155</sup> and by using a rotating ball inlet MALDI-MS interface.<sup>156</sup> The latter two strategies will be discussed. Piezo-actuated silicon flow-through dispensers and nozzles have been developed to reproducibly generate picoliter-sized sample droplets for MALDI-MS analysis (Figure 53.11).<sup>155,157–160</sup> The matrix solution was spotted on the MALDI target simultaneously, in mixture with the sample, or separately, after sample deposition. The droplets were deposited on MALDI targets at a maximum ejection frequency of 500 Hz, and the droplet size could be varied from 30 to 200 pL (depending on nozzle dimensions). The spot size on the MALDI plate was 100–500  $\mu\text{m}$ , a good match for the size of the laser focal point. Pyramid-shaped nozzles that prevented the wetting of the dispensing orifice front surface seemed to improve the directivity of the droplets. Detection limits for peptide/protein samples were in the low amol/fmol range, and multiple depositions on the same spot enabled sample detection from 31 nM solutions. Such a piezoelectric microdispenser with an internal volume of 250 nL (60 pL droplet size) was used for the interfacing of high-resolution LC to MALDI-MS.<sup>157</sup>

**FIGURE 53.11** Piezo-actuated flow-through microdispenser. (a) Schematic diagram of the microdispenser. (b) SEM of a microfabricated dispenser silicon nozzle. (Reprinted from Miliotis, T., et al., *J. Mass Spectrom.*, 35, 369–377, 2000. Copyright 2000. With permission from Wiley-VCH.)

**FIGURE 53.12** Microfluidic chip-MALDI-MS rotating ball interface. (a) Schematic diagram of the chip-to-ball direct contact deposition process. (b) SEM image of an embossed microchip tip. (Reprinted from Musiyimi, H.K., et al., *Electrophoresis*, 26, 4703–4710, 2005. Copyright 2005. With permission from Wiley-VCH.)

As an alternative technology, PMMA CE chips fabricated by hot embossing were machined with a triangular tip at the CE channel terminus, to enable MALDI-MS detection by direct contact deposition of the CE effluent onto a rotating ball inlet mass spectrometer (Figure 53.12).<sup>156</sup> The rotating ball acted as a cathode transfer electrode of the sample into the vacuum of the MALDI mass spectrometer, and matrix addition was accomplished in-line, on the surface of the ball. This interface was demonstrated for the CE separation and low fmol MALDI-MS detection of tryptic peptides from 10 nL sample injection volumes.

Microfluidic chips are commonly used for surface plasmon resonance (SPR) biomolecular interaction analysis, as well, and their interfacing to MS, which is highly complementary to SPR detection, was also pursued. MALDI-MS was performed either directly on the SPR chip,<sup>161</sup> or off-chip, either by elution of the binding partners in small volumes and transfer to standard MALDI target plates,<sup>162–164</sup>

or by online ESI-MS.<sup>165,166</sup> Alternatively, bifunctional SPR fluid cells with optimized surfaces for SPR and MALDI-MS were fabricated.<sup>167</sup> As a miniaturized SPR sensor has been designed as an online detector for CE,<sup>168</sup> the future integration of microfluidic CE, SPR, and MALDI-MS detection is anticipated to occur.

### 53.4.2.2 On-Chip MALDI-MS Detection for Microfluidic Sample Processing

**MALDI-MS from Open Channels and Reservoirs.** Microfluidic CE separations with on-chip MALDI-MS detection were accomplished by performing the separation in the matrix solution in an open CE channel, followed by solvent evaporation and CE channel scanning with the desorption laser beam.<sup>169</sup> The system was demonstrated for the separation and detection of peptide and oligosaccharide samples. Alternatively, CIEF was performed in PMMA or resin chips with imprinted pseudoclosed channels that were covered only during the IEF step. After focusing, the cover plate was removed, matrix solution was deposited on the top of the focused sample with a syringe<sup>170</sup> or by electrospraying,<sup>171</sup> and MALDI-MS detection occurred in the open channel.

MALDI-MS was also implemented as a detection system for monitoring the reaction products of chemical or biochemical reactions in microfluidic reactors. In one approach, a continuous flow glass or silicon microchip that comprised a microdigestion reactor was incorporated into the standard MALDI plate of the MS instrument (Figure 53.13).<sup>172</sup> The vacuum of the MS chamber was used as a driving force for inducing flows in the reaction microchannels. The device was used for organic synthesis and biochemical reactions carried out entirely inside the MALDI-MS vacuum chamber,

**FIGURE 53.13** Microfluidic device integrated into a standard MALDI-TOF target plate. The vacuum of the MALDI-MS vacuum chamber is used as the driving force for inducing fluid flows on the chip (self-activating chip). (Reprinted from Brivio, M., et al., *Anal. Chem.*, 74, 3972–3976, 2002. Copyright 2002. With permission from American Chemical Society.)

and enabled the monitoring of Schiff base reaction products, of polymer separations, oligonucleotide digestions, and peptide sequencing. An improved approach involved the incorporation of a monitoring window along the microfluidic path of a serpentine microreactor chip.<sup>173</sup> The silicon/glass chip contained a rectangular boron doped silicone membrane monitoring window ( $\sim 2 \mu\text{m}$  thick,  $2.2 \text{ mm} \times 2.5 \text{ mm}$ ) that was positioned over the microreactor channel. The window was relatively large, to enable laser beam irradiation at an incidence angle of  $30^\circ$ . Fine holes ( $250 \text{ nm} \times 250 \text{ nm}$  or  $500 \text{ nm} \times 500 \text{ nm}$ ) were fabricated in the silicon membrane by a focused ion beam system to allow for ion desorption. The ions were extracted from the channel through the holes by the hitting action of the laser on the silicon window. This chip was used to monitor the reaction products formed in the serpentine microreactor, and opens the way to on-chip kinetic studies with MALDI-MS detection. A more simple approach involved the use of a silicon or glass protein digestion microreactor connected to a reservoir that enabled sample collection, MALDI matrix addition, and MALDI-MS detection from the exposed reservoir. For detection, the chip was simply glued to a standard MALDI target plate.<sup>174</sup>

**Centrifugal Compact Disks.** A clever microfluidic device that relies on centrifugal fluidic propulsion was developed for sample preparation tasks before MALDI-MS detection, and is presently a commercially available device ([www.gyros.com](http://www.gyros.com)). A high density, fully automated compact disk (CD) microfluidic system contains 96 sample processing lines placed radially on the chip.<sup>175,176</sup> The samples and solvents are loaded in microreservoirs near the center of the disk, the fluids are pumped through microchannels and microchambers to the outer edge of the CD by differential spinning, and the samples are collected in small spots ( $200 \mu\text{m} \times 400 \mu\text{m}$ ) at the end of each working line on the CD. The CD is then inserted into a MALDI mass spectrometer for analysis. These centrifugal CDs can handle sample volumes as low as  $1 \mu\text{L}$  and enable the detection of low 500 amol to 5 fmol sample amounts (Figure 53.14).

**Electrowetting-On-Dielectric Actuation Chips (EWOD).** A novel microfluidic technique, which relies on electrowetting forces for moving, dispensing, merging, mixing, and reacting droplets at specific locations on an array of electrodes, has been used to perform various sample preparation tasks before MALDI-MS analysis. The technique, also called droplet-based digital microfluidics, was utilized for mixing droplets containing peptides, proteins, matrix, and rinsing solutions, and for generating purified sample/matrix solutions amenable to MALDI-MS detection (Figure 53.15).<sup>177–179</sup> Good quality spectra were generated from  $\sim 1 \text{ pmol}$ /spot samples ( $S/N > 10\text{--}20$ ).

### 53.4.2.3 Microfabricated/Functionalized MALDI Target Plates

Micromachined, high-density silicon nanovial target plates that allow for precise sample positioning and confinement, and thus improved MALDI-MS analysis, were fabricated by standard anisotropic wet etching techniques.<sup>180,181</sup> The nanovials had a size of  $100 \mu\text{m} \times 100 \mu\text{m}$  to  $400 \mu\text{m} \times 400 \mu\text{m}$ , had a pyramidal shape, and were very shallow (i.e.,  $\sim 20 \mu\text{m}$  deep). Array densities of up to 4000 nanovials/square inch are achievable with this technology.<sup>182</sup> Piezo-actuated flow-through dispensers were used to deposit sample on such nanovial target plates, and repetitive microdispensing and accurate deposition of 60-pL droplets of a dilute sample to a confined area of  $300 \mu\text{m} \times 300 \mu\text{m}$ , allowed for on-spot sample enrichment and 10–50 times signal amplification.<sup>155,158,159</sup> Alternatively, nanovial arrays were fabricated by precision micromilling, cold embossing, and injection molding from PMMA and polycarbonate substrates. The array density was  $165 \text{ nanovials}/\text{cm}^2$ , corresponding to 3300 vials/conventional MALDI plate. Signal intensity from 10 nM peptide solutions, mass resolution, and mass accuracy were similar to that obtained with silicon nanovials.<sup>183,184</sup> These low cost, disposable polymeric nanovial arrays represent ideal platforms for high-throughput proteomic profiling applications.

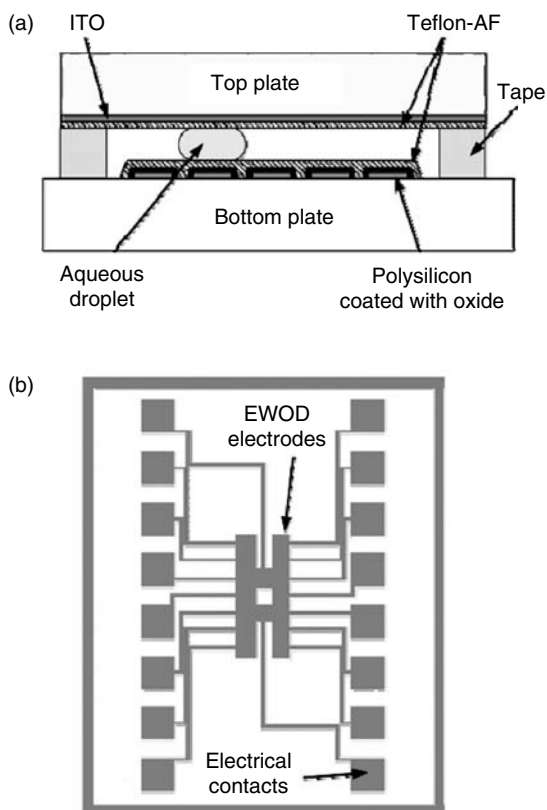

The functionality of the silicon nanovial target plates was extended by the development of so-called integrated selective enrichment target (ISET) technology. The ISET device contains

**FIGURE 53.14** Centrifugal CD for high-throughput MALDI-MS analysis. (Reprinted from Lazar, I.M., et al., *Mass Spectrom. Rev.*, 25, 573–594, 2006. Copyright 2006. With permission from Wiley-VCH.)

96 perforated nanovals that can be filled with 30–40 nL of reversed-phase beads. The system was used to perform sample pretreatment before MALDI-MS analysis with minimal sample loss due to transfer and surface adsorption.<sup>185</sup> Essentially, Poros R2 beads were used to capture tryptic peptides from a digest solution, were transferred to the front of the ISET device, rinsed by applying negative pressure to the back side of the device through the opening at the bottom of the vial, and eluted with acetonitrile/MALDI matrix to deposit the sample into a  $\sim 500\ \mu\text{m}$  spot on the back side of the chip for MALDI-MS detection (Figure 53.16). The ISET device enabled multiple analyses on a limited amount of sample and the identification of proteins isolated by affinity chromatography.

Microfabricated MALDI sample targets were also prepared from PMMA by computer numerical control (CNC) milling. In this case, enzyme functionalized cylindrical posts ( $360\ \mu\text{m} \times 360\ \mu\text{m}$ ) served as individual sample targets on the MALDI plate and were used for on-probe characterization of nucleic acids.<sup>186</sup> The advantages of this device included reduced sample consumption and handling and reduced analysis times. Alternatively, MALDI targets with twin anchors ( $400\ \mu\text{m}$ ) were prepared from silicon wafers by anisotropic dry etching in an inductively coupled plasma.<sup>187</sup> A pair of elevated anchors with hydrophilic top surface allowed for sample and standard deposition in very close proximity (on the anchors), and thus improved mass calibration with an external standard. The approach actually mimicked an internal standard mass calibration procedure and enabled the analysis of 30 pL sample solutions corresponding to  $\sim 1.5$  amol of angiotensin peptides.

**FIGURE 53.15** Schematic diagram of an EWOD device. (a) Side view and (b) top view. The bottom plate served as the base for a pattern of polysilicon EWOD electrodes buried under thermal oxide. A top plate was formed from ITO on glass; both plates were coated with Teflon-AF. The plates were joined with double-sided tape as a spacer. (Reprinted from Wheeler, A.R., et al., *Anal. Chem.*, 76, 4833–4838, 2004. Copyright 2004. With permission from American Chemical Society.)

### 53.4.3 OTHER MICROCHIP-MS DEVICES

While ESI and MALDI are the most commonly used ionization techniques for the MS analysis of biological samples, many other ionization mechanisms do exist and some of them were already implemented on microfluidic devices. APCI and various laser desorption ionization sources were pursued. A miniaturized APCI nebulizer chip, fabricated from silicon and Pyrex glass wafers, was designed to accommodate sample inlet capillaries, a stopper, a vaporizer channel, and a nozzle.<sup>188</sup> The nebulizer chip was used to interface capillary LC to MS, but could be integrated within CE separation chips as well.

Surface-enhanced laser desorption ionization (SELDI) MS is an array-based technology that enables MS detection from functionalized target plates prepared for selective capture and enrichment of proteins from crude biological samples.<sup>189</sup> These functionalized targets are marketed as “protein chips” ([www.ciphereg.com](http://www.ciphereg.com)) and contain hydrophilic, hydrophobic, cation or anion exchange, enzyme, antibody, and affinity capture spots on organic or inorganic surfaces. The addition of a MALDI matrix is optional depending on the specifics of the application. Alternatively, antibody-coated capture surfaces have been prepared within silicon nanovial target plates or on macroporous silicon targets.<sup>190,191</sup> With the aid of computer algorithms for pattern recognition and differentiation between two groups of subjects, the technique has been demonstrated for biomarker discovery in biological fluids. However, a more intense scrutiny of the SELDI chip approach has established that the technique is not sufficiently sensitive and reproducible to detect very low abundance biomarker components.<sup>192</sup> A recent manuscript reviews the latest developments in SELDI MS.<sup>193</sup>

Surface-assisted laser desorption ionization (SALDI) MS is used as an alternative to MALDI-MS for the analysis of small molecules that are difficult to detect with MALDI because of the interfering low-mass ions from the matrix.<sup>194,195</sup> In SALDI, micrometer-sized inorganic particles with low atomic mass and good stability during desorption such as graphite, nanoparticles, carbon nanotubes, ZnO, TiO<sub>2</sub>, SiO<sub>2</sub>, Si, W, Ag, and so forth, are used as a matrix that facilitates the desorption of analytes. The technique was successfully demonstrated even in its simplest form (i.e., desorption/ionization on porous silicon (DIOS)-MS) for the detection of pharmaceuticals, peptides, and polymers from bare porous silicon surfaces.<sup>196</sup> In this context, the fabrication of ordered silicon nanocavity arrays on Si wafers, by using reactive ion etching and a closely packed SiO<sub>2</sub> nanoparticle array as a mask, was demonstrated for metabolite detection in *Arabidopsis thaliana* root extracts.<sup>197</sup>

## 53.5 MICROFLUIDIC APPLICATIONS WITH MASS SPECTROMETRY DETECTION

While still in early stages of development, microfluidic devices with MS detection are capable of successfully performing a number of bioanalytical tasks and have been demonstrated in various application areas. In particular, areas requiring capabilities for high-throughput processing of small sample amounts, such as proteomics and drug development, have been pursued. Online and offline sample infusion, preparation, and separation tasks have been implemented on chips interfaced to both ESI and MALDI-MS detectors.

### 53.5.1 MICROFLUIDIC SAMPLE INFUSION ANALYSIS

The very first microfluidic-MS applications have involved sample infusion analysis from chips with a flat spraying surface or with inserted ESI capillary emitters. These relatively simple devices were fabricated from glass or polymeric substrates and were interfaced to IT, TOF, or hybrid Q-TOF instruments, and sample infusion was accomplished by connecting syringe pumps, N<sub>2</sub> cylinders, or external EOF pumping capillaries to the chip. Alternatively, infusion experiments have

been used to evaluate the effectiveness of ESI-microfabricated emitters. The previous section provides detailed information related to the performance of these chips. These initial single-channel infusion devices were later developed into multiplexed configurations. Completely independent channel arrays connected to multiple ESI emitters,<sup>83,104</sup> or channel arrays connected to a single ESI emitter,<sup>107</sup> were utilized for high-throughput infusion analysis of standard protein digest or yeast proteomic cellular extracts separated on a 2D-gel.<sup>107</sup> Low fmol–pmol sample amounts/spot were detected. At the present time, microfluidic chips with a variety of ESI emitters are used for the infusion analysis of peptides/proteins,<sup>198</sup> glycoconjugates,<sup>199–201</sup> pharmaceuticals,<sup>202</sup> and metabolites.<sup>203</sup>

A multielectrospray device composed of an array of nine microfabricated emitters arranged in a  $3 \times 3$  configuration, placed  $\sim 1.5$  mm apart, was used for infusion experiments. For a given flow rate, the device was shown to improve the ESI signal in comparison with conventional-fused capillaries with a single opening.<sup>134</sup> The device was fabricated in polycarbonate substrates by laser etching, and shows potential for applications that need to handle large eluent flow rates.

### 53.5.2 MICROFLUIDIC SAMPLE PREPARATION

A number of microfluidic applications include the development of sample preparation tasks that are aimed at improving the detection limits. Most commonly, these tasks include processes such as cleanup, desalting, preconcentration, and enzymatic microdigestion.

**Sample Cleanup.** Sample cleanup and desalting were among the first processes implemented on the chip to improve the detection limits and the quality of MS analysis. Polycarbonate or polyimide chips were devised to enable the incorporation of a sandwiched microdialysis cellulose membrane for sample desalting,<sup>105</sup> or of two microdialysis membranes for the removal of low- and high-molecular weight contaminants.<sup>204</sup> Alternatively, sample desalting was accomplished on poly(vinylidenedifluoride) membranes inserted in the microfluidic sample reservoir,<sup>205,206</sup> or on methacrylate-based monolithic polymeric columns incorporated in SU-8 chips.<sup>207</sup> Such devices enabled the ESI-MS detection of 1.5–5  $\mu\text{M}$  proteins (horse cytochrome c, bovine serum albumin, ubiquitin) from complex matrices containing 100–500 mM NaCl, 100 mM Tris, and 10 mM EDTA, or complex *Escherichia coli* cell lysates.<sup>105</sup> Ultrarapid (tens of milliseconds) desalting of protein solutions was accomplished in a microchannel laminar flow device.<sup>208</sup> The device used a two-layered laminar flow geometry that exploited the differential diffusion of macromolecular analytes and of low molecular weight contaminants.

Recently, EWOD actuation chips were developed into a multiplexed device that was used to simultaneously cleanup four samples. A sequence of seven actuation steps were performed for each sample: (1) generation of sample droplets (0.02–4  $\mu\text{L}$ ), (2) transport and drying of sample droplets, (3) generation of rinsing droplets, (4) transport of rinsing droplets to the sample sites for selective dissolution of urea, (5) transport and disposal of the rinsing droplets, (6) generation of MALDI matrix solution droplets, and (7) delivery of matrix droplets to the dried peptide spots.<sup>179</sup>

**Sample Preconcentration/Solid-Phase Extraction.** A microfluidic device with an external EOF pumping capillary was used as a nanoflow solvent gradient delivery system to a reversed-phase microcolumn to enable peptide sample preconcentration, elution, and detection from 100 pM solutions.<sup>103</sup> The small C18 preconcentration cartridge was placed between the chip and the ESI source of a mass spectrometer. Later, microfluidic designs have integrated the preconcentrator on the chip. For example, trace level peptide samples (2–10 nM) were enriched before MALDI-MS analysis using a microfluidic device that comprised a high-aspect ratio silicon vertical grid structure (silicon microextraction chips, SMEC) that enabled the immobilization of reversed-phase packing materials.<sup>209–211</sup> The need for adequate structures for particle immobilization was avoided by developing porous monolithic structures, polymerized into a miniaturized solid-phase microextraction (SPME) unit,

that enabled  $10^3$ -fold peptide/protein sample preconcentration.<sup>212</sup> Multiplexed SPME methacrylate-based monolithic columns, operated by syringe pumps, were integrated within Zeonor polymeric chips, and were used for the extraction and ESI-MS detection of drugs spiked in urine at  $0.025 \mu\text{g/mL}$  level.<sup>213</sup> The implementation of the technology in high-throughput chips comprising 96 or 384 monolithic SPME columns is anticipated.

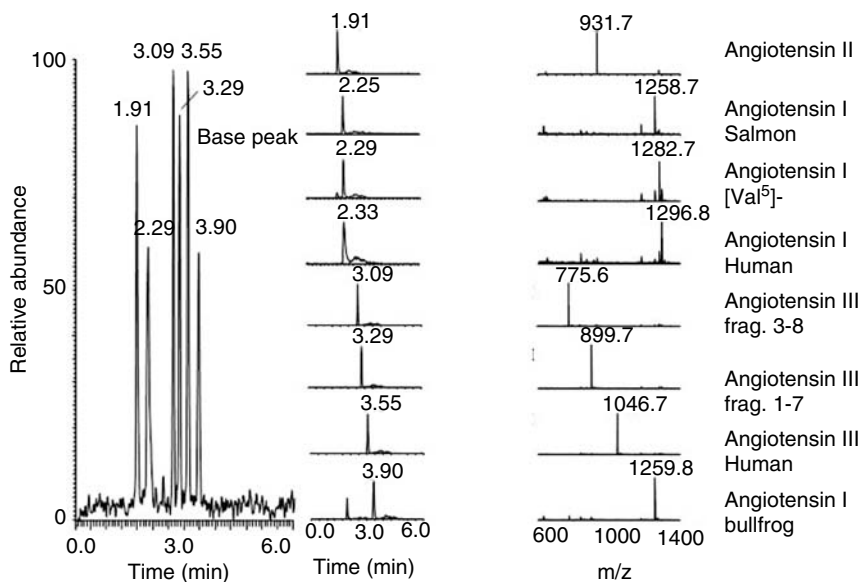

A variety of microfluidic designs have also been used for affinity enrichment tasks. Methacrylate-based porous monolithic packings, photopolymerized within microfluidic channels and derivatized with Cibacron-blue-3G-A, were used for the capture of lysozyme and albumin from human cerebrospinal fluid.<sup>214</sup> The proteins were eluted with the aid of a syringe pump and analyzed with MALDI-MS. PDMS chips comprising poly(vinylidene fluoride) membranes were used for affinity dialysis/ultrafiltration and concentration of aflatoxin B1 antibody/aflatoxins and phenobarbital antibody/barbiturates. ESI-MS detection sensitivity was improved by  $\sim 1$ – $2$  orders of magnitude.<sup>215</sup> Affinity capture resins (*c-myc*-specific antibodies immobilized on protein G-Sepharose beads) were also incorporated into complex microfluidic CE-MS platforms to facilitate the trace-level analysis of antigenic peptides spiked at  $20 \text{ ng/mL}$  into human plasma.<sup>216</sup> In addition, high-throughput parallel screening of 96 samples for tryptic phosphopeptides was made possible by using a microfluidic CD that incorporated a small bed of immobilized metal affinity chromatography (IMAC) beads.<sup>176</sup> Each processing line on the microfluidic CD was devised to perform one or more sample preparation steps: sample preconcentration, affinity selection, desalting, and digestion.

**Enzymatic Microdigestion.** Several approaches have been taken to perform fast protein digestion (3–12 min) on a chip. Microreactors packed with immobilized trypsin beads,<sup>217,218</sup> PDMS sandwich-type chips incorporating poly(vinylidene fluoride) membranes with immobilized trypsin,<sup>219</sup> or simple chips that relied on a fast liquid-phase digestion protocol<sup>220</sup> were used for this purpose. A representative nanoflow sample processing device included a microchip immobilized enzyme reactor ( $\mu$ -chip IMER) interfaced to a piezo-actuated flow-through dispenser to deposit the sample from the IMER onto a nanovial-MALDI target plate.<sup>180,221</sup> The IMER was fabricated in silicon and comprised high-aspect ratio, parallel channel structures with porous surface and immobilized proteolytic enzymes, to enable protein digestion in as little as 20 s to 3 min. Alternatively, an IMER chip with immobilized endoglucanases was utilized for the fast hydrolysis ( $\sim 20$ – $100$  times faster than conventional batch hydrolysis) and infusion ESI-MS analysis of methyl cellulose. To speed up the overall analysis, online interfacing of this endoglucanase IMER to LC-ESI-MS and offline interfacing to size exclusion chromatography MALDI-MS, were also performed.<sup>222</sup> Alternatively, a poly(ethyleneterephthalate) chip enabled the multilayer assembly of natural polysaccharides (positively charged chitosan and negatively charged hyaluronic acid) onto the surface of a channel to form a microstructured biocompatible network for enzyme immobilization. Controlled adsorption of trypsin enabled very fast ( $< 5$  s) digestion of standard proteins on the chip.<sup>223</sup>

Simple infusion microfluidic chips have been used to quickly (5–15 min) digest proteins for peptide mass fingerprinting.<sup>220</sup> High enzyme:substrate ratios (1:5) were used to perform the tryptic digestion of standard hemoglobin variants from  $0.1$  to  $2 \mu\text{M}$  ( $5$ – $10 \mu\text{L}$ ) solutions, or of hemoglobin isolated from  $\sim 5 \mu\text{L}$  human blood samples. Sequence coverage of 70–97% was reported. Alternatively, continuous flow serpentine microreactors, coupled to online HPLC-ESI-MS, were used for the implementation of enzymatic assays for bioactivity screening (enzyme inhibition and substrate conversion).<sup>224</sup> Reaction times were only  $\sim 36$  s and detection limits were  $0.17$ – $2.6 \mu\text{M}$ , that is, comparable to microtiter plates and bench-top continuous flow assays.

### 53.5.3 MICROFLUIDIC SAMPLE SEPARATIONS

A variety of electrically driven separation techniques with MS detection have been implemented on the chip, and performance similar to bench-top systems has been demonstrated. Various ESI

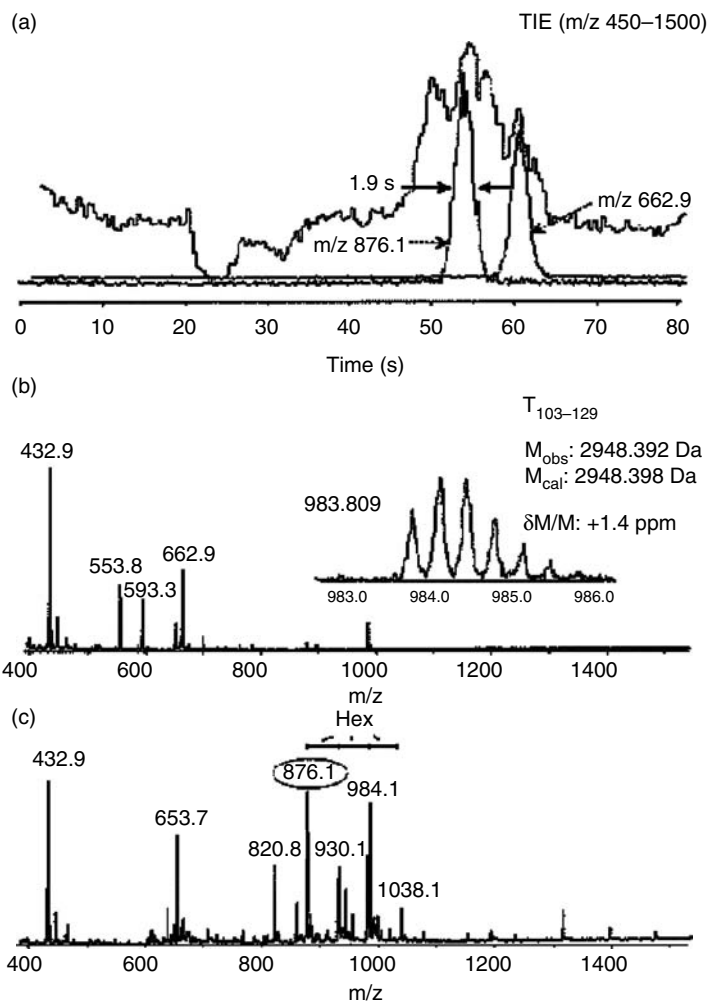

**FIGURE 53.17** Microchip-CE/ESI-IT-MS analysis of a mixture of angiotensin peptide (10  $\mu\text{g/mL}$ ) using the device shown in Figure 53.7. (Reproduced from Zhang, B., et al., *Anal. Chem.*, 72, 1015–1022, 2000. Copyright 2000. With permission from American Chemical Society.)

and MALDI-MS interfaces have been used in combination with chips that enabled complex sample processing. Relevant examples are discussed in the following text.

**Capillary Electrophoresis Chips.** Some of the first microchip-CE separations have been performed on glass chips that used on-chip miniaturized pneumatic nebulizers,<sup>90</sup> or on-chip or off-chip liquid junction interfaces coupled to a subatmospheric ESI ion trap instrument.<sup>90,96,225</sup> High-efficiency ( $\sim 31,000$  plates/chip or  $\sim 300,000$  plates/m) separations on 11 cm long channels, or fast separations on 4.5 cm channels, of peptide/protein samples were achieved (Figure 53.17).<sup>96</sup> Some of these chips were also tested for performing transient isotachopheretic sample preconcentration.<sup>90</sup>

Glass microfluidic chips with inserted nano-ESI emitters, electroosmotic pumping capillaries, or capillary transfer lines inserted in the liquid sheath interface of a Q-TOF instrument, were also used for the CE analysis of standard peptide/protein digests and of gel-isolated proteins from complex cellular extracts (*H. influenza*, *P. sativum*).<sup>93,95,216,217,226,227</sup> Some of these chips enabled sample enrichment by C18-membrane off-chip preconcentrators, on-chip stacking, or on-chip tryptic digestion with immobilized beads. Typically, CE separations were performed in 1–5 min, and concentration detection limits of 2–40 nM for standard peptides were reached.<sup>93</sup> A relevant proteomic application performed on such a device included the fast ( $< 2$  min) CE-MS analysis of 1D-gel-isolated membrane protein digests from *H. influenza*. Approximately 1–2  $\mu\text{g}$  protein extract was applied to the gel and  $\sim 25$  ng (1–5  $\mu\text{L}$ ) was loaded in the chip reservoir (Figure 53.18).<sup>93</sup> An on-chip sample desalting module packed with solid phase extraction (SPE) hyper-crosslinked polystyrene beads, followed by CE separations, was also developed in PDMS substrates for the separation and detection of peptides with ESI-TOFMS.<sup>228</sup>

A free-standing liquid junction interface was coupled to a flat edge glass CE microchip for the analysis of small molecules (drugs, metabolites).<sup>115</sup> It was demonstrated for the detection of recovered carnitine, acylcarnitines, imipramine, and desipramine spiked into urine or plasma at 5–500  $\mu\text{g/mL}$  level. Separations were typically performed in  $< 1$  min and intra-assay precisions ranged from 4.1% to 7.3% Relative Standard Deviation RSD.<sup>116,117</sup> A similar device, but fabricated in polymeric Zeonor material, was demonstrated for the analysis of carnitine standards.<sup>229</sup>

**FIGURE 53.18** Microchip-CE/ESI-QqTOF-MS analysis of tryptic peptides from the seed lectin PHA-L using the device shown in Figure 53.5. (Reproduced from Li, J., et al., *Anal. Chem.*, 72, 599–609, 2000. Copyright 2000. With permission from American Chemical Society.)

Microfluidic CE separation chips were also interfaced to MALDI-MS detection. The CE separation of oligosaccharides and peptides (0.5–5 mg/mL) was performed in open CE channels ( $\sim 250 \mu\text{m}$  deep) that contained buffer and MALDI matrix. The chips were prepared in glass. After separation, the solvent was evaporated, the chips were placed into a specially designed MALDI source, and the CE channels was scanned with the laser beam.<sup>169</sup> It is anticipated that the CE chip-MALDI-MS protocol could provide a fast and effective alternative for applications that utilize 2D-gel separations followed by MS detection.

**Capillary Isoelectric Focusing Chips.** Polycarbonate devices comprising a laser-ablated separation channel ( $50 \mu\text{m} \times 30 \mu\text{m} \times 16 \text{cm}$ ), a poly(ethyleneterephthalate) film sandwiched between the polycarbonate substrates to seal the channels, and a pointed mechanically machined ESI tip were used for the isoelectric focusing of proteins.<sup>230</sup> After protein focusing, the analytes were mobilized into the ESI source by applying a slight pressure at the separation channel inlet, and the spray was stabilized with sheath liquid and sheath gas ( $\text{N}_2$ ) supplied through side channels placed close to the separation channel terminus. Alternatively, PMMA or resin chips were designed to enable

MALDI-MS detection of proteins separated by IEF. The chips contained pseudoclosed channels (i.e., channels that were covered only during the IEF step but not during MALDI) to facilitate the addition of the matrix solution after the focusing step.<sup>170,171</sup> The performance of these microfluidic IEF chips was demonstrated for the detection of standard proteins from  $\sim 0.05$  to  $0.5$  mg/mL concentration solutions.

**Capillary Electrochromatography Chips.** Electrochromatography is an attractive alternative to both CE and LC separations, and since it relies on electrically driven fluid flows, its implementation on microfluidic chips is particularly useful. Recent reviews describe relevant achievements in this area with focus on column technologies.<sup>25,26,154,231</sup> The interfacing of a CEC chip comprising a methacrylate monolithic polymeric separation channel, a double-T injector, and a capillary ESI-MS interface was demonstrated for the separation of  $< 1$   $\mu\text{M}$  concentration standard protein tryptic digests (Figure 53.19).<sup>32</sup> The ESI interface consisted of a porous glass gate that enabled the transfer of ions to maintain electrical continuity through the channels, but not of bulk flow, which was redirected to the ESI capillary emitter inserted in the chip. Stable spray was generated for hours of chip operation. The dimensions of one CEC analysis line were small enough ( $6\text{ cm} \times 0.5\text{ cm}$ ) to enable the integration of four CEC channels on a  $3'' \times 1''$  chip, or of eight channels on a  $3'' \times 2''$  chip. More complex, dual function microanalytical devices for SPME and enzymatic digestion, were fabricated by in situ photolithographic grafting of porous polymer methacrylate monoliths in  $50\text{ }\mu\text{m}$  capillaries. Transfer of this technology on microfabricated chips will open new avenues for the simple construction of complex  $\mu\text{TAS}$  systems.<sup>154</sup>

**Liquid Chromatography Chips.** Most attempts of implementing LC separations on microfluidic devices involved the fabrication of the separation channel on the chip but made use of external pumping/valving systems to drive the fluids. Initially, the LC analysis of caffeine, with UV and amperometric detection, was demonstrated on a silicon substrate incorporating microfluidic channels of various dimensions ( $20\text{--}200\text{ }\mu\text{m}$  in width,  $0.5\text{--}10\text{ }\mu\text{m}$  in depth, and  $15\text{--}50\text{ cm}$  in length) coated with

**FIGURE 53.20** Microchip-LC driven by a bench-top HPLC pumping system interfaced to ESI-IT-MS. (a) Schematic diagram of a LC polyimide chip comprising laser-ablated channels, ports, frits, and ESI tip. (b) Base peak chromatograms of BSA digest running under different LC flow rate: (A) 100, (B) 150, (C) 200, (D) 300, and (E) 400 nL/min. (Reprinted from Yin, H., et al., *Anal. Chem.*, 77, 527–533, 2005. Copyright 2005. With permission from American Chemical Society.)

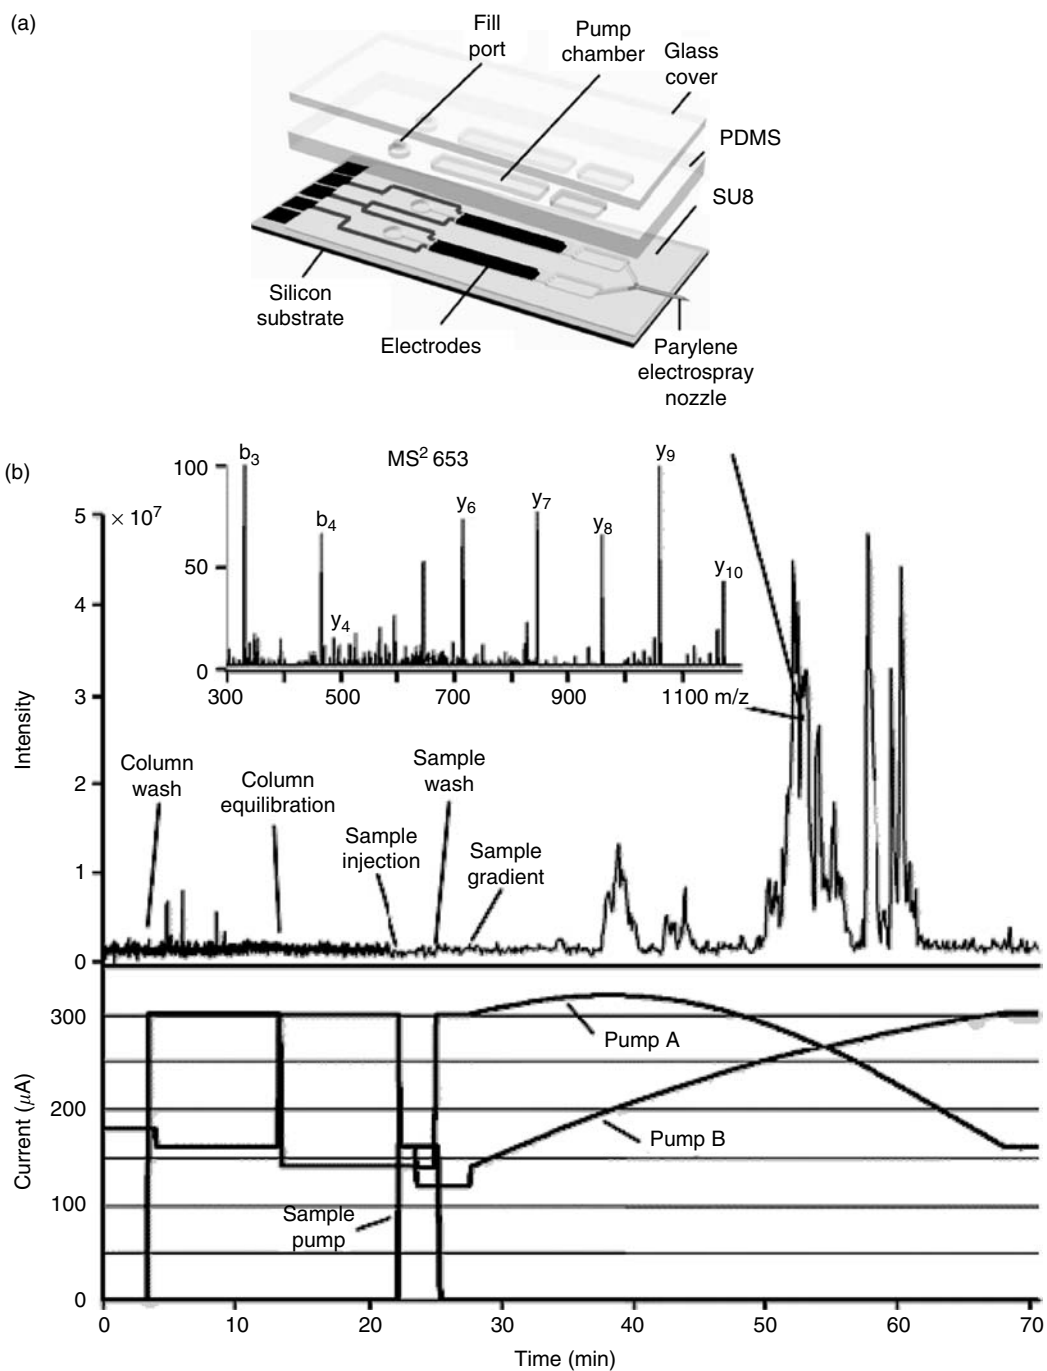

*n*-octyltriethoxysilane.<sup>232</sup> Later, a fused-silica chip that incorporated a laser-polymerized cylindrical fluoropolymer element, which served as a switchable valve for sample injection, was fabricated.<sup>233</sup> Fluidic propulsion, however, was accomplished by connecting the chip to a syringe pump. Recently, a polyimide microfluidic LC chip that comprised laser-ablated separation channels, enrichment columns, ports, frits, and a triangular shape ESI tip, was fabricated (Figure 53.20).<sup>131–133</sup> Sample loading and mobile phase delivery was accomplished by connecting the chip to an external rotary valve, a gradient pump, and a microwell plate autosampler. The chip was demonstrated for the analysis of standard samples and proteins isolated from plasma (1–5 fmol detection limits). Presently, these chips are commercially available analysis platforms ([www.agilent.com](http://www.agilent.com)).

Standalone microfluidic LC devices with ESI-MS detection were fabricated by incorporating the pumping and valving components on glass or silicon chips. In one design, a chip-integrated LC system was devised by developing an on-chip electrochemical pumping system that generated pressure for fluidic propulsion as a result of gas produced by electrolysis (200 psi, 20 nL/min).<sup>125,126</sup> The chip was demonstrated for the LC analysis of standard peptides (Figure 53.21). In another design, a glass microfluidic chip that incorporated a multichannel electroosmotic pumping/valving system (200–400 nanochannels, 1.5–2  $\mu\text{m}$  deep), a packed LC channel, and a capillary ESI-MS interface was developed.<sup>112,113</sup> The pumping/valving system enabled fluidic propulsion and sample loading in electrical field-free regions on the chip. The generated pressures and flow rates ( $\sim 80$  psi,  $\sim 80$ –100 nL/min) were fully consistent with the requirements of bench-top nano-LC platforms that are used routinely in proteomic applications. The system was demonstrated for data-dependent LC-MS/MS analysis of protein mixture digests and protein extracts from the MCF7 breast cancer cell line (Figure 53.22). Two microfluidic LC systems could be integrated on a 1''  $\times$  3'' chip, and under identical experimental conditions, the performance of the microfluidic LC was identical to the one of a commercial  $\mu\text{LC}$  instrument. The microfluidic LC system enabled the confident detection ( $p < .001$ ) of 77 proteins by using conventional data filtering parameters, and of five putative cancer biomarkers.

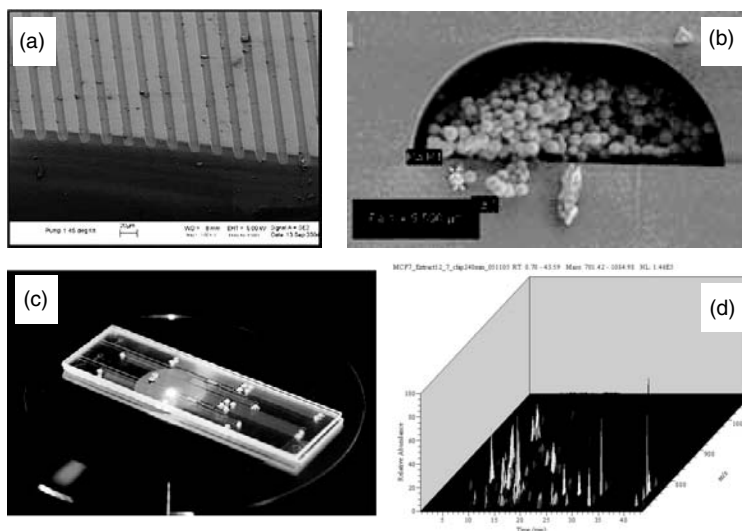

Alternatively, a microfabricated piezo-actuated flow-through dispenser was utilized to interface capillary LC to MALDI/TOF-MS. Accurate deposition of 60-pL sample droplets to a confined area of 300  $\times$  300  $\mu\text{m}$ , and repetitive microdispensing, allowed for on-spot sample enrichment and 10–50 times signal amplification.<sup>157,181</sup> Detection limits were  $\sim 100$  amol from 1 nM solution.

#### 53.5.4 HIGH-THROUGHPUT SAMPLE PROCESSING CHIPS

Parallel or fast sequential processing was demonstrated with chips that performed both infusion and separation experiments. Initially, Liu et al.<sup>104</sup> has demonstrated high-throughput electrospray-MS

**FIGURE 53.21** Microchip-LC driven by an electrochemical pump interfaced to ESI-IT-MS. (a) Schematic representation of an electrochemically driven LC chip. (Reprinted from Xie, J., et al., *Anal. **FIGURE 53.23** High-throughput ESI-MS analysis from a microfluidic infusion-MS device. (a) Diagram of a 96-well plate multichannel electropneumatic sample delivery system with multiple ESI emitters. (b) High-throughput ESI-MS analysis (alternate injections) of angiotensin II and III ( $10\ \mu\text{g/mL}$ ). (Reprinted from Liu, H.H., et al., *Anal. Chem.*, 72, 3303–3310, 2000. Copyright 2000. With permission from American Chemical Society.)

from a parallel infusion channel device that comprised 96 channels equipped with an array of 96 capillary emitters. Individual sample wells on the chip were pressurized for infusion-MS with  $\text{N}_2$  gas, and the device enabled the fast infusion analysis of 96 peptide samples within 480 s (Figure 53.23). At the present time, silicon ESI chips with 400 emitters are commercialized devices ([www.advion.com](http://www.advion.com)) that are integrated into an ESI-MS ion source (the NanoMate) that can be mounted on a variety of mass spectrometers. Simple infusion experiments, or pipette tip-based sample desalting followed by infusion-MS, can be reliably performed with this disposable microfabricated device (Figure 53.24).

**FIGURE 53.24** (a) ESI silicon chip with an array of nano-ESI nozzles. (b) Cross-section of the silicon ESI chip with a disposable pipette tip that presses and seals against the inlet side of the silicon chip. (Reprinted from Zhang, S., et al., *Electrophoresis*, 24, 3620–3632, 2003. Copyright 2003. With permission from Wiley-VCH.)

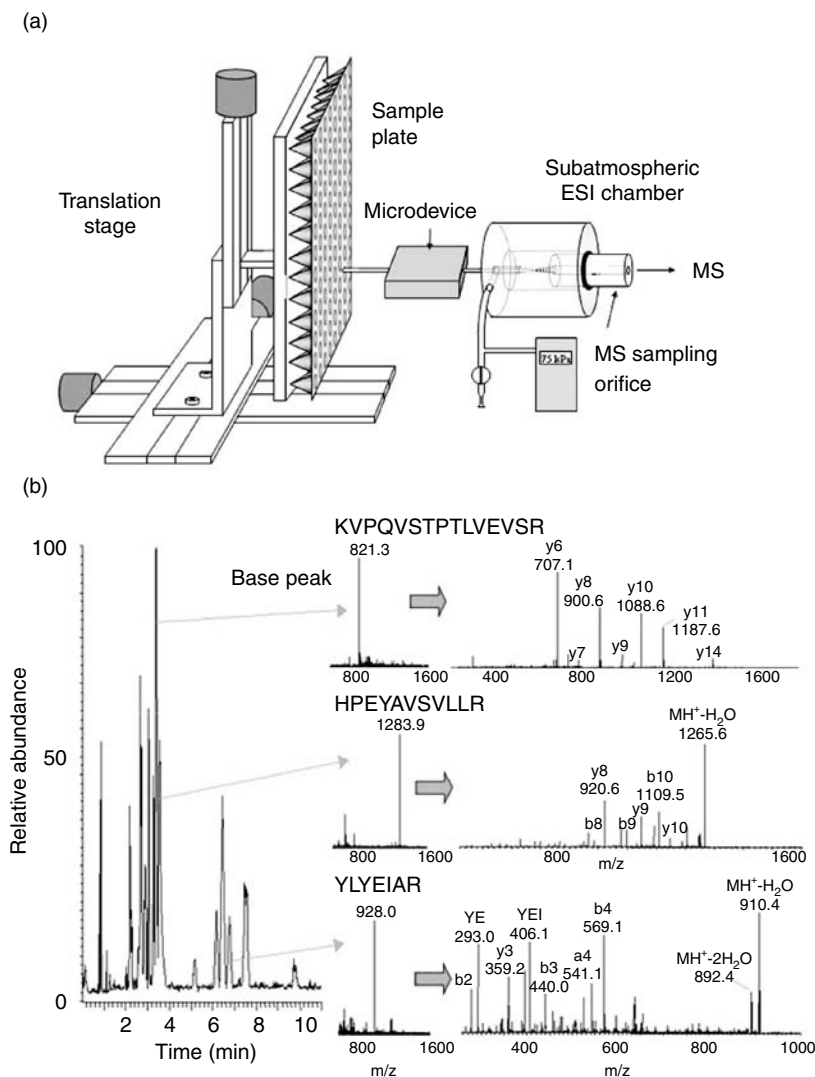

Some common applications include automated chip-based nano-ESI-MS for rapid identification of proteins separated by 2D-gels,<sup>198</sup> the study of noncovalent protein–protein and protein–ligand interactions,<sup>234</sup> the quantitation of drugs and metabolites in plasma in the low ng/mL range,<sup>202,203</sup> carbohydrate analysis,<sup>199,200</sup> and so forth. In terms of throughput, 40–55 s/sample is achievable with this automated chip-infusion technology.<sup>203</sup> A relevant example involves the fully automated MS characterization of complex carbohydrate systems using a nanoscale liquid delivery system and a chip-based nanoelectrospray silicon emitter array assembly.<sup>200</sup> Recently, these 400 nozzle silicon chips have been incorporated into an analytical platform that performs bench-top LC, fraction collection, and chip-based infusion for MS detection. The system enables extended investigations of sample components/subfractions that are difficult to characterize on a chromatographic time scale.

Alternatively, Foret et al.<sup>225,235</sup> have devised a microfabricated device that incorporated a sample injection loop, a separation channel for CE, IEF, or chromatography, and a liquid junction MS interface. The samples were loaded sequentially from a microtiter plate with the aid of an electropneumatic distributor, and microfluidic manipulations on the chip were accomplished with electrokinetic and pressure fluidic control. The sequential CE-ESI-MS analysis of protein tryptic digests is shown in Figure 53.25.

Li et al.<sup>216,227</sup> have demonstrated a highly integrated analysis system that included a CE separation channel, a microfabricated chamber for sample preconcentration, affinity selection or digestion, and a nano-ESI capillary interface. Sequential sample loading was accomplished with a bench-top autosampler (Figure 53.26). Using peptide mass fingerprinting and online tandem MS, such chips were utilized for the identification of gel-isolated proteins from *Neisseria meningitidis* and prostate cancer cell lines, of affinity selected *c-myc* antigenic peptides spiked into human plasma at 20 ng/mL level, and of IMAC-selected phosphopeptides. Up to 12–30 samples/h were analyzed with such a device, and detection from less than 7 fmol/injection (or 5nM solutions) was achieved. In one example, from a total of 67 tryptic digest bands, only three proteins remained undetected. Sample carryover was estimated to be < 3%.

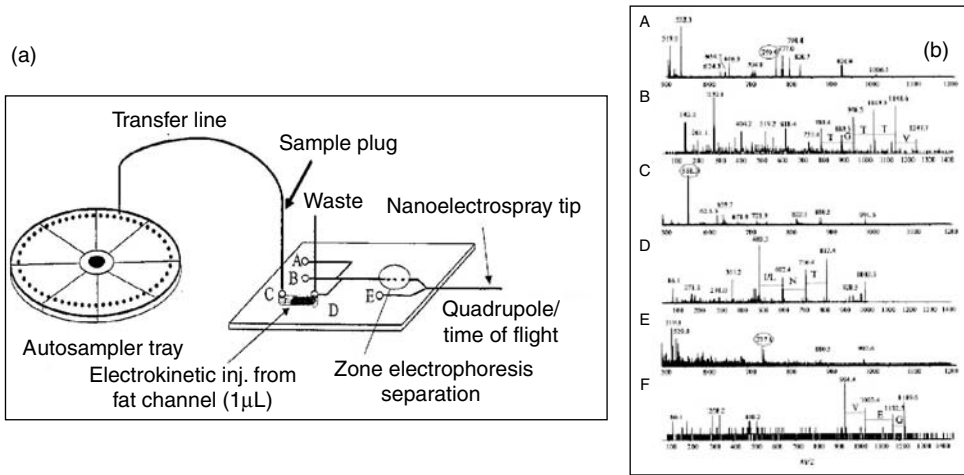

With MALDI-MS detection, the microfluidic compact disk was demonstrated for the high-throughput analysis of protein digests<sup>175</sup> and phosphorylated peptides.<sup>176</sup> For protein digests,

**FIGURE 53.25** Microfluidic system for high-throughput separations and MS analysis. (a) Diagram of the total system (automated microwell plate positioning system, sample separation microdevice, and subatmospheric ESI-MS interface). (b) Automated CE-MS/MS analysis of a BSA tryptic digest. (Reproduced from Zhang, B.L., et al., *Anal. Chem.*, 73, 2675–2681, 2001. Copyright 2001. With permission from American Chemical Society.)

96 samples (1  $\mu\text{L}$ ) were simultaneously loaded, preconcentrated (on 10 nL nanostructures packed with reversed-phase chromatography particles), desalted, and subsequently eluted onto MALDI target areas (200  $\mu\text{m} \times 400 \mu\text{m}$ ) to enable detection directly from the CD. Fluidic manipulations through the microstructures on the CD were accomplished using the centrifugal force developed during the rotation of the disk at 1000 rpm. The detection of 50–200 amol amounts of proteolytic peptides was demonstrated. For phosphorylated protein digests, CD nanoscale structures (16 nL) packed with IMAC particles were used to enrich the sample in phosphorylated peptides. Each sample was processed on two lines containing IMAC particles, one with, and one without subsequent

**FIGURE 53.26** Microfluidic chip interfaced to an autosampler and to an ESI-TOF-MS detection system. (a) Schematic diagram of the total system. *in situ* alkaline phosphatase treatment for peptide dephosphorylation—a process often needed to confirm the presence of a phosphorylation site. Thus, the CD enabled the parallel processing of 48 samples. Detection limits for phosphorylated peptides were ~15 fmol. Alternatively, a  $\mu$ TAS platform that comprised automated sample pretreatment and injection, a silicon microchip IMER, a silicon microdispenser, and a silicon nanovial-MALDI target, enabled automated MALDI-TOF fingerprinting of 100 protein samples within 3.5 h (Figure 53.27).<sup>180</sup>

## 53.6 METHOD DEVELOPMENT GUIDELINES

### 53.6.1 PROTOCOL TO EVALUATE DETECTION LIMITS/IONIZATION EFFICIENCY FROM THE CHIP

Up-to-date, the best performance in terms of ESI efficiency is provided by nanospray fused-silica capillaries ( $\sim 5 \mu\text{m}$  i.d.  $\times 10\text{--}15 \mu\text{m}$  o.d.). The performance of the chip ESI emitter, per se, could be evaluated by a direct comparison with these capillary emitters. For infusion experiments, the nanospray fused-silica capillary should be connected to a syringe pump and tested at a flow rate of 50–100 nL/min. For example, the infusion of a 0.1  $\mu\text{M}$  solution of a standard peptide mixture at a flow rate of 60 nL/min, should generate mass spectra with  $S/N > 5\text{--}10$  when the ion accumulation or spectrum averaging time is lesser or equal to 1 s. Under these conditions, the amount of sample consumed per spectrum and per second, will be 100 amol, an amount that is detectable by most modern mass spectrometers. The peptide solution should be prepared in  $\text{H}_2\text{O} : \text{CH}_3\text{CN} : \text{CH}_3\text{COOH}$ , 50:50:0.1, % v/v ( $\text{CH}_3\text{OH}$  could be used instead of  $\text{CH}_3\text{CN}$ ). An efficient chip ESI emitter should provide for comparable performance. A microfluidic setup that eliminates the effect of possible contributions from other processes that occur on the chip, will be essential to the success of testing the performance of the chip emitter. Preferably, for this particular experiment, the chip should be connected to a syringe pump such that the flow rate can be precisely set.

For separation chips, a similar experiment should be performed. The injection of a 100 pL plug (the approximate volume of a cross-injector on a chip) of a 10  $\mu\text{M}$  peptide solution (amount injected will be  $\sim 1$  fmol) should be detectable ( $S/N > 3$ ) if the peptide is eluting within a lesser or equal to 1 s time window. To clearly define the peak shape for such an experiment, the MS instrument should be capable of acquiring data at a storage rate of 5–10 mass spectra/s.

For on-chip MALDI-MS experiments, the performance of the chip should be similar to a regular MALDI target plate as long as the sample can be deposited in a similar dimension spot and the chip material or eluent additives do not alter or suppress the analyte ionization process. However, microfabricated devices that enable on-spot enrichment should provide for better performance than regular MALDI targets. If the deposition from the chip to a regular target plate is pursued, the effect of the interface design on the separation efficiency should be considered.

### 53.6.2 OPTIONS AND TRADES

**CE versus LC versus CEC.** CE will provide for faster separations, while LC will provide for increased sample loading capacity. Complex interactions between the sample, the stationary phase, and the mobile phase can result in a difficult optimization process of CEC-MS methods. LC and CEC do not necessitate high buffer concentrations, thus the ESI signal is not suppressed during analysis. The higher the efficiency of either separation method, the more intense the analyte peaks will be, the better the detection limits, and the more complex samples can be analyzed.

**ESI versus MALDI.** ESI from the chip will enable chip interfacing to a broader range of mass spectrometers with MS/MS capabilities, and ESI-MS/MS will generally produce more informative peptide fragmentation patterns in comparison to MALDI-MS/MS. This is an outcome of the fact that the ESI process favors multiple charging, while the MALDI process favors single charging of peptides. Singly charged species often do not produce informative fragmentation patterns when subjected to CID, and thus structural information cannot be extracted from the tandem mass spectrum. MALDI ionization, however, provides for simplicity, fast analysis, and high-throughput processing. In addition, high-energy collision fragmentation capabilities, such as the ones available with MALDI-TOF/TOF systems, can provide for more complex structural information.

**On-Spot Enrichment versus Separation.** On-spot enrichment such as with SELDI-MS is very easy to perform. However, the method is not appropriate for the detection of low abundant

components in complex mixtures that are better handled by using enrichment and sample separation steps before MS analysis.

### 53.6.3 ADDITIONAL EXPERIMENTAL CONSIDERATIONS AND USEFUL TIPS

**Detection Limits.** The eluent pH will affect the charge state distribution envelope of proteins, that is, low pH values will favor higher charge states. Large MW proteins are capable of acquiring a large number of charges, and thus the ESI signal will be distributed over a larger number of charge states (i.e., ions). This will inherently result in worse detection limits for proteins than for peptides or other small molecules. In addition, the ESI droplet surface gets saturated faster with protein analytes that carry multiple charges, and on the overall, this also results in worse detection levels for protein analytes. For micro-/nano-ESI sources tested with infusion experiments, the ESI signal starts to level out at analyte concentrations higher than 10–30  $\mu\text{M}$ , as at these levels, the ESI droplets become saturated with charged species. Thus, for infusion experiments, the sample should be prepared at lower level concentrations. For MALDI-MS ion sources, a proper choice of matrix components and of their concentration, as well as through mixing of the sample with the matrix, are essential to obtaining good quality signals.

**Buffer Systems.** Buffer systems should be preferentially volatile and of low concentration. Detergents are particularly detrimental to the ESI process. Volatile buffers should be prepared fresh every day to maintain a stable pH, EOF, and thus stable ion signal. Solvent evaporation, and/or buffer depletion in the reservoirs, will result in a change in pH, EOF, and ESI signal response. Thus, the buffers should be replenished on a regular basis. The EOF must be maintained in the direction of the ESI emitter, especially when nanospray sources are used (i.e., no liquid sheath or liquid junction fluids are delivered to the source).

**EOF and Channel Surface Contamination.** Flow visualization with fluorescent dyes is very useful for evaluating the direction and magnitude of the EOF and of possible channel surface contamination. Channel coatings must be covalently attached to ensure stable EOF and to prevent bleeding and the generation of background ions in the mass spectrometer. Gluing systems that are used to affix the reservoirs on the chip, or to assemble the chip, can dissolve in the eluent (especially if there are organic constituents), suppress the EOF, and also generate undesirable background ions. Organic contaminants can be potentially burned out from glass chips at 550°C (however, this process will destroy the channel coating), although complete EOF recovery may not be possible.

## 53.7 CONCLUDING REMARKS

The substantial progress witnessed by microfluidics during the past 18 years demonstrates that the early promises of miniaturization have started to turn into reality. While still in relatively early stages of development, integrated systems with broad functionality deliver today performance similar to or better than the one displayed by conventional instrumentation. Miniaturized systems are capable of performing complex sample preparation tasks and 2D separations. The development of cost-effective, disposable analysis platforms is essential for applications that involve high-throughput analysis of hundreds of microliter-sized samples. Advanced integration with state-of-the-art MS detection will provide a unique and powerful technology that will enable fast, unambiguous detection of trace level components. Continuous improvements in MS instrument sensitivity and the development of miniaturized and possibly multiplexed mass spectrometers will further support the miniaturization trends in bioanalytical instrumentation.

A recent manuscript has compiled a list of over 100 companies that produce and commercialize miniaturized analytical devices.<sup>236</sup> In future, off-the-shelf chips with versatile configurations could become easily available for customary needs. Comprehensive integration of  $\mu\text{TAS}$ , microelectromechanical systems (MEMS), and biosensor technologies will benefit practically any

field of biological, biomedical, biochemical, or pharmaceutical sciences. It is envisioned that throughput, disposability, and contamination-free analysis will be the key ingredients that will advance these miniaturized systems even in more demanding areas, such as the clinical environment, for high-throughput population screening applications.

## ACKNOWLEDGMENTS

This work was supported by NSF grant Career BES-0448840. The author thanks Ms. Jodi Lewis and Ms. Xu Yang for support with the preparation of the manuscript.

## 54.1 INTRODUCTION

As other entries in this handbook have made clear, capillary electrophoresis has led to tremendous improvements in electrophoretic separations, both in terms of separation speed and automation. From the standpoint of speed, the dominant advantage of capillary electrophoresis is the faster dissipation of Joule heat as the surface area to volume ratio increases, permitting much higher applied voltages. Automation has also played a key role, for example in DNA sequencers, by allowing massively parallel operation and high throughput without much user input.

The successes of electrophoresis in narrow bore, fused silica capillaries has spurred further research into miniaturization and integration of capillary electrophoresis into lab-on-a-chip systems. These new devices, fabricated using the same techniques (and concomitant precision) employed in the microelectronics industry, generally consist of a number of interconnected narrow channels. Silicon and glass are common substrates, although the semiconductor properties of silicon make it less attractive for electrophoresis. The field is rapidly moving towards polymeric chips, which are usually formed by polymerizing (molding) the polymer on a templated substrate, itself fabricated

in silicon or photoresist. Typical on-chip channel cross-sections range from tens to several hundred microns, with aspect ratios varying from unity to approximately 10.

The capillary electrophoresis techniques discussed elsewhere in this handbook can often be directly translated “on-chip.” Chip-based capillary electrophoresis possesses a number of advantages over conventional capillary electrophoresis, most notably (i) the ability to work with channels that are much smaller than what is possible in fused silica (especially as chip fabrication techniques move towards the nanoscale); (ii) the potential to integrate with other upstream operations, such as DNA isolation and polymerase chain reaction (PCR) for bioanalyses; and (iii) the performance of more precise “pinched” or “gated” injections, which increase the resolution versus separation time ratio. One notable downside of chip-based capillary electrophoresis of DNA, especially as the channel dimensions are reduced, is the increased pressure drop needed to load an entangled polymer sieving matrix. While this can be alleviated somewhat through the use of novel thermosensitive polymers [1] that undergo dramatic changes in viscosity with temperature, the use of classical sieving polymers such as linear polyacrylamide will become untenable as the dimensions of the channels are further reduced.

## 54.2 BACKGROUND

One possible solution to the pressure drop problem is to fabricate the channels and an artificial sieving matrix simultaneously. In principle, such a strategy offers a number of advantages over loading a channel with polymer solution. The channel size can be reduced at will, since a high pressure drop is no longer needed to load a polymeric sieving matrix. At the same time, highly regular sieving matrices can readily be fabricated by lithographic patterning, which should lead to more reproducible separations with reduced band broadening. In the context of materials science, such a lithographic fabrication process is a “top-down” approach—the pattern for the sieving matrix is defined by the user and then etched into the substrate, much in the way a sculptor creates a statue.

The “top-down” approach to fabricating sieving matrices for DNA electrophoresis was pioneered by Volkmuth and Austin [2], who created a hexagonal array of millions of micron-sized posts in silicon. This general principle has since been demonstrated to rapidly separate long DNA [3]. However, these arrays are difficult and time consuming to manufacture, requiring a great deal of specialized equipment. Indeed, the current state-of-the-art quartz post array [3] requires seven clean-room processing steps, including an e-beam lithography step to pattern the nanoscale support. As a result, although microfabricated post arrays offer order-of-magnitude increases in separation efficiency over conventional gel separations, their high cost and easy fouling by contaminants such as dust has prevented their adoption for routine use. This contrasts starkly with the circumstances surrounding the introduction of other revolutionary methods in DNA electrophoresis, such as pulsed-field electrophoresis and capillary sequencers, which found immediate use in the community at large and were quickly commercialized.

The focus of this chapter is on another approach to forming regularly structured stationary phases for capillary electrophoresis: so-called “bottom-up” techniques that take advantage of the transport and thermodynamic properties of small colloidal particles. We will discuss two such methods: (i) assembly of superparamagnetic beads by an external magnetic field and (ii) the convective assembly of colloidal particles in an evaporating water film. Both techniques successfully form DNA separation matrices without the need for a complicated top-down lithography step, and may eventually provide a route for bringing emerging lab-on-a-chip technologies into routine use. However, fabrication by self-assembly is not as well developed as lithography, and suffers from a number of technical difficulties. We will explore both the promise and the limitations of bottom-up approaches to forming stationary phases for capillary electrophoresis, illustrating the potential of this technique and the obstacles that lie ahead in future research.

## 54.3 THEORY

### 54.3.1 SELF-ASSEMBLED MAGNETIC ARRAYS

We begin our discussion with the self-assembly of superparamagnetic beads in external magnetic fields. This method has been dubbed “Ephesia,” after the Temple of Artemis, one of the seven wonders of the ancient world [4]. The temple, whose roof was supported by a number of columns, was repeatedly destroyed and rebuilt in exactly the same manner throughout history. The magnetic bead system operates in an analogous manner—the array can be repeatedly formed and destroyed by turning the magnetic field on and off.

#### 54.3.1.1 Formation of the Array

The magnetic beads used in the early stages of development of the method were essentially an oil-in-water emulsion, stabilized by surfactant. The oil droplets were relatively monodisperse with an average diameter of 570 nm, and contained small grains of iron oxide that impart superparamagnetic properties to the beads. The technology for manufacturing superparamagnetic nanobeads has advanced significantly since the initial report on their self-assembly processes [5]. Successors of these magnetic emulsions are commercially available from Ademtech SA in Pessac, France: they are now stabilized by replacing the oil with a polymerized material. Indeed, numerous magnetic latexes, differing in composition and size, can be used to assemble arrays, depending on the application (scale, strength). A requirement, however, is that the size distribution of the particles be rather monodisperse. The external magnetic field is supplied by a cooled electromagnet surrounding the microchip [6].

Figure 54.1 [7] illustrates the general principle underlying the formation of the Ephesia array. In the absence of a magnetic field, illustrated in Figure 54.1a, thermal motion leads to the magnetic moments of the grains in the beads being randomly oriented. As a result, the net magnetic moment

**FIGURE 54.1** (a) In the absence of a magnetic field ( $B = 0$ ), the magnetic moments of the iron grains in the bead are randomly oriented and the Brownian motion of the bead center of mass gives rise to the quasiuniform distribution indicated in the lower figure. (b) When the magnetic field is turned on ( $B \neq 0$ ), the magnetic moments align and the beads form columns. (Adapted from Minc, N. *Microfluidique et billes magnétique auto-organisées pour les analyses biologiques*, Ph.D. Thesis, Université Paris VI, 2005.)

of a given bead vanishes. In this unpolarized state, the beads can be easily injected into a standard poly (dimethylsiloxane) (PDMS) microchannel, where they form the homogeneous suspension depicted at the bottom of Figure 54.1a. When the magnetic field is turned on, the iron grains in the bead become aligned, leading to a net magnetic moment in each bead. This is what is meant by superparamagnetic—the beads only have a magnetic field in the presence of the field (paramagnetism), and the paramagnetic effect occurs because the energy for aligning the local magnetic moments is comparable to thermal energy (the “super” part). Each bead then acts like a “mini-magnet,” whereupon nearby beads align their N–S poles and begin to form columns. The column spacing is generally independent of the volume fraction  $\phi$  of the beads [5]—as the bead concentration increases, the column width increases like  $\phi^{1/2}$  to maintain a constant column spacing [5].

The ability to form columns depends strongly on the strength of the magnetic field. This effect is quantified by the coupling constant [5] (i.e., the ratio of the magnetic and thermal energies). Column structures only form when the coupling parameter is much greater than unity. The change in the suspension morphology with magnetic field is clearly seen in the optical micrographs presented in Figure 54.2 [8]. At weak fields, the beads do not associate and the suspension is homogeneous. As the

**FIGURE 54.2** The growth of the columns depends on the strength of the magnetic field. At a low magnetic fields, (a) there is a coexistence of individual beads and chains. As the magnetic field increases, (b) the distribution shifts towards chains and eventually includes columns, and (c) the columns span the channel. At higher magnetic fields, (d) the columns are stabilized by solid friction with the walls and the structure is a “solid.” (Reprinted from Ivey, M., et al., *Phys. Rev. E*, 63, 011403, 2000. With permission.)

field increases, the morphology moves from a mixture of beads and chains towards a solid columnar structure. The columns repel one another because their effective magnetic charges have the same sign at the top and the bottom of the column [8]. The repulsion ultimately leads to the hexagonal structure seen in Figure 54.1.

While the hexagonal structure is the equilibrium state for an infinitely wide (unbounded 2D) magnetic array, electrophoretic applications require channels of finite width. For example, the array in Figure 54.1 typically contains several dozen columns across the channel width. Brownian dynamics simulations [9] and related experiments [10] have shown that the steady-state structure of a confined matrix is a strong function of the wall spacing. When the wall spacing is not commensurate with the crystal lattice spacing, defects form near the wall and propagate into the bulk array [9]. Intuitively, one would expect that perfect arrays would form perfectly flat walls if the gap height  $h$  is some integer multiple of the bead radius  $R$ . Remarkably, this is not the case [9]. As seen in Figure 54.3, the perfect arrays do not form integer values of  $h/R$ . In experiments on real two-dimensional (2D) crystals (formed by sedimenting the beads to the bottom of the channels), imperfections in the PDMS channel walls also play a strong role in determining the bead density across the channel [10]. Although it is useful to think of the imperfections of the array as propagating from a disordered wall “region,” it is in fact impossible to unambiguously define the border between the wall region and the bulk crystal [11].

In very large Hele–Shaw cells, at a distance from the walls much larger than the cell thickness, a hexagonal order is obtained only locally, and defects destroy the long-range order. This is expected to arise from the randomness of the interactions between columns and the bottom of the cell. Once a column spans the narrow height of the cell, the solid friction with the floor and ceiling “freezes” the

**FIGURE 54.3** For finite gap widths  $h$ , the distribution of the particles depends on the number of particle radii  $R$  between the two walls. Surprisingly, the most uniform density profiles (indicated by the sharpest peaks in the density profiles on the right) do not correspond to integer values of  $h/R$ . (Reprinted from Haghgooei, R., and Doyle, P.S., *Phys. Rev. E*, 70, 061408, 2004. With permission.)

column location. In effect, these columns serve as nucleation sites for the growth of the hexagonal crystal. Inasmuch as the position of a given nucleation site is random (with respect to the lattice spacing of nearby crystals formed from other nucleation sites), the hexagonal order emanating from a nucleation site is maintained only until the boundaries of two different nucleated crystals merge.

The column spacing in the array can be controlled by the surfactant used to wash the beads [12]. Figure 54.3 presents three different arrays formed by using Tergitol NP-10, Triton X-405, and Tergitol NP-40 as the stabilizing surfactant. These molecules are amphiphilic, with a hydrophobic head that associates with the oil phase (the bead) and a hydrophilic tail extending into the aqueous phase. As the length of the hydrophilic tail decreases, the steric repulsion energy decreases, leading to denser arrays. The maximum density of the array is limited, however, by an intrinsic instability in ferrofluid suspensions [13]. Indeed, the array depicted at the bottom of Figure 54.4 is close to the highest density that still forms columnar structures in this particular Hele-Shaw cell (of height  $12\ \mu\text{m}$ ). At higher bead densities, the columnar structure is destabilized and the hexagonal array devolves into a labyrinthine structure.

The self-assembly process possesses an intrinsic limit with respect to the column spacing. Explicitly, the array must be sufficiently concentrated so that the repulsive energy between the different columns is strong enough to enforce the hexagonal structure. The repulsive dipolar energy scales

**FIGURE 54.4** The density of the array can be altered by changing the length of the surfactant used to stabilize the bead suspension. The pictures on the left side correspond to decreasing hydrophilic arm lengths, from top to bottom. The plots on the right-hand side are cross-sections of the Fourier transforms of the left-hand images. The mean column diameter and spacing, as well as the variance in the spacing, can be computed from these plots [6]. (Reprinted from Minc, N., et al., *Electrophoresis*, 26, 362, 2005. With permission.)

**FIGURE 54.5** Highly regular arrays of magnetic bead columns can be produced by patterning the surface with Ni “anchors.” (a) Ni spots on the surface, spaced 10  $\mu\text{m}$  apart. (b) Beads that have assembled onto the anchors. (Reprinted from Saliba, A.E., et al., *Proceedings of MicroTAS 2006*, Eds. T. Kitamori, H. Fujita, and S. Hasabe, Tokyo, Japan, Transducers Research Society, 2006.)

like  $1/r^3$ , which leads to a rapid drop-off in repulsive energy as the array is diluted. This limitation can be side stepped by incorporating magnetic “anchors” into the floor of the channel [14]. The anchors are created by nanopatterning the substrate with nickel spots through e-beam patterning and metal lift-off. The results of this process are illustrated in Figure 54.5. The bead columns faithfully reproduce the nickel surface pattern, without any columns assembling away from the nickel spots. However, the introduction of the nickel pattern eliminates one of the strongest points of the magnetic bead array, namely the fact that it is a bottom-up strategy that does not require any sophisticated lithographic steps. Nevertheless, the nickel patterning is still considerably less complicated than the fabrication required to produce the equivalent post array in quartz [3], and is only necessary for forming very dilute arrays. Another advantage of this “templated” self-assembly is that it allows the formation of structures with an aspect ratio (up to a hundred or more) impossible to reach solely with “top-down” microlithographic techniques. Finally, the cost and complexity of the fabrication of the initial magnetic pattern can be greatly reduced, as compared to the lift-off process, by preparing magnetic plots by microcontact stamping of a magnetic “ink” [15].

### 54.3.1.2 Separation Resolution

The ability to simply create controlled array structures with a variety of pore sizes (as in Figures 54.4 and 54.5) has led to the development of a number of theoretical models for the transport in such arrays. The first model [4] simply assumed that each time the DNA passes one row of the postarray, it has some probability  $\Pi_c$  of colliding with the post. If there is a collision, the DNA is held up on the post for some average time  $\tau$ , which depends on the molecular weight and the electric field.

Several simple scaling laws can be readily derived from this Markovian model by assuming that (i) the collision probability  $\Pi_c$  only depends on the density of the array (and not the electric field or the DNA size) and (ii) the trapping time  $\tau$  varies inversely with the electric field, which is consistent with the “rope-over-pulley” mechanism of escape [16]. In this limit, the mobility  $\mu$  is independent of the electric field  $E$ , while the effective diffusivity (or dispersivity)  $D^*$  scales linearly with  $E$ . As a result, the separation resolution should be independent of  $E$  for a fixed separation length, implying that the separation time in these arrays could be reduced indefinitely by increasing the field. This scaling law is born out for intermediate fields between 20 and 40 V/cm [6], where the model is expected to be valid. The resolution is lower outside of this regime. The loss of resolution at weak fields was subsequently shown to be the result of an increase in  $D^*$  due to incomplete stretching of the chain during the unhooking process [17]. The strong field result remains unexplained, although it is speculated [6] that the DNA cannot completely relax between collisions.

This leads to an anomalously long translation time between the collision events, thereby reducing the number of “separation steps” per unit length. Besides this observation, other physical phenomena put a practical limit on the applicable field. First, the surface treatment is never perfect, and it results in a residual electroosmotic flow that can destroy the column array in too strong fields (practically, around 50–100 V/cm). Second, too high fields may result in Joule heating, which is also a cause of loss of resolution (above typically 500 V/cm for channels 50  $\mu\text{m}$  thick; the present experiments [6,12] use channels 10–12  $\mu\text{m}$  thick).

Minc et al. [12] compared this simple model to single-molecule observations of DNA migration in the arrays. The microscale parameters  $\Pi_c$  and  $\tau$  were measured directly from the single-molecule observations, and the macroscopic parameters  $\mu$  and  $D^*$  were determined from the first-passage time statistics for DNA moving through the viewing area. Although the scaling arguments remain in accord with both the ensemble and single-molecule data, the quantitative agreement between theory and the single-molecule experiments was not satisfactory. Several other transport models also failed to explain the experimental data.

Building upon the insights from the single-molecule experiments [12], a more sophisticated mathematical model was constructed [18]. The model, shown schematically in Figure 54.6, is inspired by the so-called geometration model of gel electrophoresis [19]. The DNA motion is modeled as a three-step process: (i) collision with the post and unraveling into two arms; (ii) a rope-over-pulley disengagement process; and (iii) uniform translation to the next collision, which occurs at some random distance downfield. By making some simple assumptions about the transport processes, most notably by requiring that the probability of a collision in any given row be proportional to the areal post density, and that all DNA motion occurs with the free solution mobility  $\mu_0$ , the mobility  $\mu$ , and dispersivity  $D^*$  can be computed exactly without any adjustable parameters. The qualitative predictions of the model agree very well with the experiments reported above, and the quantitative agreement is satisfactory given the limited amount of data available [18]. This model was subsequently modified to account for incomplete stretching at weak fields [17], which explains the loss in resolution at weak fields.

### 54.3.2 COLLOIDAL-TEMPLATED CRYSTALS

We now turn our attention to the use of nonmagnetic colloidal particles to form sieving matrix templates. Much in the same way that microelectronics manufacturing has provided the toolbox for creating lab-on-a-chip systems via lithography, photonic crystal production has provided the tools that will be presented in the present section. While we will focus exclusively on the use of colloidal templates to create sieving matrices for DNA electrophoresis, the general methods used here are a burgeoning field of research in materials science and promise to impact a range of applications much broader than capillary electrophoresis. At the same time, the sheer volume of research currently underway into the materials side of the problem promises to greatly improve the variety and regularity of the structures that could ultimately be employed for electrophoresis.

In the present section, we cover the two steps for creating stationary phases from colloidal assembly. In the first step, the colloids are assembled into a regular, close-packed structure through the evaporation of the solvent or a flow-through system. As we will see later, the colloidal crystal, when filled with electrophoresis buffer, can be used directly as a solid support for capillary electrophoresis [20,21]. Alternatively, a polymeric structure can be formed around the bead template. After dissolving the beads, one is left with a regular structure of cavities and pores that can also serve as an electrophoresis support [22].

#### 54.3.2.1 Colloidal Crystals

In the Ephesia system, discussed in Section 54.3.1, an external magnetic field is used to assemble the superparamagnetic particles into an organized array of columns. As illustrated in Figure 54.7,

**FIGURE 54.6** Schematic of the geometration model of DNA electrophoresis in micropatterned arrays. Representative DNA conformations are superimposed on an image of a self-assembled magnetic bead array. (Reprinted from Minc, N., et al., *Phys. Rev. Lett.*, 94, 198105, 2005. With permission.)

colloidal templating uses the forces exerted by an evaporating liquid film to guide the crystal formation. In the simplest case [23,24], the liquid is evaporated from a flat substrate. The thickness of liquid film is commensurate with the diameter of the colloids, which suppresses Brownian motion of the beads. Once the film evaporates below the level of the colloids, they form a nucleation site for the crystal [24]. This results in a curvature of the water/air interface, whereupon the surface tension and convection in the water phase combine to drive additional colloidal particles towards the nucleation site. An alternate process for driving the crystal formation is to dip the substrate into a suspension of the colloids and slowly withdraw it to form a film, similar to a Langmuir trough [23]. The colloids are then assembled through the convection of the fluid along the meniscus, driven again by the water flux.

The range of particle sizes that can be assembled in this manner is very large, with reports ranging from 200 nm [25–27] to several microns [24,26]. Also note that, although the figure only illustrates the formation of a single layer of colloids, multiple layers are typically formed during the process.

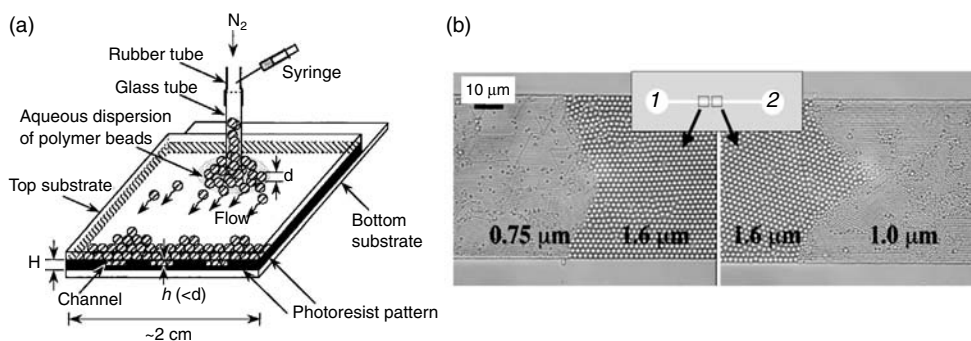

**FIGURE 54.7** Mechanism of convective assembly on (a) flat and (b) vertical surfaces. (Adapted from Nagayama, K., *Coll. Surf. A*, 109, 363, 1996.)

**FIGURE 54.8** SEM image of a seven layer colloidal crystal assembled from 396.6 nm particles. (Reprinted from Jiang, P., et al., *Chem. Mater.*, 11, 2132, 1999. With permission.)

For example, the dip coating of a slide will normally form 10–50 layers of colloids [27]. Figure 54.8 illustrates a typical scanning electron micrograph (SEM) picture of a colloidal crystal formed in this manner.

Colloidal crystals possess long-range order, although there are usually defects and stacking faults over the longer length scales needed for electrophoresis [22]. Moreover, since the faults seen in Figure 54.8 are not necessarily colinear, the electric field will not always be aligned with a symmetry axis of the crystal. As we will see shortly, this has important implications for electrophoresis [22]. The presence of domain boundaries is probably the biggest drawback in applications, since the medium does not possess uniform properties over the distances required for DNA separations. Likewise, the boundaries force the DNA to move along the defects until they reach a new, defect-free region [22].

**FIGURE 54.9** Two mechanisms for flow-based assembly of colloidal arrays. (a) Assembly through a template weir. (Reprinted from Park, S.H., and Xia, Y., *Chem. Mater.*, 10, 1745, 1998. If the colloidal crystal is to be used directly for electrophoresis, it can be sealed on the sides and then covered with a PDMS lid with holes bored for the reservoirs [21]. Similar to the magnetic bead system, a colloidal crystal is a simple method of fabricating a regular nanoscale stationary phase for electrophoresis.

Colloidal crystals can also be assembled through flow-based methods. One of the earliest strategies for flow assembly is depicted in Figure 54.9a [26]. The microfabricated “frame,” constructed on the lower substrate in SU-8 resin, has periodic holes to define flow channels. The entire apparatus was covered with an upper substrate and connected to a glass tube. When the colloidal suspension is introduced into the gap between the substrates, the solvent escapes through the gaps in the frame, while the beads remain trapped against the photoresist. This creates a well-defined bead pattern with a height equal to the lower part of the frame.

An alternate flow-based method to form colloidal crystals is to use the permeability of PDMS to form the crystals *in situ* in the channels [28], which could subsequently be used for electrophoresis. The basic strategy is illustrated in Figure 54.9b. The colloidal suspension in the reservoirs creates a pressure head, and the flux of solvent through the walls of the channel leads to a stagnation plane in the center of the channel, with the area-averaged velocity increasing as one moves from the center plane toward the reservoirs. This mode of crystal growth works well in very thin channels; the experimental results in Figure 54.9b used a 2- $\mu\text{m}$  deep, 50- $\mu\text{m}$  wide, 1-cm-long channel. As indicated in the figure, it is possible to create a crystal/crystal interface by seeding each reservoir with different sized colloids.

Finally, if heavy beads such as silica ( $SG = 2.1$ ) are used, they can be assembled into a regular matrix by sedimentation [20]. One particular advantage of silica beads is that, after assembling them in a glass cell, sucrose can be added to the electrophoresis buffer to closely match the index of refraction of silica. This leads to a transparent material that is ideal for optical detection (at the expense of separation time, since sucrose increases the medium’s viscosity, and thus reduces electrophoretic mobility). A second advantage is that some of the well-documented surface treatment strategies against electroosmosis developed for capillary electrophoresis can be directly transposed.

### 54.3.2.2 Polymer Matrices

Although colloidal crystals can be used directly for electrophoresis [20,21], it is also possible to use the crystals as templates for polymer matrices. In this approach [26,27], the colloidal crystal

**FIGURE 54.10** SEM image of a polymer matrix formed by infusing the monomers into a colloidal crystal, polymerizing the monomers, and then etching away the crystals. The nanopores between the cavities are the result of incomplete wetting of the colloids at their junctions. (Reprinted from Jiang, P., et al., *J. Am. Chem. Soc.*, 121, 11630, 1999. With permission.)

is perfused with a monomer solution that is then polymerized. The solution flows spontaneously into the matrix due to capillary action, although it is suspected that the beads are not completely wetted by the fluid [27]. A large variety of polymers can be used to create the matrix, including polyurethane, polymethyl methacrylate (PMMA), polymalic acid (PMA), polystyrene, and epoxy [27]. For electrophoresis, a mixture of 30% acrylamide monomer and 6% bis-acrylamide was used to create a templated polyacrylamide gel with well-defined pore spaces [22]. Following polymerization, the beads are chemically dissolved. Thus, the key restriction in the choice of polymer matrix is that the polymer must resist degradation by the solvent. For electrophoresis applications [22], the polystyrene beads used to form the matrix were dissolved by toluene, which does not destroy the polyacrylamide. A successful polymerization is easy to see after the toluene is removed; owing to Bragg diffraction of light, the polymer matrix is iridescent.

Figure 54.10 depicts a polystyrene matrix formed by templating of 260.4 nm silica beads and then dissolving the beads with hydrofluoric acid [27]. As is evident from the figure, the polymer matrix consists of an ordered array of cavities with a diameter close to the diameter of the silica beads. The cavities are connected by pores that are typically one-fourth of the bead diameter. The size of the pores can be controlled by changing the viscosity of the monomer solution perfusing the matrix (via the solution temperature), presumably due to a change in the wetting properties and subsequent shrinkage during polymerization [27]. Also note that all cavities are not completely connected, although it is suspected that the network as a whole is simply connected [27].

## 54.4 APPLICATIONS

### 54.4.1 SELF-ASSEMBLED MAGNETIC ARRAYS

The first separations of DNA in self-assembled arrays were reported in the literature by Doyle et al. in 2002 [29], although the method appeared in conference proceedings as early as 1997 [30]. In the initial experiments, the magnetic beads were loaded into the channel using a pressure head generated by different fluid heights in the various reservoirs on the chip. While this method will load the beads, much more reproducible arrays are obtained using a pressure control system for the

**FIGURE 54.11** Electropherogram for separations in magnetic bead arrays. (a) Separation of *XhoI* digests of  $\lambda$ -DNA (48.5 kbp) at 4.8, 7.0, and 10 V/cm. (b) Separation of  $\lambda$ -DNA concatemers at 3.2 V/cm. (Reprinted from Doyle, P.S., et al., *Science*, 295, 2237, 2002. With permission.) (c) Separation of  $\lambda$ -DNA and  $2\lambda$ -DNA in a more recent experimental setup at different electric field strengths. (Reprinted from Minc, N., et al., *Anal. Chem.*, 76, 3770, 2004. With permission.)

reservoirs [31]. Likewise, the pressure control system eliminates any hydrodynamic flows that might occur from experimental artifacts, such as someone opening the door to the room or nonuniform evaporation from the reservoirs, yielding purely electrophoretic transport through the array. The prototype pressure control system used in experiments [6,12] has since been commercialized by Fluigent.

Following the initial report of this technique [29], Minc et al. [6] made significant technical improvements on the method, which ultimately led to an order-of-magnitude improvement in the separation time and reproducibility. Amongst the technical advances made in this work were (i) the use of the flow control system to load the beads and suppress hydrodynamic flows during the experiment; (ii) an improved electromagnet for forming the array and trapping the structure in the local minimum; and (iii) the use of a pretreatment of the microchannel with a dimethylacrylamide/allyl glycidyl ether copolymer for suppressing electroosmotic flow. In conventional PDMS, this treatment has a limited lifetime, about 90 min of operation, and it must be repeated periodically (for a more detailed account about surface treatments of PDMS and other polymers, see for example Reference 32). The veracity of this new system for DNA electrophoresis has been verified extensively [6].

The key results from the initial separation experiments, using static fluid heads to load the beads, are depicted in Figure 54.11. In each set of experiments, the column spacing was approximately  $5.7 \mu\text{m}$ . Figure 54.11a presents the results for separations between different fragments of a *XhoI* digest of  $\lambda$ -DNA (48.5 kilobase pair or kbp). As is evident from the figure, these DNA fragments can be base-line resolved at 4.8 V/cm after a separation time of approximately 15 min. This compares favorably with traditional pulsed-field gel electrophoresis separation of the same fragments, which requires many hours for an equivalent resolution. The separation time reduced results from the increased post spacing, which breaks the biased reptation with orientation migration mechanism [33], since the DNA can easily coil up into its equilibrium conformation between collisions with the posts. These initial arrays were also able to separate larger DNA, as seen in Figure 54.11b. Two concatemers of  $\lambda$ -DNA and the template were well resolved by an electric field of 3.2 V/cm after approximately 30 min.

The success of the second-generation magnetic bead system [6] is evident from the data presented in Figure 54.11c. In these experiments, the average column diameter is  $1.4 \mu\text{m}$  (indicating aggregation of several single-bead columns) and the average center-to-center spacing is  $4.1 \mu\text{m}$ , implying a pore size of  $2.7 \mu\text{m}$ . These arrays can separate  $\lambda$ -DNA and  $2\lambda$ -DNA with a resolution greater than unity in several minutes. Indeed, the fastest separation (using an electric field of 35.2 V/cm, an order

of magnitude higher than the experiments discussed above) achieves a resolution of 1.36 in only 60 s. The improved performance is the direct result of the technical developments discussed above.

## 54.4.2 COLLOIDAL CRYSTALS

### 54.4.2.1 Entropic Trapping

The first application of templated colloidal matrices was a fundamental study of entropic trapping [34]. Entropic trapping is predicted to occur whenever DNA moves through a medium consisting of cavities comparable to the radius of gyration of the DNA that are connected by small pores. The diffusion of the DNA is hindered because it loses entropy during the transit between cavities, since the DNA must uncoil to move through the pores. Theory [35] predicts that, in the entropic trapping limit, the diffusivity of DNA will decay exponentially with molecular weight.

To provide an ordered entropic trapping environment in these experiments, 0.895  $\mu\text{m}$  polystyrene spheres were used to form the crystal and acrylamide was used for the polymer matrix. The resulting structure has a cavity size of 0.92  $\mu\text{m}$ , which is slightly larger than the bead size due to swelling and comparable to the radius of gyration of DNA in the 10 kbp range. The connecting pores are 0.10  $\mu\text{m}$  in radius, which is slightly larger than the DNA persistence length. The matrix was filled with buffer and DNA and then sealed, and no electric field was used.

The dynamics of 7.23 kbp DNA in the array are illustrated in Figure 54.12. The radius of gyration of this size DNA is considerably less than the cavity diameter, allowing them to easily coil therein. At any given instance in time, each DNA molecule occupies a single cavity. The four DNA in Figure 54.12a are indicated by the bright cavities. Over the course of time, as seen in Figure 54.12b, the DNA explore nearby cavities by rapid jumps. These jumps are separated by long periods of time during which the DNA is stationary. The particular trajectory for the right-most DNA is highlighted in Figure 54.12c, where the shading of the lines indicate the broad distribution of waiting times between jumps.

**FIGURE 54.12** (See color insert following page 810.) DNA dynamics in a polymer matrix formed from colloidal templating in the absence of an electric field. (a) At a given instance in time, four DNA molecules are localized in different pores. (b) Over time, the DNA explore the local pores. (c) The jumping between pores is random in both direction and the waiting time between jumps. (Reprinted from Nykypanchuk, D., et al., *Science*, 297, 987, 2002. With permission.)

The diffusivity of DNA in this matrix, measured by both the jump-time distribution and the growth of the mean-squared displacement, indicates an exponential decay with respect to molecular weight, although the amount of data is very limited. If these data are fit by a power law, one obtains  $D \sim N^{-1.1 \pm 0.7}$ . Although this is very close to inverse dependence on molecular weight predicted by the Rouse model, the dynamics are very different. It is clear from these experiments that direct visualization is necessary to determine the true mode of migration [34].

When the radius of gyration exceeds the cavity size, the entropic trapping mechanism breaks down. For example,  $\lambda$ -DNA was observed to move like an inchworm, simultaneously spanning multiple pores [34]. The DNA is not completely extended, however, since it can relax to fill the cavities due to a gain in entropy.

#### 54.4.2.2 DNA Electrophoresis

The first experiments using colloidal templates were performed without the polymerization step, using silica beads with a diameter of  $1.04 \pm 0.4 \mu\text{m}$  [20]. The beads were not well-packed over the entire  $O(\text{cm})$  region, with monocrystalline regimes periodically interspersed by polycrystalline regimes. Electrophoresis experiments with a range of DNA samples essentially confirmed that the DNA dynamics in this array correspond to the predictions of biased reptation [33]—the mobility scales like  $N^{-0.9 \pm 0.1}$  and the diffusivity scales like  $N^{-1.9 \pm 0.2}$ . A reptation plot [36] of the mobility indicates that the occupied pore sizes are consistent with predictions from geometric arguments for the packing of the spheres. Thus, these experiments demonstrated that biased reptation in fact describes the transport of DNA in well-ordered porous media where the pore sizes are much smaller than the radius of gyration of the DNA.

Smaller colloidal crystals, formed by 300 nm silica spheres, have also been used to for DNA electrophoresis [21]. The mean pore size of such an array is around 0.45 nm, considerably smaller than that above and smaller than the persistence length of DNA. Single-molecule observations of  $\lambda$ -DNA moving through this crystal showed that at weak fields (11 V/cm), the DNA moves like an inchworm, occasionally forming the rope-over-pulley shape seen in Figure 54.6. At higher fields, the DNA is stretched and forms strong rope-over-pulley collisions. Thus, it is reasonable to conclude that this smaller silica crystal generates similar dynamics to a quartz nanopillar array [3] without the need for e-beam lithography.

The silica crystal array can also be used for pulsed fields by adding two additional reservoirs to the PDMS cover to create a  $120^\circ$  crossed field. The mobility of different size long DNA (48.5, 23.1, and 9.4 kbp) vary in the pulsed-field array, indicating that they could be separated in such an array if a suitable injection system were employed. The high electric fields and rapid pulse times employed in these experiments are comparable to pulsed-field electrophoresis in the “DNA prism” pillar array [37].

Polymeric matrices formed from a colloidal template have also been used for DNA separations [22]. In contrast to the case in entropic trapping in this type of matrix [34], the electric field compresses the long  $\lambda$ -DNA into a single pore. As illustrated in Figure 54.13, at weak fields the DNA move slowly between the pores, with the direction of the motion biased by the electric field. As the field increases, rope-over-pulley dynamics are observed, whereas at the highest fields the DNA jumps across multiple pores and then coils up. This behavior can only be observed over limited stretches of the medium, since the DNA dynamics change sharply as it tries to transit from one domain to another at the boundaries [22].

The local mobility of DNA in these arrays exhibits a peculiar dependence on molecular weight and electric field, as seen in Figure 54.14. At weak electric fields, the shorter DNA are more mobile. In contrast, there exists a plateau regime at higher electric fields where the longer DNA moves more quickly. The plateau region is of particular interest for applications, since it would allow rapid separations.

**FIGURE 54.13**  $\lambda$ -DNA dynamics in a polymer matrix formed from colloidal templating in the presence of an electric field. (a) Under a weak field (10 V/cm), the DNA move sluggishly between pores, analogous to Figure 54.12. (b) Under a moderate field (25 V/cm), the DNA forms a rope over a pulley, analogous to Figure 54.6. (c) At the highest field (50 V/cm), the DNA jumps over multiple pores. (Reprinted from Zeng, Y., and Harrison, J.D., *Electrophoresis*, 27, 3747, 2006. With permission.)

**FIGURE 54.14** Electrophoretic mobility of  $\lambda$ -DNA (48.5 kbp) and calf thymus DNA (13 kbp) as a function of electric field in a polymer matrix formed from colloidal templating. (Reprinted from Zeng, Y., and Harrison, J.D., *Proceedings of MicroTAS 2006*, Eds. T. Kitamori, H. Fujita, and S. Hasabe, Tokyo, Japan, Transducers Research Society, 2006. With permission.)

The mobility dependence in Figure 54.14 can be explained qualitatively by a relatively simple model of the transport process [22]. At weak fields, the transport is dominated by entropic trapping, since the change in potential energy for moving in the field is not much greater than the decrease in entropy required to move between the cavities. As a result, the shorter DNA moves more quickly in

weak fields, since the entropy loss is lower. The mobility crossover at higher fields is attributed to electrical trapping at the cavity walls. The entropic trapping effect becomes ever less important as the field increases, since the change in potential energy from moving to a new cavity becomes large compared with the entropy cost during transit. However, as noted in section 54.3.2.1, the crystal axes are not necessarily aligned with the field. As a result, if the axes are not aligned with the field, the electrical force pushes the DNA against the cavity walls and flattens it like a pancake. This is a peculiar consequence of the polymer used of creating the “negative” of the bead array, which is a hydrogel that is permeable to ions (and thus to the electric field) but not to DNA. If the “pancake radius” is large enough, then the edges of the pancake will reach the nearby pore entries, whereupon the electric field can pull the DNA out of the cavity. Since larger DNA will have larger pancake radii, they will escape more easily.

The initial experiments discussed above focused on single-molecule observations (i.e., without an injection step), and the matrix was enclosed in a custom electrophoresis cell. A preliminary report [38] using an array of microchannels to sculpt the field [37] indicates that this matrix can be used as an analytical tool. Moreover, pulsed-field separation are possible by mimicking the DNA prism protocol [37,38].

Interestingly, the three-dimensional (3D) network of interconnected cavities described in Reference 22 is a perfect practical realization of the “lakes–straits” model proposed by Zimm [39] as an early model of gel electrophoresis. To be in this regime, a molecule must span several pores, so DNA molecules significantly larger than those used in the experiments described above would be necessary to reach this regime. It would be interesting to check the validity of the lakes–straits model with such molecules.

The above discussions have highlighted the utility of both magnetic arrays and colloidal-templated crystals for DNA electrophoresis. While the variety of solid supports that can be fabricated by these techniques is limited when compared to those available through micro- and nanofabrication, the ease with which these self-assembled arrays can be constructed confers significant advantages for routine use.

While we have only focused here on applications for DNA electrophoresis, colloidal crystals have also been used as a stationary phase for separating hydrophobic dyes and proteins [40]. The arrays may prove especially interesting for electrophoretic protein separations, since the pore size provides a steric constraint, no pressure drop is required for transport through the small pores and the bead surfaces serve as a substrate for reversed-phase adsorption. These arrays thus offer a tunable variety of separation mechanisms. Indeed, proteins with similar hydrophobic groups, which cannot be separated by high performance liquid chromatography (HPLC) due to their similar adsorption properties, are rapidly separated by charge in colloidal arrays [40].

## 54.5 METHODS DEVELOPMENT GUIDELINES

The array structure (and the formation of the labyrinth) of magnetic arrays on the rate that the magnetic field is applied. In the reported separations [6,12], the magnetic field is applied by ramping the current in the electromagnet to its highest setting as quickly as possible. This traps the bead suspension in a local energy minimum, which may not necessarily correspond to the thermodynamic equilibrium state. As a result, the slow evolution process depicted in Figure 54.2 is not realized and thermodynamic instabilities, such as the labyrinth structure, can be suppressed to a certain extent. Moreover, rapidly applying the magnetic field also appears to increase the reproducibility of the array structure. From a purely theoretical standpoint, this cannot be true, since the thermodynamic minimum should be perfectly reproducible. However, in these experiments, interactions with the wall immobilizing columns through a mechanism resembling solid friction prevents this equilibrium from being reached. Supporting this interpretation, the regularity of the array structure is in general improved if the field is turned on and off several times before the separation to “train” the beads.

Most likely, the initial application of the field brings the beads from an initially random distribution to something close to a local energy minimum. When the field is turned off, Brownian motion allows the beads to perturb their positions. While the magnetic attraction/repulsion is no longer active in the absence of the field, steric effects and van der Waals forces persist, forcing the beads to retain a short-term memory of their previous positions in the presence of the field. If the field is turned back on after a short period of time, the beads now reform the columns, but start from an initial condition closer to the local energy minimum, thereby increasing the probability that they will assemble into a more regular hexagonal structure. Each time the off–on cycle is repeated, the beads reassemble from an initial position closer to the local minimum. This cyclic approach will yield ever more regular arrays until the array is very close to the local energy minimum.

## 54.6 CONCLUDING REMARKS

In this chapter, we have discussed two different bottom-up approaches to forming stationary phases for capillary electrophoresis: the self-assembly of superparamagnetic beads (the Ephesia system) and colloidal templating. Both methods have proven successful in separating long DNA without the need for a complicated lithographic fabrication step. As a result, they essentially side-step the dedicated clean-room facilities and expensive nanolithography tools needed for comparable top-down approaches and open the possibility of bringing these systems into routine use in biological laboratories. However, as we have seen, the range of structures that can be created through self-assembly is limited. Indeed, for the Ephesia system, it is only possible to create highly open structures by incorporating magnetic anchors into the surface, which itself requires some lithography, and colloidal crystals are plagued by stacking faults at large length scales. Thus, although bottom-up methods offer many exciting possibilities for designing stationary phases for capillary electrophoresis, they are not without their drawbacks.

Given the technological importance of nanofabrication for microelectronics and colloidal assembly for photonic crystals, it is inevitable that (now) conventional lithographic approaches to lab-on-a-chip stationary phases and the newer self-assembled techniques will continue to benefit from advances in related fields. At the present stage, it is difficult to determine which of these approaches will ultimately prevail. If lithographic fabrication costs continue to follow Moore's Law, it is conceivable that methods that are prohibitively expensive today could become affordable in the near future. We suspect, however, that this simple transposition from the microelectronics world will rapidly encounter limitations: biomolecules are by far larger than electrons, and with micron-sized structures, one is already facing limitations associated with the small number of molecules of a given kind contained in the volume of interest. The relative weight of Brownian motion also increases with downscaling. A major element in the success of downscaling in microelectronics, is that it allowed a simultaneous *increase* in the number of components in a microprocessor, and a *decrease* in its footprint, that is, increase the number of processors made in a single step on the same wafer. For the reasons recalled above, this “win-win” strategy will probably not work so well for “lab-on-chips.” Likewise, if methods for colloidal templating continue to improve, in particular for generating larger scale and more varied structures, then the ease of this bottom-up strategy could ultimately trump the flexibility of lithography, especially for 3D structures. We anticipate that “hybrid” methods such as the “templated magnetic assembly” seen in Figure 54.5. above, combining relatively simple and inexpensive “top-down” methods to define a bidimensional structure, and “bottom-up” self-assembly to build on it structures too difficult or too expensive to produce by purely top-down approaches, will play an important role in the following years. Other examples, combining microlithography and surface-tension driven self-assembly of nanoparticles, to achieve nanostructures with dimensions much smaller than those of the initial template, can be found, for example in Reference 41.

## 55.1 INTRODUCTION

Microchip electrophoresis has been developed as a promising technology for detection of DNA in samples.<sup>1–3</sup> However, the development of systems for the separation of long DNA strands [greater than several kilo basepairs (kpbs)] using commercially available media, has not been successful.<sup>4</sup> In recent years, efforts have been focused on the overcoming the limitations of current DNA electrophoresis methods. Those limitations largely result from an application base that only required the separation of DNA fragments in a narrow size range, one where using fundamental separation modes based on sieving using conventional methods.<sup>5</sup> In conventional gel electrophoresis, DNA molecules move in the electric field based on a size-dependent mobility through pores in a gel matrix.<sup>6</sup> However, length-dependent mobility vanishes for DNA molecules longer than ~40 kpbs,

primarily due to tendency of DNA molecules to become stretched and oriented to the direction of electric field.<sup>7,8</sup>

Buoyed by the knowledge of micro- and nanofabrication technologies, nanotechnology has been shown to be quite successful for long fragment DNA analysis. To achieve the required efficiency needed for this type of DNA electrophoresis, two directions in the field of nanotechnology have been established: one focused on providing artificial gel structures produced with nanofabrication technology, and the other on nanomaterials for DNA separation.

In this chapter, we discuss the developments and capabilities of nanoscale methods for DNA electrophoresis, and provide some important technical information for each method. Considering the point that the mechanism of DNA separation in each nanotechnique is different (and sometimes unique) from other better-understood separation modes, these will be explained separately.

## 55.2 NANOFABRICATED STRUCTURES

### 55.2.1 OBSTACLE ARRAYS

The first report on these structures was by Volkmuth in 1992<sup>9</sup> involving a microlithographically constructed obstacle array in SiO<sub>2</sub>. Using these arrays, they showed that the DNA molecule could be hooked on the post and DNA fractionation could be done in a direct current (DC) electric field. DNA from *Micrococcus luteus* with an original uniform length of 100 kb (30 μm contour length) was fractionated in a DC field of 1 V/cm (Figure 55.1). Briefly, the highly purified *Micrococcus luteus* was sheared by pipetting leading to a range of fragment sizes, and then introduced to the designed chip; ethidium bromide (EtBr) was used to observe the hooked DNA via epifluorescent video microscopy. Arrays were designed based on unphysical agarose gel, with the effective pore size of 1 μm theoretically corresponding to a physically unstable 0.05% agarose gel. Arrays were fabricated on a standard 3 in. diameter silicon wafer with a 0.5 μm SiO<sub>2</sub> layer created on the surface of the array for optical emission measurement. The arrays consist of a 2.7 × 2.7 mm rectangular containing 2 million posts 0.15 μm high by 1.0 μm in diameter with 2 μm center-to-center spacing. Two different sets of lattices were developed. One set of arrays with the posts on a square lattice, and another set with a square—45°—rotated lattice. For loading the samples, a flat loading area was made at the two ends of the array with a depth equivalent to that of the posts. Field-assisted silicon-glass fusion was utilized to fuse a Pyrex coverslip to the posts. The authors purported that the key to the DNA separation was a dispersion time that correlated with the time required for hooked DNA to thermally free itself from a post.

#### 55.2.1.1 Assymmetric Obstacle Courses: Rectification of Brownian Motion

While the separation of DNA based on hooking on micro- or nanoposts has presented an alternative method for gel electrophoresis, it still suffers from the fact that, when an electric field is applied to DNA molecules, different sizes of DNA molecules mobilize at the same speed. To circumvent this problem, an approach was developed by Duke, Austin<sup>10</sup> and Ertas<sup>11</sup> which take advantage of the fact that, while a molecules move, they diffuse at the same time—and at a diffusion rate that is size dependent. In theory, they have shown the possibility of using a two-dimensional obstacle course to sort the fast moving molecules from the slower ones. The elegance of this is that a regular lattice of asymmetric obstacle course, rectifies the lateral Brownian motion of the molecules, so molecules of different size follow different trajectories while they are passing into the device.

Additional effort by Chou et al.<sup>12</sup> applied the above methodology to microfabricate of silicon array. With this device, it was possible to separate a mixture of *Xho*I-cut λ DNA fragments (15 and 33.5 kbp) in the vertical electric field of 1.4 V/cm. They calculated that the DNA fragments moved in trajectories at different angles through the array. Interestingly, molecules that diffuse very slowly

**FIGURE 55.1** A scanning electron micrograph of the obstacle course. The obstacles are 0.35  $\mu\text{m}$  high and measure  $1.5 \times 6.0 \mu\text{m}$ . The gap between adjacent obstacles is 1.5  $\mu\text{m}$ . An electric field propels the molecules directly through the gaps between the posts with velocity  $v$ . Transverse Brownian motion may cause a molecule to skip one channel to the right if it diffuses through displacement  $a_R$ , or very rarely, one channel to the left if it diffuses through  $a_L$ .

are likely to travel straight without being deflected by the obstacles. In contrast, molecules that diffuse rapidly veer mostly to right in the device. Such a device is advantageous because it provides the possibility for sorting the molecules continuously, in contrast to batch modes in conventional methods. The authors demonstrated that the predicted movement could be done practically with a well-designed device containing 0.5X tris-borate buffer (TBE), 0.1% performance-optimized POP-6 (Perkin Elmer Biosystems, Foster City, California) and 0.1 M dithiothreitol (DTT) as separation buffer. The device contained a lattice of rectangular obstacles with the size  $1.5 \times 6 \mu\text{m}$  and an angle of  $45^\circ$  relative to the direction of electric field, designed in a way that allowed for a uniform flow over the whole area of the device. A sacrificial layer was deposited over the silicon nitride floor of the device while the ceiling had a layer of silicon nitride deposited over it using chemical vapor deposition. Small irrigation ducts made it possible to remove the sacrificial layer with a wet etchant (tetramethylammonium hydroxide), followed by sealing the irrigation holes with  $\text{SiO}_2$  and etching the loading holes so as to provide a final device that was a quasi-two-dimensional chamber containing patterned silicon nitride obstacles.

A major improvement in fractionation of biomolecules based on rectification of Brownian motion was developed by Oudenaarden.<sup>13</sup> With this technique, originally applied for the analysis of lipid bilayers, a laterally asymmetric diffusion array was fabricated. The separation was done in a direction that was not parallel to the direction of main flow, and lead to the components of the sample to physically discrete positions in the device. This approach brings with it the distinct possibility of inject sample continuously with separation accomplished in a DC electric field.

Cabodi et al.<sup>14</sup> used a laterally asymmetric diffusion array with modified injection strategy termed *out-of-plane sample injection*; enabling separation of diverse biomolecules ranging from long strand DNAs to small proteins. Basically, the laterally asymmetric obstacles rectify the motion to one side. All migrating molecules diffuse laterally according to their diffusion coefficient, with larger molecules diffusing less and traveling straight down in the channel, while smaller molecules, on average, are deflected more extensively than larger ones. Figure 55.2 shows the separation principal of laterally asymmetric diffusion array. Coliphage T2 and T7 were spatially resolved using this device, with a final DNA concentration of 2  $\mu\text{g}/\text{mL}$  in 0.5X TBE with 3%  $\beta$ -mercaptoethanol as an antiphotobleaching agent, and YOYO-1 dye was as an intercalating dye. An inverted microscope (Olympus America, Melville, New York, USA), illuminated by a 100-W mercury arc lamp was used for DNA observation.

**FIGURE 55.2** Principal of separation in asymmetric obstacle array. Basically the latterly asymmetric obstacles rectify the motion to one side. All migrating molecules diffuse laterally according to their diffusion coefficient through the device. Larger molecules diffuse less and travel straight down in the channel and smaller molecules on average are deflected more than larger ones. (Adapted from Cabodi, M, Chen, Y.F, Turner, S.W.P, Craighead, H.G, Austin, R.H, *Electrophoresis*, 2002, 23, 3496–3503. With permission.)

The above technique was further improved by Huang<sup>15</sup> with tilted Brownian ratchet array. Using this design, the flow is tilted relative to vertical axis of the array, since the probability that a molecule could be deflected is greatly increased compared to the previous status (where flow is aligned along the vertical array axis). By this method the separation resolution and speed of DNA separation by the Brownian ratchet array in microchips was increased three and ten times, respectively. A mixture of 48.5 and 164 kb DNA was separated in  $\sim 70$  min using a 12-mm-long (Figure 55.3).

### 55.2.2 ENTROPIC NANOTRAPPS

Craighead and coworkers<sup>16</sup> were the first to show that a nanofluidic channel containing entropic traps could be designed for separation of long DNA molecules. Entropic trap array systems include alternating thin and thick regions that correspond to the molecular dimensions of DNA, and were designed for static (DC) electric field and fast separation of large DNA molecules. Figure 55.4 shows the motion of lambda DNA in one of the early designs for an entropic trap device.<sup>16</sup> The fundamental hypothesis describing the function of the device has been described elsewhere.<sup>17</sup> An entropic trap array device designed for the separation of DNA similar to conventional slab gel-pulsed field gel electrophoresis (PFGE), was described by the same group later.<sup>18</sup>

#### 55.2.2.1 Separation Mechanism

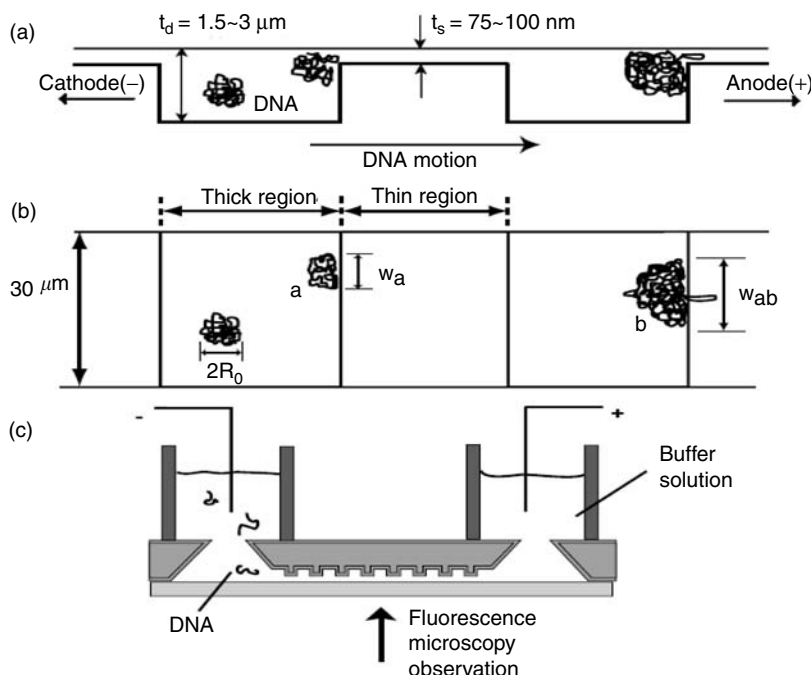

In order to fully exploit the power of a microfabricated PFGE system, the principles of this separation should be explained. Basically, the microfabricated entropic trap array system consists of alternating thin and thick regions. With the channel depth of the thin region smaller than the radius of gyration ( $R_0$ ) of DNA, the system can serve as a molecular sieve. In contrast, the thickness of thick region is larger than  $R_0$ , therefore, the DNA can form spherical equilibrium shape in thick region while, in

**FIGURE 55.3** Basic principle of the Brownian ratchet array. Particles are driven through the array hydrodynamically or electrophoretically (pictured). (a) The rectangular obstacle array prevents particles emerging from gap A and diffusing to the left (1) from reaching gap B– but ratchets particles diffusing to the right (2) to gap B+. (b) Particles of different sizes diffuse to different extents (bell-shaped curves represent lateral distributions of small and large particles), resulting in different probabilities of deflection to B+. The vertical dotted line within the distributions represents the required diffusion for ratcheting to gap B+. (c) The probability of a particle being deflected to B+ is increased by tilting the flow at a small angle with respect to the vertical axis of the array.

**FIGURE 55.4** Sequence of video frames showing the motion of a lambda DNA molecule. Brighter regions are the thick regions of the channel. The left DNA molecule was trapped for 6 s, then escaped the trap and jumped to the next thick region within a second. After traveling the thick region for about 3 s, it was trapped again at the next entropic trap for about 10 s. In this device,  $l \approx 51.4$  mm and  $t \approx 590$  nm. (Reprinted with permission from Han, J., Craighead, H. G., *J. Vac. Sci. Technol. A*, 1999, 17, 2142–2147. Copyright 1999, American Institute of Physics.)

**FIGURE 55.5** Nanofluidic separation device with many entropic traps. (a) Cross-sectional schematic diagram of the device. Electrophoresed DNA molecules are trapped whenever they meet a thin region, because their radius of gyration ( $R_0$ ) is much larger than the thin region depth (here,  $t_d$  and  $t_s$  are the thick and thin region depths, respectively). (b) Top view of the device in operation. Trapped DNA molecules eventually escape, with a probability of escape proportional to the length of the slit that the DNA molecule covers ( $w_a$  and  $w_b$ ). Larger molecules have a higher escape probability because they cover wider regions of the slit ( $w_b > w_a$ ). (c) Experimental setup. Reservoirs are made at both ends of the channel and filled with DNA solution. (Reprinted from Han, J., Craighead, H. G., *Science*, 2000, 288, 1026–1029. With permission from AAAS.)

thin region, the DNA molecules are deformed. Once the electric field is applied, DNA molecules are temporarily trapped at the entrance to the thin regions, because the relaxed-spherical DNA stretches in electric field facilitating entrance to thin region. This conformation is not entropically preferential, and the DNA tends to escape from the thin region. While the DNA travels in thin and thick regions, a frequent conformational change occurs. Consequently, the DNA mobility will be length dependent. For escape of DNA molecule from the thin region, longer DNA molecules have a larger surface area to contact with the boundary of the thin region, and have a higher probability for escape. As a result, larger DNA molecules move faster than shorter ones (in contrast to normal gel electrophoresis).

The schematic in Figure 55.5 shows the properties and mechanism of separation achievable with a nanofluidic device containing numerous entropic traps for PFGE. Using this system, DNA molecules ranging from 5,000 to  $\sim 160,000$  base pairs were successfully separated using a 15-mm-long channel. T2 (164 kbp) and T7 (37.9 kbp) DNA, were separated with an electric field of 21 V/cm in 30 min using this microfabricated array system. The authors also showed utility of this device for multiple-channel analysis useful for parallel sample separation.<sup>18</sup> Moreover, the ability of this system to work, (1) with a DC electric field, (2) in the absence of a gel matrix, (3) with miniscule masses of DNA, and finally (4) without the need for high-resolution lithographic techniques, provides distinct advantages for manufacturing integrated devices.

### 55.2.3 DNA ELECTROPHORESIS ON NANOPATTERNED SURFACE

Nanopatterned surfaces for DNA separation was first introduced several years ago by Young-soo Seo.<sup>18</sup> In earlier works, it has been shown that it is possible to separate DNA on a flat-attractive surface without any topological boundaries or any sieving matrix. The separation mechanism is based on the differences in conformational associated with DNA molecules of different length adsorbed on the surface. This surface-directed separation has opened a new vistas for nonsieving polymer-based DNA separation.

#### 55.2.3.1 Separation Mechanism

On of adsorption of DNA on a flat surface, the balance between the loss of entropy (due to the localization of DNA at the surface) and the energy gain (due to adsorption) determines the resultant conformation of DNA—the resultant conformation may be in the form of loops that extend into solution or “train like” with neighboring segments adsorbed on the surface. In the case of a fixed surface attraction, shorter fragments have higher entropy and have larger number of loops, whereas longer fragments will exploit the energetics achieved upon adsorption and form larger “trains.” As a result, in the presence of an electric field applied to the surface, there should be a conformationally based response and, therefore, a length-dependent mobility should result.<sup>19</sup>

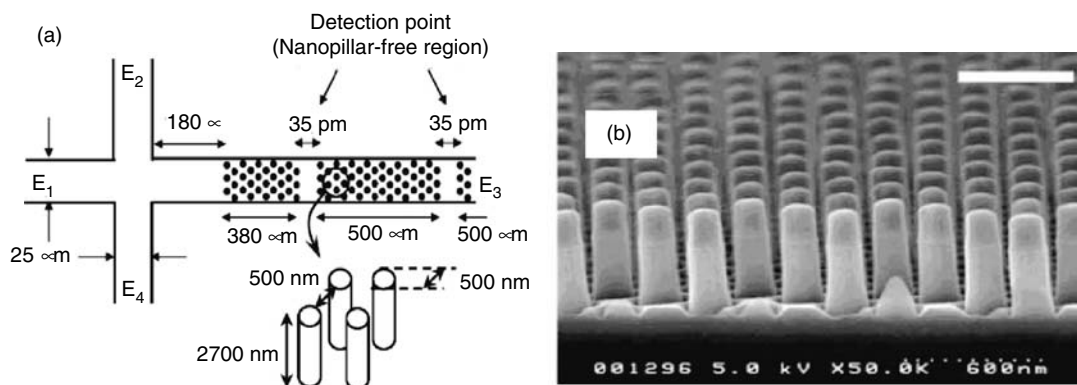

The dependence of the separation on the conformational differences emphasizes the need for special care to be taken in the surface design. The sensitivity of conformational changes on a surface can be tuned by increasing the complexity of the design. A design of nanopatterned surface of Ni patches imposed on a Si matrix was developed for DNA electrophoresis.<sup>19</sup> It has been demonstrated that using this method, simultaneous separation of a broad range of DNA sizes, from a few hundred base pairs to genome-size DNA, could be achieved with good resolution. Figure 55.6 shows the schematic of fabrication process and the scanning electron micrograph of surface image of Ni nanopatterned on a Si wafer. The need for only very small amounts of sample and low operating voltages make this technique affordable for integration into chip-based portable devices.

### 55.2.4 NANOPILLARS

Micrometer-sized pillars were fabricated and then used for separation of very long DNA molecules over a hundred thousand base pairs.<sup>20,21</sup> As a follow up to this, Baba's group used a new fabrication technique to create a nanopillar chip on a quartz plate.<sup>22</sup> DNA fragments ranging from 1 to 38 kp were rapidly separated as clear bands, within the analysis time of 170 s. Even long DNA molecules that are difficult to separate on conventional gel and capillary electrophoresis (CE) could be separated using the nanopillars. A mixture of  $\lambda$  DNA (48.5 kbp) and T4 DNA (165.6 kbp) was successfully separated by flow through a 380- $\mu$ m-long nanopillar channel within only 10 s even under a direct current (DC) electric field. Using electron-beam lithography, Ni electroplating, and neutral loop discharge etching, 100–500-nm diameter and 500–5000-nm tall nanopillars were fabricated, and the nanopillar chamber sealed with by quartz coverplate to minimize the loss of resolution that normally accompanies silicon or even silicon-coated insulation materials. Figure 55.7 Shows a schematic representation and a scanning electron micrograph of a microchannel equipped with nanopillar structures fabricated on a quartz glass plate. For analysis, the final DNA concentration was 20–100  $\mu$ g/mL for DNA separation and  $\sim$ 50 ng/mL for single DNA molecule observation in the 5X TBE electrophoresis buffer (45 mM Tris-borate, 1 mM ethylenediamine tetraacetic acid (EDTA), pH 8.0) containing 4% (v/v) 2-mercaptoethanol to reduce photobleaching. Before electrophoresis, the surface was dynamically coated with 1% poly(vinylpyrrolidone) ( $M_w$  1,300,000, Aldrich) to reduce electroosmotic flow (EOF), and then the solution was substituted with 0.5X TBE electrophoretic

**FIGURE 55.6** Surface image of Ni nanopattern on Si wafer using SEM. Inset (a) schematic of etching process, (b) the topography of Ni nanopattern, (c) a fluorescence chemical map of the surface, and (d) scanning probe microscope (SPM) image in air of a  $\lambda$ -DNA adsorbed onto the nanopatterned surface. Copyright 2004, American Chemical Society.)

buffer. DNA separation and a single DNA molecule observation were performed on an inverted microscope.

#### 55.2.4.1 Separation Mechanism

The linear relationship between the logarithmic value of the relative mobilities versus the size of DNA over the range of 1–23 kbp, provided evidence that the electrophoretic behavior of DNA in this size range separated in a nanopillar chip obeyed the Ogston model. In this model, DNA molecules

are assumed to be globular in nature, passing through a random network with an average pore size in size range. In contrast to this, T4 DNA shows a cyclic type of motion, and seems to obey a model better described by in “reptation with orientation” regime. Interestingly, single DNA molecule observation in a nanopillar channel revealed that the optimal nanopillar structure induced T4 DNA to form a narrow U-shaped conformation during the electrophoresis, whereas  $\lambda$  DNA maintained a rather spherical conformation.<sup>22</sup>

The most important advantage of nanopillar structure design and fabrication is the capability to modify, with spatial accuracy, particular surfaces in the chip structure. On the other hand, since in separation by nanopillars does not require a DNA sieving matrix, it is more easily implemented in chips designed for totally integrated sample processing, where the different requirements of each domain present challenges. Simplifying the detection domain of multifunction chips will accelerate microfluidic device development for bioanalysis so that the entire analytical process (cell culture, cell selection, DNA extraction, amplification, detection, and collection on a single chip)<sup>22b</sup> overcoming the limitations stemming from injection of high viscosity polymers.

### 55.3 NANOMATERIALS FOR DNA ANALYSIS

Nanomaterials were developed as an alternative for separation of large DNA fragments. Compared with the difficulties, complexities and costs in the fabrication of micro- and nanofabricated devices, nanomaterials provide a potentially promising system for simple and affordable for lab-on-a-chip technology in medical diagnostics.

#### 55.3.1 SUPERPARAMAGNETIC PARTICLES

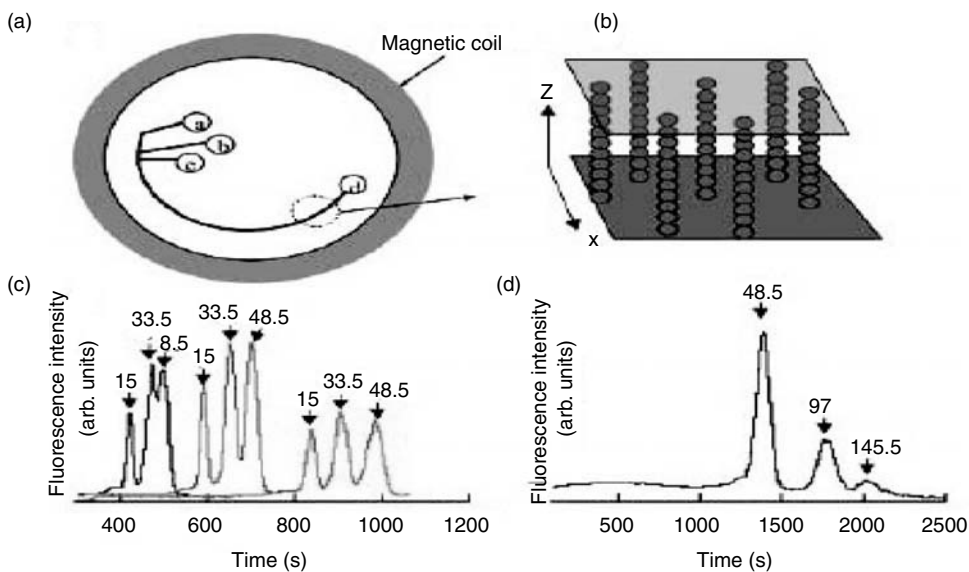

Upon applying a magnetic field to superparamagnetic particles with a dielectric constant or magnetic permeability different than that of the surrounding liquid, dipolar interactions are induced within the particles. Provided that these interactions are strong enough, a phase transition of the particle occurs, changing them from liquid to solid. Consequently a column-like structure will appear.<sup>23</sup>

On the basis of this basic theory, self-assembled magnetic particles can be used as a sieving matrix for DNA separation. Doyle et al.<sup>24</sup> have shown that a suspension of superparamagnetic microscale particles can self-assemble into an array with an average interparticle distance of 5.7  $\mu\text{m}$  inside a microchannel device. The device was created using soft lithographic methods that have been previously described by this group.<sup>25</sup> Figure 55.8 shows the columnar structure of magnetic particles as well as the resultant long DNA fragment separation which shows surprisingly good efficiency.

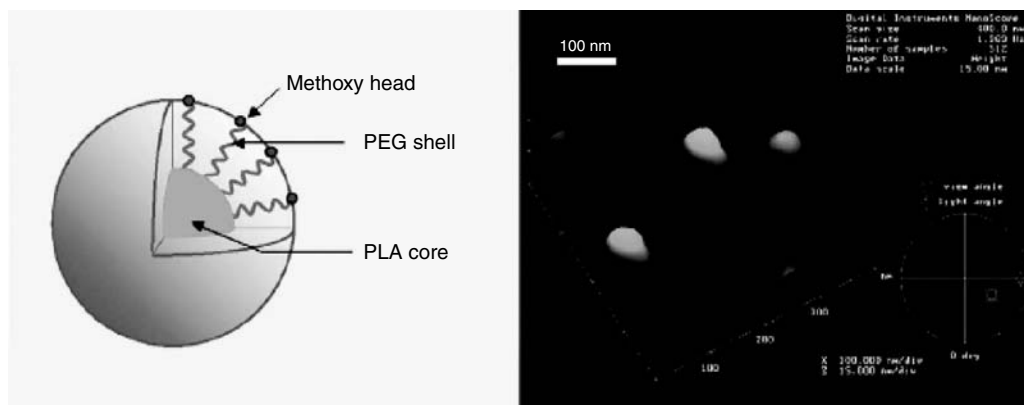

The separation was optimized at an intermediate electric field, where hooking and incomplete extension occurs at the same time. With larger DNA molecules taking on a more extended form, this provides the mobility difference that allows for a size-based DNA separation. Having a low viscosity in the absence of magnetic field, tunable pore size (typically 1–100  $\mu\text{m}$ ) and obviating the need for sophisticated microlithography, of the use of suspensions of paramagnetic particles becomes attractive. In addition, they should be potential to the analysis of other analytes like cells, organelles and micro- or nanoparticles.

#### 55.3.2 NANOSPHERES FOR DNA SEPARATION

With the development of core-shell type of globular nanoparticles (nanospheres or nanoballs),<sup>26</sup> Tabuchi et al. recently introduced this technology as a potential new type of DNA separation matrix.<sup>27</sup> Nanoballs with low viscosity (0.94 cp at 1.0%; 10 mg/mL) owing to their globular structure, are promising sieving matrixes for long fragment size DNA separation. Using nanospheres, DNA fragments in the range of 100–1000 bp and 1–15 kb were successfully separated with

**FIGURE 55.8** (a) Schematic of the microchannel and magnetic coil. (b) Columnar structure formed by a suspension of superparamagnetic particles. (c) Fluorescence intensity at 10 mm from the injection zone versus time. Separation of a mixture of  $\lambda$ -phage DNA and  $\lambda$ -DNA digested with *XhoI* (Pharmacia) (the numbers refer to the size of the DNA fragments in kbp) at fields strengths of 4.8 (right), 7 (middle), and 10 left V/cm. (d) Separation of  $\lambda$ -phage DNA concatemers at a field of 3.2 V/cm. Other conditions are identical to those in (c). (Adapted and reprinted from Doyle, P. S., Bibette, J., Bancaud, A., Viovy, J. L., *Science*, 2002, 295, 2237. With permission from AAAS.)

**FIGURE 55.9** Schematic of the structure and an atomic force microscope (AFM) image of nanoballs. (From Manz, A., Graber, N., and Widmer, H.M., *Sens. Actuat. B*, 1990, 1, 244–248. Copyright 1990. With permission from Elsevier.)

high resolution and high speed (60 and 100 s, respectively). Figure 55.9 shows the structure of nanospheres.

### 55.3.2.1 Nanospheres Preparation and Properties

Nanospheres were created by the following procedure: multimolecular micellization, followed by core polymerization of block copolymer of poly(ethylene glycol) (PEG) with poly(lactic

acid) processing a methacryloyl group at the polylactide (PLA) chain end ( $\text{PEG}_m\text{-}\beta\text{-PLA}_n\text{-MA}_1$ ;  $M_w(\text{PEG/PLA}) = 6100/4000$ ,  $m \approx 100$ ,  $n \approx 40$ ,  $1 \approx 70$ ) in an aqueous condition.

Core-shell type nanosphere technology is applicable for separation of wide range of DNA fragments.<sup>27</sup> The PLA segment, forming a spherical core and covered by a relatively high density PEG chains and methacryloyl groups, make stable 30-nm diameter nanospheres. The nanospheres have no surface charge, and a narrow size range and low viscosity. A SV1100 microchip electrophoresis system (Hitachi, Japan) and i-chip 3 microchip (Hitachi, Japan) made of poly(methyl methacrylate) with channels 100- $\mu\text{m}$  wide and 30-mm effective separation channel was used for the DNA analysis. For electrophoresis, all channels were filled with 1% nanosphere solution, sample loaded into the sample well and pressure injected at 1–10 kPa for 1 s using a syringe, with the corresponding well and outlet wells open. Before electrophoretic separation, a second pressure injection (1–10 kPa) for 1 s was applied to the separation channel from the inlet without an electric field. The electrophoresis was then initiated at 220 V/cm with squeezing voltage of 130 V without any pressure.

The double pressurization technique applied for DNA separation was key to achieving high-speed analysis and improved resolution. A primary pressure is needed for sample injection, while the second pressure accelerates the separation speed of the DNA. One of the interesting points in using nanospheres is the focusing effect on the DNA as it migrates in nanosphere solution under an electric field. Observing a single DNA molecule move through a nanoball solution shows that “lumps” of DNA (intrachain aggregated structure) are generated in this condensed environment. The wide range DNA separation ability with high-speed using low viscosity nanoballs provides promising potential for DNA separation in microchannels and could have a widespread application for high-throughput analytical systems in medical diagnostics.

### 55.3.3 GOLD NANOPARTICLES

Primary trials for manipulation of polymers for long DNA separation have been attempted using ultralow viscosity solutions. Barron et al.<sup>28,29</sup> and Braun et al.<sup>30</sup> have utilized ultradiluted polymer solutions (e.g., down to 0.01%), while Heller et al.<sup>31</sup> and Ren et al.<sup>32</sup> used streptavidin in an end-labeled free solution for CE. The efficiency of gold nanoparticles (GNPs) was shown for the separation of shorter DNA fragments (2–2176 bp),<sup>33</sup> however, recently Huang et al. used GNPs or GNPs mixed with polyethylene oxide (PEO) to demonstrate the effectiveness of nanoparticles for the separation of longer DNA molecules in a low viscosity medium using nanoparticle-filled CE (NFCE).<sup>34</sup> For prevention of aggregation of the GNPs and facilitate a strong interaction with the DNA molecules, the GNPs were noncovalantly bonded to the PEO to make gold nanoparticle/polymer composite (GNPPs).

Separation of high molecular weight DNA with the size range from 8.27 to 48.5 kbp and  $\lambda$  DNA (0.12–23.1 kbp) was accomplished in 6 and 5 min, respectively, using these modified polymers.

#### 55.3.3.1 pH and Salt Dependence of Separation

It has been shown that the resolution of peaks in a GNPP solution depends on pH value, and the concentration ratio of the EtBr and GNPPs. Furthermore, the efficiency of separation is greater if it conducted in the presence of small amounts of salts.

The resolving power of the separation depends on the interactions between the DNA and GNPPs bonded to PEO. A 32-nm GNPPs coated with PEO was reported to have the best resolving power.<sup>34</sup>

#### 55.3.3.2 Separation Mechanism

As described for the transient entanglement mechanism, DNA molecules, in the short term, intertwine with the polymer-adsorbed on the GNPs.<sup>35</sup> There are reasons where slowing the entanglement of DNA fragments may be desired. First, polymer-adsorbed on the GNPs are stiffer and less extended,

a character that is dependent on the size of GNPs and the length of the polymer chain. This property causes the polymer-adsorbed nanoparticles to be slightly deformed under the flow.<sup>33,36–38</sup> Second, there is a strong intercalating between the DNA and EtBr adsorbed on the GNPPs. Finally, the DNA migration is affected by the GNPPs ( $2.0 \times 10^8$  g/mol for the 32-nm GNP) which are much heavier than the linear polymer and, to a great extent, slows the DNA migration as well. Therefore it has been proposed that the GNPPs play a similar role to that of streptavidin (that is in providing additional friction) in end-labeled free solution CE.<sup>39,40</sup> Since longer DNA molecules interact with more than one GNPP, the “drag” power would be stronger and, as a result, the mobility of longer DNA is slightly lower than that of shorter ones.

This technique was the first CE method to provided high-speed and separation efficiency for long DNA fragment separation. The potential of polymer-adsorbed nanoparticles in separation science and in the life sciences have been shown in numerous ways. Band broadening depends on the polydispersity of the GNPPs and making more monodispersed GNPPs would certainly offer high resolution.

### 55.3.4 PEGYLATED-LATEX MIXED POLYMER SOLUTION

PEGylated-latex solution mixed with usual water soluble polymer has been shown by Tabuchi et al.<sup>41</sup> to be an effective micro-CE ( $\mu$ -CE) medium for DNA separation.

A higher separation of DNA fragments from 10 bp to 2 kbp was achieved using the fixed concentrations of 2.25 wt% of 80-nm-PEGylated-latex and 0.49 wt% of hydroxypropyl methylcellulose (HPMC) solution under low viscosity of (<5.5 cp).

#### 55.3.4.1 Synthesis of Methoxy-PEG-VB Macromonomer and PEGylated-latex

Synthesis of Methoxy-PEG-VB macromonomer was done by anionic ring-opening polymerization at room temperature and under argon gas<sup>42</sup> and could be accomplished using the following procedure:

1. A mixed solution of 0.16 of mL 2-methoxyethanol (2 mmol) and 5.6 mL (2 mmol) of a 0.35 M potassium naphthalene solution in tetrahydrofolate (THF) should be prepared. Then it should be inserted in a round bottomed-flask containing 30 mL dry hydrofolate (HF) under argon gas and stir for several minutes.
2. Addition of condensed ethylene oxide (11.3 mL, 227 mmol) by a cooled syringe and continuing the stirring for 2 days for polymerization.
3. Addition of 2.8 mL (20 mmol) vinyl benzyl chloride to the polymer and stirring for 24 h at room temperature.
4. Precipitation of the polymer with 100-folds excess of diethyl ether and freeze drying with benzene.

Under these conditions, a 91% yield of polymer could be obtained.

The PEGylated-latex could be obtained by an emulsion polymerization of styrene in presence of PEG macromonomers,<sup>43</sup> and could be done by the following procedure:

1. Dissolving of methoxy-PEG-VB macromonomer ( $M_n = 5500$ , 0.75 g) and Potassium peroxydisulfate (KPS0 (74  $\mu$ mol, 20 mg) in 25 mL of deionized water in a round bottomed flask under argon atmosphere.
2. Addition of styrene monomer (0.75 g) and divinyl benzene (76  $\mu$ mol, 0.01 mL) to the PEG solution and stirring in a mechanical stirrer at 500 rpm for 1 h.
3. Incubation of the suspension in an incubator at 60°C for 24 h.
4. Purification of the latex from water by three-time centrifugation at 150,000 g for 15 min.

**FIGURE 55.10** SEM image of nanosized PEGylated-latex beads. (From Tabuchi, M., Katsuyama, Y., Nogami, K., Nagata, H., Wakuda, K., Fujimoto, M., Nagasaki, Y., Yoshikawa, K., Kataoka, K., Baba, Y., *Lab Chip*, 2005, 5, 199–204. Reproduced by permission of the Royal Society of Chemistry.)

Nanoparticles of PEGylated-latex with the size and polydispersity of 79 nm and  $D_w/D_n = 1.23$ , respectively, could be prepared by this method. In a similar way, larger PEGylated-latex with the diameter of 193 nm and polydispersity of  $D_w/D_n = 1.17$  could be prepared. Figure 55.10 shows the scanning electron micrograph (SEM) image of nanoballs produced by this method.

#### 55.3.4.2 Separation Mechanism

Basically, the enhancement in separation using this system seems to be related to the balance between decreased polymer concentration which provide wider polymer mesh size and the structural obstacles of the particle.

Ultimately, the separation performance depends on the quality, size, and concentration of particles as well as the polymer concentration. The simplicity, low viscosity solution and effective separation of large DNA fragments, are some of advantages of this technique.

#### 55.3.5 NANOGELS

Sparsely cross-linked nanogel was developed with covalently linked linear polyacrylamide (%LPA) by the Barron and coworkers.<sup>44</sup> Using nanogel, they achieved a higher-selectivity separation of ssDNA sequencing fragments of longer than 375 bases with reasonable time frames for the analysis. They also produced nanogels with inverse emulsion (water in oil) copolymerization<sup>45,46</sup> of acrylamide and *N,N*-methylbisacrylamide (Bis). They purport that the presence of covalent bond enables stabilization of the network and, hence, improves the DNA sequencing read length (~63 bases, 10.4% improvement). In later work, they improved the matrix selectivity via optimization of nanogel cross-linked density with the proper linear polymer.<sup>47</sup> Copolymerization of acrylamide and a low percentage ( $10^{-4}$  mol%) of *N,N*-methylbisacrylamide (Bis) was utilized to produce a flowable, sparsely cross-linked matrix.

Using this matrix they achieved at 98.5% accuracy for the base calling of 680 bases with 18.7% improvement over the LPA. The power of the system became clarified by wedding this with a high-throughput microfabricated DNA sequencing device. The replaceable, highly entangled nanogel provides a new potential matrix that could match the performance of commercial capillary array electrophoresis (CAE) instruments and chip-based sequencing.

### 55.3.6 CARBON NANOTUBES

Carbon nanotubes (CNs) could be defined as the ultimate fiber formed of perfectly graphitized closed seamless shell<sup>48</sup>—this was discovered in 1991 by Ijima.<sup>49</sup> Xu et al.<sup>48</sup> have verified the enhanced separation of DNA fragments with multiple-wall carbon nanotubes (MWCNs) as buffer additive. An improved resolution of the fragments in a *HaeIII* digest of  $\phi$ X174 DNA was observed with an optimized concentration of MWCN. A greater improvement in resolution for separation of 2-Log DNA ladder was shown in the concentrations of MWCN near or below its threshold concentration. They used negatively charged MWCN, which could be suspended in deionized water, and prepared by wet oxidation in concentrated acids.<sup>50</sup> Predetermined amounts of MWCN solution were added to the buffer and stirred for at least 60 min to make a homogenous suspension, which was used as a buffer to dissolve the PVP polymer in it. For this analysis, contactless conductivity detection was used instead of usual ultraviolet (UV) or laser-induced fluorescence (LIF) detection in order to avoid the interference provided by the black color of the CN.

#### 55.3.6.1 Separation Mechanism

Briefly, CNs could form polymer-like networks in buffer.<sup>51</sup> Figure 55.11 shows this network and its corresponding network in PVP solution. On the other hand, CNs can also form DNA-CN hybrids.<sup>52,53</sup> and it is not unreasonable to envision that this adduction might alter DNA fragment mobility. The improved sieving ability generated by adding low concentrations of MWCNs to 1% w/v PVP, might be explained by the fact that large DNA fragments (up to 10 kb) encountering MWCN molecules in a way that is similar to separation of DNA with low concentration polymers (below the entanglement threshold).<sup>33</sup>

The authors concluded that optimized concentrations of MWCNs could be a complementary buffer additive to polymer for CE charged-coupled device (CCD) based DNA separation.

### 55.4 CONCLUDING REMARKS

Although by introduced techniques, many aspects of DNA migration in different physical or chemical environments has been clarified, still there are some uncertainties in the mechanism, and the behavior of DNA molecules in some environments or on some surfaces is still not well understood.

**FIGURE 55.11** TEM image of MWCN. (a) 100 ppm MWCN in deionized water. (b) 25 ppm MWCN in 2% w/v PVP solution. (From Xu, Y., Yau Li, S. F., *Electrophoresis* 2006, 27, 4025–4028. With permission.)

New techniques for better understanding of the movement of this macromolecule are essential and nanotechnology is promising field for this purpose.

 Artificial sweeteners, 894  
 Ascorbic acid content, CE detection, 865  
   in vegetables/blue berries, 865  
 Asymmetric obstacle array, principal of separation in, 1530  
 Atmospheric pressure chemical ionization (APCI), 111  
 Atmospheric pressure photoionization (APPI), 112  
 Atomic emission lamps, 310  
 Axial-capillary illumination, 311  
 Axial illumination, 577

## B

Background electrolyte (BGE), 413, 888, 1086  
   zones, 788  
 Bacterial contamination, detection by CE, 874  
 Bacterial endotoxins in protein complexation, detection by CE, 871  
 Band broadening, 560  
   in CEC, principles of, 188  
 $\beta$  – 1, 4 Cellooligosaccharides bonds, 254  
 Beckman-Coulter (Fullerton, CA), 84  
 Beer-Lambert law, 309, 413  
 Bence-Jones proteins, 793  
 Benzoate, 803  
 Benzylamine, 803  
 Beta globin isoforms identification, by CIEF, 93–96  
   hemoglobin analysis by, 93–94  
   principles and approach used for evaluation, 94  
 Biased reptation model (BRM), 475  
 Biased reptation with fluctuations (BRF), 475  
 Bioanalysis, ionization sources in, 1463

Biogenic amines (BA)  
   analysis of content, in food products, 860–861  
   physiological effects of, 858  
   standards, analysis, 860  
 Biogenic DL-amino acids, chiral analysis, 882  
 Biological analysis, polymer microchips for, 1420  
 Biomolecules detection, 318  
   derivatization (end-column, on-column, or precolumn), 318–319  
 Biomolecules fractionation, based on rectification of Brownian motion, 1529  
 Biotin–streptavidin complex, 834  
 Bloodstream, flow properties, 844–845  
 BODIPY, 12  
 BODIPY-FL, 493  
 BODIPY-fluorescein primer, 493  
 BODIPY505/515 (molecular probes), 485  
 Borosilicate glass etches, 340  
 Botanical DNA analysis, 776–777  
 Bottom-up systems biology, 78  
   approach to biomarker discovery, 79  
 British Pharmacopoeia (BP), 154  
*Bromus inermis* L., analysis of PCs in, 877  
 Brownian ratchet array principle, 1531  
 Brugada syndrome, 233  
 Bubble cell, 117, 136, 144  
 “Bubble jet” printing, 986  
 Buffer additives, 23, 30  
 Buffer composition, 549–551  
 Buffer discontinuity, 789  
 Buffer-related viscosity constant, 17  
 Buffer type (ionic species) effect, on CE separation, 32  
 Buffer viscosity, 552  
 Butylated hydroxyanisole (BHA), 894  
 Butylated hydroxytoluene (BHT), 894

## C

CAE protein immunoassays, 77  
 Caffeic acid, analysis of PCs  
   in coffee extracts, 878  
   in plants, 878  
 Caged fluorescein, 450  
 Calixarene EKC, 918  
 Calixarene probe, 816  
 Capillaries  
   coating methods, 37–38  
   conditioning of, 20  
   dimensions of  
     internal diameter and length, 29  
     plugging problem in, 21  
     and preparation for CE, 19–20  
     regeneration or reconditioning of, 20–21  
     storage for better functioning, 21  
     successive multiple ionic layer (SMIL) coating in, 111  
     use as electromigration channel for separation, 7  
 Capillary affinity electrophoresis (CAE), 77  
   for carbohydrate characterization, 268  
     SP 1 mobility shift assay by CAE, 96–97  
 Capillary-based DNA sequencing, multiplexing, 240  
 96-Capillary CE instruments, 1078  
 Capillary coatings, in CE, 830  
 Capillary electrochromatography (CEC), 786, 864

- applications of
    - CEC separations of drug
      - mixtures/Pharmaceuticals, 213–214
      - separation of estrogens and nucleotides, 212
      - separation of insecticidal pyrethrin esters, 211
  - concepts and operational principles of, 184
  - CEC column role and types of, 191–196
  - EOF contrast to parabolic laminar flow profile, 185
  - factor affecting electroosmotic mobility, buffer pH., 186
  - hybrid separation method, couples CE with HPLC, 184
  - impact of EOF in, 184–185
  - inside capillary column, schematic representation of, 187
  - molecularly imprinted polymer sorbents for CEC, 193–195
  - publications on topic of, 183–184

  - utility for PCR product, 230–231
- Capillary electrophoresis, clinical applications of advantages, 787

- Capillary electrophoresis, clinical applications  
of (*Continued*)  
compounds difficult and suited for CE analysis, 790  
enzymes, measurement of, 793–797  
hemoglobin, measurement of  
  globin chains of, 799  
  hemoglobin HbA<sub>1C</sub>, 797–798  
  variants, 797  
limitations, 787  
practical applications  
  coated capillary, 789  
  concentration variability, in sample analysis,  
  788–789  
  precision improvement, of sample preparation, 789  
  protein concentration, in sample analysis, 788  
  salt concentration, in sample analysis, 788  
  sample matrix effects, 787–788  
  stacking of compounds, 789–790  
proteins and peptides, measurement of  
  cerebrospinal fluid (CSF) protein, 793  
  cryoglobulins analysis, 792–793  
  immunofixation (immunosubtraction), 791–792  
  serum proteins, 791  
  urinary proteins, 793  
and proteomics, 799–801  
small molecule analysis  
  amino acids, 801–802  
  drug analysis, 801  
  endogenous compounds, 801  
  ion analysis, 802–805  
special aspects, 786–787
- Capillary electrophoresis, in food analysis  
amino acids and biogenic amines, 854–863  
carbohydrates, 854  
chiral separations of food components, 876–886  
DNA and microchips, 891–893  
food additives, 893–894  
food quality, 895–898  
organic acids and inorganic ions, 864–867  
phenolic compounds (PCs), 876  
proteins and peptides, 886–891  
toxins, contaminants, pesticides, and residues,  
867–876  
vitamins, 863–864
- Capillary electrophoresis (CE), application in forensic  
science  
background, 762  
practical application in forensic biology  
  animal STR analyses, 775–776  
  application of mini STRs, 768–770  
  botanical DNA analysis, 776–777  
  detection and analysis of short tandem repeats  
  (STRs), 765–768  
  microbial detection and analysis, 777–779  
  mitochondrial DNA analysis, 770–771  
  mutation detection, 775  
  single nucleotide polymorphisms, 773–775  
  Y-chromosome markers, 771–773  
theoretical aspects, in DNA analysis  
  electrokinetic injection, 763–764  
  size estimation, 764  
  using capillary and sieving matrix, 762–763
- Capillary electrophoresis-mass spectrometry (CE-MS)  
qualitative analysis by, 136
- Capillary electrophoresis mobility shift assay  
(CEMSA), 96–97
- Capillary electrophoresis sequencing system  
technologies  
achievements, 468  
algorithms

   pH and salt dependence of separation, 1537  
   separation mechanism for, 1538  
 Graft rejection, 236  
 Granulocyte colony-stimulating factor (G-CSF), 268  
 Gray-scale photolithography, 988  
 Guanylate cyclase (GC), 844

## H

Hadamard transform injection profile, 453–454  
 Halogenated AA, chiral analysis, 883  
 Halophenols, 815  
 HA oligomers determination, by CE-MS, 266  
 Heat-based fluid displacement technique, 986  
 Heat dissipation, in CE  
   factors influencing  
     capillary material, 553–554  
     capillary outer diameter, 555  
     cooling system design, 553  
     type of cooling system, 552–553  
   theory, 552  
 Heat generation, in CE  
   factors affecting  
     applied voltage, 551  
     buffer composition, 549–551  
     buffer viscosity, 552  
     capillary internal diameter, 551–552  
   theory, 546–548  
 Heat transfer coefficient, 557–559  
 Height equivalent of a theoretical plate (HETP), 15, 190  
 Hele–Shaw cells, 1511  
*Helicobacter heilmannii*, determining species identity of, 237  
*Helix aspersia*, 436  
 Hematopoietic stem cell transplants (HSCT), 301  
 Hemoglobin, measurement by CE  
   globin chains of, 799  
   hemoglobin HbA<sub>1C</sub>, 797–798  
   variants, 797  
 Hemoglobin analysis, by CE, 797–799

- Hemoglobin (Hb), 797  
 Hemoglobin Hb<sub>A1C</sub>, 797  
 HeNe laser, 483, 490  
 Heteroduplex analysis, 233  
 Heteroduplex polymorphism, 775  
 Hexadecyl trimethylammonium bromide (HDTAB), 895  
 Hexamethyl disiloxane poly(dimethyl acrylamide), 789  
 High-density lipoprotein (HDL), 790  
 High-density MALDI target plate, 1351  
 High-performance liquid chromatography (HPLC), 445, 516, 786–787, 789  
   effective for analysis of small molecules, 5  
 High-performance liquid chromatography (HPLC)-MS, 111  
 High-pH anion-exchange chromatography (HPAEC)  
   for carbohydrate analysis, 252  
 High-salt stacking, 422–423  
 High sensitivity detection cell, 136  
 High-sensitivity electrophoresis, 614  
 Hjertén protocol, 500  
 Homogenization process, 886  
 Horvath model, for HPLC, 190  
 Hückel equation, 587  
 Human genome, 78  
 Human immunodeficiency virus reverse transcriptase (HIV-RT), 831  
 Hyaluronic acid (HA), structural analysis and quantification of, 264  
 4-Hydrazinobenzoic acid (HBA), 936  
 Hydrodynamic injection, 423  
 Hydrodynamic injections, 448  
 Hydrofluoric acid (HF) etches, 337  
 Hydrogen peroxide, 805  
 Hydrophilic peptides, 458  
 Hydrophobic chromatography, 788  
 Hydrophobic storage proteins, 890  
 $\beta$ -Hydroxyacyl CoA-dehydrogenase ( $\beta$ -HADH)  
   activity, in foods, 897  
 Hydroxychloroquine (HCQ), 590  
 Hydroxyethylcellulose (HEC), 479, 763  
 Hydroxyethyl cellulose (HEC)  
   gel separation matrix, 485  
 Hydroxymethylfurfural (HMF), 895  
 Hydroxypropyl- $\beta$ -CD (HP- $\beta$ -CD), 894  
 Hydroxypropyl- $\beta$ -cyclodextrin, 460, 591  
 (Hydroxypropyl)methylcellulose (HPMC), 575  
 5-Hydroxytryptamine (5-HT), 454  
 5-Hydroxytryptophan (5-HT<sub>Trp</sub>), 454  
 Hypericum perforatum, analysis of PCs in, 877  
 Hyphenation, of microchip electrophoresis, 458–459
- I**
- Identifiler™STR multiplex, 767  
 Idiopathic ventricular fibrillation, 233  
 Iloprost, 846  
 Imidazole, 802–803  
 Immobilized pH gradients (IPGs), 1349  
 Immunoassay microchips, 1014–1016  
   applications, 1016–1018  
 Immunofixation, 791–792  
 Immunoglobulin E (IgE), 831
- Immunoisolation, 584  
 Immunology, single cell CE analysis in, 437  
 Immunosubtraction, 792  
 Imprinting procedures, schematic illustration of  
   covalent and noncovalent, 195  
 Industrial-scale carbohydrate profiling methods, 275  
 Injection block, 624–625  
 Injection technology, 448–451  
 Inkjet printing technology, 986–987, 1346  
   microfluidics in and use of droplet dispensers, 1346  
 Inorganic anions, 941  
 Inorganic cations, 939  
 Inorganic ions, 864–867  
 Inorganic sacrificial materials, 1422  
 Insecticide (pirimicarb) in soil and tomatoe, detection  
   by CE, 870  
 Integrated microfluidic systems, sample processing with  
   cell sorting, cell lysis, and DNA quantification,  
   1215–1216  
   DNA purification, 1208–1213  
   integrated-sample processing with online detection,  
   1221–1225  
   integrated sample processing without online  
   detection, 1216–1221  
   integration of microfluidic hardware, 1216  
   PCR amplification, 1213–1215  
   Integrated sample processing and detection, 494–495  
 Integrated Selective Enrichment (ISET), 1359  
 Integrated system control, 1338  
 Integrated transducers, 1243–1245  
 International Conference on Harmonization (ICH), 154  
 International Union of Pure and Applied Chemistry  
   (IUPAC), 76  
 Intracellular signaling compounds, derivatization of,  
   318  
 In-vial dephosphorylation, of  $\hat{\alpha}$ -casein, 1354  
 In-vial digestion protocol, 1353–1354  
 In-vial digestion technology, 1353  
 Ion-exchange EKC, 918  
 Ion-trap instrument (IT-MS), 266  
 Ion traps (IT), 1344  
 ISET sample preparation protocols, used for SPE, 1360  
 Isoelectric focusing, 527–529  
 Isoelectric focusing (IEF), 516  
 Isoelectric point (pI), of protein, 81  
 Isotachopheresis and moving boundary electrophoresis,  
   525–527  
 Isotachopheresis (ITP), 415, 417, 516, 1086  
 Isotropic etching, 341  
 Isovaline, chiral analysis of standards, 883  
 ITP, 790
- J**
- JOE-labeled primers, 483  
 Joule heating, 446, 546, 556, 560, 568
- K**
- Kaempfero in plants, analysis of PCs in, 877  
 Karyotyping (chromosome banding), 238

Ketamine, 848  
 Kinetic capillary electrophoresis (KCE)  
   for aptamer selection and drug discovery  
     of affinity ligands from DNAencoded libraries, 377  
     nonSELEX selection, 374–376  
     smart aptamers, 373–374  
   methods  
     cNCEEM, 371  
     NCEEM, 364–369  
     ppKCE, 369–371  
     sSweepCE, 371  
     sSweepCEEM, 371  
     SweepCE, 369  
   multimethod toolbox for, 371–372  
   theory, 363  
 Known to be difficult (KD stretches) metric, 498  
 Kohlrausch regulation function and stacking, 413–414  
   solutions to, 414–416  
*K-ras* oncogene, 231

## L

Labeling proteins, 577  
 Lab-on-a-chip method, 893  
 LabVIEW software, 348  
 Lactate detection, in whole blood, 1333  
 $\beta$ -Lactoglobulin, 888  
 Landers' group, 233  
 Laser cavitation, 430–431  
 Laser desorption technique, 1345  
 Laser direct-write systems, 337  
 Laser-induced fluorescence (LIF) detection, 136,  
   144–145, 434, 471, 588, 603–604, 762, 802,  
   819, 829, 863, 889, 1254–1255  
   for low concentration analytes, 111  
 Laser-induced fluorescence (LIF) spectrophotometers,  
   296  
 Laser-induced fluorescence polarization (LIFP), 318  
 Laser-induced native fluorescence, 320  
 Lateral trapping, 1243  
 Lauryl gallate (LG), 894  
*Leuconostoc* spp., 898  
 Library size, in CE-SELEX, 828–829  
 LIF detectors, 87  
 LIF instrumentation  
   application of, 1268–1272  
   detectors, 1264  
   sources, 1263–1264  
 LIF system, 348  
 Ligase detection reaction (LDR), 231  
 Light-based detection modes, for CE, 306–307,  
   325–326  
   absorbance detection system and instrumentation  
     detection cells for, 311–312  
     focusing optics, 311  
     light sources for absorbance-based detectors,  
       309–311  
     wavelength selection in, 312  
   chemiluminescence (CL), 322  
   considerations for detectors  
     detector cell, 307  
     figures of merit, 308

    indirect detection, 309  
     maximizing separation efficiency, 308  
     qualitative *versus* quantitative information, 308  
     resolution and response time in, 307–308  
   fluorescence detection system and instrumentation  
     appropriate light source for, 313–315  
     collection optics in, 316  
     detection cell used in, 315–316  
     multidimensional fluorescence, 316–320  
     radionuclide detection, 322–324  
     thermo-optical detection, 321  
 Light-emitting diodes (LEDs), 310  
 Light sources, in absorbance-based detectors, 310  
 Linear 96-channel systems, 502  
 Linear polyacrylamide (LPA) gel, 474, 477, 789, 801  
 Lipoarabinomannans (LAMs), 271  
 Liquid chromatography, sources of dispersion in, 191  
 Liquid chromatography chips, 1485–1486  
 Liquid-liquid extraction (LLE), 918, 1401–1403  
*Listeria monocytogenes*, 898  
 LOC concept, for bioanalytical and biomedical  
   applications, 1460  
 Long injection stacking, 416–418  
 Longitudinal trapping, 1242–1243  
 Long QT syndrome, 233  
 Lorazepam, CE and CE-ESI-MS for analysis of, 270  
 Lower critical solution temperature (LCST), 480  
 LPSs characterization, by CE-MS, 271  
 Lund-separator, standard, 1241–1242  
 Lysozyme, 890  
   from egg white, using CE, 887  
   molecules, purified and separation by CZE, 89–92

## M

Macroporous monoliths, for chromatographic  
   separations  
   applications  
     affinity chromatography, 1306–1308  
     reversed-phase HPLC, 1298–1306  
     separations in electrochromatographic mode,  
       1308–1319  
   background, 1297–1298  
 Maillard reaction or “browning,” 95  
 Maillard reaction products (MRP), 895  
 MALDI microspot technique, 1355  
 MALDI-MS  
   important step, optimal matrix-sample preparation,  
     1345  
   microfabricated/functionalized MALDI target plates,  
     1477–1479  
   microfluidic sample processing, on-chip for  
     centrifugal compact disks, 1477  
     electrowetting-on-dielectric actuation chips  
       (EWOD), 1477  
     MALDI-MS from open channels and reservoirs,  
       1476–1477  
   with miniaturized SPE, 1348  
   off-chip sample collection for, 1474–1476  
   sample deposition, applications of piezoelectric  
     dispensing for, 1352  
   sample preparation, applications

- MALDI-MS (*continued*)
- in-nanovial chemistry, 1352–1353
  - microdispensing and nanovials applications for, 1350–1352
  - microfabricated protein arrays for, 1353–1355
  - miniaturized enzymatic digestion of proteins, 1352
  - post-translational modifications, in-vial identification of, 1353
  - SPE sample preparation before MALDI-MS, 1355
  - spot-on-a-chip sample preparation platform, 1355
- $\alpha$ -1,4 Maltooligosaccharides bonds, 254
- Mask design, 341
- Mass analyzers, 256
- Mass spectrometry (MS), 111, 434–435, 453, 921
- Matrix-assisted laser desorption ionization (MALDI), 256
- Matrix-assisted laser desorption/ionization (MALDI), 1006–1007
- Matrix-assisted laser desorption–ionization time-of-flight mass spectrometry (MALDI-TOF-MS), 435
- MegaBACE DNA sequencing system, 486
- MegaBACE system, 479
- MegaBACE 1000 system, 502–503
- MEKC-sweeping technique
  - for determination of flunitrazepam and its metabolites, 122
- Membrane-organelle proteins, 588
- Mendel, Gregor, 227
- Metabolic cytometry, 620–624
- Methacrylic acid, 816
- $\gamma$ -Methacryloxypropyltrimethoxysilane, 473
- Methanol, 548, 819
- 3-Methyl-2-benzothiazoline hydrazinone (MBTH), 936
- Methyl cellulose (MC), 566, 575
- Methylenetetrahydrofolate (*MTHFR*) gene, C677T mutation of, 231
- Methylmalonic acid, 803
- MFold program, 835
- Micellar electrokinetic chromatography (MEKC), 77, 586, 786, 864, 895, 915–917, 1002
  - for analysis of food components or nutrients, 124–126
  - analysis of pesticides or herbicides in food, 125
  - analyte separation, based on hydrophobicity, 83
  - applications in pharmaceutical analysis, 120–122
  - chiral separation in MEKC and by MEEKC, 150
  - choice of additives in (Cyclodextrins), 112–113
  - for environmental analysis, 126–127
  - Ewing's group, developed ultramicro separation technique using CE, 123
  - instrumentation in, 111
  - Kennedy's group, microdialysis sampling for extracellular dopamine concentration, 123–124
  - Linear solvation energy selectivity relationship (LSER), 117
  - method development guidelines, 127–129
  - micellar or running solution in, 113
  - migration time window, 116
  - for neutral analytes and utilise chromatographic principle into CE, 110
  - number of theoretical plates in, 115
  - online sample preconcentration techniques, 117
  - principle of field-enhanced sample stacking, 117–118
  - sweeping, principle of, 118–120
  - operating conditions in, 113
  - principle of, 110
  - retention factor and resolution equation in, 114–116
  - selectivity factor, imp. parameter in optimizing separation, 115
  - solute hydrogen bond acceptor capability, 117
  - stir-bar sorptive extraction (SBSE) with MEKC, 126
  - surfactants used in, 112
  - types of interaction between micelle and analyte, 116–117
  - used in body fluids analysis, 122–124
- Micellar solubilization, 116
- Micelle marker, 113–114
- Michaelis–Menten constants, *K<sub>m</sub>*, 1351
- Microarray-based proteomics, 1353
- Microbial detection and analysis, capillary electrophoresis, 777–779
- Microchannel imprinting, 1426
- Microchannels fabrication
  - in polymer substrate using PCSLs, 1424–1425
  - using sacrificial materials, 1422
- Microchip-based electrophoresis (ME)
  - amino acid and peptide analysis, 1429
  - electrophoretic separations in, 348–349, 1429
  - exemplary separations, 349–354
  - major components required for, 347
- Microchip bonding methods, 338
- Microchip capillary electrophoresis (MCE), 1441
  - of FITC-BSA, 352
  - substrate used in
    - polymeric materials as, 1445–1447
    - silicon-based materials, 1441–1443
  - surface characterization methods, 1453
  - physical and chemical characterization, 1453–1456
  - surface modification and methods used for adsorbed coatings, 1449–1451
  - covalent coatings and methods, 1448–1449
  - dynamic coatings for, 1452–1453
- Microchip CE of FITC-BSA, 352
- Microchip fabrication
  - development guidelines, 1331
  - using photolithography and wet chemical etching methods, 338–341
- Microchip immunoassay, 1014–1016
  - applications, 1016–1018
- Microchip-mass spectrometer interfaces, 1466, *see also* microfluidic devices
  - designing considerations, 1461
  - CE related
    - buffer systems and channel coatings, 1462
    - CEC considerations, 1462
    - electrical field strength and chip design, 1461–1462
  - MS detection related
    - detection limit of mass spectrometer, 1464–1465
    - dynamic range and analysis speed /data acquisition/quantitation, 1465
    - ion sources/chip-MS interfaces/ionization efficiency, 1462–1464
    - mass analyzer choice, 1462–1463
    - quantitation/sample complexity, 1465

- electrospray ionization interfaces
  - from chip edge, 1466
  - electrospray generation from capillary emitters, nano-ESI emitters, 1468–1470
  - ESI from the chip, 1466–1468
  - liquid sheath or liquid junction ESI interfaces, 1470
  - microfabricated ESI emitters, 1470–1474
- matrix-assisted laser desorption ionization interfaces, 1474
- microfabricated/functionalized MALDI target plates, 1477–1479
- off-chip/on-chip MALDI-MS detection for microfluidic sample processing, 1474–1477
- Microdevices, problems with glass and silicon, 1420
- Microdialysis and microchip system
  - background, 1328–1329
  - method development guidelines
    - detection, 1332
    - integrated system control, 1338
    - microchip fabrication, 1331
    - microdialysis sampling, 1331–1332
    - separation, 1334–1338
    - validation, 1338
  - practical applications, 1330–1331
  - theoretical aspects, 1329–1330
- Microdialysis probe, 820
- Microdialysis sampling, development guidelines, 1331–1332
- Microdispensing in combination with nanovials
  - advantages of, 1350
- Microelectrode arrays (MEA), 996
- Microemulsion electrokinetic chromatography (MEEKC), 129, 864, 917–918
  - advantages over MEKC, 130
  - versatile mode for pharmaceutical analysis, 141–142
- Microemulsion liquid chromatography (MELC), 142
- Microextraction array, process steps in preparing, 1358
- Microfabricated electrophoresis devices, for high-throughput genetic analysis
  - advantages, 1288–1293
  - 384-channel  $\mu$ CAE bioanalyzer, 1287–1288
  - evolution to 96 sample reservoirs, 1280–1281
  - optimizing microchip DNA sequencing, 1283–1287
  - transition to radial formats, 1281–1283
- Microfabrication technology
  - applications in 3D culture systems
    - dielectrophoresis, 984–986
    - inkjet printing, 986–987
    - photopatterning, 983–984
    - physical entrapment, 983
  - electrical microenvironment, 994–997
  - engineering the cellular microenvironment
    - chemical manipulations, 991–994
    - dynamic manipulations, 989–991
    - mechanical manipulations, 988–989
  - tools for, 982
- Microfabrication tools, 982
- Microfluidic analysis devices fabrication, using micromachining techniques, 1420
- Microfluidic applications, 457–459
  - direct-printing process
    - fabrication of glass-toner microchips and toner-mediated lithography, 1179–1180
    - fabrication of other microanalytical devices, 1178–1179
    - fabrication of pt microchips with integrated electrodes, 1180–1181
    - microelectrode preparation, 1175–1178
    - PT microchips fabrication, 1173–1175
  - fundamental aspects, 1170–1173
- Microfluidic array-based antibody assays, 1355
- Microfluidic CE separation chips, 1484
- Microfluidic devices
  - background of, 336–338
  - for electrophoretic separations
    - background of, 336–338

- Neurotransmitter synthesis, 594
- Neutral markers, 12
- Newton rings, 343
- Newton's iteration method, 521
- Niacin content analysis, 865
- Nicotinoids, 926
- Nitrate and nitrite analysis, by CE, 804
- Nitric oxide (NO), 842, 848
- 2-(*N*-morpholino)ethanesulfonic acid (MES), 551
- 3-(*N*-morpholino)propanesulfonic acid (MOPS), 551
- NMR spectroscopy, 555
- N,N*-diethylacrylamide (DEA), 480
- N,N*-dimethylacrylamide (DMA) solutions, 478
- N,N*-disuccinimidyl carbonate (DSC), 920
- N,N,N',N'*-tetramethylethylenediamine (TEMED), 477
- 10-*N*-nonyl acridine orange (NAO), 596
- Nonaqueous CE (NACE), 139–140  
 for resolution of water-soluble charged solutes, 139
- Noncoated (untreated) capillary, 789
- Nonenzymatic glycation, 95
- Nonprotein AA, chiral analysis, 884
- Nordihydroguaiaretic acid (NDGA), 894
- N*-[Tris(hydroxymethyl)methyl]-3-aminopropanesulfonic acid, 416
- N-tris*[hydroxymethyl]methyl-3-aminopropanesulfonic acid (TAPS), 763
- Nuclear membrane proteins, 588
- Nucleic acid libraries, 829
- Nucleic acids and gene expression, single cell CE analysis in, 437–439
- Nucleic acids (DNA molecules), capillary electrophoresis of, *see also* capillary electrophoresis  
 DNA sequencing, 239–240  
 efficiency and resolution in, 230  
 electrophoretic migration of, 229–230  
 large DNA fragment analysis, 241–242  
 mononucleotides and nucleosides, analysis of, 242  
 mononucleotides and nucleosides analysis  
 DNA adducts, 244  
 in nucleoside analogs, 244  
 in nucleotides, 243–244  
 in oligonucleotides, 241  
 polymerase chain reaction product analysis  
 cellular mRNA/expression analysis, quantification of, 238–239  
 in diagnostic and therapeutic purposes, 237  
 in forensic application/identity testing, 236–237

Nucleic acids and gene expression, single cell CE  
 analysis in, 437–439 (*continued*)  
 in molecular karyotyping, 238  
 mutation detection and polymorphism studies,  
 230–236  
 synthetic nucleotides, purity control of, 241–242  
 Nucleoside analogs, 244  
 Nucleotide analyses, by CE, 243–244  
 Nucleotide polymorphisms, single, 773–775  
 Nucleotides, 801

## O

Obstacle arrays, 1528  
 and asymmetric obstacle courses, 1528–1530  
 Octyl gallate (OG), 894  
 Offline interfacing, 817  
 Off-line separations, 295–296  
 liquid-based separations, SCX, 295–296  
 O-glycan core structures, 259  
 Ogston theory, 229  
 Ohm's Law, 33, 546  
 Oligonucleotide library, 829  
 Oligonucleotides, used for DNA amplification in PCR  
 mixtures, 241  
 Oligosaccharide maps, of trastuzumab by CE, 269  
 Oligosaccharides sequencing, 268  
 Oligosaccharide structural isomers, high-resolution CE  
 separation of, 254  
 Olive oil, analysis of PCs in, 877  
 On-capillary sample concentration  
 isotachoporetic sample enrichment, 43  
 online concentration, 43  
 and sample focusing, 42–43  
 and sample stacking, 41–42  
 On-chip labeling, of analytes, 1334  
 On-chip SPE devices coupling, to MALDI-MS, 1349  
 On-column analyte derivatization, 319  
 On-column capillary detection, 307, 315  
 One-color primer sequencing chemistry, 470  
 One-dimensional capillary electrophoresis, 617–619  
 One-mask microfabrication, 336  
 Online cIEF-mass spectrometer coupling, 577  
 Online sample preconcentration, for CE  
 Kohlrausch regulation function and stacking,  
 413–414  
 solutions to, 414–416  
 long injection stacking, 416–418  
 sample stacking in MEKC  
 electrokinetic injection, 423  
 field-amplified stacking, 420  
 field-enhanced sample injection, 423–426  
 high-salt stacking, 422–423  
 sweeping, 421–422  
 Online sample preconcentration techniques, in MEKC  
 combination of different techniques, 120  
 cation-selective (or anion-selective) exhaustive  
 injection-sweeping  
 (CSEI/ASEI-sweeping), 120  
 field-enhanced sample injection (FESI), 120  
 dynamic pH junction, 117, 120  
 field-enhanced (amplified) sample stacking, 117

sweeping, principle of  
 under suppressed EOF conditions, 117, 119–120  
 transient isotachopheresis (t-ITP), 117  
 On-target purification (SPE) technology, 1348  
 OPA-derivatized amino acids, 454  
 O-phthaldialdehyde (OPA), 453  
 Optical detection systems  
 absorbance, 1255  
 chemiluminescence, 1255–1256  
 detector cell types used, 312  
 electrochemiluminescence, 1256–1257  
 laser-induced fluorescence, 1254–1255  
 Raman spectroscopy, 1257  
 refractive index detection, 1259  
 surface plasmon resonance, 1258–1259  
 thermal lens microscopy, 1257–1258  
 Optical gating, 449–450  
 Optical trapping, 433  
 Optimizing resolution, 560  
 Orange juices and concentrates, chiral analysis, 885  
 Organelle separations, 433  
 Organelle-specific fluorescent labels, 601  
 Organic acids, 864–867  
 Organophosphorus, 924–925  
 Ornithine transcarbamylase, 797

## P

P/ACE MDQ instrument utility  
 for monitoring DNA release from virus particles, 237  
 Packed beds, 816  
 Packed capillary columns, 191  
 columns packed with particles, 191  
 PAH, PCB, and PCDD emission, 928  
*P*-aminobenzoic acid, 854  
 Parabolic reflector concept, 488  
 Paralytic shellfish toxins (PSTs), detection by  
 CE, 873  
 Partial-filling technique, 112  
 Passive microfluidic flow control, in microfluidic  
 devices  
 capillarity, 1160–1161  
 fluidic resistors for controlled flow-splitting,  
 1158–1160  
 gravimetric control, 1160  
 passive structural components, 1161–1163  
 Patch clamping, 995  
 PCR amplification, 1213–1215  
 PCR-based methods, in molecular genetics, 231  
 PCSL, *see* phase-changing sacrificial layers  
 PDMS, chemical structure of, 345  
 PDMS/divinyl benzene (DVB) probe, 815  
 PDMS microfluidic devices, 345  
 PE Biosystems Inc., 491  
 PEGylated-latex mixed polymer solution, 1538  
 synthesis of methoxy-PEG-VB macromonomer and,  
 1538–1539  
 PEGylated proteins, 574  
 Peltier thermoelectric device, 553  
 Penicillin V and related substances, detection by CE,  
 873  
 Peptide analysis, by CE, 799

- Peptide isolation, from foods, 886–890
- Peptide mass fingerprinting (PMF), 1344
- Peptide nucleic acid, antisense DNA, 241
- Perfluorooctanic acetate (PFOA<sup>-</sup>) surfactant, 918
- Peripheral neuropathy, 793
- Pesticide contamination, 921–927
- Pesticides, detection by CE, 871–872
- Pharmaceutical analysis
- advantages of CE for, 136
  - capillary electrophoresis-mass spectrometry, 142–143
  - CE application to
    - CD modified MEKC (CD-MEKC) and MEEKC in, 150
    - chiral selectors and chiral CE separating techniques, 147–148
    - crown ethers for use in chiral CE, 148–149
    - oligo- and polysaccharides, chiral selectors, 149
    - pharmaceutical applications of chiral, 150–151
    - protein for separation of enantiomeric mixtures, 149
    - use of cyclodextrins in chiral CE, 148
    - use of macrocyclic antibiotics in, 149
  - chiral CE methods and validation criteria for, 151–152
  - choice of suitable CE mode, 146–147
  - choosing detection method, 146
  - comparison of HPLC, GC, and CE for, 167
    - analysis times for, 169
    - peak efficiency for each method, 167
    - reagents and consumables used, 169
    - required sample volumes, 168
    - sample types, 167–168
    - sensitivity and precision, 168
  - detection methods for CE analysis of pharmaceuticals, 143–144
    - electrochemical detection, 145–146
    - features and limits of detection of, 146
    - Laser-induced fluorescence detection, 144–145
    - mass spectrometric detection, 145
    - UV/Vis absorbance, 144
  - free solution CE (FSCE), 138
  - micellar electrokinetic chromatography (MEKC), 140–141
  - microemulsion electrokinetic chromatography (MEEKC), 141–142
  - multiplexed CE, applications of, 143
  - nonaqueous CE (NACE)
    - for resolution of water-soluble charged solutes, 139
    - with TLC and GC, 136–138
- Pharmaceutical assay
- advantages of CE as an alternative to HPLC methods in, 153
  - of substances and formulated products, 152–154
  - validated CE methods for, 153, 156
- Pharmaceutical CE methods
- development and validation of, 163–167
    - optimization of separation conditions, 166
    - selecting and optimizing a number of variables, 164
  - method validation guidelines for, 166–167
- Pharmaceuticals
- impurity applications of, 158
  - impurity profiling of, 154
    - modes of CE, for impurity determination, 155
    - quantification of impurities levels of 0.04–0.08% of, 157
  - physicochemical profiling of, 157
    - analysis of small organic and inorganic ions, 161, 164
    - Log *P* measurements using MEKC and MEEKC, 162
    - log *P*ow measurements, 161
    - p*K*a values determination, 159
    - principles and applications of CE in, 158
- Pharmalyte mixture (pH 3–10 and pH 5–8 at 1:3 ratio), 569
- Pharmalyte solution, 574
- Phase-changing sacrificial layers (PCSLs), to fabricate microfluidic devices, 1419–1421
- applications in, 1429–1432
  - PCSL-fabricated microchips evaluation, 1428
  - sacrificial layer fabricated devices, 1423–1424
  - sacrificial materials, 1422–1423
  - solvent bonding method development considerations, 1433

- Reversed-phase HPLC, 1298–1306
- Reversed-phase (RP), 295
- Reverse transcriptase-polymerase chain reaction (RT-PCR), 437
- Rhodamine, 764
  - green primer, 493
- Riboflavins vitamers concentration, CE detection, 865
- Ricin, 831
- 6-ROX, 493
- ROX fluorophores, 483
- Runge-Kutta-Fehlberg time step, 521
- Rutin and quercetin in plants, analysis of PCs in, 877
- Rutin in plants, analysis of PCs in, 877–878

## S

- Sacrificial etching methods, 1423
- Sacrificial materials (phase changing), for microdevice
  - fabrication, 1422–1423
  - fabricated microfluidic devices, 1423–1424
    - polymeric materials, 1424
    - silica and glass materials, 1423–1424
  - techniques and method development
    - filling microchannels with PCSL, 1427
    - microchannel imprinting, 1424–1426
    - microchip evaluation, 1428–1429
    - microdevice bonding, 1427
    - sacrificial layer removal, 1427–1428
    - template fabrication, 1424
- Safety of food, 867
- Salmonella* spp., 898
- Salt mobilization, 566
- Sample decomposition, 560
- Sample injection, importance, 763
- Sample matrix, role in attaining optimal separation, 25
- Sample matrix effects, 787–788
- Sample preconcentration techniques
  - background, 1087
  - practical applications
    - field-amplified sample stacking, 1095–1102
    - isotachopheresis, 1108–1116
    - temperature gradient focusing, 1102–1108
  - theoretical aspects
    - scaling relations to estimate dispersion effects, 1093–1095
    - Taylor dispersion equation using an area averaging approach, 1087–1093
  - types, 1085–1086
- Sample processing, with integrated microfluidic systems
  - cell sorting, cell lysis, and DNA quantification, 1215–1216
  - DNA purification, 1208–1213
  - integrated-sample processing with online detection, 1221–1225

- Sample processing, with integrated microfluidic systems (*continued*)
- integrated sample processing without online detection, 1216–1221
  - integration of microfluidic hardware, 1216
  - PCR amplification, 1213–1215
- Sample self-stacking, 416
- Sample stacking technique, 159
- Sanger–Coulson sequencing chemistry, 471–472, 481, 494
- Sanger method, 239
- Sarcoplasmic/myofibrillar meat proteins, CE analysis, 887
- Sarcoplasmic protein profiles, 890
- SBE technique
- with CGE and electrochemical detection, 232
- SDS marker, 114
- Sealing methods, for plastic microdevices, 1421
- Sebia Electrophoresis (Norcross, GA), 84
- Seed-layer method, 1346
- Self-assembled arrays, first separations of DNA in, 1509–1513, 1518–1520
- Self-assembly process, 1512
- Self-coating method, 473
- Sensitivity enhancement strategies, 918–921
- Separation buffer, in CE, *See also* Capillary electrophoresis
- effect of modifiers of EOF on separation, 39
  - effect of organic salts on, 35
  - impact of ionic strength, 33–35
  - organic solvents, 35
- Separation conditions, in CE for analytes
- for ions and small molecules, charged/neutral, 60–63
  - for nucleic acids, 68–69
  - for peptides, 63–65
  - for proteins, 65–68
- Separation matrix concentration, 229
- Separation mechanism, “pseudo-stationary phase” forms, 137
- Separation parameters, on CE analysis of mixtures
- capillary temperature effect on migration time and fluorescence intensity (RFU), 27–28
  - electrode polarity effect, 26
  - voltage effect on separation efficiency and resolution, 26–27
- Separation strategies for environmental analysis, CE application
- algal toxins, determination of, 960
  - approaches to enhance sensitivity in CE
    - alternate detection schemes, 919–921
    - preconcentration schemes, 918–919
  - endocrine disruptors and pharmaceuticals
    - pharmaceuticals residues, 954–959
    - phenolic compounds, 954
    - phthalate esters, 954
  - explosives and warfare residues
    - aromatic sulfonates, 949–952
    - explosives, 942

Zwitterionic buffers, 461, 550  
Zwitterions, 791

**FIGURE 12.10** Electropherograms of multiplexed SBE-FSCE separation of 16 loci in a wild-type *p53* gene. (a) CE separation in 36 cm capillary (47 cm total length, 50  $\mu\text{m}$  inner diameter) in 1  $\times$  TTE (89 mM Tris, 89 mM TAPS, 2 mM EDTA), 7 M urea and 0.5% (v/v) POP-6 for dynamic coating. (b) Separation on 8 cm microchip in 1  $\times$  TTE (49 mM Tris, 49 mM TAPS, 2 mM EDTA) with 7 M urea on chip coated with Poly-*N*-hydroxyethylacrylamide. Both separations were performed at 55°C. (Reprinted with permission from Meagher, R. J., et al. *Analytical Chemistry*, 79, 1848–1854, 2007.)

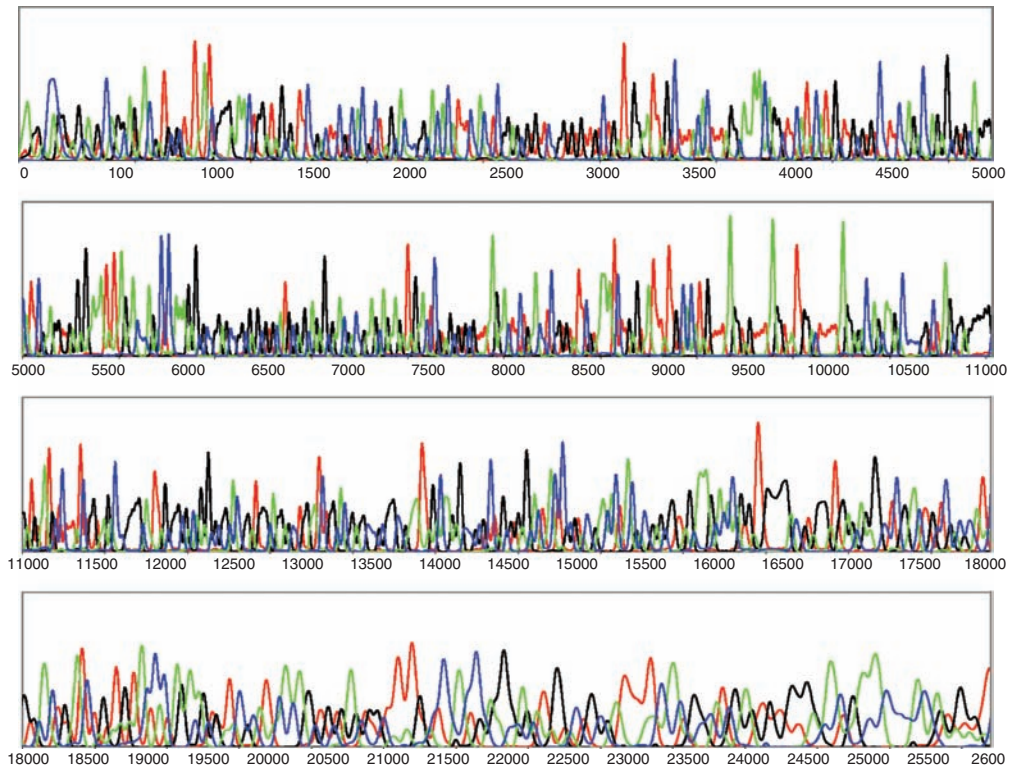

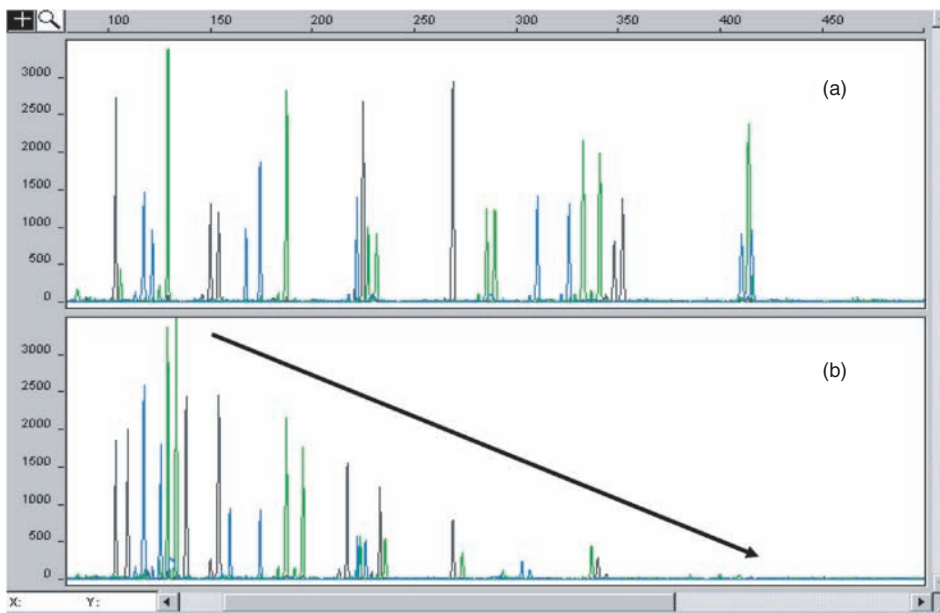

**FIGURE 12.11** DNA sequencing analysis of M13mp18 ssDNA in free-solution with genetically engineering protein polymer drag-tag in 36 cm capillary (47 cm total length, 50  $\mu\text{m}$  inner diameter) with 312 V/cm field strength and electrokinetic injection of 1 kV for 20 s. Capillaries were filled with 1 $\times$  TTE (89 mM Tris, 89 mM TAPS, 2 mM EDTA) with 7 M urea and 0.5% (v/v) POP-6 to dynamically coat the walls of the capillary. (Reprinted with permission from Meagher, R. J., et al. In preparation 2007.)

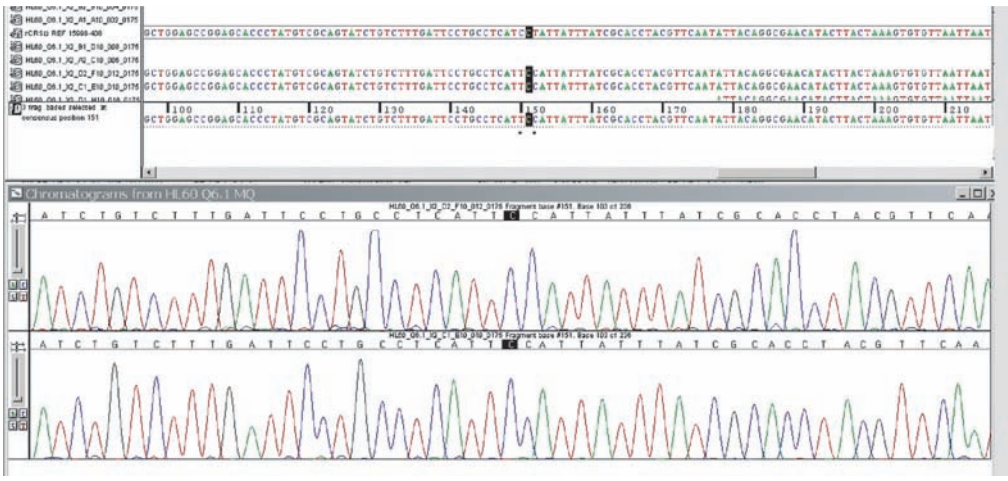

**FIGURE 14.4** CE system with simultaneous multiwavelength fluorescence detection. Cellular samples were electrokinetically drawn into a capillary (1) from a steel microvial (2). The analytes were separated in the capillary, and eluted into a square-cuvette sheath-flow cell (3) where fluorescence was induced with a laser beam (4). The fluorescent light was collected orthogonally and directed into a spectrograph and CCD where a complete spectrum was obtained for each separated analyte (5). (From Fuller, R.R. et al., *Neuron*, 20, 173, 1999. With permission.)

**FIGURE 16.7** Analyzed four-color dye-terminator sequencing from a CEQ analysis system (Beckman Coulter): 1009 bases called to 98% accuracy.

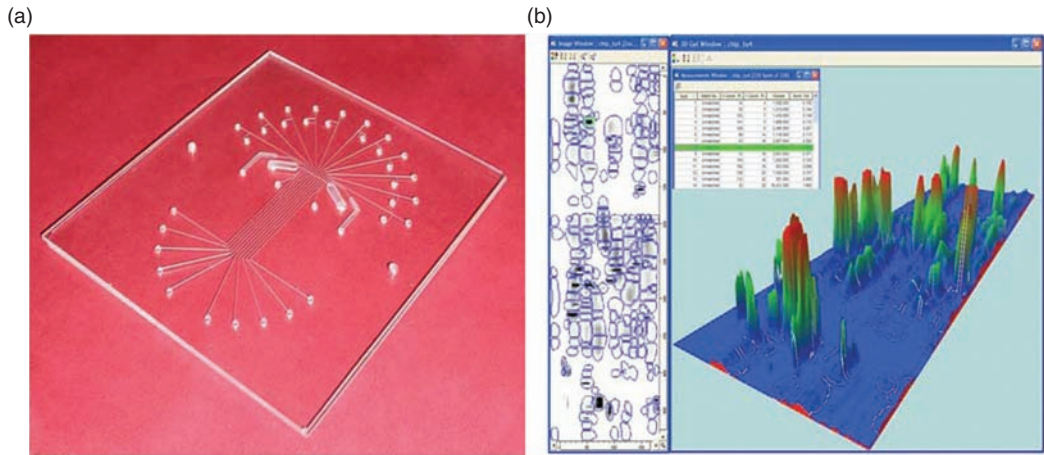

**FIGURE 25.4** A comparison between a 9947 control DNA sample (a) and a degraded DNA sample (b) extracted from a recovered bone fragment. There is an evident loss of signal at the larger size loci in sample b (arrow) due to sample degradation. The sample is extracted and amplified DNA prepared using the Promega Powerplex STR multiplex kit and consists of 16 separate genetic loci labeled with three different dyes and separated via capillary gel electrophoresis using the ABI 310 genetic analyzer. (Courtesy of Kerry Opel, International Forensic Research Institute, Florida International University.)

**FIGURE 25.7** Mitochondrial DNA profile of an HVII sequence from a hair shaft. A repetitive analysis of the same hair sample is used to compare and align the sequences. The nuclear DNA in hair is often badly degraded and difficult to amplify. mtDNA provides an alternative procedure that can provide a DNA haplotype for forensic DNA profiling based on point mutations detected in the sequence when compared to a reference sample. Analysis performed on an ABI 310 Genetic Analyzer. (Courtesy of the DNA Analysis Unit II at the FBI Laboratory, Quantico, VA.)

**FIGURE 25.10** The recovery of information from degraded DNA using the Identifiler™STR multiplex and an SNP multiplex, both analyzed using the ABI 310 genetic analyzer. The top electropherogram depicts a degraded sample amplified via STRs. The bottom profile depicts a SNP multiplex on the same sample. The STR profile is blank for many larger alleles such as D7 CSF, D16, D2, TPOX, D18, and FGA. The smaller sized SNP fragments permit recovery of additional genetic information from the sample. (From Vallone, P.M., Decker, A.E., and Butler, J.M., The evaluation of Autosomal SNP assays, *Chemical Science and Technology Laboratory, National Institute of Standards and Technology, Div. 831.*)

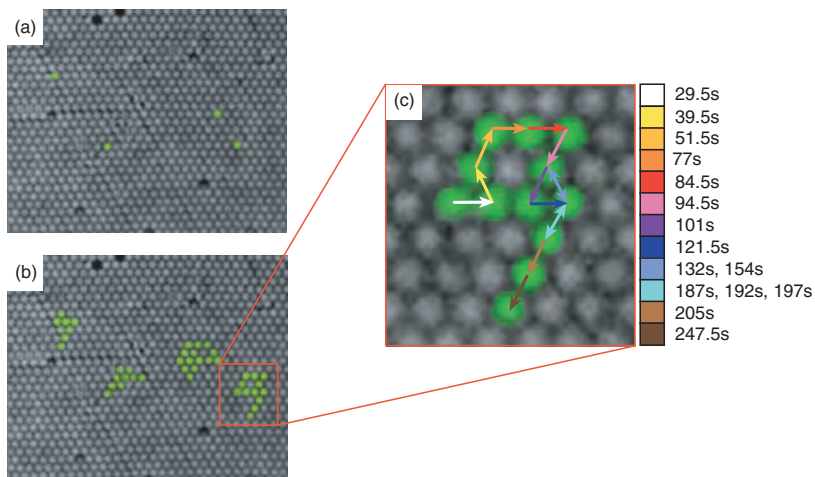

**FIGURE 33.3** (a) Microfluidic PMMA chip for 2-D IEF/SDS-CGE protein separations and (b) pseudo-gel image resulting from a yeast cell lysate separation.

**FIGURE 38.14** CCD camera images of on-chip sample peaks of AlexaFluor 488 at the LE/TE interface in two different ITP experiments. In (a) there is finite (nonuniform) EOF and the sample peak streamwise dimension is on the order of channel width or larger. In (b) EOF is suppressed and the sample is concentrated in narrower zone ( $\sim 5 \mu\text{m}$ ) at relatively high electric field. While Taylor dispersion based analysis is probably applicable in the first case, more comprehensive modeling is required for case (b).

**FIGURE 46.7** Electropherograms from a multiplexed short tandem repeat sizing separation on a 150-mm diameter, 96-channel  $\mu$ CAE device. Separations are successful in all lanes and sizing against DNA standards (blue and red) was accurate to within 1% of known values. (Reproduced from Medintz, I.L. et al., *Clin. Chem.*, 47, 1614, 2001. With permission.)

**FIGURE 54.12** DNA dynamics in a polymer matrix formed from colloidal templating in the absence of an electric field. (a) At a given instance in time, four DNA molecules are localized in different pores. (b) Over time, the DNA explores the local pores. (c) The jumping between pores is random in both direction and the waiting time between jumps. (Reprinted from Nykypanchuk, D., et al., *Science*, 297, 987, 2002. With permission.)

# HANDBOOK OF CAPILLARY and MICROCHIP ELECTROPHORESIS and ASSOCIATED MICROTECHNIQUES

THIRD EDITION

## *Demonstrating the True Practicality of Capillary Electrophoresis Technology in Science and Medicine*

Although capillary electrophoresis (CE) technology has evolved quickly from the research laboratory into practical application in numerous fields, many scientists still debate its merits. Experts still question whether it has provided the speed, resolving power, peak capacity, sensitivity, robustness, and cost-reduction promised by its pioneers. Responding to these criticisms, this third edition brings together cutting-edge researchers to demonstrate the utility of CE across a broad spectrum of disciplines including—

Forensic science

Medical diagnostics

Pharmaceutical science

Biotechnology

Environmental science

## *Detailed Analysis of New Methodologies and Applications*

Eagerly awaited by researchers and technicians who transformed the first two editions into bestsellers, this latest volume once again delivers. Emphasizing microseparations and microfluidics, the **Handbook of Capillary and Microchip Electrophoresis and Associated Microtechniques, Third Edition** features new chapters describing the use of microchip electrophoresis and associated microtechniques, with a focus on the extraordinary breadth of work undertaken to expand CE methodologies in recent years. Aided by contributions from leading international experts, this text remains a seminal reference for numerous chemistry, biology, and engineering fields.

## *Features*

Provides detailed descriptions of inherent problems within specific areas of research and application, along with novel approaches to overcoming them

Presents current information from leading experts actively engaged in CE or microchip research

Features updated and expanded material reflecting new methodologies and applications for CE

Contains new chapters on microchip electrophoresis and associated microtechniques

Includes fundamental as well as specialized information
