## *Dedication*

---

*This undertaking would not have been possible without the support of my family and colleagues. Dedication is, first and foremost, to family—first, my wife, Lianne, and my children, Miranda, Kate, and Ben—who not only recognize my passion for these academic endeavors but also fully encourage me to pursue them. I appreciate the sacrifices they made en route to completion of this undertaking. Second, this laboratory compendium would not exist without the immeasurable effort from the scientists who authored the chapters—they are leaders in their particular fields, both nationally and internationally—I am grateful that they saw value in contributing here. In recognition of their willingness to contribute to this handbook, even in the midst of their already overextended commitments, this book is also dedicated to them.*

# Contents

<b>Foreword</b> .....	xi
<b>Editor</b> .....	xiii
<b>Contributors</b> .....	xv
<b>Part I Fundamentals and Methodologies</b> .....	<b>1</b>
<b>Chapter 1</b> Introduction to Capillary Electrophoresis .....	3
<i>James P. Landers</i>	
<b>Chapter 2</b> Protein Analysis by Capillary Electrophoresis .....	75
<i>James M. Hempe</i>	
<b>Chapter 3</b> Micellar Electrokinetic Chromatography .....	109
<i>Shigeru Terabe</i>	
<b>Chapter 4</b> Capillary Electrophoresis for Pharmaceutical Analysis .....	135
<i>Eamon McEvoy, Alex Marsh, Kevin Altria, Sheila Donegan, and Joe Power</i>	
<b>Chapter 5</b> Principles and Practice of Capillary Electrochromatography .....	183
<i>Myra T. Koesdjojo, Carlos F. Gonzalez, and Vincent T. Remcho</i>	
<b>Chapter 6</b> Capillary Electrophoresis of Nucleic Acids .....	227
<i>Eszter Szántai and András Guttman</i>	
<b>Chapter 7</b> Analysis of Carbohydrates by Capillary Electrophoresis .....	251
<i>Julia Khandurina</i>	
<b>Chapter 8</b> The Coupling of Capillary Electrophoresis and Mass Spectrometry in Proteomics .....	295
<i>Haleem J. Issaq and Timothy D. Veenstra</i>	
<b>Chapter 9</b> Light-Based Detection Methods for Capillary Electrophoresis .....	305
<i>Cory Scanlan, Theodore Lapainis, and Jonathan V. Sweedler</i>	
<b>Chapter 10</b> Microfluidic Devices for Electrophoretic Separations: Fabrication and Use ....	335
<i>Lindsay A. Legendre, Jerome P. Ferrance, and James P. Landers</i>	
<b>Part IIA Capillary-Based Systems: Core Methods and Technologies</b> .....	<b>359</b>
<b>Chapter 11</b> Kinetic Capillary Electrophoresis .....	361
<i>Maxim V. Berezovski and Sergey N. Krylov</i>	

<b>Chapter 12</b>	DNA Sequencing and Genotyping by Free-Solution Conjugate Electrophoresis .....	381
	<i>Jennifer A. Coyne, Jennifer S. Lin, and Annelise E. Barron</i>	
<b>Chapter 13</b>	Online Sample Preconcentration for Capillary Electrophoresis .....	413
	<i>Dean S. Burgi and Braden C. Giordano</i>	
<b>Chapter 14</b>	Capillary Electrophoresis for the Analysis of Single Cells: Sampling, Detection, and Applications .....	429
	<i>Imee G. Arcibal, Michael F. Santillo, and Andrew G. Ewing</i>	
<b>Chapter 15</b>	Ultrafast Electrophoretic Separations .....	445
	<i>Michael G. Roper, Christelle Guillo, and B. Jill Venton</i>	
<b>Chapter 16</b>	DNA Sequencing by Capillary Electrophoresis .....	467
	<i>David L. Yang, Rachel Sauvageot, and Stephen L. Pentoney, Jr.</i>	
<b>Chapter 17</b>	Dynamic Computer Simulation Software for Capillary Electrophoresis .....	515
	<i>Michael C. Breadmore and Wolfgang Thormann</i>	
<b>Chapter 18</b>	Heat Production and Dissipation in Capillary Electrophoresis .....	545
	<i>Christopher J. Evenhuis, Rosanne M. Guijt, Miroslav Macka, Philip J. Marriott, and Paul R. Haddad</i>	
<b>Chapter 19</b>	Isoelectric Focusing in Capillary Systems .....	563
	<i>Jiaqi Wu, Tiemin Huang, and Janusz Pawliszyn</i>	
<b>Part IIB</b>	<b>Capillary-Based Systems: Specialized Methods and Technologies.....</b>	<b>581</b>
<b>Chapter 20</b>	Subcellular Analysis by Capillary Electrophoresis .....	583
	<i>Bobby G. Poe and Edgar A. Arriaga</i>	
<b>Chapter 21</b>	Chemical Cytometry: Capillary Electrophoresis Analysis at the Level of the Single Cell.....	611
	<i>Colin Whitmore, Kimia Sobhani, Ryan Bonn, Danqian Mao, Emily Turner, James Kraly, David Michels, Monica Palcic, Ole Hindsgaul, and Norman J. Dovichi</i>	
<b>Chapter 22</b>	Glycoprotein Analysis by Capillary Electrophoresis .....	631
	<i>Michel Girard, Izaskun Lacunza, Jose Carlos Diez-Masa, and Mercedes de Frutos</i>	
<b>Chapter 23</b>	Capillary Electrophoresis of Post-Translationally Modified Proteins and Peptides .....	707
	<i>Bettina Sarg and Herbert H. Lindner</i>	
<b>Chapter 24</b>	Extreme Resolution in Capillary Electrophoresis: UHVCE, FCCE, and SCCE .....	723
	<i>Wm. Hampton Henley and James W. Jorgenson</i>	
<b>Chapter 25</b>	Separation of DNA for Forensic Applications Using Capillary Electrophoresis .....	761
	<i>Lilliana I. Moreno and Bruce McCord</i>	
<b>Chapter 26</b>	Clinical Application of CE .....	785
	<i>Zak K. Shihabi</i>	

<b>Chapter 27</b> Solid-Phase Microextraction and Solid-Phase Extraction with Capillary Electrophoresis and Related Techniques .....	811
<i>Stephen G. Weber</i>	
<b>Chapter 28</b> CE-SELEX: Isolating Aptamers Using Capillary Electrophoresis .....	825
<i>Renee K. Mosing and Michael T. Bowser</i>	
<b>Chapter 29</b> Microfluidic Technology as a Platform to Investigate Microcirculation .....	841
<i>Dana M. Spence</i>	
<b>Chapter 30</b> Capillary Electrophoresis Applications for Food Analysis.....	853
<i>Belinda Vallejo-Cordoba and María Gabriela Vargas Martínez</i>	
<b>Chapter 31</b> Separation Strategies for Environmental Analysis .....	913
<i>Fernando G. Tonin and Marina F.M. Tavares</i>	
<b>Part IIIA Microchip-Based: Core Methods and Technologies.....</b>	<b>979</b>
<b>Chapter 32</b> Cell Manipulation at the Micron Scale .....	981
<i>Thomas M. Keenan and David J. Beebe</i>	
<b>Chapter 33</b> Multidimensional Microfluidic Systems for Protein and Peptide Separations .....	1001
<i>Don L. DeVoe and Cheng S. Lee</i>	
<b>Chapter 34</b> Microchip Immunoassays .....	1013
<i>Kiichi Sato and Takehiko Kitamori</i>	
<b>Chapter 35</b> Solvent Extraction on Chips.....	1021
<i>Manabu Tokeshi and Takehiko Kitamori</i>	
<b>Chapter 36</b> Electrophoretic Microdevices for Clinical Diagnostics .....	1037

# Foreword

The esteemed Chinese philosopher Confucius placed works such as this in succinct context when he wrote “*You cannot open a book without learning something.*” Each chapter of this book describes remarkable advancements in one of the most controversial and yet, powerful, analytical tools in separation sciences. Even the most accomplished practitioners in separation science will extract new information on methods and applications that can serve unmet needs in science and medicine.

Even after more than two-and-a-half decades of research and development, many scientists debate whether capillary electrophoresis (CE) technology has provided the speed, resolving power, peak capacity, sensitivity, robustness and cost reduction promised by the pioneers of CE during its genesis in the 1980s and 1990s. Thousands of researchers, focusing on some of the most widespread and practical analytical goals ever considered (that utilize microscale volumes of sample), have demonstrated the utility of CE on a wide range of applications across many disciplines, such as forensic science, medical diagnostics, pharmaceutical science, biotechnology, and environmental science. The last 7 years have seen CE technology evolve quickly from the research laboratory into practical applications in many fields, and the total body of international CE literature continues to grow at an ever-increasing rate.

The first flush of excitement came with the key role that the CE technology played in completion of the Human Genome Project. The project was successfully completed ahead of schedule and at a fraction of the predicted cost. This monumental breakthrough allowed the placement of CE-based DNA sequencers in the most prestigious institutions providing medical-legal testing and in numerous research centers worldwide working on different DNA projects. In addition, an official compendium for the analysis of erythropoietin is now part of a monograph of the European Pharmacopeia. Consequently, CE is now part of the quality control that precedes the release of commercial batches of this critically important drug. Other major biopharmaceutical companies also have official CE-based quality control methods filed with the FDA. In fact, the growth of widely used biotechnology compounds now rivals the growth of conventional pharmaceutical products and, thus, stricter regulations have been applied to biomolecule development due to the complexity of their physicochemical properties.

Each contributor to this book has been actively engaged in CE or microchip research and is a leader in the field. Accordingly, each author contributes various aspects of their experience, specifically the detailed descriptions and awareness of the practical problems inherent in their particular area of research and application. Furthermore, contributors provide sound advice on how to overcome practical problems, thus enabling readers to pursue novel applications equipped with much of the practical knowledge and wisdom possessed by the leading researchers in the field.

The chapters in this book indicate the extraordinary breadth and scope of the work carried out in capillary electrophoresis and microchip technology over the last few years. The core section on “Fundamentals and Methodologies” contains 10 chapters focused on CE technology. These chapters provide an introduction to CE in general, followed by in-depth descriptions of the most widely used modes of CE and their associated detection methods. Several important applications related to protein, nucleic acid, and carbohydrate research are presented, as well as an overview of the emerging field of fabrication and use of microchips. The next 20 or so specialized chapters continue to describe specific applications and methodologies that can be addressed with capillary systems, including studies on the analysis of cellular and subcellular entities, food analysis, environmental science,

clinical and forensic applications, solid-phase microextraction/online sample preconcentration, and extreme resolution CE.

This bandwidth of applications is illustrative of the exploding world of microchip systems that perform chemical and biochemical analysis. It is difficult, if not impossible, to determine whether microfabricated analytical devices were predominantly inspired by capillary systems, or by visionaries who recognized the potential of microfabrication techniques (originally designed for microelectronics) to revolutionize chemical, biomolecular, and cellular analysis. Clearly, inspiration has flowed in both directions, and the revolution is upon us. Techniques to exploit the precision, scalability, and unique microscale phenomena enabled by microchip technology now span much of the routine practice of biochemistry and biology, including cell manipulation, protein separations, forensic science, molecular and nanomaterial synthesis, etc. The second part of this book explores core microsystem technologies, such as immunoassays, flow control, device fabrication and reliability. These core technologies are widely used in many applications, such as those outlined in the specialized chapters that conclude this book, and they span everything from on-chip sample preparation to genetic analysis to devices coupled with mass spectrometry.

It would appear that the days of categorizing capillary and microchip electrophoresis as narrow endeavors with limited impact are long gone. The confluence of chemistry, biology, and microengineering undoubtedly will continue to produce new tools for scientific discovery, as well as for forensic applications and clinical diagnostics. These latter applications are poised for a technology revolution that will paradigm shift their respective fields. Microdevices that accept and analyze the components of whole blood—ions, proteins, nucleic acids—using integrated sample preparation domains fluidically interfaced with the analytic process are coming to fruition and will soon become available. Moreover, microfluidics offers the unique capability to control and manipulate (sub)nanoliter volumes of liquids in unique, precise, and reproducible ways that were previously unimaginable in capillary systems. This fact, together with innumerable new developments and insight on cell manipulation and analysis, and recent progress in (inexpensive) polymer microfabrication combine to create exciting opportunities for future analytical microsystems that can be applied as disposable diagnostic tools for site-of-analysis testing. It is our hope that readers will find this book as helpful as the last two editions have been. This work is an outstanding contribution to the development of increasingly powerful analytical tools that will continue to have a positive impact on science and society in the years ahead.

# Editor

**James P. Landers** is professor of chemistry and professor of mechanical engineering at the University of Virginia, as well as an associate professor of pathology at the University of Virginia Health System.

Professor Landers received a Bachelor of Science degree in biochemistry with a minor in biomedicine from the University of Guelph in Ontario, Canada, in 1984. He earned his Ph.D. in biochemistry from the same department in 1988. After a one-year postdoctoral fellowship at the Banting Institute at the University of Toronto School of Medicine, he was awarded a Canadian Medical Research Council Fellowship to study cancer biology and diagnostics under Dr. Thomas Spelsberg, a breast cancer biochemist at the Mayo Clinic. He launched and directed Mayo Clinic's Clinical Capillary Electrophoresis Facility in the Department of Laboratory Medicine and Pathology developing clinical assays based on capillary electrophoretic technology—some are still on-board at Mayo today. Beginning as an assistant professor of analytical chemistry at the University of Pittsburgh in 1997, he forayed into analytical microfluidic systems with the goal of developing the next-generation molecular diagnostics platform. These efforts were bolstered by a move to the University of Virginia, where access to a dedicated class-100 cleanroom for microchip fabrication allowed his group to rapidly prototype microdevices for separations, DNA purification, and DNA amplification. In addition to editing the first two editions of this book, he has authored more than 175 papers and 25 book chapters on receptor biochemistry, capillary electrophoretic method development, microchip fabrication, and integrated microfluidic systems for application in the clinical and forensic arenas.

## 1.1 INTRODUCTION

While the term “electrophoresis” was coined in 1909 by Michaelis,<sup>1</sup> it was the pioneering experiments of Tiselius in 1937<sup>2</sup> that first showed the separation of serum proteins—albumin, and  $\alpha$ -,  $\beta$ -, and  $\gamma$ -globulins—by “moving boundary electrophoresis”; this provided the first intimation of the potential use of electrophoretic analysis for biologically active molecules. However, this approach to electrophoresis was limited by the incomplete separation of proteins, the relatively large sample volume needed, and the necessity of relatively low electrical fields due to the convection currents generated by Joule heating, even in the presence of dense sucrose solutions. The historical events that followed in electrophoretic method development were paradigm shifting—for historical detail, the reader is referred to two reviews in the journal *Electrophoresis*, one by Hjertén<sup>3</sup> in the late 1980s and the other by Rilbe<sup>4</sup> in the mid-1990s. The 1940s saw major efforts directed at improving anti-convective media for zone electrophoresis, while paper electrophoresis was shown to be applicable to the analysis of a wide variety of molecules.<sup>5,6</sup> Gels formed from starch<sup>7</sup> and, later, agarose<sup>8,9</sup> were developed for the analysis of peptides, proteins, and oligonucleotides. In the 1950s, Kolin<sup>10</sup> attempted isoelectric focusing (IEF), but the absence of “ampholytes” led to short pH gradients that had poor stability over time. It was in this period that the pioneering work of Hjertén<sup>3</sup> laid the groundwork for the capillary electrophoresis (CE) analysis of diverse analytes, ranging from small molecules (inorganic ions, nucleotides) to proteins and viruses. Much of this work was conducted with a functional CE-like instrument, albeit with 3 mm tubes that Hjertén constructed as early as 1959 (see Figure 1.1).

It was not until the late 1960s that Vesterberg<sup>11</sup> synthesized ampholines to create stable pH gradients that allowed for effective IEF to be accomplished and take its place among the routine molecular tools for biochemical and biomedical analysis. The functionality and acceptance of starch gels was followed by the introduction of acrylamide as a sieving matrix in 1959 where, for the first time, control over pore size and stability was possible.<sup>12</sup> Ornstein<sup>13</sup> and Davis<sup>14</sup> independently introduced disc gel electrophoresis in 1964, which was followed by the introduction of sodium dodecyl sulfate (SDS) as a denaturing agent for protein separation in 1969. Building on 30 years of development, the 1970s bought the concept of stacking gel together with the use of SDS for the separation of the components in T4 phage,<sup>15</sup> which laid the groundwork for the seminal work by two-dimensional electrophoresis [combination of IEF separation followed by polyacrylamide gel electrophoresis (PAGE)] that was described by Dale and Latner<sup>16</sup> and Macko and Stegemann.<sup>17</sup> Stegemann introduced IEF in polyacrylamide gels followed by SDS-PAGE,<sup>18</sup> which was developed

**FIGURE 1.1** Photograph of the CE system designed by Hjertén. On the left are stacked the high voltage supply and electronic components for the detector, topped off by a strip-chart recorder. In the center is the carriage with the capillary and the electrode vessels above the immersion bath, while the cooling reservoir flanks it on the right.

into a fine art by O'Farrell<sup>19</sup> in 1975. Interestingly, around this time, Virtanen<sup>20</sup> followed the work of Hjertén a decade earlier with the use of smaller internal diameter (0.2 mm) tubes, which eliminated convection problems and simplified instrumental design. In numerous ways, all of this work seeded the later advances that included development of sequencing gels in 1977, agarose gels a short time later, and then pulsed-field gel electrophoresis in 1983. It was in the very same year (1983) that Jorgenson and Lukacs<sup>21</sup> defined electrophoresis in micron-scale capillaries.

The concurrent development of advanced separation technology in the form of high-performance liquid chromatography (HPLC) made speed, high resolution, quantitative results, and automation a reality. This platform saw widespread adoption in industrial and clinical laboratory settings, filling the need where electrophoresis could not to meet the demands of quantitative analysis, preparative isolation, or automation. These advantages proved HPLC effective for the analysis of small molecules, oligonucleotides, peptides, and small proteins, but with the disadvantage that larger analytes (e.g., structural proteins) were problematic. Moreover, more stringent regulations on waste resulted in increased cost for waste disposal, leading to organic solvent waste generated by HPLC considered as a major contributor to operating costs. Micro LC, in both open-tubular and packed formats,<sup>22–24</sup> were shown to have promise,<sup>25</sup> but technical difficulties in the design of high-pressure, low-volume solvent delivery systems and operational challenges in handling the severe pressure drop in packed column chromatography deterred commercial development.

It was with this historical backdrop of increasing demands for high resolution, quantitative precision of biopharmaceuticals, and control of waste management costs that CE arrived on the analytical scene. The pioneering work of Hjertén<sup>3</sup> and Virtanen<sup>20</sup> preceded the demonstration that CE was shown to be a viable analytical technique by Mikkers et al.<sup>26</sup> and Jorgenson and Lukacs.<sup>21</sup> CE demonstrated the potential for producing high-resolution separations of biopolymers, as well as smaller pharmaceutical agents, and used miniscule amounts of both sample and reagents. In 1989, a decade after Mikkers et al.<sup>26</sup> carried out their defining CE experiments, CE was ready for primetime

**FIGURE 1.2** Growth of the CE and microchip literature. The ISI Web of Science database was searched with the subject keywords of “CE” on a year-by-year basis beginning in 1983 through March 2007 and plotted as a function of publication year.

as a result of improvements in the sensitivity of detectors, advances in automation technology, and, most importantly, the widespread availability of high-quality narrow-bore capillary silica tubing. Beckman Instruments introduced the scientific community to CE with the commercial launch of the first fully automated CE instrument in the form of the *P/ACE*<sup>TM</sup> 2000. The result of sound engineering is that some of these models can still be found in labs today (ours being one of them).

Within a few years, research groups throughout the world had expanded the horizons of CE. Hjertén,<sup>3</sup> Mazzeo and Krull,<sup>27</sup> and Wehr<sup>28</sup> were early in the pursuit of improvements in capillary coatings to prevent analyte adsorption to the capillary surface while techniques, for casting polyacrylamide and agarose gels in capillaries were developed and applied to protein<sup>29,30</sup> and DNA<sup>31–33</sup> separations. These have now evolved into more sophisticated coatings involving phospholipids,<sup>34</sup> lipoproteins,<sup>35</sup> cholesterol,<sup>36</sup> and polyelectrolytes.<sup>37</sup> Terabe et al.<sup>38,39</sup> pioneered micellar electrokinetic chromatography (MEKC), with the use of micellar solutions to separate neutral and charged species, while IEF was adapted to the capillary format,<sup>40–42</sup> using chemical mobilization methods to move the focused protein zones past the detector. In addition Zhu et al.,<sup>43</sup> Bruin et al.,<sup>44,45</sup> and Ganzler et al.,<sup>46</sup> developed non-gel sieving matrices for size-based separation of biopolymers, which began a flurry of activity defining linear polymers for DNA and proteins analysis by CE.<sup>47</sup> Theoretical studies have led to understanding the problems associated with the technique, and the methods required to overcome them. Productization of more effective and sophisticated instrumentation has made room for the development of new detectors<sup>48–50</sup> and mass spectrometer interfaces.<sup>51</sup> Many of these topics are covered in detail in the chapters that follow in this book.

Beginning with four publications in 1983, growth of the CE literature was exponential for roughly the first decade (not surprising with such small numbers), linearized from 1993 to 1998, and then slowed (but did not plateau) over the next 5 years (1999–2003) (Figure 1.2). While these types of plots often seem superfluous, the point is this—despite the slowing of growth in the CE field around the turn of the century, interest in CE has not stalled. In fact, there has been modest resurgence since then. Method development still continues, but the application focus has intensified in the last half decade. Diversity is evident by application of the technique to a wide spectrum of analyses in a variety of disciplines ranging from the detection and quantitation of priority pollutants in environmental samples, to the analysis of the components of a single cell, the screening for abnormal proteins or DNA fragments indicative of disease or specific typing an individual.

Consistent with the theme of the handbook, this chapter has a practice-oriented focus, with the presentation of select theoretical aspects of CE limited to the basic principles needed for understanding how molecules separate in an applied voltage, and the factors that affect the separation. Appendix 2 provides the reader with a guide to troubleshooting typical problems that may be encountered with CE.

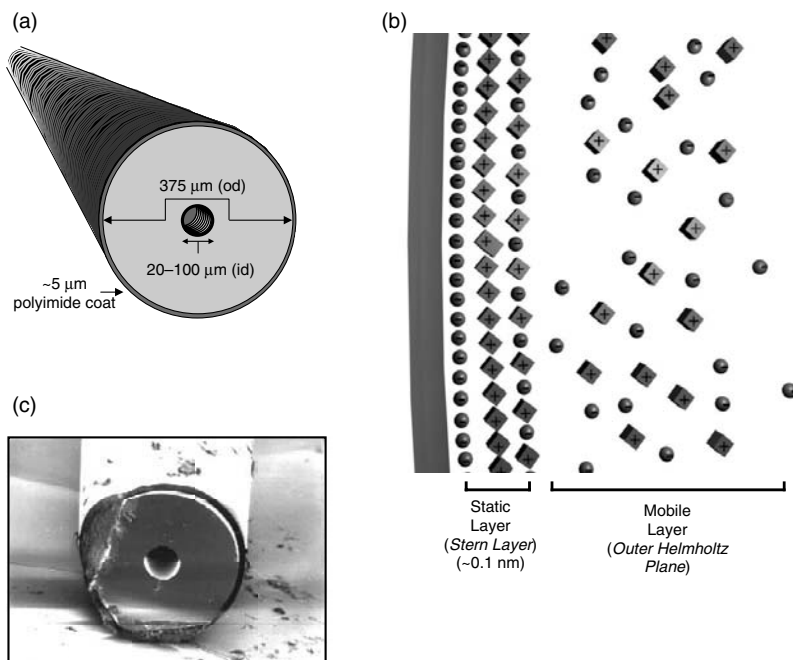

## 1.2 CAPILLARY ELECTROPHORESIS

### 1.2.1 WHY ELECTROPHORESIS IN A CAPILLARY?

As introduced in Section 1.1, electrophoresis has been one of the most widely utilized techniques for the separation and analysis of ionic substances. Almost all modes of electrophoresis utilize some form of solid support to prevent convectational distortion of the analyte bands. This has been in the form of paper (high voltage separation of amino acids and other small organic molecules) or, more commonly, polyacrylamide or agarose gels, which have been used extensively for both protein and deoxyribonucleic acid/ribonucleic acid (DNA/RNA) analysis. In light of this, there is little doubt that gel electrophoresis has been an invaluable analytical tool for modern biochemical research. However, despite the ability to resolve the components of complex systems, traditional forms of electrophoresis suffer from several disadvantages, most of which scientists had endured for lack of an effective alternative. Perhaps the most obvious disadvantage is the speed of separation, which is ultimately limited by Joule heating (the heating of a conducting medium as current flows through it). The relatively poor dissipation of Joule heat in slab systems limits their use to low potential electric fields. Moreover, from a methodological perspective, the entire process is a series of cumbersome, time-consuming tasks, from the casting of the gel, preparation and loading of samples, electrophoretic resolution of the ionic/molecular species, to the final stage where the gel is stained, and the results obtained. Other problems include poor reproducibility, particularly with two-dimensional analysis, analyte-dependent differences in staining, which makes quantitative accuracy difficult to achieve (e.g., glycosylated proteins have different dye-binding properties than their unglycosylated counterparts), and the cumbersome methodology involved in modern gel electrophoresis that makes it virtually impossible for the entire electrophoretic procedure to be automated.

The use of capillaries as an electromigration channel for separation of a diverse array of analytes, not only presents a unique approach to separation, but is also associated with several advantages over the standard solid supports used during the evolution of electrophoresis. In particular, the physical characteristics of narrow-bore capillaries make them ideal for electrophoresis. Fused-silica capillaries employed in CE typically have an internal diameter (i.d.) of 20–100  $\mu\text{m}$  (375  $\mu\text{m}$  outside diameter, o.d.), lengths of 20–100 cm, and are externally coated with a polymeric substance, polyimide, which imparts tremendous flexibility to a capillary that would otherwise be very fragile (Figure 1.3). The high surface-to-volume ratio of capillaries with these dimensions allows for very efficient dissipation of Joule heat generated from large applied fields. This is illustrated in Table 1.1, which compares the surface-to-volume ratio of a standard analytical slab gel system with standard capillaries used in CE. From this table, it is clear why the slab gel is limited to fields in the range of  $\approx 15\text{--}40$  V/cm whereas up to 800 V/cm can be applied to a capillary containing the same type of gel matrix shown early on by Dovichi and coworkers.<sup>52</sup> As a result of this ability to dissipate heat, electrophoretic separations can easily be performed at up to 30,000 V with the external capillary environmental thermostatted at ambient temperature.

In addition to the ability to dissipate Joule heat efficiently, the use of capillaries for electrophoresis is associated with many advantages. With typical electrophoresis capillaries, the small dimensions yield total column volumes in the microliter range, thus requiring the use of only milliliter quantities of buffer. Moreover, adhering to the chromatographic rule of thumb restricting sample volume to 1–5% of the total capillary volume, sample volumes introduced into the capillary are in the nanoliter range (as low as 0.2 nL). As a result, as little as a 5  $\mu\text{L}$  of sample will suffice for repetitive analysis on some commercial instruments. Considering the small reagent (buffer) and sample requirements, as well as the rapid analysis times associated with the application of high fields (30,000 V), it is clear why CE has been applied to, and has provided the solution to, a diverse number of analytical problems.

**FIGURE 1.3** Diagram of the capillary, its inner surface and the ionic layer. (a) Shows an end view of a capillary with a 375  $\mu\text{m}$  o.d. and a 50  $\mu\text{m}$  i.d. (b) An illustration of the double-ionic layer formed in bare silica capillaries critical in generating endosmotic flow. (c) A scanning electron photomicrograph of a 375  $\mu\text{m}$  (o.d.)  $\times$  75  $\mu\text{m}$  (i.d.) capillary enlarged 170 times. The polyimide coating which grants the capillary flexibility is visible and the “etch” used to break the capillary is clearly seen on the left.

**TABLE 1.1**

**A Comparison of Surface-to-Volume Ratios for an Analytical Slab Gel and a 57 cm Capillary Having a Varied Internal Diameter**

	Surface Area ( $\text{mm}^2$ )	Volume ( $\mu\text{L}$ )	Surface-to-Volume Ratio
Slab gel ( $14 \times 11.5 \times 0.15$ cm)	32,200	24,150	1.3
20 mm i.d. capillary	35.81	0.179	200
50 mm i.d. capillary	89.53	1.119	80
75 mm i.d. capillary	134.3	2.518	53
100 mm i.d. capillary	179.1	4.477	40
200 mm i.d. capillary	258.1	17.907	20

### 1.2.2 THE FAMILY OF CE MODES

In much the same way that standard gel electrophoretic techniques diversified, so did CE. This has resulted in a family of specialized modes that collectively constitute “CE.” The main modes of CE that have been developed and are presently being exploited include capillary zone electrophoresis (CZE), MEKC, capillary electrokinetic chromatography capillary (CEC), capillary isoelectric focusing (CIEF), capillary gel electrophoresis (CGE), and capillary isotachopheresis (CITP). Over the last decade or so, this latter mode has been primarily used as an on-capillary preconcentration technique.

**TABLE 1.2**  
**Modes Used for Analysis of Various Classes of Analytes**

CZE	MEKC	CEC	CIEF	CGE
Ions	Small molecules	Small molecules	Peptides	Nucleic acids
Small molecules	Peptides	Peptides	Proteins	
Peptides		Proteins		
Proteins		Carbohydrates		
Carbohydrates				

CZE is the most universal of the techniques, having been shown to be useful for the separation of a diverse array of analytes varying in size and character. Although a brief description of CZE is given in this chapter, various aspects of the technique will be discussed in a number of chapters to follow in this handbook. The other CE modes are covered exclusively, and in detail, in separate chapters dedicated specifically to the theoretical and practical aspects of those modes, along with examples illustrating applications amenable to that particular mode. Table 1.2 provides a reference table categorizing the modes used for the analysis of various classes of analytes.

### 1.2.3 CAPILLARY ZONE ELECTROPHORESIS

Capillary zone electrophoresis is not only the simplest form of CE, but also the most commonly utilized. Discussion of this mode permits the presentation of a generic design for the instrumentation for CE. The addition of specialized reagents to the separation buffer readily allows the same instrumentation to be used with the other modes mentioned in the previous section: addition of surfactants with MEKC, ampholines for CIEF and a sieving matrix (linear polymers, entangled matrices) for CGE. The discussion on CZE in the following subsections allows for analysis of some of the basic principles governing analyte separation by this technique.

#### 1.2.3.1 Instrumentation and CE Analysis

A diagrammatic representation of a CE instrument is presented in Figure 1.4. The basic components include a high voltage power supply (0–30 kV; possibly 60 kV if you are in Jorgenson's lab), a polyimide-coated capillary with an internal diameter  $\leq 200 \mu\text{m}$ , two buffer reservoirs that can accommodate both the capillary and the electrodes connected to the power supply, and a detector. As will be discussed later in this chapter, thermostating of the capillary is critical to efficient and reproducible separations and, hence, some type of capillary thermostating system should be used. To perform a capillary zone electrophoretic separation, the capillary is filled with an appropriate separation buffer at the desired pH and sample is introduced at the inlet. Both ends of the capillary and the electrodes from the high voltage power supply are placed into buffer reservoirs and up to 30,000 V applied to the system. The ionic species in the sample plug migrate with an electrophoretic mobility (direction and velocity) determined by their charge and mass, and eventually pass a detector where information is collected and stored by a data acquisition/analysis system.

Electrophoretic mobility ( $\mu$ ) of a charged molecular species can be approximated from the Debye–Hückel–Henry theory

$$\mu = q/6\pi\eta r \quad (1.1)$$

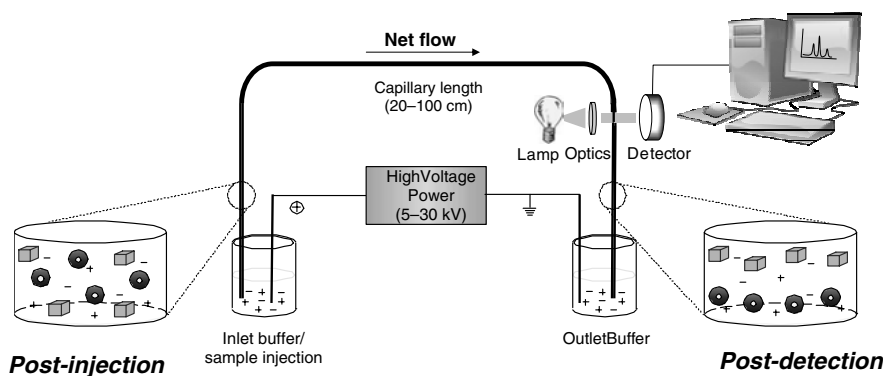

FIGURE 1.4 General schematic of a CE instrument.

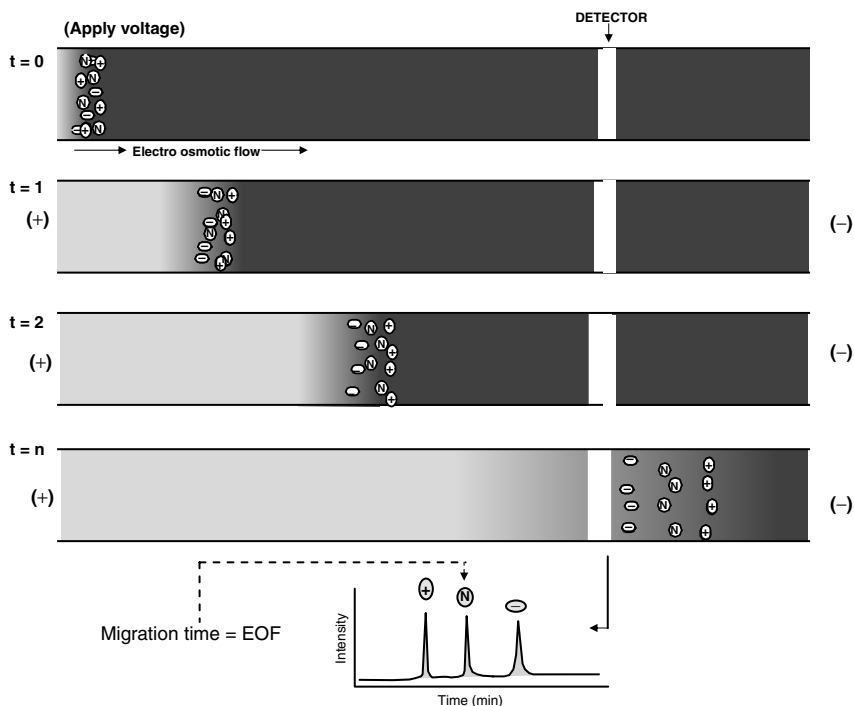

where  $q$  is the charge on the particle,  $\eta$  is the viscosity of the buffer, and  $r$  is the Stokes' radius of the particle. The mass of the particle may be related to the Stokes' radius by  $M = (4/3)\pi r^3 V$ , where  $V$  is the particle specific volume of the solute. Although one might infer the direct proportionality of mass and radius of the particle, empirical data suggest modifications of Equation 1.1 to allow for the nonspherical shape, the counterion effects, and nonideal behavior of proteins and biological molecules.<sup>53</sup>

With CZE, the “normal” polarity is considered to be [inlet—(+), detector—(–) outlet] as shown in Figures 1.4 and 1.5. As electrophoresis ensues, the analytes separate according to their individual electrophoretic mobilities and pass the detector as “analyte zones” (hence, the term capillary zone electrophoresis or CZE). The fact that, under appropriate conditions, all species (net positive, net negative, or neutral) pass the detector indicates that a force other than electrophoretic mobility is involved. If the applied field were the only force acting on the ions, net positively charged (cationic) substances would pass the detector while neutral components would remain static (i.e., at the inlet) and anionic components would be driven away from the detector. It is clear that, if this were the case, CE would be of limited use. Fortunately, there is another force, “electroosmotic flow” (EOF), driving the movement of all components in the capillary towards the detector when under an applied field (and a normal polarity). EOF plays a principle role in many of the modes of CE and most certainly in CZE. This is discussed briefly in the next section.

### 1.2.3.2 Role of EOF in CE Analysis

Electroosmotic flow was first identified in the late 1800s when Helmholtz<sup>54</sup> conducted experiments involving the application of an electrical field to a horizontal glass tube containing an aqueous salt solution. Curious about the ionic character of the inner wall and the movement of ions, he found that the silica imparted a layer of negative charge to the inner surface of the tube, which under an applied electric field, led to the net movement of fluid toward the cathode. More than a century later, this phenomenon still plays the fundamental role in CE analysis. Moreover, the importance of the control of EOF has been realized and has become the focus of several research groups.

As a continuation of the pioneering work of Helmholtz, the basic principles governing EOF have been evaluated extensively. As shown by the expanded region of the inner wall of a capillary in Figure 1.3, the ionized silanol groups (SIO) of the capillary wall attract cationic species from the buffer. Obviously, the buffer pH will determine the fraction of the silanol groups that will be ionized; understanding the amorphous nature of silica and the  $pK_a$  range (4–6) associated with the various types of silanol groups<sup>55</sup> is key. The ionic layer that is formed has a positive charge density that

**FIGURE 1.5** Mobility of charged and uncharged molecules in an applied field.

decreases exponentially as the distance from the wall increases. The double layer formed closest to the surface is termed the “Inner Helmholtz” or Stern” layer and is essentially static. A more diffuse layer formed distal to the Stern Layer is termed the “Outer Helmholtz Plane” (OHP). Under an applied field, cations in the OHP migrate in the direction of the cathode carrying waters of hydration with them. Because of the cohesive nature of the hydrogen bonding of the waters of hydration to the water molecules of the bulk solution, the entire buffer solution is pulled toward the cathode. This EOF or “bulk flow” acts as a pumping mechanism to propel all molecules (cationic, neutral and anionic) toward the detector with separation ultimately being determined by differences in the electrophoretic migration of the individual analytes. The importance of EOF in capillary electrophoretic analysis is highlighted in Figure 1.5. The buffer entering the capillary inlet behind the sample plug is represented by a “graded shading” for illustrative purposes, and is identical to the buffer preceding the sample. As electrophoretic migration occurs, all analytes are swept towards the detector by bulk flow. Provided that the EOF is adequate but not too strong, the respective electrophoretic mobilities of each of the analytes leads to the formation of discrete zones by the time they pass the detector. If the EOF is low, diffusion of the analyte zones could result in substantial band broadening and, under conditions of very low EOF, some of the analytes may not reach the detector within a reasonable analysis time.

As previously mentioned, the EOF is pH dependent and can be quite strong. For example, in 20 mM borate buffer at pH 9.0, the EOF is  $\approx 2$  mm/s, which translates to a flow of  $\approx 4$  nL/s in a 50  $\mu\text{m}$  i.d. capillary. The inclusion of EOF into the calculation of velocity is essential and results in

$$v_i = \mu_{\text{app}}E = (\mu_{\text{ep}}\mu_{\text{eo}})E \quad (1.2)$$

where  $\mu_{\text{ep}}$  is the mobility due to the applied electric potential and  $\mu_{\text{eo}}$  is the mobility due to EOF. From a practical perspective, EOF acts as an electric field-driven pump that may be considered analogous to the mechanical pump used in HPLC. While the simplicity of this pumping system has

obvious advantages over mechanical pumps (e.g., no moving parts, no mechanical wear) one does not have the same degree of control associated with mechanical systems.

It is important to have some idea of the magnitude of EOF under the conditions used for a given separation for two reasons. First, under conditions where EOF is very fast, components of the mixture may not have adequate “on-capillary time” for separation to occur. Second, it is useful to know where neutral compounds migrate in the obtained electropherogram. Knowing this, information about the charge character of the sample components is obtained on the basis of whether they migrate faster (cationic) or slower (anionic) than EOF. The EOF marker is also useful as an internal standard for calculating “relative” migration times for the components of the sample from the apparent migration times. Some compounds that adequately serve as neutral markers include dimethyl formamide (DMF), dimethyl sulfoxide (DMSO), and mesityl oxide, although, because of rapid volatilization, the latter compound is of limited use with samples kept at ambient temperature. Typically, a “marker” is a 0.1% solution in water; a 1-s hydrostatic (0.5 psi) sample injection of the 0.1% solution provides an adequate signal with ultraviolet (UV) detection at either 214 or 200 nm. Fluorescent markers (e.g., BODIPY) can serve the same purpose for LIF detection.

These markers are not of use with low pH separations where most analytes migrate faster than the EOF, which is extremely low. If a peak is still required as an internal standard for correction of migration time, any compound with a fast cathodic electrophoretic mobility will suffice as a “frontal marker.” We have found that a synthetic peptide containing seven lysine residues and a single tryptophan (K<sub>3</sub>WK<sub>4</sub>) functions adequately for this purpose at pH 2.5. A frontal marker may also be useful at higher pH (e.g., when the neutral marker comigrates with a species of interest), where cationic species such as normetanephrine can suffice.

It is interesting that, since its inception, the holy grail in CZE has been a mechanism to control EOF. The application of radial field in a manner that controls the magnitude of the “zeta potential” (or the thickness of the double layer) on the capillary wall would, in theory, allow one to simply dial up the desired magnitude of EOF. This mechanism has been illusive for the better part of 15 years, still has not been determined, but clearly still is of interest.<sup>56</sup>

### 1.2.3.3 A Description of the Electrophoretic Process

In the early 1980s, Jorgenson and Lukacs<sup>21</sup> discussed the theory and basis for electrophoretic separations in capillaries. The following brief discussion develops, albeit at a basic level, the theoretical concepts describing the movement of charged molecules in a buffer-filled capillary under an applied electrical field and the shape of the zone during the electrophoretic process. The separation process is discussed in terms of resolution (how adequately two components are separated) and efficiency (how long the separation takes). Finally, we discuss factors that affect the resolution. For more detailed evaluation of these processes, the reader is referred to several excellent discussions on this subject.<sup>57–59</sup>

#### 1.2.3.3.1 Mobility of an Analyte in a Capillary

A charged particle in solution will become mobile when placed in an electric field. The velocity,  $v_i$ , acquired by the solute under the influence of the applied voltage  $H$ , is the product of  $\mu_{\text{app}}$ , the apparent solute mobility, and the applied field  $E$  ( $E = H/L$ , where  $L$  is the length of the field)<sup>21</sup>

$$v_i = \mu_{\text{app}}E \quad (1.3)$$

$\mu_{\text{app}}$  is a property of the particle, and proportional to its charge, and inversely proportional to the frictional forces acting upon it in solution. The electrical force can be given by

$$F_{e1} = qE \quad (1.4)$$

and the frictional force on a spherical ion is

$$F_{fr} = -6\pi\eta r v_i. \quad (1.5)$$

During the electrophoresis, a steady state is attained, where the two forces are equal, but in opposite directions:

$$qE_r = -6\pi\eta r v_i \quad (1.6)$$

Solving for velocity (or  $E$ ) and substituting Equation 1.6 into Equation 1.3 and rearranging for  $\mu$ , we obtain

$$\mu_{app} = q/6\pi\eta r \quad (1.7)$$

From this equation, it is evident that the mobility of the analyte is a property of both the charge and size; a small, highly charged particle will have a high mobility, while a large, minimally charged species will have a low mobility. Refer to Appendix 1 for example on calculating mobility.

#### 1.2.3.3.2 Shape of the Analyte Zone

Under the initial conditions of electrophoresis, the boundary between the buffer solution and the solute mixture forms a zone of infinitesimal thickness at right angles to the direction of applied current and migration. As migration proceeds, this initially sharp boundary will undergo a progressive deterioration in shape. The most important influence on this process is diffusion, as the initial conditions impart a severe concentration gradient across the zonal boundary. By applying Fick's second law of diffusion, Weber<sup>57</sup> has shown that the variation of solute concentration in the direction of migration is given by the equation

$$C_{x,t} = \frac{k}{2(D_i\pi t)^{1/2}} e^{-\frac{(x-v_it)^2}{4D_it}} \quad (1.8)$$

where  $C$  is the solute concentration at a distance  $x$  from the initial position after time  $t$ ,  $v_i$  is the electrophoretic velocity of the solute,  $D_i$  is the diffusion coefficient of the solute, and  $k$  is a constant. By integration, initially with the boundary conditions at  $t = 0$ , at distant  $x = \infty$ ,  $C = 0$ , and a second time with  $t = 0$ ,  $x = 0$  and  $dC/dx = 0$ , we obtain a mathematical description of the concentration profile. As the solute migrates a distance  $x$  from the origin after time  $t$ , the zone may be described by a Gaussian curve.

The characteristics of a Gaussian profile describe the peak maximum and the peak width. The maximum is dependent on initial concentration of solute. The width depends on the length of time from initial conditions (i.e., application of sample in to the system) and the diffusion constant,  $D_i$ . The width may be given by the distance between the inflection points, in our case,  $2/(2D_it)^{1/2}$ . From analogy with probability calculations, the width of a Gaussian curve is termed the standard deviation ( $\sigma$ )

$$\sigma = (2D_it)^{1/2} \quad (1.9)$$

and the square of standard deviation is called the variance

$$\sigma^2 = 2D_it. \quad (1.10)$$

Remembering that

$$t = L_d/v_i = L_d L_t / \mu_{\text{app}} V = L_d / \mu_{\text{app}} E, \quad (1.11)$$

where  $L_d$  is the distance from the origin to the detector, and  $L_t$  is the total length of the capillary (i.e., the length of the applied electric field), we may substitute into Equation 1.10, to obtain

$$\sigma^2 = 2D_i L_d / (\mu_{\text{app}} E). \quad (1.12)$$

One should remember that the discussion to this point has only dealt with diffusion as a dispersive phenomenon affecting peak shape. Other factors that contribute to what is observed on the electropherogram as band broadening, the practical result of variance, will be discussed later.

#### 1.2.3.3.3 Resolution and Efficiency

The simplest way to characterize the separation of two components is to divide the difference in migration distance by the average peak width to obtain resolution (Res)

$$\text{Res} = 2(x_{i2} - x_{i1}) / (w_1 + w_2) \quad (1.13)$$

where  $x_i$  is the migration distance of the analyte  $i$ , and the subscript 2 denotes the slower moving component, and  $w$  is the width of the peak at the baseline.<sup>57</sup> We can readily see that the position of a peak,  $x_i$ , is determined by the electrophoretic mobility. The peak width,  $w$ , is determined by diffusion and other dispersive phenomena. For two neighboring peaks,  $w_1 = w_2$ , and

$$\text{Res} = (x_{i2} - x_{i1}) / w_2. \quad (1.14)$$

From the equation describing a Gaussian curve, the two peaks touch at baseline when  $\Delta x_i = x_2 = 4\sigma$ , and Res = 1, or

$$\text{Res} = \Delta x_i / 4\sigma. \quad (1.15)$$

Remembering that distance is equal to velocity multiplied by time ( $x_i = v_i t$ ) and substituting for  $\sigma$  from Equation 1.9 into Equation 1.15, we obtain

$$\text{Res} = (\Delta \mu_{\text{app}} E) t / 4(2D_{i,\text{avg}} t)^{1/2} \quad (1.16)$$

where  $\Delta \mu_{\text{app}}$  is the difference in apparent electrophoretic mobility of the two solutes and  $D_{i,\text{avg}}$  is the average diffusion of the two solutes.

To obtain a measure of efficiency for the process, we use probability theory.<sup>58</sup> For a random walk process of length  $L$ , made of  $n$  steps, the variance is given by

$$\sigma = l(n)^{1/2} \quad (1.17)$$

where  $l$  is the length of each step. If each step is independent of any other step, each contributes to the total variance of the process<sup>59</sup>

$$\sigma_{\text{tot}}^2 = \sum \sigma_i^2. \quad (1.18)$$

Substituting from Equation 1.17 and rearranging

$$1/n = L^2 / \sigma_{\text{tot}}^2 = N. \quad (1.19)$$

The number of steps in the random process,  $n$ , is inversely related to the number of theoretical plates,  $N$ , a measure of efficiency for the process.

We may substitute for  $L$  and  $\sigma$  in Equation 1.19 to express

$$N = (\mu_{\text{avg}}E)^2 t^2 / (2D_i t) \quad (1.20)$$

where  $\mu_{\text{avg}}$  is the average mobility of the two solutes. By comparing the expression for Res (Equation 1.16) with the definition of  $N$  (Equation 1.20), we obtain an expression relating resolution to the number of theoretical plates

$$\text{Res} = (1/4)(\Delta\mu_{\text{app}}/\mu_{\text{avg}})N^{1/2}. \quad (1.21)$$

The utility of Equation 1.21 is that it permits one to independently assess the two factors that affect resolution, selectivity, and efficiency. The selectivity is reflected in the mobility of the analyte(s), while the efficiency of the separation process is indicated by  $N$ .

If Res = 1, then

$$N = 16/(\Delta\mu_{\text{app}}/\mu_{\text{avg}})^2. \quad (1.22)$$

Another expression for  $N$  is derived from Equation 1.19, using the width at half-height of a Gaussian peak

$$N = 5.54(L/w_{1/2})^2, \quad (1.23)$$

where  $5.54 = 8 \ln 2$ , and  $w_{1/2}$  is the peak width at half-height.<sup>60</sup>

At this point, it is important to note that it is, in fact, misleading to discuss theoretical plates in electrophoresis. The concept is a carry-over from chromatographic theory, where a true partition equilibrium between two phases is the physical basis of separation. In electrophoresis, separation of the components of a mixture is determined by their relative mobilities in the applied electric field, which is a function of their charge, mass and shape. The theoretical plate is merely a convenient concept to describe the analyte peak shape, and to assess the factors that affect separation. Refer to Appendix 1 for examples on calculating resolution and efficiency.

#### 1.2.3.3.4 Source of Variance

While  $N$  is a useful concept to compare the efficiency of separation among columns, or between laboratories, it is difficult to use to assess the factors that affect that efficiency. This is due to the fact that it refers to the behavior of a single component during the separation process, and is unsuited to describing the separation of two components or the resolving power of a capillary. A more useful parameter is the height equivalent of a theoretical plate (HETP).<sup>58</sup>

$$\text{HETP} = L/N = \sigma_{\text{tot}}^2/L. \quad (1.24)$$

HETP might be thought of as the fraction of the capillary occupied by the analyte. It is more practical to measure HETP as an index of separation efficiency, rather than  $N$ , as the individual components that contribute to HETP may be individually evaluated and combined to determine an overall value. The variance of multiple dispersive phenomena on the analyte may be summed:

$$\sigma_{\text{tot}}^2 = \sigma_{\text{diff}}^2 + \sigma_T^2 + \sigma_{\text{int}}^2 + \sigma_{\text{wall}}^2. \quad (1.25)$$

A consideration of all the factors influencing  $\sigma_{\text{tot}}^2$  should include not only diffusion, but also differences in mobility or diffusion generated by Joule heating, the reality that the sample is not introduced

as a thin disk but as a plug of finite dimensions, and interaction of analytes with the capillary wall. Each of these factors will be addressed separately in a simplistic manner. Theoretical derivation will be given only to emphasize the importance of various parameters, and how they contribute to the overall result. References shall direct those desiring more information to the appropriate literature.

Two studies have addressed the variance due to a variety of sources. Huang et al.<sup>61</sup> investigated small molecules; Jones et al.,<sup>62</sup> studied proteins as well as amino acids and a neutral marker. The two studies demonstrate that the band broadening observed in CE is in excess over calculated values of diffusion and analyte interaction. Huang et al.<sup>61</sup> and Jones et al.<sup>62</sup> attribute the excess variance to sample introductory practices.

*1.2.3.3.4.1 Variance Caused by Temperature* Temperature control is an issue, because it may be effected by the efficiency with which the capillary is thermostatted, or by choice of buffer ionic species or ionic strength. Thus, from a practical point of view, we discuss the variance caused by temperature to impress upon the practitioner the importance of controlling temperature in obtaining reproducible electropherograms.

Current passing through a conducting solution generates heat. A sample way of looking at the problem is to compare the equivalent expressions for the applied potential,  $H$ , and heat generation,  $W$

$$H = i/\kappa\pi r^2 \quad (1.26)$$

$$W = i^2/\kappa(\pi r^2)^2 \quad (1.27)$$

where  $i$  is the current through the electrolyte solution,  $\pi r^2$  the cross-sectional area of the capillary, and  $\kappa$  is the specific conductance of the buffer. By combining Equations 1.26 and 1.27, to take the ratio we obtain

$$H/W = (i/\kappa\pi r^2)(\kappa(\pi r^2)^2/i^2) = \pi r^2/I \quad (1.28)$$

From Equation 1.28, it can be readily seen that the reduction of heat production can be achieved by reducing the current density in the capillary. This may be accomplished by increasing the cross-sectional area of the capillary or by reducing the current. The latter is preferred, since increasing the diameter of the capillary results in a reduction of the surface-to-volume ratio, and leads to less efficient heat dissipation (see Table 1.1). The choices to reduce the system current lie in carrying out the separation at a lower voltage, or reducing the ionic strength of the separation buffer.

To develop the quantitative expression for thermal heating, we need to describe the electrophoretic front, and its behavior under a thermal gradient. According to the Poiseuille equation, which describes the parabolic flow due to pressure,

$$v_z = \Delta P r^2 / 8L\eta. \quad (1.29)$$

Joule heating of the electrolyte solution creates a similar flow profile, the equivalent expression being

$$v_z = v(1 + E^2 \Lambda C_b B r^2 / 4k_b T^2)[1 - (r_x/r)^2] \quad (1.30)$$

where  $E^2 \Lambda$  is the rate of heat generation per unit volume,  $C_b$  is the buffer concentration,  $k_b$  is the thermal conductivity of the electrolyte solution.  $\Lambda$  is the equivalent conductance of the electrolyte

solution,  $T$  is the absolute temperature,  $r_x$  is the radial position (which varies from 0 at the center of the capillary to  $r$  at the capillary wall), and  $B$  is a buffer-related viscosity constant.<sup>63</sup> The variance caused by dispersion in a parabolic velocity profile is given by

$$\sigma_T^2 = 2D_i t + \left( r^6 E^4 C_b^2 B^2 \Lambda^2 t \right) / \left[ 24D_i \left( 8k_b T^2 - E^2 \Lambda C_b B r^2 \right)^2 \right]. \quad (1.31)$$

For most capillary applications, where radius is small (25–50  $\mu\text{m}$ ), and  $E$  is  $kV$ ,  $E^2 \Lambda C_b B r^2$  is  $\ll 8k_b T^2$  and the second term reduces to

$$\sigma_T^2 = r^6 E^4 C_b^2 B^2 \Lambda^2 t / 1536 D_i k_b^2 T^4. \quad (1.32)$$

The strong dependence of  $\sigma_T^2$  on the radial dimension of the capillary ( $r^6$ ) and the field strength ( $E^4$ ) demonstrate the importance of performing high voltage electrophoretic separations in narrow-bore capillaries. It also highlights the necessity of obtaining efficient capillary cooling, to prevent thermal effects from not only affecting sample liability, but also to avoid affecting solute mobility. For small molecules with relatively larger diffusion constants (on the order of  $10^{-5}$   $\text{cm}^2/\text{s}$ ) Grushka et al.<sup>63</sup> have calculated a maximum radius of 65  $\mu\text{m}$  with a 0.1 M buffer solution at 30 kV, and 130 mm with 10  $\mu\text{M}$  buffer for less than 5% increase in dispersion. With larger molecules, having diffusion constants on the order of  $10^{-6}$   $\text{cm}^2/\text{s}$ , these dimensions were halved. Jones et al.<sup>62</sup> have introduced a novel method to study Joule heating effects and nonideal plug flow contributions to analyte dispersion, with polarity reversal at constant voltage. By recording the variance (band broadening) of the peaks over time and plotting the slope of the obtained line versus applied potential, these authors have developed a measure of nonideal behavior. A comparison of charged analyte behavior with neutral solute variance (which should be unaffected by electrophoretic mobility effects of thermal heating, but affected equally by the temperature-dependent effects on a diffusion and viscosity) allows an estimate of the Joule heating effect. With adequate thermostating, one need not worry about thermal dispersion under normal operating conditions (see Reference 64), but one needs to be aware of how temperature generated within the capillary can affect the separation and resolution of the analytes.

*1.2.3.3.4.2 Variance Caused by Finite Sample Introduction Volume* In the mobility section above, we assume the solute was initially present as a think disk that dispersed into a zone or band. In reality, the sample is introduced into the capillary as a cylindrical plug. Sternberg<sup>60</sup> derived the commonly used equation describing variance due to sample introduction.

$$\sigma_{\text{int}}^2 = l_{\text{int}}^2 / 12 \quad (1.33)$$

where  $l_{\text{int}}$  is the length of the sample introduction plug. This formula assumes that the sample is introduced as a rectangular plug, which is a close approximation for CE. As the plug has a finite volume, it also has measurable length. Huang et al.<sup>61</sup> and Jones et al.<sup>62</sup> have investigated the relative contribution of introduction plug length (by hydrodynamic or electrokinetic methods) to the observed peak width, and concluded that  $l_{\text{int}}/L_d$  of less than 3% does not lead to excessive band broadening. Only at very small plug lengths (<200  $\mu\text{m}$ ) does one observe variance due to diffusion of the sample plug; typical sample introduction plug lengths of 300–6000  $\mu\text{m}$  (0.3–6 mm) obscure this effect. Huang et al.<sup>61</sup> and Jones et al.<sup>62</sup> conclude that sample introduction volume, that is, plug length, is the most significant factor in excessive band broadening observed in CE.

*1.2.3.3.4.3 Variance Caused by Analyte–Wall Interactions* The interactions of analyte and capillary wall, or components within the sample solution are numerous, complex and sample specific. The best approach to understanding the band broadening due to adsorption is the approach of McManigill and Swedberg.<sup>64</sup> The general equation of Giddings<sup>59</sup> may be adapted to include an adsorption term

$$\text{HETP} = l^2/12L + 2D_{i,T}/u + \left[ k' \mu / (1 + k')^2 \right] \left[ r_0^2 / 4D_{i,T} + 2 / k_d \right], \quad (1.34)$$

where  $l$  is the length of the injected plug,  $L$  is the total length of the capillary,  $u$  is the flow rate,  $k'$  the capacity factor,  $r_0$  is the radius of the capillary,  $D_{i,T}$  is the diffusion coefficient in the designated solvent at the specific temperature, and  $k_d$  in the first-order dissociation constant off the surface.

Through carefully designated and executed experiments, a value of for  $k'$  may be determined at differing flow rates, and the effect on plate height calculated. McManigill and Swedberg<sup>64</sup> have shown that the value for  $k'$  is not zero under any conditions, and that a value for  $k'$  as low as 0.001 can affect the shape of the peak, and, consequently, the efficiency of separation.

To obtain estimates of the relative contribution to overall variance, Jones et al.<sup>62</sup> used a voltage interruption/polarity reversal method. Huang et al.<sup>61</sup> attribute part of the excessive peak width observed in their experiments to analyte–wall interaction. One may minimize such interactions by the appropriate choice of buffer pH, ionic strength, or buffer additives (see Section 1.3).

The variance of multiple dispersive phenomena on the analyte may be summed as

$$\sigma_{\text{tot}}^2 = \sigma_{\text{diff}}^2 + \sigma_T^2 + \sigma_{\text{int}}^2 + \sigma_{\text{wall}}^2. \quad (1.35)$$

To enable the reader to visualize the magnitude of the contributions by each of these variances, we include some typical calculations.

For a small molecule,  $D_i = 10^{-5}$  cm<sup>2</sup>/s, time of analysis might be 10 min (600 s), introduction plug of 1.2 nL into a 50 μm by 47 cm capillary, 40 cm to the detector, results in a plug length of 0.6 cm

$$\sigma_{\text{diff}}^2 = 12 \times 10^{-3},$$

$$\sigma_T^2 = \sigma_{\text{diff}}^2 = 12 \times 10^{-3},$$

$$\sigma_{\text{int}}^2 = 3.0 \times 10^{-2},$$

$$\sigma_{\text{tot}}^2(\text{exp. observed}) = 5 \times 10^{-2}.$$

$$\begin{aligned} \sigma_{\text{tot}}^2(\text{calculated}) &= 1.2 \times 10^{-2} + 1.2 \times 10^{-2} + 3.0 \times 10^{-2} + \sigma_{\text{wall}}^2 \\ &= 5.4 \times 10^{-2} \end{aligned}$$

These figures indicate  $\sigma_{\text{int}}^2$  is, by far, the largest contributor to the band broadening with a small, highly diffusible analyte.

For a protein,  $D_i = 10^{-6} \text{ cm}^2/\text{s}$ , time of analysis might be 10 min (600 s), introduction plug of 1.2 nL into a  $50 \mu\text{m}$  by 47 cm capillary, 40 cm to the detector, results in a plug length of 0.6 cm

$$\begin{aligned}\sigma_{\text{diff}}^2 &= 12 \times 10^{-4}, \\ \sigma_{\text{T}}^2 &= \sigma_{\text{diff}}^2 = 12 \times 10^{-4}, \\ \sigma_{\text{int}}^2 &= 3.0 \times 10^{-2}, \\ \sigma_{\text{tot}}^2(\text{exp. observed}) &= 5 \times 10^{-2}. \\ \sigma_{\text{tot}}^2(\text{calculated}) &= 1.2 \times 10^{-3} + 1.2 \times 10^{-3} + 3.0 \times 10^{-2} + \sigma_{\text{wall}}^2 \\ &= 5.0 \times 10^{-2}\end{aligned}$$

The injection plug is the largest contributor to the band broadening observed, but the wall interaction has nearly equal contribution.

### 1.2.3.4 The Capillary

Having the discussed EOF and its dependence on the capillary wall surface, one can understand how the capillary and its inner surface condition can have an impact on the efficiency and reproducibility of CE analyses. Hence, the treatment of the capillary before, during, and following electrophoretic separations is crucial. Microbore capillaries employed in CE can be purchased from a number of companies in either bare silica or coated format. As shown in Figure 1.3, the standard fused-silica capillary typically has an internal diameter of 50–100  $\mu\text{m}$ , although a range of internal and external diameters are commercially available (<1  $\mu\text{m}$ –>1 mm i.d.; 60  $\mu\text{m}$ –>1 mm o.d.) in shapes that are commonly cylindrical, but also rectangular. The following sections describe some pertinent points regarding capillary preparation, conditioning before use, maintenance, and storage respectively.

#### 1.2.3.4.1 Preparation for CE

For use in CE, the capillary is cut to the appropriate length with a ceramic knife, or an ampoule file, so that both ends are square and flat. This is of particular importance with the inlet end of the capillary where sample is to be introduced. Closer to the outlet, a “window” is created through removal of the polyimide coating so that online detection is possible. The window should ideally be approximately 0.3 cm in length (no longer than 1.0 cm) and can easily be made by burning off the polyimide with a flame and wiping the surface with an ethanol-soaked lens tissue. Another, more labor-intensive method is to scrape off the polyimide surface, being careful not to scratch the silica, or break the capillary. Several mechanical devices have been devised to accomplish this task.<sup>65,66</sup> Commercial instruments are available for carrying this out (e.g., Capital Analytical, UK) Caution must be taken when handling the capillary once the window is created since the window area is extremely fragile. It is important to note that with internally coated capillaries, detector windows cannot be created by burning off the polyimide since the heat required will damage the internal coating. Alternatively, dropwise addition of 103°C sulfuric acid<sup>33</sup> or hot concentrated KOH<sup>67</sup> from a burette or glass pipette have been reported to remove the polyimide coating to create a window without damaging the internal coating. We use an adaptation of the hot sulfuric acid method. A drop of concentrated sulfuric acid is placed on the capillary where the window is desired, and the tip of a hot soldering iron is briefly touched to the drop. This readily removes the polyimide coating without overheating the interior surface, and prevent the necessity of heating a larger volume of acid than would otherwise be needed. The excess acid must be washed off the exterior surface, especially if the capillary is to be placed into a cartridge where the acid would damage the cartridge housing.

When the capillary is installed, it is useful to determine the “capillary fill time.” This information will be useful for determining the length of time for each rinse step (NaOH, separation buffer or rinse solution), as well as for diagnosing potential capillary problem, such as partial or complete obstruction. One approach for accomplishing this (with ultraviolet, UV detection) is to pressure rinse the capillary with water, zero the detector, and follow with a rise with 100 mM, NaOH. The time required for a maximum change in absorbance to occur is the “fill time” to the detector. Factoring in the length between the detector and the capillary outlet yields the “capillary fill time.”

Before using new bare fused-silica capillary for analysis, the capillary should be “preconditioned” by rinsing with 5–10 column volumes of 100 mM NaOH followed by 5–10 column volumes of water, before rinsing with 3–5 column volumes of separation buffer. If the capillary is coated, preconditioning should be performed as per the protocols recommended by the manufacturer or as deemed necessary by the surface coating.

#### 1.2.3.4.2 *Conditioning of the Capillary*

When using a newly installed capillary or changing to a new separation buffer, the capillary must be adequately equilibrated with the separation buffer, a process termed “conditioning.” Equilibration is particularly important when a phosphate-containing buffer is involved. For acceptable reproducibility, a phosphate-containing buffer should be equilibrated in the capillary for a minimum of 4 h before use.<sup>68</sup> This process can be slightly accelerated by applying a separation-scale voltage to the system during the equilibration period. When preparing to use a new separation buffer in a capillary that has been equilibrated with a phosphate-containing buffer, extensive washing and equilibration of the capillary is typically required. The capillary should be equilibrated with the desired separation buffer for at least several hours before use and, if possible, conditioned overnight. It is for this reason that “dedication” of capillaries to individual buffer systems may be highly recommended. In this manner, no pre-equilibration time may be required, since the capillary can be stored in the buffer to which it is dedicated. However, users often report reproducibility problem that are suspect of surface chemistry deviation, particularly in the buffer pH range of 4–7. Watzig et al.<sup>69</sup> describe preliminary results using x-ray photoelectron spectroscopy to probe the Si-C landscape of fused-silica surfaces. This led the authors to suggest that, in order to yield capillaries that will provide stable migration times, especially in the pH range 4–7, preconditioned for longer than 1 h is required.

#### 1.2.3.4.3 *Regeneration of the Capillary Surface*

Capillary maintenance plays a critical role in attaining reproducible results with CE. As with any untreated silica surface, ionized silanol groups are ideal for interaction with charged analytes, particularly peptides and proteins in neutral/basic pH buffers. Hence, following each separation, the capillary surface must be “regenerated” or “reconditioned”, that is, cleansed of any wall-adsorbed material. This is accomplished by following each run with a 3–5 column-volume rinse with 100 mM NaOH, followed by flushing with 5–8 column volumes of fresh separation buffer. This, of course, should be optimized for the particular buffer system used. However, the users should heed the results of Watzig and coworkers.<sup>69</sup> Alternative solutions for cleaning the capillary are 100 mM sodium tetraborate, pH 11, or mM trisodium phosphate, particularly for use with phosphate containing buffers.

When using acidic buffers, rinsing with NaOH may be a disadvantage since the drastic changes in pH may induce the requirement for extensive rinsing with the separation buffer for adequate pH re-equilibration of the capillary. Under these conditions, it may be advisable to follow the NaOH trines with a brief rinse with a concentrated separation buffer (10X or more), followed by the normal rinse with the IX separation buffer. Alternatively, depending on the sample, the 10X separation buffer rinse alone may be adequate for regenerating the capillary and, hence, the NaOH rinse may be avoided completely. For peptide separations in phosphate buffer, pH 2.5, 1.0 M phosphoric acid solutions may be used for capillary regeneration. Another good protein cleaning solutions is 1 M HNO<sub>3</sub>.

Occasionally, after extensive use with protein solutions, the capillary will become fouled and will need to be cleaned to remove strongly adsorbed material. This is usually noticed with migration times that are excessive, with peaks distinctly asymmetrical with extensive tailing, or filling times become noticeably longer. A rinse with sodium ethoxide solution (blended from equal volumes of 1 M NaOH and 95% ethanol) for 5 min, followed by extensive (10–20 column volumes) water rinses usually suffices. A partially plugged capillary may be unplugged by filling with sodium ethoxide and allowing the solution to stand for 5 min before flushing with fresh solution, and following with an extensive water rinse before buffer equilibration. It should be noted that the sodium ethoxide will etch a new surface by removing the surface layer of silica, eventually making the capillary brittle. While we have used this procedure in our laboratory, keeping some capillaries in use for up to one year, this solution should NOT be used with coated capillaries, as it will remove the coating.

#### 1.2.3.4.4 Storage

Because of the small dimensions of the capillary, plugging is always a potential problem. This may occur as a result of solvent evaporation at the capillary ends, which leads to salt crystal formation. This may be avoided in several ways. Dedicated capillaries to be stored for a short time (less than a week) should be rinsed with 100 mM NaOH, re-equilibrated with separation buffer and stored with the ends immersed in buffer/distilled water, or capped with silicone rubber stoppers. Optionally, the capillary may also be stored dry using the procedure below. If the capillary is to be stored for longer periods of time (i.e., >1 week), it should be washed with 100 mM NaOH, rinsed thoroughly with distilled water, purged with nitrogen or air (by pressure) and stored dry. If a capillary has been used with a detergent-/surfactant-containing solution, all traces of the additive must be removed before storage. If this is not done, the capillary will require longer than normal re-equilibration time upon reuse owing to the presence of the residual additive.

To place a stored capillary back into service, one should follow the same procedure outlined for a new capillary. If the capillary has been stored dry, we have found it useful to rehydrate the luminal surface with a 5 min rinse of distilled water before rinsing with 100 mM NaOH and re-equilibration with buffer.

Before storing coated capillaries, they should be thoroughly rinsed with the appropriate buffers or solvents. For example, we have found that it is best to rinse hydrophobically coated capillaries with one-column volume 100 mM NaOH, then extensively with water (5–10 column volumes), and finally with methanol (5–10 column volumes), followed by drying and storage. Capillaries used with physical gels should be rinsed, filled with fresh buffer, and stored with both ends tightly capped. Capillary coating for particular CE applications can be of paramount importance because of the affinity of some analytes, particularly proteins, for interaction with the wall. A number of methodologies have been described in the literature for coating the internal surface of the capillary.<sup>70</sup> The pH stability, as well as the effectiveness for preventing adsorption of analyte to the wall (i.e., separation efficiency), varies with the chemical nature of the coating. Some precoated capillaries are commercially-available from several suppliers.

#### 1.2.3.4.5 Basic Aspects of a Typical CE Method

As a means of collating the above information into practical form, the following provides what might be considered to be a rudimentary CE method.

1. **Mount capillary in the instrument playing close attention to alignment with the aperture/detection optics.** Once the new uncoated fused-silica capillary has been conditioned as described above, the capillary is mounted in the instrument and properly equilibrated.
2. **Determine the capillary fill time.** First fill the capillary with some low-absorbing solution (buffer or dH<sub>2</sub>O) and then zero the detector. Using the rinse mode, fill the capillary with a strongly absorbing solution (e.g., 0.1 M NaOH) noting the amount of time to reach

the detector. Knowing the ratio of the effective length (inlet → detector) and the total length (inlet → outlet), calculate the time required to fill the entire capillary.

3. **Conditioning the capillary as described in Section 1.2.3.4.2.**
4. **Make sure capillary is equilibrated.** The capillary should be equilibrated preanalysis with a minimum of a two capillary volume rinse with *unelectrophoresed separation* buffer, that is, a separate vial of separation buffer that has *not been electrophoresed*. This assumes that the capillary is well conditioned and equilibrated if new, or well re-equilibrated if it is not the first run.
5. **Inject sample.** Sample is injected either by hydrostatic pressure or electrokinetically depending on the nature of the analyte and the sample matrix. Ideally, the injection should be followed by a second injection of separation buffer (equivalent of 1–2 s at 0.5 psi) to avoid any loss of sample into the inlet vial during the first few seconds of voltage application. This is particularly important with sample matrices that end to generate significant Joule heat.
6. **Apply voltage to the system.** With most applications, it is recommended that a low voltage is applied for a short period of time (e.g., 1 kV for 1 min) before application of the higher separation voltage. If the desired resolution is not obtained, one may consider examining voltage ramping.
7. **Regenerate the capillary surface.** The capillary should be regenerated with a minimum two capillary volume rinse with regenerating solution before re-equilibration with separation buffer. For neutral to high pH separations, 0.1–1.0 M NaOH is effective while 0.1–0.5 M phosphoric acid (or the acid equivalent of your separation buffer) is adequate for low pH separations. This should be followed with a short (one capillary volume) rinse with distilled water.
8. **Re-equilibrate the capillary surface.** The capillary should be re-equilibrated with at least 8–10 capillary volumes of *unelectrophoresed* separation buffer. If this is not the first run, this can be shortened to 5–6 capillary volumes since the first step in the method (step 4 above) precedes injection with a 2–3 capillary volume rinse with separation buffer. This is also an appropriate end point following the last run since the capillary remains in separation buffer (and not 0.1 M NaOH) overnight.

It should be clear that these are basic guidelines for setting up a CE method. As emphasized throughout this book, no method is universally applicable to all separations. Each method is likely to require the incorporation of idiosyncratic steps specific to the mode, sample, type of capillary, buffer, pH, etc. used.

### 1.3 METHOD DEVELOPMENT\*

As with HPLC, there will be no universal CE conditions that will be appropriate for the analysis of all types of samples/analytes. In fact, it has been shown that one set of conditions is not sufficient for the analysis of one class of proteins, for example, glycoproteins,<sup>71,72</sup> or even variants of the same proteins from different species.<sup>73</sup> One of the first steps in designing a method is to determine, on the basis of the type or “class” of analyte involved, which of the CE modes is best suited to the sample (Table 1.2). Once the appropriate CE mode has been identified, analysis is carried out and separation optimization initiated. Optimal separation of the components of any sample requires a logical approach to sample solubilization and/or dealing with diverse sample matrices as well as identification and utilization of the correct combination of CE operating parameters. Each of these will have distinct effects on the resultant separation and resolution. There is a massive literature on

---

\*Based on information given in the p/ACE 2000 Customer Training Manual. With permission.

CZE method development, not so much in the form of papers that address this per se, but more in the papers that describe a novel separation of a previously unstudied analyte. In these it is likely that fairly extensive details are provided on the developed method.<sup>74–80</sup> In addition, several reviews have been written on aspects of this (e.g., References 81 and 82).

### 1.3.1 STEPS IN DESIGNING A METHOD

A general strategy for CE analysis of a sample is diagrammed in Figure 1.6. The first step is an obvious but important one: choosing the optimum wavelength for detection. This may not necessarily be the most sensitive wavelength (i.e., 200 nm for proteins), but more importantly, one that specifically enhances the detectability of the substance of interest and minimizes the absorbance of background components. Choice of a buffer system is of the utmost importance. The buffer needs to be selected with strict attention to not only the pH requirements of the sample from a stability perspective, but also to the wavelength restrictions of the buffer (i.e.,  $\lambda_{\min}$  for detection; see Table 1.3 in this chapter). If the use of a specific high ionic strength (high conductivity) buffer system is required (e.g., for preservation of bioactivity), the maximum working voltage should be determined by an Ohm's Law plot (discussed in Section 1.3.3.5 on buffers) to avoid buffer overheating problems. A review of the literature will provide a general idea of the basic parameters for an initial test run. A quick trial should establish the appropriateness of the sample introduction method, initial field strength, and capillary length. Optimization of the separation and resolution should include modification of the field strength, modification of the buffer by either altering pH or using additives to alter analyte mobility or EOF, and changing the length of the capillary as necessary. If peak resolution is poor, one might consider increasing the length of the capillary and/or the frequency of data collection. The remainder of the steps rely largely on the experience and intuition of the operation based on the characteristics of the sample/analyte. Once adequate separation of the sample components is attained, sample introduction should be optimized for a maximum signal-to-noise ratio. This step might include, where possible, altering the sample concentration or the buffer composition (ionic strength, type, pH, etc.). Typical starting conditions for analysis of unknowns (e.g., proteins or some drugs) in our laboratory are 50  $\mu\text{m}$  i.d.  $\times$  30 or 40 cm in effective separation length capillary, 100 mM borate, pH 8.3, 25 kV, with a 3 s pressure injection at 0.5 psi. We find 200 nm to be a good wavelength for UV detection of most organic compounds with most buffers; due to the absorbance of conjugated bonds, there is a 5–10-fold enhancement of the signal over that observed at 280 nm with most proteins and peptides. A reasonable starting concentration for protein samples is 0.1–1.0 mg/mL, usually in 10 mM borate, pH 8.3 or 10–20 mM Tris, pH 7.5.

### 1.3.2 SAMPLE PARAMETERS TO CONSIDER

Clearly, analysis of a sample requires that it be solubilized. Although it is not always possible to know the physicochemical properties of the sample to be analyzed, it is important to be familiar with at least some of the physical properties of the specific analyte of interest in the sample. Some physicochemical properties may ultimately have to be determined empirically. Different questions should be posed depending on whether the sample involved is lyophilized or already solubilized, as in a biological fluid. In either case, it is important to have some knowledge of the detectability, purity, and stability of the sample/component of interest. A number of questions need to be addressed. How complex is the sample? Is the substance of interest a major or minor component? What other substances in the sample might interfere with the detection or separation of the analyte of interest? What is its  $\lambda_{\max}$ ? Is it thermally stable? If structural information is available, what are the  $pK$  values of the ionizable groups? If the sample contains proteins or peptides, what pIs are involved? If the sample is not in solution, there are additional questions that must be considered. Is it soluble in water or low ionic strength buffer at mg/mL concentrations? Does it require extremes of pH for solubility and, if so, is it stable at this pH? Is solubility enhanced by buffer additives such as urea, methanol,

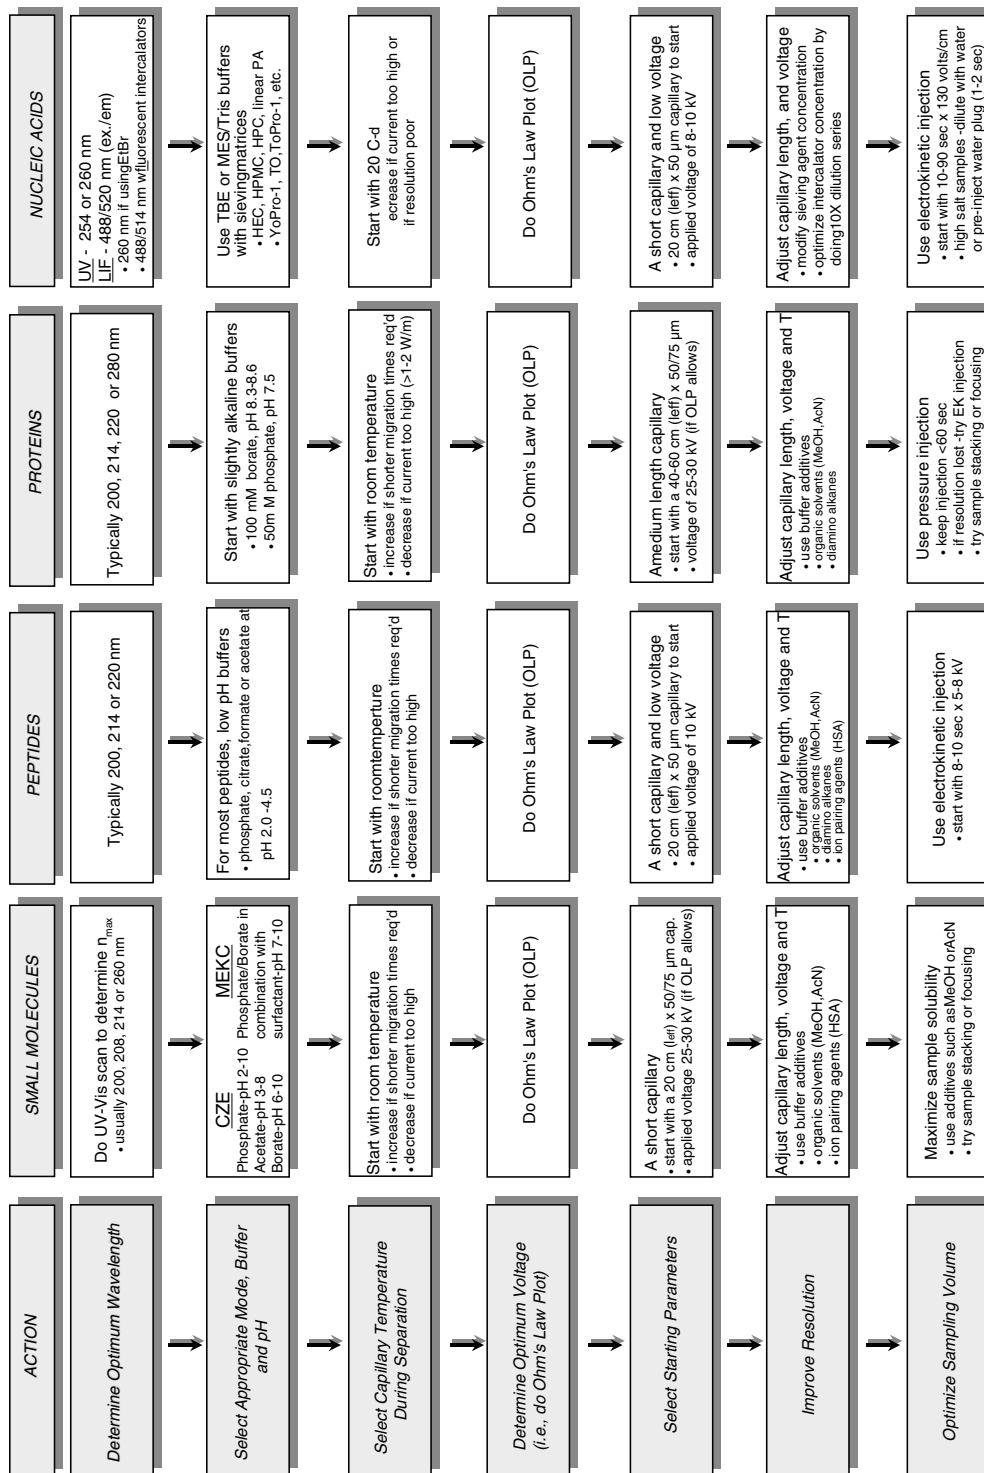

FIGURE 1.6 Flow diagram for CE method development.

**TABLE 1.3**  
**Commonly Used CE Buffers and Their Associated Properties**

Buffer	Useful pH Range	Minimum Useful $\lambda$ (nm)
Phosphate	1.14–3.14	195
Formate	2.75–4.75	200
Acetate	3.76–5.76	200
Citrate	3.77–4.77	200

Phytic	1.9–9.5	200

\* Zwitterionic buffers.

acetonitrile, hexane sulfonic acid (HSA), SDS, and so forth? It is these types of questions that will allow for a sound methodological approach to methods development.

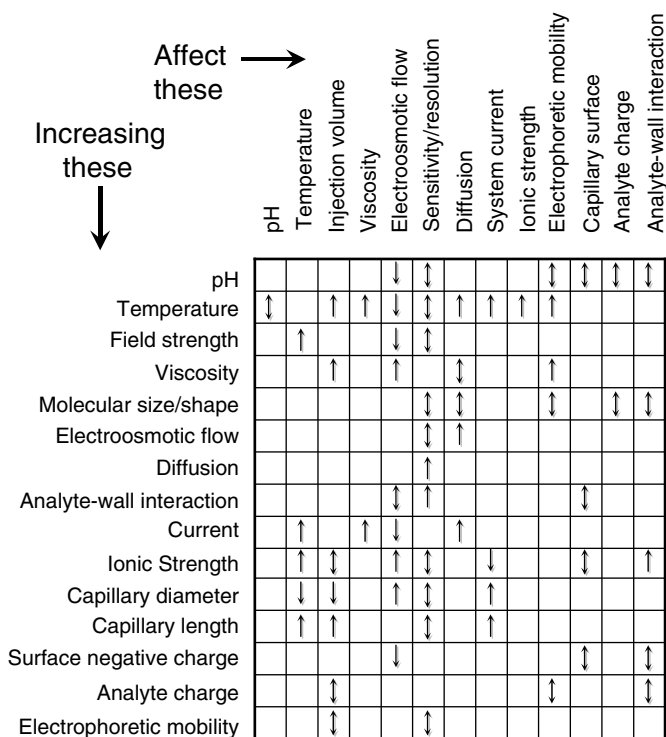

A final point worthy of note in this section is the importance of the sample matrix. As per the discussion in Chapter 13 by Burgi and Giordano, the constituents of the sample matrix will play an important role in attaining optimal separation of sample components. The conditions required for solubilization may not provide an adequate sample matrix for introduction to analysis. Compromises may have to be made between complete solubility and an ideal sample matrix. Moreover, it is crucial to view the sample matrix in relation to the separation buffer. Ideally the sample matrix should be approximately 10- to 200-fold less in total ionic strength than the separation buffer, in order that the sample does not contribute to the EOF. This disparity will also enhance the possibility of adequate detection, since the lower ionic strength sample matrix will lead to sample stacking and, hence, on-capillary concentration.

Once solubility has been attained in a reasonable sample matrix, the sample should be filtered through a 0.45  $\mu\text{m}$  filter to remove unsolubilized particulates. A trial analysis is then conducted and the efficiency of the separation optimized. This is accomplished by altering/adjusting a multitude of variables (discussed below) in search of the combination that provides the best separation of the next sample components within a reasonable analysis time.

### 1.3.3 SEPARATION PARAMETERS TO CONSIDER

With the relatively large number of parameters to contend with in CE methods development, it is beneficial to understand how a change in one parameter will affect others. Figure 1.7 provides a quick reference chart for evaluation of the relationships between the variables discussed below. In this table, the direction of the effect of altering effects on the parameters described on the vertical axis on those in the horizontal is given ( $\updownarrow$ , signifies the effect is bidirectional). Parameters not covered in Figure 1.7 include the composition of the sample matrix and the presence of buffer additives that either interact with the sample components (e.g., surfactants) or affect the chemical nature of the wall (through dynamic/covalent modification). It is clear that, with any particular sample, each of these variables should be examined systematically for effective methods development.

**FIGURE 1.7** A reference chart detailing the relationships between variables influencing performance in CE.

The following sections describe the qualitative effects on separation that result from alteration of the parameters described above. For example illustrating the effects of many of these parameters on CE analysis of mixtures, the reader is referred to an excellent review by McLaughlin et al.<sup>83</sup>

### 1.3.3.1 Electrode Polarity

Establishing the electrode polarity is of paramount importance in CZE and, obviously, one of the first considerations before beginning analysis. As mentioned earlier, the normal polarity for CE is to have the anode (+) at the inlet and cathode (−) at the outlet. In this format, EOF is toward the cathode (detector/outlet). This is the standard polarity for most modes of CE utilizing a bare fused silica capillary. If set in reverse polarity (cathode—inlet; anode—outlet) by mistake, the direction of EOF is away from the detector and only negatively charged analytes with electrophoretic mobility greater than EOF will pass the detector. This format is typically used with capillaries that are coated with substances that reverse the net charge of the inner wall (and subsequently reverse EOF), or when all analytes are net negatively charged (e.g., DNA or SDS-complexed proteins).

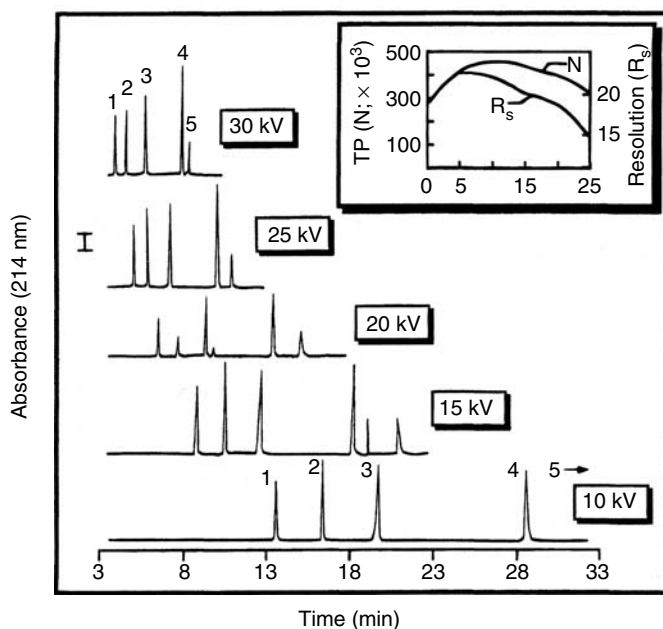

### 1.3.3.2 Applied Voltage

It is advisable to begin analysis with a mid-range voltage (10–20 kV). Increasing the voltage will have a number of effects. While it will increase sample migration and EOF rate, as well as shorten analysis time, it may increase the sharpness of the peaks and improve resolution. However, the advantages associated with increasing the voltage may be lost if the sample matrix ionic strength is much greater than the running buffer ionic strength such that the increased production of Joule

heat cannot be efficiently dissipated. Joule heating of the capillary results in a decreased solution viscosity. This leads to a further increase in EOF, ion mobility, and analyte diffusion, which may ultimately result in band broadening. An excellent example of the effects of increased voltage on the separation of five vitamins has been provided by McLaughlin et al.<sup>83</sup> and shown in Figure 1.8. Decreasing the applied voltage from 30 to 10 kV has the expected effect of increasing the migration time of all analytes in the mixture. At 10 kV the separation is inconveniently long and peak 5 had not reached the detector after 33 min. However, adequate separation at higher applied voltages is obtained at the expense of both resolution and efficiency (theoretical plates) (Figure 1.8 inset).

### 1.3.3.3 Capillary Temperature

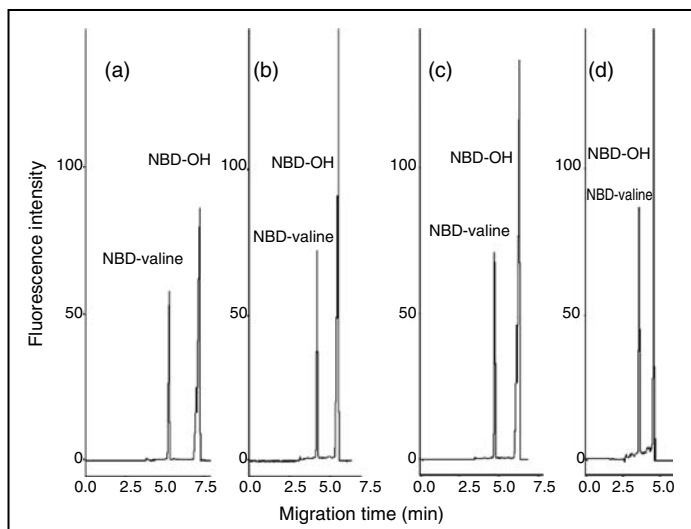

Separations should initially be attempted with the capillary thermostatted at close to ambient temperature. The capillary temperature can be increased on most commercial CE units to as high as 60°C without substantially increasing current with most buffers. When this is done using the same applied voltage, decreased buffer viscosity leads to an increase in analyte electrophoretic mobility, thus, decreasing separation times. Also, it is important to note that, when sample introduction is hydrostatic (same pressure/vacuum and time), increased capillary temperature will lead to an increase in the injected sample volume as a result of decreased buffer viscosity.<sup>2,84–89</sup> Sensitivity may not necessarily be increased. However, Undesirable effects include concurrent changes in buffer pH, band broadening due to increased diffusion, and possible thermal denaturation of the sample.

**FIGURE 1.8** Effects of voltage on separation efficiency and resolution. A mixture of five vitamins (1) niacinamide, (2) cyanocobalamine (vitamin B<sub>12</sub>), (3) pyridoxine (vitamin B<sub>6</sub>) niacin, and (5) thiamin (vitamin B<sub>1</sub>). Separation conditions were as follows: capillary: 75  $\mu\text{m}$   $\times$  50 cm (effective length) fused-silica;  $T$ : 25°C; buffer: 60 mM borate, 60 mM SDS, 15% methanol, pH 8.92; voltage varied as indicated to the right of each electropherogram. (Modified from McLaughlin, G. M. et al., *J. Liq. Chromatogr.*, 15, 961, 1992. With permission.)

Increasing the capillary temperature can have both positive effects and negative effects on separation. In some cases, the effects of elevated capillary temperatures are not only advantageous but necessary. A study by Guttman et al.<sup>89</sup> showed that separation of a mixture of five proteins in a physical gel was poorest at 20°C and optimized at 50°C. Apparently, higher temperatures were needed to obtain the appropriate structural conformation of the physical gel required for sieving of the proteins. Another positive effect of increasing capillary temperature is the substantial decrease in analysis time (which may or may not be associated with an increase in resolution). Figure 1.9 shows the effect of increasing temperature on the separation of 4-hydroxy-7-nitro-2,1,3-benzoxadiazole (NBD-OH) from the derivatized valine (NBD-valine) at temperatures ranging over 20°C. The temperature shift from 25°C to 45°C was not only associated with the expected decrease in analysis time (reduced by roughly half), but also with a change in the fluorescence signal intensity for the peaks, lower fluorescence intensity observed at lower temperatures. Other effects can include the negative effects of elevated capillary temperature on the stability of the sample. This has been shown with the temperature-dependent CE analysis of  $\alpha$ -lactalbumin<sup>87</sup> where separations were optimal at 20°C and 50°C; however, the authors demonstrate that the faster migration time is not solely due to increased EOF, but also to a temperature-induced conformational change in the protein. Hence, while elevated capillary temperatures shorten analysis times, one should be cognizant of the potential for adverse effects on analyte stability. More recently, Giordano et al.<sup>90</sup> defined a new approach for calculating intracapillary temperatures. In an interesting twist, they define a potential positive outcome of Joule heating that overcomes the thermostating capability of the instrument—the ability to exploit the elevated temperatures for fluorescent labeling proteins.

In the first edition of this CE handbook, Nelson and Cooke<sup>91</sup> addressed the developmental issues associated with capillary temperature control in CE systems. This topic is revisited anew by Haddad in Chapter 18.

**FIGURE 1.9** Effect of temperature on migration time and fluorescence intensity (RFU) with the separation of 4-hydroxy-7-nitro-2,1,3-benzoxadiazole (NBD-OH) and the derivatized valine (NBD-valine). Temperatures were (a) 25°C, (b) 30°C, (c) 35°C, and (d) 45°C. The conditions of the separation were 15 kV applied voltage, 40/47 cm effective/separation length, 20 mM borate buffer pH 10.0, injection of  $5.56 \times 10^{-5}$  M valine for 4 s, followed by absolute ethanol for 1 s, and then  $5.24 \times 10^{-2}$  M NBD-F for 2 s. (Modified from Zhang et al. *Anal. Bioanalyt Chem.*, 2006, 386, 1387–1394. With permission.)

### 1.3.3.4 Capillary Dimensions

#### 1.3.3.4.1 Internal Diameter

The main advantage resulting from increasing the capillary i.d. is the enhancement in detection sensitivity due to increasing the path length. However, a decrease in the surface–volume ratio accompanies an increase in diameter (see Table 1.1). This may lead to less efficient dissipation of Joule heat, which then results in a temperature gradient across the capillary and band broadening. While a narrower capillary will accommodate a smaller sample volume (keeping  $L_{\text{int}}/L_{\text{t}} < 3\%$ ), owing to the concentrating phenomenon during electrophoresis, the narrower diameter allows detection a lower initial sample concentration.

#### 1.3.3.4.2 Length

It is recommended that initial separations be performed on shorter capillaries (20–30 cm to detector), which provide short analysis times for determining sample introduction mode and buffer choice, and so forth. Once successful analysis has been achieved, the capillary length can then be increased to improve resolution of closely migrating species since an increased on-capillary time allows for subtle differences in analyte electrophoretic mobility to separate the components. Also, as the length increases, there will be a concomitant decrease in the electrical field strength at constant voltage and, hence, higher voltage may be used. There is a practical limit on capillary length, where the trade-off with increased resolution is overcome by the decrease in sensitivity due to band broadening effects, or the limits of the applied field. This practical limit appears to be about 100 cm.

### 1.3.3.5 Buffers

The choice of a buffer is critical to obtaining successful CE separation of the analytes. Once the optimal wavelength for detection has been established, a buffer must be selected that does not interfere with the ability to detect the analytes of interest, maintains solubility of the analytes, maintain buffering capacity through the analysis, and produces the desired separation. These topics are covered in more detail in the following sections, with examples highlighting the importance of each parameter. Refer to Appendix 3 for some exemplary buffer systems and associated conditions for separation of various analytes.

#### 1.3.3.5.1 Selection and Preparation of a Separation Buffer

A wide variety of electrolytes can be used to prepare buffers for CE separations. When using absorbance detection, a major requirement of any component used in the buffer system is a low UV absorbance at the wavelength used for detection. This restriction substantially limits the choices to a moderate number of non-UV absorbing electrolytes. However, a number of UV-absorbing organic buffers have been used with success at low concentrations to minimize background absorbance. For low pH buffers phosphate, acetate, formate, and citrate have commonly been used effectively. For buffers in the basic pH range, Tris, Tricine, borate, and 3-(cyclohexylamino)propane-1-sulphonic acid (CAPS) are acceptable electrolytes. For detection modes other than UV absorbance, a number of other electrolytes can be utilized. In fact, for indirect detection, one might desire a buffer with high background absorbance to enable detection limits of analytes. However, if one is considering methods utilizing electrochemical detection, the buffer must not only be compatible with the analytes, but present a stable background conductivity against which the analytes can be detected. This is covered by Lunte in Chapter 48 on electrochemical detection. Table 1.3 presents a list of useful electrolytes for preparing separation buffers for CE. In addition, an indication of their useful pH range and minimum functional wavelength (for absorbance detection) is given.

Perhaps one of the most important aspects of buffers used for CE is the requirement of pure reagents. It is recommended that the water used for buffer preparation be of Milli-Q (or equivalent) purified quality and that the reagents be highly purified or ultrapure (Gold Label) quality; the small

**TABLE 1.4**  
**Common Buffer Additives in CE and Their Effects**

Additives	Example	Function
Inorganic salts	NaCl, CaCl <sub>2</sub> , K <sub>2</sub> SO <sub>4</sub>	Modification of EOF; protein conformational changes; protein hydration
Organic solvents	Methanol, acetonitrile, ethylene glycol	Modification of EOF; analyte solubilization; analyte salvation
Organic additives	Urea	Modification of EOF; protein solubilization
	Pyrenebutanoate	Denaturation of oligonucleotides
Inorganic additives	Borate	Denaturation of oligonucleotides; dynamic modification of protein
Zwitterionic additives	Z1-Methyl	Complex <i>cis</i> -diols; carbohydrate or glycoprotein separations
Sulfonic acids	hexane, heptane, octane, or nonane analogs	Reduce wall interaction; augment EOF
Divalent amines	hexane, heptane, octane, or nonane analogs	Analyte ion-pairing; hydrophobic interaction
	diaminoalkanes; hexamethonium bromide; decamethonium bromide	Modification of EOF; charge neutralization; analyte interaction
Cationic surfactants	Dodecyltrimethylammonium bromide (DTAB); cetyltrimethylammonium bromide (CTAB); tetradecyltrimethylammonium chloride (TTAC)	Charge reversal on-capillary wall; hydrophobic interaction
Cellulose derivatives	Hydroxyethyl cellulose; methyl cellulose; hydroxypropyl methylcellulose	Reduce EOF; provide sieving medium
Miscellaneous polymers	Polyethylene glycol	Protein stability; reduce wall interaction
	Dextran	Manipulate the electrophoretic mobilities
	Polyvinylpyrrolidone	Enhance resolution of peptides and amino acids

amounts required for CE do not entail great expense. Passage of buffers through an 0.22 or 0.45  $\mu\text{m}$  filter is recommended before use to remove any particulate matter. For buffers stored in 4°C, it is imperative that they be brought to room temperature and thoroughly degassed before use.

Buffer additives may also be used to obtain enhanced or differential selectivity in a separation. Several classes of additives have been identified as applicable to CE. Table 1.4 outlines some common buffer additives and their mode of action. As can be seen from the table, the additives are multi-functional, not only suppressing analyte–wall interactions, but also affecting analyte solubility, and in some cases affecting selectivity. Some examples of the use of additives for enhancing/optimizing CE separations are given later in this chapter.

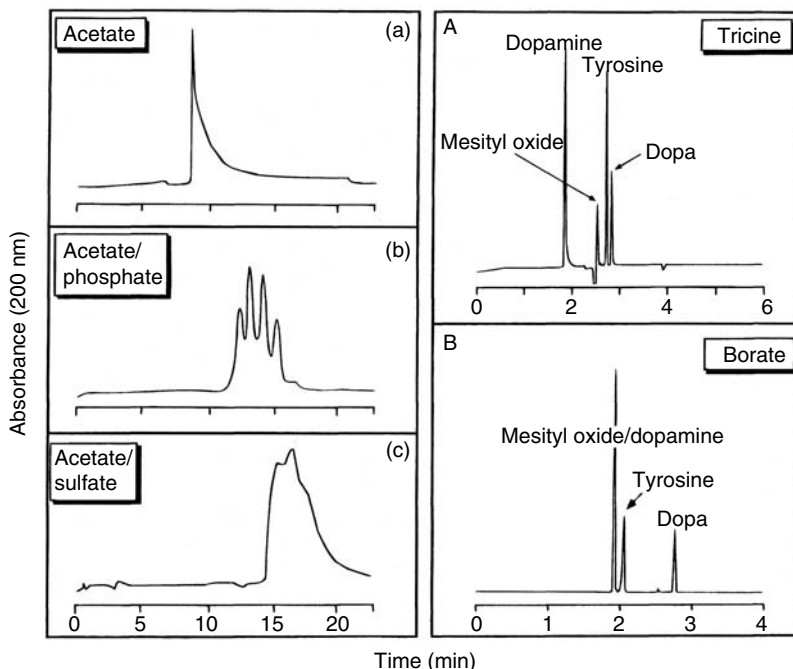

**1.3.3.5.1.1 pH** Assuming that information about the sample is available, it is advisable to choose a buffer pH that approximates the  $pK$  of the solute mixture. This choice is simple with pure or partially purified preparations. With crude biological mixtures, the  $pK_{\text{avg}}$  will typically be close to neutrality.

**FIGURE 1.10** Dependence of electrophoretic separation and resolution on buffer pH. Proteins: Ovalbumin [1.0 mg/mL, in 100 mM borate, pH 8.3; 3 s pressure (0.5 psi) injection] was introduced into a pre-equilibrated capillary containing 100 mM borate buffer at the appropriate pH, indicated above each trace. Analysis performed on a Beckman P/ACE System 2050. Separation conditions: capillary: 50  $\mu\text{m}$   $\times$  80 cm (effective length), 87 cm total length bare fused silica;  $T$ : 28°C; voltage: 25 kV; detection: 20 nm. (Modified from Landers, J. P. et al., *Anal. Biochem.*, 205, 115, 1992. With permission.) Peptides: Five peptides containing the same 12 amino acids but in varied sequence were analyzed under different pH conditions as labeled. Sequence of native, reverse, and shuffled peptides are provided in the inset table. Separation conditions: capillary: 50  $\mu\text{m}$   $\times$  20 cm (effective length), 27 cm total length bare fused silica;  $T$ : 20°C; voltage: 25 kV; detection: 20 nm. Separation buffer: 100 mM borate, plus 10 mM diaminopentane, adjusted to the appropriate pH with NaOH.

Remember that increasing the pH between 4 and 9 results in an increase in the EOF. Also remember that the buffer pH may be altered in a secondary manner by other parameters such as temperature, ion depletion of the buffer (caused by repetitive use of the same separation buffer) and organic additives. Examples of the effect of buffer pH on CE separation are given in Figure 1.8 for both peptides and proteins. With the separation of ovalbumin isoforms, the expected decrease in migration time with increasing pH is observed and optimal separation is observed at pH 9.0. Separation of a mixture of five peptide “isomers” over a wide range of pH is illustrated in the lower right of Figure 1.10. At pH 2.5, all five peptides, which are identical in amino acid composition but vary in sequence, comigrate as a broad peak (not shown). At pH 8.61, the peptides migrate as two groups while at 11.64, resolution of 4 of the 5 peptides is observed.

**1.3.3.5.1.2 Ionic Species** As discussed above, the choice of buffer for a particular CE separation is important from the perspective of Joule heat generation. Obviously, the pH required for the separation will limit the candidate buffer systems amenable for use. However, it is important to note that, at a given pH, the type of buffer can have dramatic effects on resolution. Figure 1.11 (left)

**FIGURE 1.11** Effect of buffer type (ionic species) on CE separation. (A) CE analysis of r-hEPO. Separation conditions: capillary:  $75\ \mu\text{m} \times 20\ \text{cm}$  (effective length) fused silica; voltage: 10 kV; detection: 214 nm. Buffers were of identical pH (4.0) and 100 mM concentration; (a) acetate buffer ( $30\ \mu\text{A}$ ); (b) acetate-phosphate ( $120\ \mu\text{A}$ ); and (c) acetate-sulfate ( $200\ \mu\text{A}$ ). (Modified from Tran, A. D. et al., *J. Chromatogr.*, 542, 469, 1991. With permission.) (B) Separation of dopamine, tyrosine, dopa [0.5 mg/mL each, in water; 3 s pressure (0.5 psi) injection] and mesityl oxide [neutral marker, 3 s pressure (0.5 psi) injection]. Analysis performed on a Beckman P/ACE System 2050. Separation conditions: capillary:  $50\ \mu\text{m} \times 50\ \text{cm}$  (effective length), 57 cm (total length) bare fused silica;  $T$ :  $28^\circ\text{C}$ ; voltage: 25 kV; detection: 200 nm. (A) Separation in 100 mM tricine, pH 8.3. (B) Separation in 100 mM borate, pH 8.3. (Modified from Landers, J. P. et al., *Anal. Chem.*, 64, 2846, 1992. With permission.)

illustrates the importance of buffer choice on the CE analysis of recombinant human erythropoietin (r-hEPO).<sup>68</sup> Although all buffers were of identical pH (4.0) and at a 100 mM concentration, resolution of the glycoforms was only observed with acetate-phosphate buffer and not with the acetate alone or acetate-sulfate solutions.

Other buffer systems that may have a dramatic effect on the separation are those capable of interaction with specific analytes. The ability of borate to form stable complexes with *cis*-diols has long as been known and this property exploited in chromatography.<sup>92</sup> Several studies have shown this property to be particularly advantageous in CE since, at a slightly basic pH, borate complexation imparts an additional negative charge to the molecule (due to ionization of one of the free hydroxyl groups;  $\text{p}K_{\text{a}} = 9.14$ ).<sup>93–95</sup> Figure 1.11 (right) highlights the importance of borate for the separation of *cis*-diol-containing compounds from those similar in structure, but lacking the functional group in the separation of dopamine, tyrosine, dopa, and mesityl oxide (neutral marker).<sup>96</sup> In tricine at pH 8.3, dopamine is positively-charged and migrates faster than EOF (mesityl oxide) while both tyrosine and dopa migrate slower than EOF (dopa more negatively-charged than tyrosine). In borate buffer at the same pH, borate complexed with dopamine negates the positive charge of the amine, while dopa becomes more negatively-charged. This example emphasizes the importance of buffer selection for enhancing selectivity in CE separations.

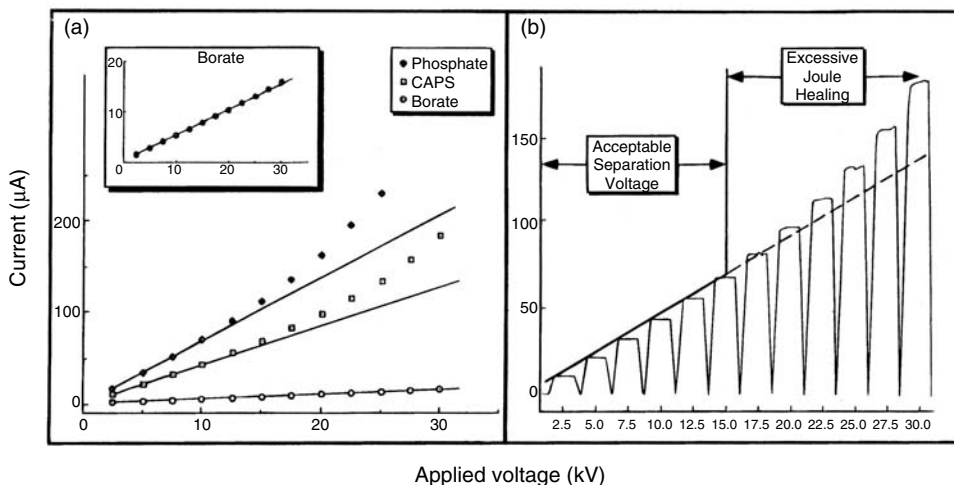

### 1.3.3.5.2 Buffer Concentration: Ohm's Law Plot

Useful buffer concentration is restricted by several parameters including the capillary length and internal diameter, the applied electrical field strength and the efficiency of the capillary thermostating/cooling system. Generally, use of moderately high ionic strength buffers is desirable for suppression of ion-exchange effects between the charged analyte ions and the ionized silanol groups on the capillary wall. However, the current (Joule heat) associated with buffer concentrations greater than 100 mM may overcome the capillary thermostating capability of the system at higher applied voltages. Excessive Joule heating can have desirable effects on both resolution and analyte stability. Buffers that may be problematic in this respect include those containing high mobility electrolytes such as chloride, citrate and sulfate. The excessive Joule heating associated with high concentration buffers can be circumvented in two ways. The easiest solution is to lengthen the capillary so that a tolerable current is maintained. However, this will increase the effective capillary length and may compromise resolution. A reduction in the cross-sectional area of the capillary will also reduce heating by decreasing the current density, and allows for more effective dissipation of heat due to a greater surface-to-volume ratio. Alternatively, buffers that run at relatively low current (and Joule heat) can be used. One such buffer in the pH 7–9 range is borate buffer that has been shown to be an excellent CE buffer at concentrations as high as 500 mM.<sup>97</sup> An added advantage of using higher ionic strength separation buffer is the increased sample loading capacity that results owing to the on-capillary stacking effect that will be described in a later section, and by Burgi and Giordano in Chapter 13.

A simple method has been described by Nelson et al.,<sup>98</sup> termed the “Ohm's Law Plot,” that allows for easy determination of the “functional” buffer concentration and the maximum voltage that can be utilized with the particular buffer system (i.e., the functional limit for capillary thermostating). After filling the capillary with the desired buffer and allowing for adequate equilibration, voltage is applied to the system for short intervals (e.g., 1 min) and the current recorded at each voltage. Linearity in a plot of observed current vs. voltage is an indication that the capillary temperature is being adequately maintained (i.e., the generated Joule heat is being effectively dissipated). At the point where linearity is lost, the thermostating capacity of the system has been exceeded. One should strive for heat generation of <1 W/m (watts per meter) for optimum separation<sup>99</sup> and should not exceed 5 W/m. An example of the Ohm's Law plot is given in Figure 1.12a for 100 mM concentrations of each of three buffers: phosphate, pH 2.5; borate, pH 8.3; and CAPS, pH 11.0.<sup>100</sup> At 20 kV, the current is lowest with borate ( $\approx 10 \mu\text{A}$ ) while CAPS ( $\approx 100 \mu\text{A}$ ) and phosphate ( $150 \mu\text{A}$ ) are dramatically higher. The power associated with each buffer at 25 kV is 0.58, 10.07 and 5.88 W/m for borate, phosphate and CAPS, respectively. Refer to Appendix 1 for example on calculating power (W/m). The recommended limits have clearly been exceeded with the latter two buffers. More importantly, linearity in the relationship is lost with the phosphate and CAPS buffer at relatively low applied voltages in comparison with borate; the 100 mM phosphate and CAPS buffers should not be used at voltages greater than 10 and 15 kV, respectively. In contrast, borate buffer (inset in Figure 1.12a) exhibits a linear relationship between current and the applied voltage, even at 30 kV. Figure 1.12b shows that this determination can be simplified if the software used for data acquisition and analysis has the ability to directly monitor/plot current as a function of time. The figure presents a direct (on screen) plot from System Gold Version 7.1 for 100 mM CAPS buffer where voltage is incremented by 2.5 kV/min. This provides the same information without having to manually plot current versus voltage.

**1.3.3.5.2.1 Ionic Strength** Increasing the ionic strength of the separation buffer increases the thickness of the ionic double layer, and has the effect of decreasing EOF, hence, increasing the analysis time. As mentioned earlier, increasing the ionic strength will also increase the current at a constant voltage and, hence, adequate thermostating of the capillary becomes a concern. An advantage of increasing ionic strength, in addition to the obvious improvement in buffer capacity,

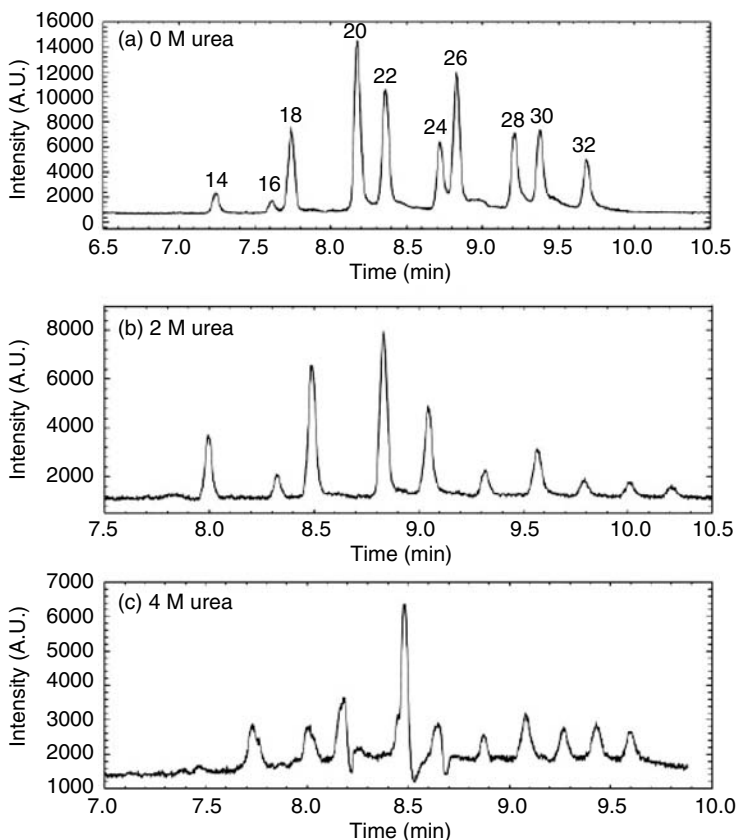

**FIGURE 1.12** The Ohm's Law Plot. (a) Plot of observed current vs. applied voltage for each of three buffers. The determinations were carried out on a Beckman P/ACE 2050. The voltage was incremented 2.5 kV/min, and the current recorded through System Gold software, Version 7.1. Buffers were 100 mM phosphate, pH 2.5, made by dilution of phosphoric acid and titration with NaOH; 100 mM borate, pH 8.3, made by titrating 25 mM sodium tetraborate with 100 mM boric acid; and 100 mM CAPS, pH 11.0, made by titration of the appropriate concentration dissolved in water with NaOH. The inset shows the borate data plotted on an expanded scale. (b) Direct plot of current versus applied voltage for 100 mM CAPS, pH 11.0. A direct plot of observed current versus applied voltage obtained through System Gold Version 7.1. Voltage is incremented by 2.5 kV/min. A straight line drawn through the front edge of the plateau illustrates the ability of the cooling system to dissipate the heat generated by the passage of current. The departure from linearity indicates the excessive increase in current at the applied voltage, and is a reflection of the increase in the capillary temperature.

will be to decrease analyte-wall interactions.<sup>100</sup> The net effect on the separation, therefore, will be to increase resolution, provided that capillary thermosetting capability is not overcome and that unwanted analyte dissociative processes (e.g., ligand-peptide/protein multimer dissociation) do not occur. On the other hand, an increase in ionic strength might improve resolution in mixtures by decreasing nonspecific analyte-analyte interaction. One example is with protein-DNA interactions. Figure 1.13 illustrates the effect of increased ionic strength on oligonucleotides electrophoresed in the presence of varying concentrations of urea. With urea, which maintains the oligonucleotides in a denatured form at the thermostatted temperature, there is an obvious improvement in resolution when increasing the urea concentration from 0 to 2 M. However, an optimum is reached and further increase (from 2 to 4 M) results in decreased resolution and a concomitant decrease in the S/N ratio with increasing urea. Other effects have been reported exploiting ionic strength in combination with bovine serum albumin (BSA) to minimize nonspecific interaction with DNA restriction fragments.<sup>100</sup> Addition of BSA to the sample obliterated resolution of the double-stranded DNA-stranded (dsDNA) fragments ranging from 72 to 310 base pairs. However, the simple addition of 50 mM NaCl to the 89 mM Tris-borate-ethylenediaminetetraacetic acid (Tris-borate-EDTA) separation buffer negated these effects. While the voltage had to be decreased to accommodate the increased Joule heating effects of the added ionic strength, there was a corresponding improvement in the detection of the low molecular weight DNA fragments, most likely due to a stacking effect produced between the lower ionic strength sample buffer and the higher ionic strength buffer.

Increasing the ionic strength is usually associated with increased Joule heating due to higher current flux. In the above example provided by Figure 1.13, the voltage had to be decreased in the separation that contained salt. One way to increase ionic strength without increasing Joule heating is to use zwitterionic additives.<sup>101</sup> Even at molar levels, zwitterionic agents, such as betaine or

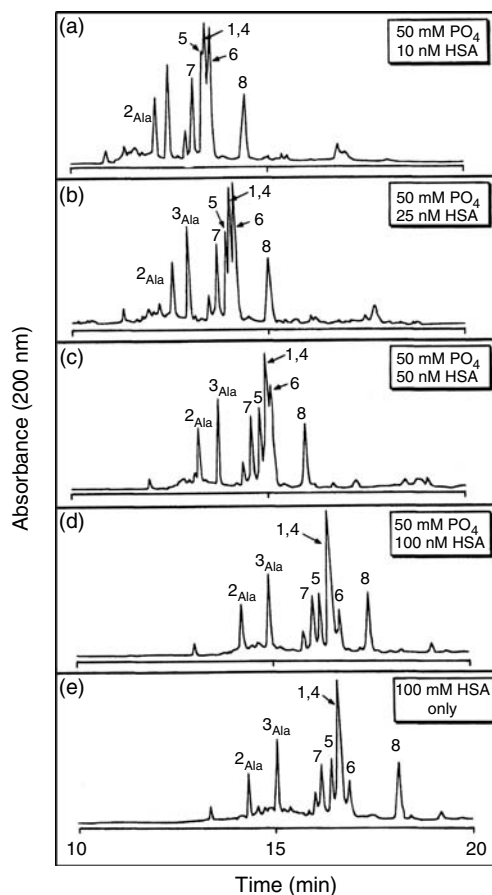

**FIGURE 1.13** The effect of increasing ionic strength on the CE separation of oligonucleotides. Dye was mixed with Pluronic F127 solution and the capillary filled by syringe. 25% w/v F127 in 1XTBE buffer as a separation medium at room temperature. Conditions:  $l$  (length to detector) = 7 cm,  $L$  (column length) = 13 cm,  $E$  (field strength) = 200 V/cm, capillary i.d. = 50  $\mu$ m, o.d. = 360  $\mu$ m, Electrokinetic injection at 300 V/cm for 1 s. Peak assignments are as indicated in the figures. (Modified from Landers, J. P. et al., *Biotechniques*, 14, 98, 1993. With permission.)

sarcosine, do not contribute to the conductivity of the buffer, and therefore, do not raise the current or induce Joule heating.

**1.3.3.5.2.2 Organic Salts** The addition of organic modifiers to the separation buffer will have differing effects dependent on the nature of the additive. The positive effects on the separation usually result from the alteration of the solvation properties of the buffer or the diminished EOF due to changes in the thickness of the double-ionic layer (and hence the zeta potential) or the viscosity of the buffer. One affect often results is a change in EOF. For example, the addition 1,4-diaminobutane to the buffer has been proposed to enhance resolution by slowing EOF through a dynamic modification of the capillary wall.<sup>71,72</sup> Ion-pairing agents, such as the alkyl sulfonic acid salts, have been used with success to resolve peptides.<sup>102</sup> Figure 1.14 demonstrates the influence of HSA on the separation of a series of peptides of identical amino acid composition but differing sequence. Here the resolution appears to be due to the differential solvation and/or the microenvironment of nearest neighbor effects on  $pK$  values of the charged amino acids in the peptides.

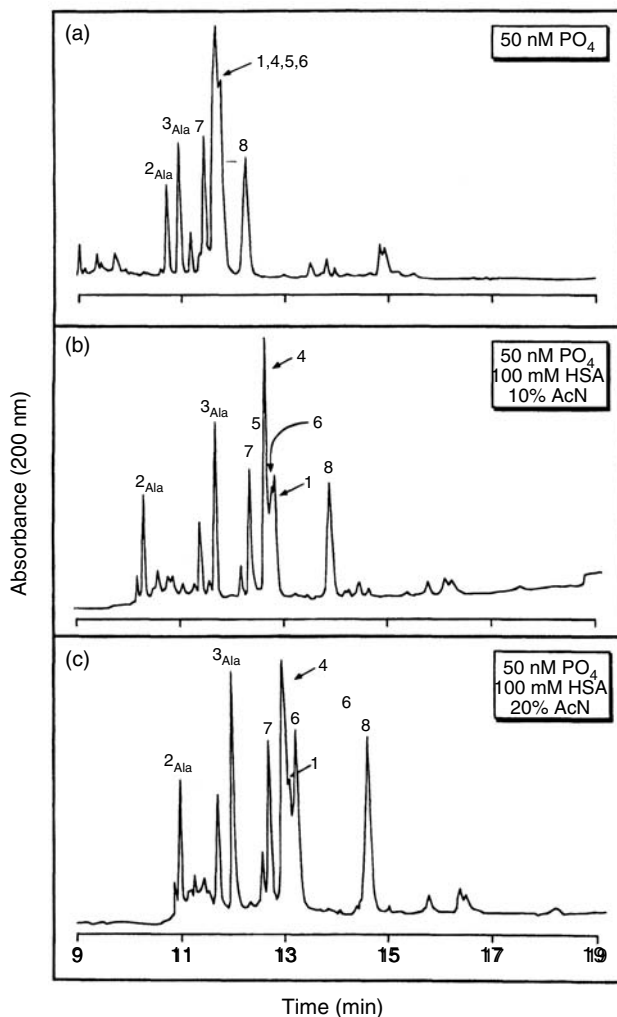

**1.3.3.5.2.3 Organic Solvents** Organic solvents such as methanol or acetonitrile have the effect of decreasing both the conductivity of the buffer and EOF through their ability to disrupt the ordered

**FIGURE 1.14** Effect of organic salts on separation. The separation of eight peptides of which six peptides contain the same 12 amino acids but a varied sequence, and two contain alanine substations for lysine residues. Sequence of native peptide: KNTYCTKPQKSY. Separation conditions: capillary: 50  $\mu\text{m}$   $\times$  50 cm (effective length), 57 cm total length, bare fused silica: T: 28°C; voltage: 15 kV; detection: 200 nm. Separation buffer: 50 mM phosphate, pH 2.0. (a) 50 mM phosphoric acid, pH 2.0, containing 10 mM HSA. (b) 50 mM phosphoric acid, pH 2.0, containing 25 mM HSA. (c) 50 mM phosphoric acid, pH 2.0, containing 50 mM HSA. (d) 50 mM phosphoric acid, pH 2.0, containing 100 mM HSA. (e) 100 mM HSA in distilled water, titrated to pH 2.0 with sulfuric acid. (From Oda, R. P. et al., *J. Chromatogr.*, 680, 341, 1994. With permission.)

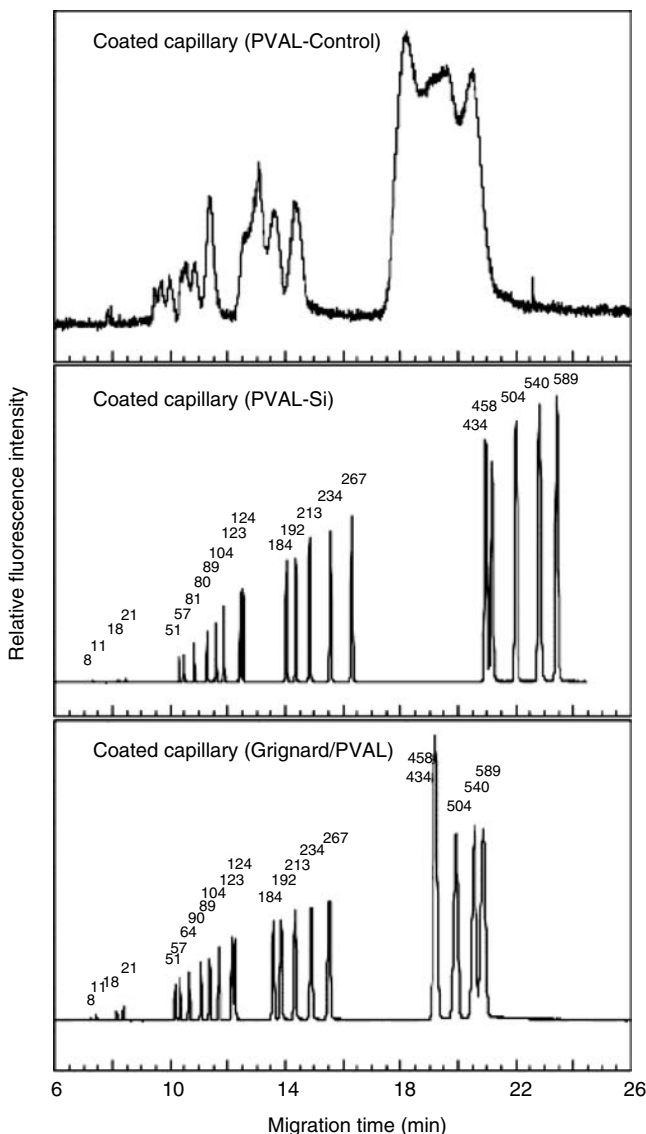

structure of the water molecules. In such cases, the subsequent enhancement in resolution may result from a combination of the decreased EOF (i.e., increased on-capillary time), decreased thermal diffusion, and improved analyte solubility. Figure 1.15 shows the effect of acetonitrile concentration on the solvation and resolution of the same series of peptides depicted in Figure 1.12.<sup>102</sup> More recently, Lookhart et al.<sup>103</sup> showed that the addition of acetonitrile to a phosphate–glycine buffer aided in the separation of storage proteins in maize. In another example illustrating the importance of analyte solvation, Gordon et al.<sup>104</sup> demonstrated that adding ethylene glycol to a borate buffer enabled resolution of serum proteins. They found, however, that the presence of the ethylene glycol in the sample, not in the buffer, led to greater sensitivity and reproducibility.

**1.3.3.5.2.4 Modifiers of EOF** Two approaches can be taken to modify EOF in an attempt to enhance resolution: covalent coverage or dynamic modification of the capillary wall. Many examples of both covalent<sup>105–107</sup> and dynamic<sup>106–113</sup> coatings are found in the literature, and

**FIGURE 1.15** Effect of organic solvents on CE separation. The separation of the same peptides from Figure 1.12. Separation conditions: capillary: 50  $\mu\text{m} \times 50$  cm (effective length), 57 cm total length, bare fused silica; T: 28°C; voltage: 15 kV; detection: 200 nm. Separation buffer: 50 mM phosphate, pH 2.0. (a) Buffer without any additive, (b) buffer containing 10% acetonitrile, and (c) buffer containing 20% acetonitrile. (From Oda, R. P. et al., *J. Chromatogr.*, 680, 341, 1994. With permission.)

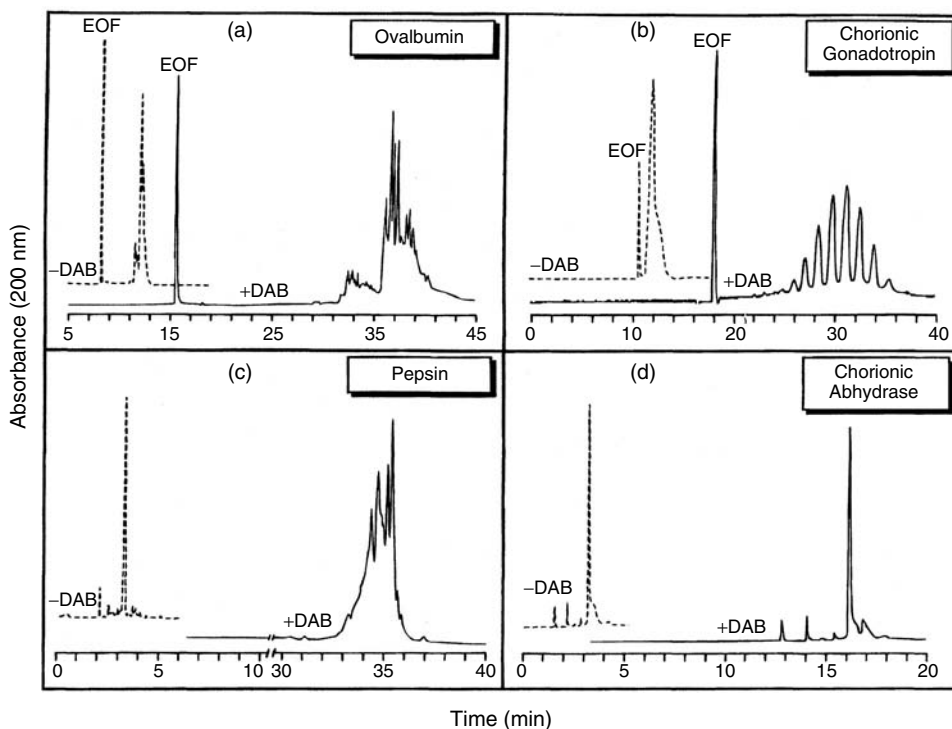

while specific to capillary, surface coating is covered in more detail in Chapter 52 by Henry. A study by Swedberg<sup>105</sup> is an excellent example of the importance of capillary coating for preventing protein–wall interactions during CE separations. A mixture containing seven proteins was clearly resolved (with efficiency  $>500,000$  theoretical plates per meter) in a capillary coated with a pentafluoroaryl compound, whereas separation in bare fused-silica resulted in only a few broad peaks barely greater than baseline. The EOF was not abolished by this coating, suggesting that not all of the silanol groups were reacted, but that the bulky aryl groups prevented protein–wall interaction. As would be expected when protein–wall interactions are diminished, the migration times are markedly shortened. Figure 1.16 highlights the effects of capillary coating on the separation of DNA fragments observed by Chu & coworkers. They describe two new methods for coating capillaries with polyvinyl alcohol (PVA) on characterize the adsorption of PVA onto the wall using atomic

**FIGURE 1.16** The effect of capillary surface coating on the resolution of DNA fragments. Capillaries were coated with polyvinyl alcohol and a pBR322 HaeIII digest used to evaluate resolution (fragment lengths from 8 to 589 bp). Capillary: 13/10 cm total/effective length, 75  $\mu$ m i.d.; medium, 1 TTE solution of polyvinyl alcohol (Mr 125 000; DH = 88 mol%; concentration = 5 wt% for a and c, 6 wt% for b); DNA: pBR322 HaeIII digest, 10 g/mL; buffer, 1 TTE, pH 8.3, including ethidium bromide at 3 g/mL; injection, 0.65 kV, 3 s; electrophoresis: 3.9 kV, 2.6 A, nominal 25°C; detection, LIF using an Ar-ion laser beam at  $\lambda = 488$  nm. (Modified from Moritani et al. *Electrophoresis*, 2003, 24, 2764–2771. With permission.)

force microscopy. The authors describe performance for tens of runs but don't comment on separation reproducibility beyond that.

The other approach to minimizing analyte–wall interactions through modification of the capillary wall is the use of additives that provide a dynamic (noncovalent) coating. Diaminoalkanes are one class of buffer additives that appear to enhance the resolution of protein mixtures by coating the capillary wall,<sup>110,111</sup> and modifying the zeta potential, although the mechanism is poorly understood.<sup>71,72</sup> Figure 1.17 shows the electropherograms resulting from the CE analysis of several

**FIGURE 1.17** Effect of modifiers of EOF on separation. (a) The effect of 1 mM 1,4-diaminobutane (DAB) on the resolution of ovalbumin glycoforms. Ovalbumin [1 mg/mL, in water; 3 s pressure (0.5 psi) injection]. Analysis was carried out on a Beckman P/ACE System 2050. Separation conditions: capillary: 50  $\mu\text{m}$   $\times$  80 cm (effective length), 87 cm total length bare fused silica;  $T$ : 28°C; voltage: 25 kV; buffer: mM borate, pH 8.3; detection: 200 nm. (Modified from Morbeck, D. E. et al., *J. Chromatogr.*, 680, 217, 1994. With permission.) (c) Partial resolution of pepsin glycoforms in the presence of 1 mM DAB. Pepsin [0.5 mg/mL, in water; 3 s pressure (0.5 psi) injection]. Analysis was carried out on a Beckman P/ACE System 2050. Separation conditions: capillary: 50  $\mu\text{m}$   $\times$  80 cm (effective length), 87 cm total length bare fused silica;  $T$ : 28°C; voltage: 25 kV; buffer: 100 mM borate, pH 9.0; detection: 200 nm. (Modified from Landers, J. P. et al., *Anal. Biochem.*, 205, 115, 1992. With permission.) (d) Lack of effect of DAB on carbonic anhydrase separation. Bovine carbonic anhydrase [1.0 mg/mL, in water; 3 s pressure (0.5 psi) injection]. Analysis was carried out on a Beckman P/ACE System 2050. Separation conditions: capillary: 50  $\mu\text{m}$   $\times$  80 cm (effective length), 87 cm total length bare fused silica;  $T$ : 28°C; voltage: 25 kV; buffer: 100 mM borate, pH 8.3; detection: 200 nm.

glycoproteins [ovalbumin, human chorionic gonadotropin (hCG), and pepsin] known to be microheterogeneous with respect to glycan content, in the absence of any modifier, and in the presence of a diaminoalkane.<sup>72,112</sup> Ovalbumin is resolved into two groups of nine peaks on the basis of protein phosphorylation states; the multitude of peaks observed in the presence of 1 mM diaminoalkane are presumed to represent the glycoforms of the protein. A similar effect has been observed by Morbeck, et al.<sup>112</sup> with the CE separation of urinary hCG, another glycoprotein known to be of microheterogeneous character. The presence of 5 mM diaminoalkane in the buffer results in a reduction in EOF (as determined by reduced mobility of the neutral marker, DMF) and leads to resolution of eight hCG glycoforms that cannot be completely resolved by any other method. Pepsin glycoforms were

only partially resolved in 1 mM diaminobutane. The nonglycosylated protein carbonic anhydrase indicates no microheterogeneity in the presence of 1 mM diaminobutane.<sup>72</sup>

A second method of dynamic coating involves the use of materials to alter the viscosity of the solution at the capillary wall. Hjertén<sup>3</sup> suggest that EOF is inversely dependent on the viscosity of the solution in the double layer. If the viscosity approached infinity, the EOF will fall to zero. Thus polymers that adsorb to the wall should reduce or eliminate EOF, and prevent protein adsorption by blocking the access to the reactive silanes. Various cellulose derivatives<sup>33,42–45</sup> and polyhydroxy compounds such as polyvinyl alcohols<sup>113,114</sup> have been used with varying degrees of success for the separation of peptides and proteins.

#### 1.3.3.5.3 Buffer Depletion

Since the electrophoretic process occurring within a buffer-filled capillary under an applied electrical field involves the movement of ions, the separation buffer can eventually be “depleted” if electrophoresis continues for extensive periods of time. This is not surprising in light of the fact that slab gels are used for electrophoresis only once and buffers up to two or three times. Use of “depleted” buffer for CE analysis can result in deterioration of resolution and poor run-to-run reproducibility.<sup>116</sup> This phenomenon is not isolated to free solution buffer systems, but also problematic in gel-based systems. For this reason buffers should be replenished after a limited number of runs (inlet and outlet every 5–8 runs; 10–15 min analysis; 4–5 mL buffer reservoirs). One method that may be useful for extending the use of a buffer without adverse effects on reproducibility is a “limited replenishment” system in which two inlet buffer reservoirs are used—one for electrophoresis and the other for rinsing the capillary with buffer that has not undergone any changes due to electrophoresis. This “limited replenishment” approach appears to substantially increase the number of runs (with the same electrophoresis buffers) before the onset of buffer-associated reproducibility problems.<sup>117</sup> Trushina et al.<sup>118</sup> have provided one example of pushing CE to the limit with respect to reproducibility under extreme buffer depletion conditions. They used a phosphate buffer containing 10 mM HCl and 250 mM KCl to separate glutathione, nitrosylated glutathione, and glutathione disulfide solubilized in a 2 M HCl sample matrix. Using 11 kV for separation, the system was pushed to the maximum current limit tolerated by the CE (249  $\mu$ A) exceeding a total power of 7 W/m. Despite the dramatic change in pH observed in the inlet and outlet reservoirs over several runs, reproducible separations of the thiols (injection-to-injection) could be obtained provided that buffer depletion issues were addressed with buffer replenishment after every run.

## 1.4 INTRODUCTION OF SAMPLE INTO THE CAPILLARY

As a result of the small dimensions of capillaries used in CE, the total capillary volume is typically in the microliter range (see Table 1.1). Adhering to the chromatography “rule of thumb” restricting sample volume to 1–5% of the total capillary volume, sample volumes must be in the low nanoliter range if overloading is to be avoided.<sup>119</sup> The technology for small sample volume introduction into a capillary has converged at three accepted methods. Introduction, or as is sometimes referred, “injection” or “loading” of sample into the capillary can be accomplished hydrostatically, by siphoning, or electrokinetically. With hydrostatic injection, sample is introduced by immersing the capillary inlet into a vial containing the sample and either pressurizing the inlet vial containing the sample or applying a vacuum to the outlet vial (opposite end). Sample introduction by gravity, which is more commonly used with noncommercial systems, relies on the siphoning of sample into the capillary by elevating the injection (inlet) end of the capillary relative to the outlet end. With electrokinetic loading, the injection (inlet) end of the capillary is immersed in the sample, the outlet in the separation buffer and a low voltage (1–10 kV) applied for durations of 1–99 s, depending on the capillary length and i.d.

With electrokinetic introduction, the quantity of sample introduced into the capillary is dependent on a number of parameters, the most important of which are the electrophoretic mobilities of the sample components and the EOF. Other parameters that can effect this mode of loading, therefore, may not be a quantitative representation of the sample components. In contrast, electrokinetic loading may be advantageous if the analyte of interest is a small percentage of the sample, but has a much higher electrophoretic mobility than other constituents. Under these conditions, electrokinetic loading provides a positive sample loading bias and may enhance the detectability of the component of interest. This is certainly the case with smaller molecules weight DNA fragments. Another situation where electrokinetic introduction is advantageous is where the capillary contains a polymerized or cross-linked matrix, where pressure injection cannot be used conveniently. Examples of samples advantageously electrokinetically loaded are DNA and SDS–protein complexes. It is important to bear in mind that sample matrices containing significant concentrations of electrolyte are not efficiently electrokinetically introduced.

This last point highlights a recurring theme in many of the chapters to follow, that is, the sample matrix plays a critical role in obtaining efficient separations. The problems associated with high-salt sample matrices and approaches to manipulating the matrix for adequate CE analysis, are addressed by Shihabi in Chapter 26 and by Burgi and Gordano in chapter 13. In contrast, under the appropriate conditions, the sample matrix can have a positive effect on a sample introduction, enhancing the detectability of the components of a dilute sample by on-capillary preconcentration. This is particularly important in light of the miniscule sample volume capacity inherent with CE and is described in the next section.

## 1.5 ON-CAPILLARY SAMPLE CONCENTRATION TECHNIQUES

One of the main drawbacks of UV detection CE is the low sensitivity resulting from the inherently small dimensions of the flow cell (i.e., the inner diameter of the capillary) and the sample volume capacity. As mentioned above, introduction of sample volumes larger than 1%–5% of the total capillary volume can be detrimental to resolution. Therefore, while CE is a good mass detector, it is a relatively poor concentration detector. This limits the use of CE as an analytical technique to samples having nominally high concentrations (10  $\mu\text{g}/\text{mL}$  or greater). For this reason, the development of several approaches for “on-capillary sample concentration” has been pivotal to the acceptance of CE as a microanalytical technique. Since an entire chapter is dedicated to this subject (Chapter 13 by Burgi and Giordano), these techniques are discussed here in only the briefest of detail.

### 1.5.1 SAMPLE STACKING

One of the simplest methods for sample preconcentration is to induce “stacking” of the sample components of this is easily accomplished by exploiting the ionic strength differences between the sample matrix and separation buffer.<sup>120,121</sup> Stacking results from the fact that sample ions have an enhanced electrophoretic mobility in a lower conductivity environment. When voltage is applied to the system, ions in the sample plug instantaneously accelerate toward the adjacent separation buffer zone. On crossing the boundary, the higher conductivity environment induces a decrease in electrophoretic velocity and subsequent “stacking” of the sample components into a smaller buffer zone than the original sample plug. Within a short time, the ionic strength gradient dissipates and the charged analyte molecules begin to move from the “stacked” sample zone toward the cathode. Stacking can be utilized with either hydrostatic or electrokinetic injection and can typically yield a 10-fold enhancement in a sample concentration and, thence, sensitivity. An example is given in Figure 1.18, which shows separation of the standard peptide mixture in 50 mM phosphate separation buffer, pH 2.5. There is an obvious enhancement in detectability when the sample matrix is 5 mM phosphate in comparison with 50 mM separation buffer. The undesirable effects of high ionic strength

**FIGURE 1.18** Sample “stacking.” Stacking of peptides in phosphate buffer. Separation of a standard peptide mixture (peptide calibration kit, Bio-Rad, Richmond, CA). Peptides were (1) bradykinin, (2) angiotensin, (3)  $\alpha$ -melanin stimulating hormone, (4) thyrotropin-releasing hormone, (5) leutinizing hormone releasing hormone, (6) leucine enkephalin, (7) bombesin, (8) methionine enkephalin, and (9) oxytocin, 50  $\mu\text{g/mL}$  each. (a) Sample was dissolved in 50 mM phosphate buffer, pH 2.5. (b) Sample diluted in 5 mM phosphate buffer, pH 2.5. (c) Sample dissolved in 100 mM phosphate buffer, pH 2.5. Analyses were performed on a Beckman P/ACE System Model 2100. Separation conditions were as follows: capillary: 50  $\mu\text{m} \times 20$  cm (effective length), 27 cm total length, bare fused silica; T: 20°C; voltage: 10 kV; separation buffer: 50 mM phosphate, pH 2.5; 5 s hydrostatic injection; detection: 200 nm.

(100 mM phosphate buffer) sample matrix are clearly illustrated in the right panel. Detailed discussion of sample matrix effects on separation can be found in Chapter 13 and Chapter 26.

When possible, dissolving the sample in dilute separation buffer may be more advisable than in water since the dramatic differences in EOF between the sample plug and separation buffer may cause laminar flow within the capillary and, hence, lead to peak broadening.<sup>63,84,85,122</sup> Moreover, excessive heat produced in the sample plug may denature sample components.<sup>84,85,88,89</sup> Therefore, it may be advisable to “stack” at lower applied voltages (e.g., 1-2 KV) or “ramp” to the separation voltage over several minutes.

### 1.5.2 SAMPLE FOCUSING

An alternative approach to sample preconcentration by stacking in on-capillary “focusing” and is based on pH differences between the sample plug and separation buffer. This has been shown to be very useful for the analysis of peptides, mainly because of their relative stability over a wide pH range.<sup>119</sup> Focusing is easily accomplished by increasing the pH of the sample above that of the net pI (isoelectric point) of the sample. The high pH sample plug is flanked between low pH separation buffer zones (i.e., an equivalent volume of low pH separation buffer following introduction of the sample plug) and, on applying a voltage, the negatively charged peptides in the initial sample zone migrate toward the anode. Upon entering the lower pH separation buffer, a pH-induced change in their charge state causes a reversal in the direction of mobility resulting in a “focusing” on the

peptides at the interface of the sample (high pH) and low pH buffer plugs. After the pH gradient dissipates, the peptides, again positively charged, migrate toward the cathode as a sharp zone. This approach, limited to samples that can withstand the inherent changes in pH without substantial denaturation, may yield as much as a fivefold enhancement in sample concentration and, hence sensitivity. The practical and some theoretical aspects of these techniques are addressed in Chapter 26 by Shihabi and Chapter 13 by Burgi and Gierdano.

### 1.5.3 ISOTACHOPRETIC SAMPLE ENRICHMENT

Isotachoporetic (ITP) is a specialized technique for sample application first described for sample concentration by Foret et al.<sup>123</sup> This technique has been covered in detail by Burgi and Chein<sup>124</sup> in a previous edition of this handbook. However, more recently Williams and colleagues<sup>125</sup> utilized this in a very clever way to exploit the original on-capillary sample concentration<sup>123</sup> to enhance injection of DNA into microchannels for higher sensitivity fluorescence detection.

### 1.5.4 ONLINE CONCENTRATION

The development of capillaries with a small “column” or plug of adsorptive resin at the inlet side of the capillary has attracted much attention owing to its ability to allow the many-fold concentration of dilute samples from large volumes. It is the simplicity of the solid-phase extraction (SPE) concept that makes it attractive—load sample by flow through the phase where the analyte of interest is adsorbed onto the resin, wash the resin to remove loosely bound or unwanted components, and then desorb the analytes from the resin and separate by electrophoresis. The notion of online sample concentrate before separation was pioneered by Guzman<sup>126,127</sup> in the early 1990s coincident with the effort of Fuchs et al.<sup>128</sup> A number of groups honed in on the potential utility of this approach for solving sensitivity problems rooted in low concentration analytes in large volume biological samples, and shown the applicability of this method to the analysis of drugs,<sup>129,130</sup> peptides,<sup>131,132</sup> and proteins.<sup>133,134</sup> More recently, this has been applied to DNA extraction<sup>135–139</sup> and immunoaffinity capture.<sup>140–142</sup> This technique is discussed in detail in a various chapters in this edition of the CE handbook including Chapter 43 by Bienvenue.

## 1.6 CONCLUDING REMARKS

Capillary zone electrophoresis (CZE) is a powerful technique, magnetic in its analytical personality as a result of the simple way diverse analytes can be resolved rapidly and with high efficiency. The attraction is easy to understand—an electrophoretic technique with as much bandwidth as (and complementary to) HPLC and multiple modes of separation available by simply changing the buffer system. Yet within the simple instrumental framework that is, at its root, a power supply, a capillary and a detector, lies the capability to analyze drugs, peptides, carbohydrates, and proteins in sample matrices as simple as buffer or as complex as serum. That power is the magnet that draws people in.

In this chapter, I hope to have imparted to the reader a taste of CE, and some practical suggestions that will be useful in developing a method for the analysis of a specific compound(s). By using the basic principles associated with electrophoretic separation as discussed here, and applying a systematic approach to assess the factors that influence the resolution of the analyte(s) under study, it is likely a successful analytical method can be developed for just about any analyte of interest. In many of the core chapters that follow this chapter, specific methods are covered in detail with an analyte-specific focus—however, method development of some kind will be found in the vast majority one of the 55 chapters that constitute this handbook.

## APPENDIX 1

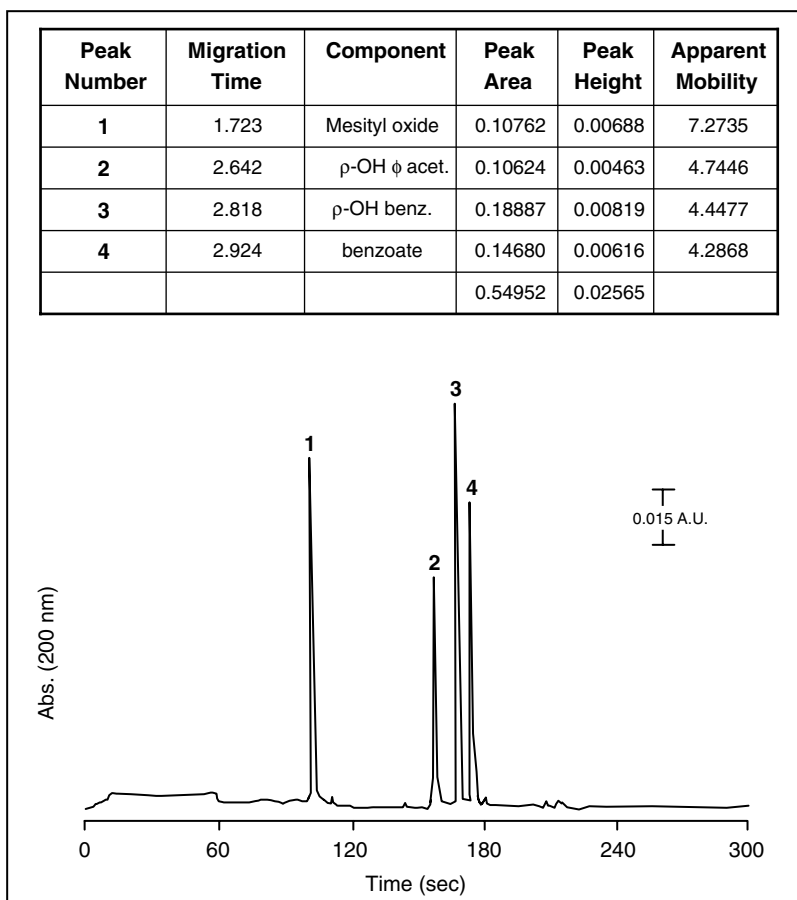

## CALCULATIONS OF PRACTICAL USE

In this section, we utilize an exemplary electropherogram (Figure A1.1) and the corresponding data obtained using the data management software (Figure A1.1, inset) to take the reader through a variety of calculations of practical use.

## A.1 MOBILITY

The velocity of an analyte,  $v_i$ , is the distance traveled during the time of electric field application. Velocity is related to mobility,  $\mu_i$ , by field strength,  $E = H/L$ . Thus,

$$v_i = \mu_{\text{app}}H/L = \mu_{\text{app}}E$$

**FIGURE A1.1** Simple separation of four small molecules for calculations of practical use. Separation of mesityl oxide [an EOF (neutral) marker], *p*-hydroxyphenylacetic acid, *p*-hydroxybenzoic acid, and benzoic acid [in borate buffer, pH 8.3; 3-s pressure (@0.5 psi) injection]. Analysis was carried out on a Beckman P/ACE System 2050. Separation conditions: capillary, 50  $\mu\text{m} \times 40\text{ cm}$  (effective length), 47 cm total length bare fused silica;  $T$ , 28°C; voltage, 25 kV; buffer, 100 mM borate, pH 8.3; detection, 200 nm. Inset: data derived from System Gold (vs7.1) data management software.

The apparent mobility  $\mu_{app}$  measured from an electropherogram is the sum of the mobility of the analyte and that due to electroosmotic flow (EOF):

$$\begin{aligned}\mu_{app,i} &= \mu_{ep} + \mu_{eo} \\ &= L_d L_t / t_{app,i} H \\ &= L_d L_t / H (1/t_{app,i} - 1/t_{ref}) + \mu_{ref}\end{aligned}$$

where  $L_d$  is length to the detector,  $L_t$  is total length of the capillary, and, if the reference peak is a neutral marker,

$$\mu_{ref} = 0.$$

To calculate  $\mu_{ref}$  for a charged reference peak, the above equation may be used, substituting  $t_{app,i}$  for the charged reference and  $t_{ref}$  for the neutral marker, with  $\mu_{ref} = 0$ .

### A.1.1 EXAMPLE

From Figure A1.1,  $L_d = 40$  cm,  $L_t = 47$  cm, and  $t_1 = 1.723$  min:

$$\begin{aligned}v &= L_d / t_1 = 0.4\text{m} / (1.723 \text{ min})(60\text{s}/\text{min}) \\ &= 0.003869 \text{ m/s} \\ &= \mu_{app} E = \mu_{app} H / L_t\end{aligned}$$

or apparent mobility  $= \mu_{app,1} = v L_t / H$

$$\begin{aligned}&= (0.003869 \text{ m/s})(0.47 \text{ m}) / 25 \text{ kV} \\ &= (0.001818 / 25) = 7.273 \times 10^{-4} \text{ cm}^2 / (\text{V} \cdot \text{s})\end{aligned}$$

Similarly for the other peaks,

$$\begin{aligned}\mu_{app,i} &= (0.4)(0.47) / (60)(25 \times 10^3) t_i = 12.533 \times 10^{-4} / t_i \text{ cm}^2 / (\text{V} \cdot \text{s}) \\ \mu_{app,2} &= 12.533 \times 10^{-4} / 2.642 = 4.744 \times 10^{-4} \text{ cm}^2 / (\text{V} \cdot \text{s}) \\ \mu_{app,3} &= 12.533 \times 10^{-4} / 2.818 = 4.448 \times 10^{-4} \text{ cm}^2 / (\text{V} \cdot \text{s}) \\ \mu_{app,4} &= 12.533 \times 10^{-4} / 2.924 = 4.286 \times 10^{-4} \text{ cm}^2 / (\text{V} \cdot \text{s})\end{aligned}$$

Using

$$\mu_{app,i} = L_d L_t / H (1/t_{app,i} - 1/t_{ref}) + \mu_{ref}$$

we may make the same calculation using  $\mu_{\text{ref}} = \mu_{\text{eo}} = 7.273 \times 10^{-4} \text{ cm}^2/(\text{V} \cdot \text{s})$ :

$$\begin{aligned}\mu_{\text{app},i} &= [(0.4)(0.47)/25 \times 10^3](1/t_{\text{app},i} - 1/1.723) + 7.273 \\ \mu_{\text{app},2} &= 12.533(1/2.642 - 1/1.723) + 7.273 \times 10^{-4} \\ &= 12.533(0.3785 - 0.5804) + 7.273 \times 10^{-4} \\ &= -2.530 + 7.273 \times 10^{-4} \text{ cm}^2/(\text{V} \cdot \text{s}) = 4.743 \times 10^{-4} \text{ cm}^2/(\text{V} \cdot \text{s}) \\ \mu_{\text{app},3} &= 12.533 \times 10^{-4}(0.3549 - 0.5804) + 7.273 \times 10^{-4} \\ &= -2.826 \times 10^{-4} + 7.273 \times 10^{-4} = 4.448 \times 10^{-4} \text{ cm}^2/(\text{V} \cdot \text{s}) \\ \mu_{\text{app},4} &= 12.533 \times 10^{-4}(0.3420 - 0.5804) + 7.273 \times 10^{-4} \\ &= -2.988 + 7.273 \times 10^{-4} = 4.285 \times 10^{-4} \text{ cm}^2/(\text{V} \cdot \text{s})\end{aligned}$$

The electrophoretic mobility,  $\mu_{\text{ep}}$ , may be calculated from

$$\mu_{\text{app},i} = \mu_{\text{ep}} + \mu_{\text{eo}}$$

as peak 1 in Figure A1.1 is a neutral marker,  $\mu_{\text{app},1} = \mu_{\text{eo}} = 7.273 \times 10^{-4} \text{ cm}^2/(\text{V} \cdot \text{s})$

$$\begin{aligned}\mu_{\text{ep},2} &= 4.744 - 7.273 = -2.529 \times 10^{-4} \text{ cm}^2/(\text{V} \cdot \text{s}) \\ \mu_{\text{ep},3} &= 4.448 - 7.273 = -2.825 \times 10^{-4} \text{ cm}^2/(\text{V} \cdot \text{s}) \\ \mu_{\text{ep},4} &= 4.286 - 7.273 = -2.987 \times 10^{-4} \text{ cm}^2/(\text{V} \cdot \text{s})\end{aligned}$$

## A.2 CORRECTED PEAK AREA

Integrators typically present peak area in dimensions of (response) (time). This calculation is a simple transformation to obtain area in (response) (width).

$$\begin{aligned}A_{\text{corr}} &= A_i(\text{mAU} \times \text{min})v_i \\ &= A_i(\text{mAU} \times \text{min})L_d(\text{cm})/t_m(\text{min}) \\ &= A_i(\text{mAU} \times \text{cm})\end{aligned}$$

This can usually be achieved through the data collection and software system.

### A.2.1 EXAMPLE

$$\begin{aligned}A_{\text{corr},1} &= (0.10762)(40)/1.723 \\ &= 2.498 \text{ mAU cm}\end{aligned}$$

Similarly,

$$\begin{aligned}A_{\text{corr},2} &= (0.10624)(40)/2.642 = 1.608 \\ A_{\text{corr},3} &= (0.18887)(40)/2.818 = 2.681 \\ A_{\text{corr},4} &= (0.14680)(40)/2.924 = 2.008\end{aligned}$$

Dividing the corrected area by peak height gives peak width, which approximates the peak width at half-height, which may be used to calculate  $N$  (see calculations, Section A.5).

$$w_{1/2,1} = 2.498 \text{ mAU} / 0.00668 \text{ } \mu\text{AU} = 374 \text{ } \mu\text{m}$$

$$w_{1/2,2} = 1.608 \text{ mAU} / 0.00463 \text{ } \mu\text{AU} = 347 \text{ } \mu\text{m}$$

$$w_{1/2,3} = 2.681 \text{ mAU} / 0.00819 \text{ } \mu\text{AU} = 327 \text{ } \mu\text{m}$$

$$w_{1/2,4} = 2.008 \text{ mAU} / 0.00616 \text{ } \mu\text{AU} = 326 \text{ } \mu\text{m}$$

### A.3 QUANTITY OF SAMPLE INTRODUCED INTO THE CAPILLARY

We assume

$$\begin{aligned} Q &= (\text{volume})_{\text{int}} (\text{concentration}) \\ &= \pi r^2 l [C_i] \end{aligned}$$

where  $r$  is the internal radius of the capillary,  $l$  is the length of the sample plug, and  $[C_i]$  is the concentration of the sample.

#### A.3.1 HYDRODYNAMIC INJECTION

$$Q = \pi r^2 [\Delta P r^2 t_{\text{int}} / (8\eta L)] [C_i]$$

where  $\Delta P$  is the pressure difference,  $r$  is the capillary inner radius,  $t_{\text{int}}$  is the introduction time,  $\eta$  is the viscosity of the sample solution, and  $L$  is the length of the column.

##### A.3.1.1 Example

Assuming typical values for the constants,

Column dimensions: 50  $\mu\text{m}$  i.d.  $\times$  47 cm, 40 cm to the detector

$$\eta = 0.9548 \text{ cP} = 9.548 \times 10^{-4} \text{ N/s/m}^2 \text{ at } 22^\circ\text{C}$$

$$\Delta P = 0.5 \text{ psi} = 3.435 \times 10^3 \text{ N/m}^2$$

$$t_{\text{int}} = 3 \text{ s}$$

Then

$$\begin{aligned} \text{vol}_{\text{int}} &= (3.1416)(25 \times 10^{-6})^2 \left\{ \left[ (3.435 \times 10^3) (25 \times 10^{-6})^2 3 \right] / \left[ 8 (9.548 \times 10^{-4}) 0.47 \right] \right\} \\ &= (19.635 \times 10^{-10}) (17.94 \times 10^{-4}) \\ &= 3.523 \times 10^{-12} \text{ m}^3 = 3.523 \text{ nL} \end{aligned}$$

which correlates with  $\simeq 1.2 \text{ nL/s}$  injection.

### A.3.2 ELECTROKINETIC INTRODUCTION

$$Q = [\pi r^2 (\mu_{\text{app}}) V_{\text{int}} t_{\text{int}} / L] [C_i]$$

where  $\mu_{\text{app}}$  is the mobility of the analyte,  $\mu_{\text{eo}}$  is the electroosmotic mobility, and  $V_{\text{int}}$  is the introduction voltage.

#### A.3.2.1 Example

Again assuming typical values,

Column dimensions:  $50\mu\text{m}$  i.d.  $\times$  47 cm, 40 cm to the detector

$$t_{\text{int}} = 20 \text{ s}$$

$$\mu_{\text{app}} = 4.744 \times 10^{-8} \text{ m}^2/\text{V/s}$$

$$\mu_{\text{eo}} = 7.273 \times 10^{-8} \text{ m}^2/\text{V/s}$$

$$V_{\text{int}} = 1.5 \text{ kV}$$

Then

$$\begin{aligned} \text{vol}_{\text{int}} &= (3.1416) (25 \times 10^{-6})^2 \left[ (4.744 \times 10^{-8}) (1.5 \times 10^3) 20 / 0.47 \right] \text{m}^3 \\ &= (19.635 \times 10^{-10}) (302.81 \times 10^{-5}) \text{m}^3 \\ &= 5.945 \times 10^{-15} \text{m}^3 = 5.945 \text{ nL} \end{aligned}$$

However, if we calculate the volume of fluid injected, which is due solely to  $\mu_{\text{eo}}$ ,

$$\begin{aligned} \text{vol}_{\text{int}} &= (3.1416) (3.1416) (x)^2 \left[ (7.273 \times 10^{-8}) (1.5 \times 10^3) 20 / (0.47) \right] \text{m}^3 \\ &= (19.635 \times 10^{-10}) (464.2 \times 10^{-5}) \text{m}^3 \\ &= 9115 \times 10^{-15} \text{m}^3 = 9.115 \text{ nL} \end{aligned}$$

With electrokinetic introduction, the amount of sampled injected is proportional to the analyte mobility. It is typically used when the sample has greater mobility than EOF. If one has a highly mobile analyte in relatively low ionic strength sample buffer ( $1/x$  times separation buffer) one may load an  $x$ -fold greater portion onto the column by electrokinetic introduction without adversely affecting separation resolution. In the above example, if the sample were in 0.1 times separation buffer, we could have loaded the equivalent of 59.5 nL of sample.

### A.4 RESOLUTION

Using the equation for resolution, we obtain

$$\text{Res} = 2(x_{i2} - x_{i1}) / (w_1 + w_2)$$

**A.4.1 EXAMPLE**

$$\begin{aligned}
 \text{Res}_{2-1} &= 2(2.818 - 2.642)/(0.02295 + 0.02306) \\
 &= 0.352/0.04601 \\
 &= 7.650 \\
 \text{Res}_{3-2} &= 2(2.924 - 2.818)/(0.02306 + 0.02383) \\
 &= 0.212/0.04689 \\
 &= 4.521
 \end{aligned}$$

Using the criterion that peaks are resolved when  $\text{Res} = 1$ , we could state that all three peaks are resolved.

**A.5 EFFICIENCY**

From the above example, we may calculate the efficiency (from Equation 1.17) of the separation of the peaks in Figure A1.1.

$$N = 5.54(L_d/w_{1/2})^2$$

where  $L_d$ , the length to the detector, is 40 cm, and the peak width is (peak area/peak height), both of which must be in the same units, either in time (min) or distance (cm). We shall calculate the efficiency using both time and distance.

**A.5.1 EXAMPLE 1**

For time calculations,

$$N_i = 5.54(L_d/w_{1/2})^2 = 5.54[t_i/(\text{area}_i/\text{peak height}_i)]^2$$

From the data in the inset of Figure A1.1, peak area is given in  $\text{mAU} \times \text{min}$ , and peak height is in AU. Thus,

$$\begin{aligned}
 N_1 &= 5.54 \{(1.732)/[0.10762(0.00668) (1000)]\}^2 \\
 &= 5.54(1.732/0.01611)^2 = 5.54(106.95)^2 = 63,368 \\
 N_2 &= 5.54(2.642/0.02295)^2 = 5.54(115.14)^2 = 73,445 \\
 N_3 &= 5.54(2.818/0.02306)^2 = 5.54(122.20)^2 = 82,728 \\
 N_4 &= 5.54(2.942/0.02383)^2 = 5.54(122.70)^2 = 83,406
 \end{aligned}$$

**A.5.2 EXAMPLE 2**

For distance calculations,

$$N_1 = 5.54(L_d/w_{1/2})^2 = 5.54[L_d/(\text{area}_{\text{con}}/\text{peak height})]^2$$

From calculations, Section A.2, corrected peak area above,

$$w_{1/2,1} = 2.498 \text{ mAU}/0.00668 \text{ } \mu\text{AU} = 374 \text{ } \mu\text{m}$$

$$w_{1/2,2} = 1.608 \text{ mAU}/0.00463 \text{ } \mu\text{AU} = 347 \text{ } \mu\text{m}$$

$$w_{1/2,3} = 2.681 \text{ mAU}/0.00819 \text{ } \mu\text{AU} = 327 \text{ } \mu\text{m}$$

$$w_{1/2,4} = 2.008 \text{ mAU}/0.00616 \text{ } \mu\text{AU} = 326 \text{ } \mu\text{m}$$

Therefore,

$$\begin{aligned} N_1 &= 5.54(40/0.374)^2 \\ &= 5.54(106.95)^2 = 63,370 \end{aligned}$$

Likewise,

$$N_2 = 5.54(40/0.347)^2 = 73,616$$

$$N_3 = 5.54(40/0.327)^2 = 82,896$$

$$N_4 = 5.54(40/0.326)^2 = 83,405$$

## A.6 JOULE HEATING

To calculate the Joule heating of a buffer, one should run an Ohm's law plot as outlined in Section 1.3.3.5.2, under Buffers. To calculate watts, we use the following:

$$\text{Watts/m} = (\text{voltage})(\text{amperage})/(\text{column length, cm}) 1000$$

### A.6.1 EXAMPLE

For 100 mM borate, pH 8.3:  $(25 \text{ kV})(13.17 \text{ } \mu\text{A})/(57 \text{ cm}) 1000 = 0.58 \text{ W/m}$

For 100 mM CAPS, pH 11.0:  $(25 \text{ kV})(134 \text{ } \mu\text{A})/(57 \text{ cm}) 1000 = 5.88 \text{ W/m}$

For 20 mM CAPS, pH 11.0:  $(25)(30.03)/57,000 = 1.32 \text{ W/m}$

For 100 mM PO<sub>4</sub>, pH 2.5:  $(25)(229.5)/57,000 = 10.06 \text{ W/m}$

For 50 mM PO<sub>4</sub>, pH 2.5:  $(25)(116.9)/57,000 = 5.13 \text{ W/m}$

For 25 mM PO<sub>4</sub>, pH 2.5:  $(25)(70.03)/57,000 = 3.07 \text{ W/m}$

## APPENDIX 2

### TROUBLESHOOTING

This table summarizes problems commonly encountered in capillary electrophoresis (CE) experiments, and plausible solutions to these problems.

Problem	Cause	Remedy
<b>I Peak-Associated Problems</b>		
<b>A. No peak observed</b>		
<i>1. Baseline on scale</i>		
	Inappropriate data collection scale	• Reset scale for appropriate absorbance parameter
	Inappropriate detector range	• Reset detector range
	Inappropriate detector wavelength	• Reset wavelength
	Separation time too short	• Lengthen analysis time • Lengthen capillary
	Reasonable current	• See Section 1.2.1
	Flow through capillary?	• See Section 1.5
	Integrity of sample	• Check sample level • Check for air bubble in bottom of sample vial • Increase sample introductory time • Check sample caps for leakage • See Section 1.5
<i>2. Baseline off scale</i>		
	Using voltage introduction	• See Section 1.2.1
	Offset baseline	• Rezero detector
	Inappropriate detector wavelength	• Reset wavelength
<b>B. Peaks present</b>		
<i>1. Too many peaks</i>		
	Random peaks may be caused by microbubbles	• Warm buffer to room temperature
	Solid contaminants in sample	• Reduce voltage • Filter sample (0.45 $\mu\text{m}$ pore size filter)
	Solid contaminants in buffer	• Filter buffer
	Residue from previous analysis	• Wash capillary
	Sample degradation	• Replace sample; check temperature of capillary chamber
<i>2. Too few peaks</i>		
	Proper wavelength used	• Reset detector wavelength
	Sufficient time	• Lengthen analysis time • Lengthen capillary
	Unreasonable current	• See Section 1.2.1
	Unreasonable voltage	• See Section 1.2.1
	Inappropriate temperature	• Reset temperature control
	Analyte–wall interactions	• Wash capillary • Check running conditions
	Fluid flow inadequate	• See Section 1.5
	Inadequate separation time	• Lengthen analysis time • Lengthen capillary • Reduce electroosmotic flow (EOF)
	Similar charge/mass ratio (not resolving components)	• Alter buffer pH • Reduce EOF • Try alternative separation mode: micellar electrokinetic chromatography (MEKC), capillary isotachopheresis (CITP), capillary isoelectric focusing (CIEF)
<i>3. Distorted peak shape</i>		
<i>a. Small peaks</i>		
	Improper wavelength	• Reset wavelength
	Inappropriate range on detector	• Reset detector
	Improper integration	• Reset integrator parameters
	Inappropriate sampling time	• Longer sample introduction time

Continued

Problem	Cause	Remedy
b. Flat-topped peaks	Sample too concentrated	<ul style="list-style-type: none"> <li>• Reduce introduction time</li> <li>• Dilute sample</li> </ul>
c. Peak tailing	Current too high	<ul style="list-style-type: none"> <li>• Ionic strength of separation buffer too high.</li> </ul> Check composition; dilute
	Sample buffer ionic strength too high	<ul style="list-style-type: none"> <li>• Reduce voltage</li> <li>• Dilute sample buffer</li> </ul>
	Analyte–wall interactions	<i>Modify separation buffer:</i> <ul style="list-style-type: none"> <li>• Increase ionic strength</li> <li>• Add organic solvents</li> <li>• Add cationic compounds</li> <li>• Add zwitterions (phosphorylethanolamine)</li> <li>• Use coated capillary</li> <li>• Consider different CE mode (e.g., MEKC)</li> </ul>
<b>II Instrument-Based Problems</b>		
<b>A. Current</b>		
1. <i>Fluctuating current during separation</i>	Vial levels low	<ul style="list-style-type: none"> <li>• Replenish buffer</li> </ul>
	Loose electrode connections	<ul style="list-style-type: none"> <li>• Tighten connections</li> </ul>
	Plugged capillary	<ul style="list-style-type: none"> <li>• Rinse/replace</li> </ul>
	Sample matrix effects	<ul style="list-style-type: none"> <li>• Check ionic strength of matrix</li> </ul>
2. <i>No current</i>	Safety interlock off	<ul style="list-style-type: none"> <li>• Reset interlock</li> </ul>
	Plugged capillary	<ul style="list-style-type: none"> <li>• Wash capillary</li> </ul>
	Broken capillary	<ul style="list-style-type: none"> <li>• Replace capillary</li> </ul>
	Buffer depletion	<ul style="list-style-type: none"> <li>• Replace buffers</li> </ul>
	Empty capillary	<ul style="list-style-type: none"> <li>• Fill reservoirs</li> </ul>
3. <i>Abrupt loss of current during separation</i>	Short in system (buffer on reservoir cap)	<ul style="list-style-type: none"> <li>• Dry cap</li> </ul>
4. <i>High current</i>	High ionic strength separation buffer	<ul style="list-style-type: none"> <li>• Decrease ionic strength</li> </ul>
<b>B. Baseline drift</b>		
	Contaminated capillary	<ul style="list-style-type: none"> <li>• Wash capillary</li> </ul>
	Contaminated aperture on detector	<ul style="list-style-type: none"> <li>• Clean aperture</li> </ul>
	Bad capillary alignment	<ul style="list-style-type: none"> <li>• Check alignment; realign or replace</li> </ul>
	Detector instability	<ul style="list-style-type: none"> <li>• Give adequate warm-up time</li> <li>• Replace lamp</li> </ul>
	Unstable capillary temperature	<ul style="list-style-type: none"> <li>• Check oven/bath temperature</li> <li>• Replace thermostat</li> </ul>
	Unstable room temperature	<ul style="list-style-type: none"> <li>• Stabilize room temperature</li> <li>• Deflect drafts away from instrument</li> <li>• Move instrument</li> </ul>
<b>C. Data analysis</b>		
Peaks observed: not analyzed	Inappropriate integration parameters	<ul style="list-style-type: none"> <li>• Reset integrator attenuation</li> </ul>
<b>III Sample Introduction</b>		
<b>A. Electrokinetic</b>		
<i>No peaks</i>	Anodic sample	<ul style="list-style-type: none"> <li>• Reverse polarity</li> <li>• Change separation buffer pH</li> </ul>
	Sample ionic strength too high	<ul style="list-style-type: none"> <li>• Dilute sample buffer</li> </ul>
	Sample pH too high	<ul style="list-style-type: none"> <li>• Adjust pH</li> </ul>
	Sample ionic strength too low	<ul style="list-style-type: none"> <li>• Raise ionic strength</li> </ul>
<b>B. Hydrodynamic</b>		
1. <i>No peaks</i>	Poor seal with sample vial	<ul style="list-style-type: none"> <li>• Replace seal</li> </ul>
	Pinched pressure/vacuum line	<ul style="list-style-type: none"> <li>• Replace line</li> </ul>

Problem	Cause	Remedy
	Depleted pressure source	<ul style="list-style-type: none"> <li>• Replace</li> </ul>
	Anodic sample	<ul style="list-style-type: none"> <li>• Reverse polarity</li> </ul>
2. Irreproducible peak height/area	Poor seal	<ul style="list-style-type: none"> <li>• Change separation buffer pH</li> <li>• Replace cap</li> </ul>
	Pinched pressure/vacuum line	<ul style="list-style-type: none"> <li>• Replace line</li> <li>• Decrease percentage volatile</li> </ul>
	Sample matrix volatility	<ul style="list-style-type: none"> <li>• Decrease solvent concentration</li> </ul>
<b>IV Poor Quantitative Reproducibility</b>		
<b>A. Migration time</b>		
1. Unstable temperature	Ionic strength too high	<ul style="list-style-type: none"> <li>• Dilute buffer</li> </ul>
	Voltage too high	<ul style="list-style-type: none"> <li>• Decrease voltage</li> </ul>
	Temperature too high	<ul style="list-style-type: none"> <li>• Decrease thermostatted temperature (see Section 1.2.2)</li> </ul>
	Sample matrix ionic strength too high	<ul style="list-style-type: none"> <li>• Dilute sample</li> </ul>
2. Others	Buffer depletion	<ul style="list-style-type: none"> <li>• Replenish with fresh buffer</li> </ul>
	Analyte–wall interactions	<ul style="list-style-type: none"> <li>• See Section 1.3.3.5</li> </ul>
	Buffer siphoning	<ul style="list-style-type: none"> <li>• Adjust level in inlet/outlet reservoirs<sup>1</sup></li> </ul>
	Contaminated capillary	<ul style="list-style-type: none"> <li>• Rinse capillary extensively</li> </ul>
	Inadequate rinse steps	<ul style="list-style-type: none"> <li>• Increase rinse time with rinse solution/buffer</li> </ul>
<b>B. Peak height/area</b>	Analyte–wall interactions	<ul style="list-style-type: none"> <li>• Increase ionic strength</li> <li>• Add dynamic coating agents (e.g., diaminobutane)</li> </ul>
	Current instability	<ul style="list-style-type: none"> <li>• See Section 1.2.1.1</li> </ul>
	Fouled capillary surface	<ul style="list-style-type: none"> <li>• See Section 1.2.3.4.3</li> </ul>
<b>V Capillary-Associated Problems<sup>2</sup></b>		
<b>A. No peaks—proper flow through capillary</b>	Anodic sample	<ul style="list-style-type: none"> <li>• Reverse polarity</li> </ul>
<b>B. Reduced flow through capillary</b>	Sample buffer too viscous	<ul style="list-style-type: none"> <li>• Dilute sample</li> </ul>
	Partially occluded capillary	<ul style="list-style-type: none"> <li>• Wash capillary. Check sample, buffers for particulates; filter if necessary</li> </ul>
	Pinched pressure/vacuum line	<ul style="list-style-type: none"> <li>• Replace line</li> </ul>
	Depleted pressure source	<ul style="list-style-type: none"> <li>• Replace</li> </ul>
<b>C. No flow</b>	Broken capillary	<ul style="list-style-type: none"> <li>• Replace capillary</li> </ul>
<b>D. Peaks irreproducible</b>	Partially occluded capillary	<ul style="list-style-type: none"> <li>• Unblock chemically (e.g., sodium ethoxide) or with pressure</li> </ul>
	Fouled capillary surface	<ul style="list-style-type: none"> <li>• Recondition capillary (e.g., NaOH or sodium ethoxide)</li> </ul>
	Poorly cut capillary inlet	<ul style="list-style-type: none"> <li>• Retrim inlet or replace capillary</li> </ul>

<sup>1</sup>This is unlikely to be significant with narrow diameter capillaries (i.e., <75  $\mu\text{m}$ ) since the hydrostatic head differential must be in range of 5 cm of water in order for this phenomenon to contribute appreciably.

<sup>2</sup>Be certain that there is adequate capillary flow. This can be accomplished as described in Chapter 1, Section 1.2.3.4. Alternatively, one may check the flow by pressure rinsing and observing droplets forming at the outlet end. If this must be done manually, a 6-cc syringe with a yellow Eppendorf pipette tip will produce enough pressure to create one drop every 20–30 s. with a 50  $\mu\text{m}$   $\times$  57 cm capillary.

## APPENDIX 3

### EFFECTIVE SEPARATION CONDITIONS FOR EACH CLASS OF ANALYTES

The following tables provide examples of buffer systems, some containing additives or using surface-modified capillaries, that have provided successful separation conditions for the select analytes. Culled from the capillary electrophoresis (CE) literature, this list is not comprehensive, but is

intended to provide the practitioner with a guide for starting conditions for method development for a particular type of analytes—no set of conditions is universally effective for any given class of analytes. For convenience, individual tables are provided for the analyte classes—ions, small molecules, peptides, proteins, and nucleic acids—in both bare silica and with coated surfaces, and with the chromatographic hybrid, micellar electrokinetic chromatography. Full details on the separation conditions can, of course, be found in the original reference.

### A.3.1 Ions

Buffer	Additives	Analytes/Sample	References
5 mM chromate or phthalate, pH 10.00	0.5 mM Nice-Pak OFM Anion-BT	Organic/inorganic ions	Romano et al. (1991)
5 mM chromate, pH 8.0	0.4 mM OFM Anion-BT	Organic/inorganic ions	Jones and Jandik (1992)
5 mM chromate, pH 11.0 (LiOH)	None		
30 mM creatinine, pH 4.8 (acetic acid)	8 mM hydroxyisobutyric acid	Metal ions	Lu and Cassidy (1993)
100 mM borate	50 mM tetrabutyl ammonium hydroxide	Inorganic/organic ions	Audalovic et al. (1993)

### A.3.2 Small Molecules: Charged and Neutral

Buffer	Additives	Analytes/Sample	Reference
CZE			
50 mM tetraethylammonium perchlorate	10 mM HCl in acetonitrile	Organic bases	Walbroehl (1984)
20–125 mM sodium phosphate, pH 2.5, 7.0–9.2	None	Cinnamic acid and analogs	Fujiwara and Honda (1986)
50 mM sodium phosphate, pH 7.0	50% acetonitrile (v/v)	Substituted benzoic acid isomers	Fujiwara (1987)
50–100 mM sodium acetate, pH 3.9–4.5	0.1% hydroxypropyl cellulose (v/v)	Isotopic benzoic acids	Terabe et al. (1988)
16 mM sodium sulfate, 5 mM MES, pH 6.7	30% methanol (v/v)	Methotrexate analysis	Roach et al. (1988)
20–125 mM sodium phosphate, pH 2.5, 7.0–9.2	None	Pharmaceuticals	Altria and Simpson (1988)
25 mM tetrahexylammonium perchlorate	50% acetonitrile (v/v)	Neutral organic molecules (e.g., polycyclic aromatic hydrocarbons)	Walbroehl and Jorger (1988)
25 mM MES, pH 5.5–5.65	10–20% 2-propanol (v/v)	Catecholamine analysis	Wallingford and Ewing (1989)
10 mM MES/His, pH 6.0	0.5 mM tetradecyltrimethylammonium bromide	Carboxylic acids	Huang et al. (1989)
5 mM sodium borate, pH 9.0	2% SDS (w/v), 0–1% ethylene (v/v) diamine, and 5% ethylene glycol (v/v)	Polyamines	Tsuda et al. (1990)
100 mM CAPS, pH 10.5	None	Nucleotides	Nguyen et al. (1990)
20 mM sodium citrate or 100 mM acetic acid, pH 2.0 or 2.9	None	Shellfish poisons	Thibault et al. (1991)

Buffer	Additives	Analytes/Sample	Reference
150 mM sodium dihydrogen phosphate, pH 2.98 or 5.98	Replacing water with D <sub>2</sub> O, pD = 2.98 or 5.98	Aniline derivatives	Okafo et al. (1991)
20 mM phosphoric acid/20% KOH, pH 7.00	None	Cimetidine in pharmaceutical preparations	Arrowood and Hoyt (1991)
50 mM CAPSO and 12.5 mM NaOH, pH 9.55	None	Tricyclic antidepressants	Salomon and Romano (1992)
10 mM sodium tetraborate and 50 mM boric acid or 40 mM NaOH, pH 9.55	Acetonitrile:water 50:50	<i>cis/trans</i> Isomers of butenedioic and retinoid acids	Chadwick and Hsieh (1991)
20 mM sodium phosphate or 3–5 mM imidazole or 50 mM acetic acid, pH 4.5–7.0	0.05% ethylene glycol (v/v)	Organic/inorganic cations and anions	Beck and Engelhardt (1992)
100 mM borate, pH 8.3	None	Chloramphenicol acetyl transferase (CAT) enzyme substrates and products	Landers et al. (1992a)
20 mM imidazolium acetate, pH 7.0	None	Sulfonamides	Ackermans et al. (1992)
20–50 mM phosphate, pH 6.8	0.02% hydroxypropylcellulose (w/v) or 0.15% CPDAPS (w/v) and 20% methanol (v/v) or 0.5% polybrene (w/v)	Cefixime and its metabolites	Honda et al. (1992)
6 mM sorbate, pH 12.1	None	Carbohydrates	Vorndran et al. (1992)
100 mM borate, pH 8.4	None	cis-diol containing compounds	Landers et al. (1992b)
100 mM tricine, pH 8.4	None	Norepinephrine, dopamine and metabolites	
8 mM sodium carbonate, 10 mM NaOH, pH 12.0	None	Simple carbohydrates	O'Shea et al. (1993)
5 mM phthalate, and 50 mM MES (1: pH 5.2; 2: pH 5.0)	0.5 mM TTAB	Organic acid counter ions (1: succinic and maleic; 2: trifluoroacetic)	(1) Altria et al. (1997) (2) Little et al. (2007)
25 mM phosphate (pH 2.3) or 0.2 M formic acid (pH 2.15)		Antifungal compounds	Crego et al. (2001)
15 mM borax-sodium phosphate monobasic (pH 8.3)	0.1 mM TAR	Uranium(VI) and other transition metal ions	Evans and Collins (2001)
50 mM borate (pH 8.15)	10 mM phytic acid	Phycobiliproteins	Viskari and Colyer (2002)
30 mM phosphate (pH 5.2)		HVA and VMA (metabolites of catecholamines)	Li et al. (2002)
10 mM sulfated $\gamma$ -cyclodextrin w/ 50 mM phosphate (pH 2.6)		Amphetamine type stimulants	Iwata et al. (2002)
30 mM phosphate (pH 9.8)		Riboflavin, flavin	Cataldi et al. (2003)
100 mM acetate (pH 4.5)		Glycosaminoglycan monosaccharides	Ruis-Calero et al. (2003)
40 mM phosphate and 10 mM borate (pH 9.0)	40 mM SDS	<i>E. coli</i> K4 polysaccharide	Volpi (2004)
10 mM glycine (pH 2.4)	5 mM QA- $\beta$ -CD (quaternary ammonium $\beta$ -cyclodextrin)	Highly negative enantiomers	Liu et al. (2004)
10 mM borate (pH 9.5)	20 mM SDS, 30% acetonitrile, 5% ethanol	Antiretroviral agents	Pereira et al. (2005)

Continued

Buffer	Additives	Analytes/Sample	Reference
0.1 M phosphate (pH 3.23)	15 mM $\beta$ -cyclodextrin	Metabolites of heroin	Qi et al. (2005)
10 mM MES and MOPSO (pH 5.5)	0.25 mM TTAB	EDTA, EDDS, IDS in cosmetics	Katata et al. (2006)
20 mM phosphate (pH 7.2)	60% acetone	Amitriptyline, doxepin, and chlorpromazine in urine	Li et al. (2006)
10 mM DBA, 2 mM 18-crown-6, and 8 mM lactic acid (pH 4.65)		Cations in beverages	Fung and Lau (2006)
15 mM chromate (pH 8.5)	1 mM CTAB	Cyanoacrylate adhesives	Whitaker et al. (2007)
32 mM borate (pH 9.2)	4.5 mM SDS	Monohydroxyl stereoisomers of flavanones	Wang et al. (2007)
Borate	Borate	Corticosteroids	Palmer et al. (1998)
MEKC	MEKC separations		
100 mM phosphate, pH 7.0	25 mM CM- $\beta$ -cyclodextrin	Cresol isomers	Terabe et al. (1983)
25 mM tetraborate/50 mM phosphate, pH 7.0	1 mM SDS	Phenols	Terabe et al. (1984)
50 mM phosphate/125 mM tetraborate, pH 7.0	50 mM SDS	PTH-amino acids	Otsuka et al. (1985)
100 mM tris-HCL, pH 7.0	50 mM DTAB		
20–50 mM phosphate, pH 7.0–8.0	10–50 mM SDS	Pharmaceuticals	Fujiwara and Honda (1987)
10 mM disodium phosphate and 6 mM borate, pH 7.0–9.0	50 mM SDS or 50 mM dodecyltrimethylammonium chloride or 50 mM STS	Phenols and polycyclic aromatic hydrocarbons	Burton et al. (1987)
10 mM phosphate/6 mM borate, pH 7.0	10 mM SDS	Catechols and catecholamines	Wallingford and Ewing (1989)
20 mM phosphate and 20 mM borate, pH 9.0	50 mM SDS and 20–60 mM tetralkylammonium salts	Vitamins and pharmaceuticals	Nishi et al. (1989)
29 mM phosphate-borate, pH 9.0	50 mM sodium cholate	Corticosteroids	Nishi and Terabe (1990)
20 mM sodium dihydrogen phosphate and 20 mM borate, pH 9.2	100 mM SDS and 10% acetonitrile (v/v)	Nucleosides and nucleotide-3-monophosphates	Lecoq et al. (1991)
50 mM phosphate, pH 6.0	50 mM SDS and 5% 2-propanol (v/v)	Creatinine and uric acid and polycyclic aromatic hydrocarbons	Mikaye et al. (1991)
50 mM phosphate and 100 mM borate, pH 8.09	8 mM $\alpha$ -cyclodextrin, 1 mM $\beta$ -cyclodextrin, and 1 mM $\gamma$ -cyclodextrin	Plant growth regulators	Yeo et al. (1991)
2.5–5.0 mM borate, pH 7.8–8.9	10–50 mM SDS	Organic gunshot and explosives	Northrop et al. (1991)
10 mM borate-phosphate, pH 8.7	50 mM SDS, 6 M urea, 20% methanol (v/v)	Benzothiazole sulfenamides	Nielsen and Mensink (1991)
8.5 mM phosphate and 8.5 mM borate, pH 8.5	85 mM SDS and 15% (v/v) acetonitrile	Acidic and neutral heroin impurities	Weinberger and Lurie (1991)
100 mM borate and 50 mM phosphate, pH 7.6	30 mM SDS, 3% 2-propanol (v/v) or 3 mM $\gamma$ -cyclodextrin	Vitamins	Ong et al. (1991)
10 mM borate, pH 9.5	75 mM SDS and 10% methanol (v/v)	Hydroquinone and related molecules in skin toning cream	Sakudinskaya et al. (1992)
50 mM phosphate and 100 mM borate, pH 6.0 or 7.0	3 mM $\beta$ -cyclodextrin or 2 mM $\gamma$ -cyclodextrin and 10 mM SDS	Sulfonamides and polycyclic aromatic hydrocarbons	Ng et al. (1992)

Buffer	Additives	Analytes/Sample	Reference
10 mM phosphate and 10 mM borate, pH 9.0	100 mM SDS and 20% methanol (v/v)	Enantiomers of amphetamine, methamphetamine, and their hydroxyphenethylamine precursors	Lurie (1992)
18 mM sodium tetraborate and 30 mM phosphate, pH 7.0	50 mM CTAB	Glucosinolates and their desulfo-derivatives	Morin et al. (1992)
60 mM tris/phosphate, pH 2.5	20 mM cyclodextrin ( $\alpha, \beta, \gamma$ )	Basic drugs	Nielsen (1993)
10 mM sodium phosphate	10% acetonitrile	Morphine-3-glucuronide	Wernly and Thormann (1993)
6 mM borate, pH 9.2	75 mM SDS	Mycotoxins	Holland and Sepaniak (1993)
10 mM sodium phosphate	7 mM cyclodextrin ( $\alpha, \beta, \gamma$ ), acetonitrile (0–15%)		
6 mM sodium borate	50 mM SDS, 50 mM deoxycholate	Phthalates/soil	Guo et al. (2005)
50 mM borate pH 8.5, 100 mM sodium cholate	MeOH 15%		
20 mM phosphate pH 2.5, 50 mM SDS	ACN 15%, 5% THF	Flavonoids	Tonin et al. (2005)
25 mM borate pH 9.5, 30 mM SDS, 10 mM Triton X-100		Chloroprotham aniline metabolites / potatoes	Orejuela et al. (2005)
20 mM borate, 20 mM phosphate pH 9, 80 mM sodium deoxycholate		Nitrofurans antibiotics	Wickramanayake et al. (2006)
50 mM borate pH 9.3, 50 mM SDS	$\gamma$ -CD 20 mM	Doxorubicin, doxorubicinol	Eder et al. (2006)
20 mM borate, 150 mM CTAB, 10% IPA in MeOH	31.5% H <sub>2</sub> O	Biphenyl nitrile derivatives	Gong et al. (2006)
15 mM borate pH 10.2, 40 mM SDS		Ibuprofen, tetrazepam/urine	Nevado et al. (2006)
20 mM Tris pH 9, 300 mM SDS	MeOH 18%	Cefepime, vancomycin/plasma, CSF	Yang et al. (2007)
100 mM borate pH 9, 60 mM SDS	IPA 2%	Pesticides/wine	Molina-Mayo et al. (2007)
20 mM borate pH 9.3, 50 mM sodium cholate, 20 mM Brij-35	$\beta$ -CD 5 mM	Amine metabolites/human biofluids	Tseng et al. (2007)
5 mM borate pH 9.3, 20 mM SDS	ACN 20%	Sudan dyes/chili powder	Mejia et al. (2007)

### A.3.3 Peptides

Buffer	Additives	Analytes/Sample	Reference
150 mM phosphate, pH 3.0	None	Angiotensin II octapeptides	McCormick (1988)
10 mM tricine, pH 8.0–8.1	5.8–45 mM morpholine and 20 mM NaCl or KCl	LGH tryptic digest	Neilsen et al. (1989a)
100 mM phosphate, pH 2.5	30 mM ZnSO <sub>4</sub>	DL-His-DL-His	Mosher (1990)
25 mM tris/25 mM phosphate, pH 7.05	50 mM HTAB	Angiotensin analogs	Liu et al. (1990)
0.5 mol/L acetic acid, pH 2.6	None	Di- and triglycine, synthetic growth hormone-releasing peptide	Prusik et al. (1990)

*Continued*

Buffer	Additives	Analytes/Sample	Reference
250 mM borate, pH 7.0	1% ethylene glycol (v/v) and 7% acetonitrile (v/v)	Proteinase-digested horse myoglobin	Tanaka et al. (1991)
20 mM citric acid pH 2.5	None	Motilin and synthetic peptides	Florance et al. (1991)
20 or 150 mM sodium dihydrogen phosphate, pH 2.93, 7.93, or 7.95	Replacing water with D <sub>2</sub> O, pD = 2.93, 7.93, or 7.95	Simple peptides, tryptic digest of calcitonin, glucagons, and cytochrome <i>c</i>	Camilleri et al. (1991)
40–80 mM tris and tricine, pH 8.1–8.2	None	$\beta$ -Casein tryptic and ACTH-endoproteinase Arg C digests	Krueger et al. (1991)
25 mM phosphate, pH 2.2 (KOH)	None	Adrenocorticotrophic hormone (ACTH) peptide fragments	Van de Goor et al. (1991)
20 mM formate, pH 3.8	Alanine		
20 mM $\epsilon$ -aminocaproate, pH 4.4 (Acetic acid)	None		
20 mM histidine, pH 6.2	MES		
40 mM imidazole, pH 7.5	MOPS		
100 mM borate, pH 8.3 (KOH)	None		
50 mM phosphate, pH 2.5	40% acetonitrile (v/v)	Multiple antigen peptides	Tanaka et al. (1991)
50 mM sodium dihydrogen phosphate, pH 3.93	0.1% TFA (v/v) and 0.05% hydroxymethylpropyl cellulose (v/v)	$\alpha$ and $\beta$ species of CGRP	Saria (1992)
20 mM citrate buffer, pH 2.50	None	Peptide monomers and dimmers	Landers et al. (1993)
50 mM formic acid, pH 2.5	10 mM sodium chloride	Basic peptides	Gaus et al. (1993)
10 mM tris and 10 mM disodium, pH 7.05	50 mM dodecyltrimethyl ammonium bromide	Angiotensin analogs	Novotny et al. (1990)
50 mM borate and 20–25 mM tris and 10–25 mM disodium hydrogenphosphate, pH 9.50 or 7.05	50 mM SDS or 20 mM $\beta$ -cyclodextrin and 1% THF (v/v) or 15% methanol (v/v) or additives such as 0.05 M HTAB or 2–50 mM DTAB	Derivatized peptides and angiotensin analogs	Liu and Novotny (1990)
10 mM sodium phosphate	7 mM cyclodextrin ( $\alpha, \beta, \gamma$ ), acetonitrile (0–15%)	Mycotoxins	Holland and Sepaniak (1993)
6 mM sodium borate	50 mM SDS, 50 mM deoxycholate		
200 mM borate buffer at pH 7.4	None	Human serum proteins: albumin, 1-globulin, 2-globulin, $\beta$ -globulin, and gamma-globulin	Bossuyta et al. (1998)
5 mM ammonium acetate, pH 4	(Coupled to mass spectrometry)	Phytochelatin in cell extracts	Mounicou et al. (2001)
15 mM sodium citrate (pH 2.1)	0.05% Tylose (methylhydroxyethylcellulose, 30,000 P, that is, viscosity of a 2% w/v solution in H <sub>2</sub> O at 20°C)	$\beta$ -lactoglobulin and $\alpha$ -lactalbumin in milk product isolates	De Block et al. (2003)
50 mM Tricine pH 8.0	20 mM NaCl and 2.5 mM 1,4-diaminobutane (DAB)	Recombinant human granulocyte colony-stimulating factor, glycosylated and nonglycosylated isoforms	Zhoua et al. (2004)
10 mM Tricine, pH 5.5	0.01 M NaCl, 0.01 M sodium acetate, 7 M urea, and 3.9 mM 1,4-diaminobutane	Human alpha-1-acid glycoprotein	Lacunza et al. (2006)

Buffer	Additives	Analytes/Sample	Reference
40 mM sodium phosphate (pH 2.65)	None	Cleavage products of peptide substrates for botulinum neurotoxin	Purcell and Hoard-Fruchey (2007)
<b>Peptides (Coated Capillaries)</b>			
150 mM phosphoric acid, pH 1.5 in polyvinylpyrrolidone-coated capillary	None	Dipeptides	McCormick (1988)
1 M Acetate and 20% MeOH, Polybrene coated capillary	MeOH	Recombinant human erythropoietin (rhEPO)	Balaguer and Neusü (2006)

### A.3.4 Proteins

Buffer	Additives	Analytes/Sample	Reference
20 mM borate, pH 8.25	None	Model proteins	Lauer and McManigill (1986)
10 mM tricine, pH 8.22	20 mM KCl	Biosynthetic human insulin derivatives and growth hormone	Neilsen et al. (1989b)
10 mM tricine, pH 8.0	5.8 mM morpholine and 20 mM NaCl		
50 mM glutamine-triethylamine, pH 9.5	Vinyl-bound polyacrylamide-coated capillaries	Model proteins	Cobb et al. (1990)
50 mM sodium phosphate, pH 7.0	Applied Biosystems coating reagent	Multiacetylated histone H4 proteins	Wiktorowicz and Colburn (1990)
50 mM sodium borate decahydrate, pH 10.0	None	Human serum proteins	Gordon et al. (1991)
50 mM tricine, pH 8.0	30% methanol (v/v)	Glycoproteins: recombinant human	Tran et al. (1991)
50 mM MES, pH 6.0	30% ethylene glycol (v/v)	Erythropoietin	Towns and Regnier (1991)
10 mM phosphate, pH 7.0 in capillaries coated with either Tween 20/alkylsilane or Brij	None	Basic proteins	
10 mM citrate, pH 3.0 in BSA-coated capillary	4 mM CHAPSO	Standard proteins	Swedberg (1993)
30 mM citrate, pH 3.0 in a polyacrylamide-coated capillary (uncrosslinked)	None	Standard proteins	Kohr and Engelhard (1991)
50 mM sodium tetraborate, pH 8.3	25–50 mM LiCl	Fluorescamine-labeled interferon and other proteins	Guzman et al. (1992)
100 mM borate, pH 9.0	1 mM diamionobutane	Ovalbumin	Landers et al. (1992c)
20 mM phosphate, pH 3.0	30 mM NaCl, 0.05% polyvinyl alcohol (w/w)	Basic proteins	Gilges et al. (1992)
TES (NaOH), pH 7.0	0.2% SDS linear acrylamide (CGE)	Proteins (3–205 kDa)	Werner et al. (1993)
SDS polyacrylamide gel		Proteins	Tsuji (1994a,b) Shieh et al. (1994)
Iminodiacetic acid (IDA), 50 mM	10% Trifluoroethanol (TFE), 0.5% hydroxyethylcellulose (HEC); or 0.5% HEC and 6–8 M urea	Proteins and peptides	Bossi and Righetti (1997)

*Continued*

Buffer	Additives	Analytes/Sample	Reference
50 mM aspartic acid	0.5% hydroxyethyl cellulose, 5% trifluoroethanol, 1 zwitterionic detergent (CHAPS)	Alpha and beta-globin chains from human adult Hb	Capelli et al. (1997)
Acetic acid	Acetonitrile and hexane sulfonic acid	Heptathelical membrane proteins	Dong et al. (1997)
Phytic acid		Proteins	Veraart et al. (1997)
Ammonium formate	Trimethylamine (TEA)	Proteins	Lee and Desiderio (1997)
Phosphate buffer	Guaran (neutral polysaccharide)	Basic proteins and drugs	Liu et al. (1991)
50 mM phosphate with 11 mM sodium pentasulfate	11 mM sodium pentasulfate (SPS)	Protein content of a single cell	Zhang et al. (2000)
Acetic acid	10 mM hydroquinone	Protein digests	Moini et al. (1999)
Methanolic buffer (methanol/formic acid/water = 60:20:20)		Enzymic digest peptides	Katayama et al. (2000)
Glutamic acid	1 mM oligoamine (tetraethylene pentamine)	Proteins/muscle acylphosphatase (AcP)	Verzola et al. (2000)
Iminodiacetic acid or aspartic acid	TEPA (tetraethylenepentamine)	Human alpha and beta globin chains	Olivieri et al. (2000)
Borate buffer	SDS and PEO	Proteins: microheterogeneities and isoforms	Tseng et al. (2002)
Acetic acid OR ammonium acetate OR ammonium bicarbonate OR sodium bicarbonate/carbonate OR phosphate OR tris OR ammonium bicarbonate	Acetonitrile	Human high density apolipoproteins	Deterding et al. (2002)
Linear polyacrylamide (sieving)		Proteins	Gomis et al. (2003)
Run buffer: Tris, 0.035 M aspartic acid, 0.1% SDS, 4% acrylamide			
1-Alkyl-3-methylimidazolium-based ionic liquids		Basic proteins	Jiang et al. (2003)
90-mM 1-ethyl-3-methylimidazolium tetrafluoroborate (1E-3MI-TFB)			
25 mM Borax pH 9.4	200 nM SSB (single-strand binding protein) for NECEEM	Basic proteins, separation via Nonequilibrium Capillary Electrophoresis of Equilibrium Mixtures (NECEEM)	Berezovski et al. (2003)
Acidic buffers	Tetraalkylammonium and tetrabutylammonium cations	Peptides and proteins	Quang et al. (2003)
6 mM phosphate buffer	Mexiletine (chiral CE)	Human Serum Ablumin: conformational change	Xu et al. (2004)

Buffer	Additives	Analytes/Sample	Reference
SDS-pullulan (capillary sieving electrophoresis) followed by MECC		Protein fingerprinting of single mammal cells	Hu et al. (2004)
Formic acid (1 M, pH 1.78) for CZE followed by 125 mM ammonium formate (pH 4) for tCITP		Human metal binding proteins	Stutz et al. (2004)
Phosphate buffer (50 mM)	Heptanesulfonic acid (ion pairing agent)	Proteins and peptides	Miksik et al. (2004)
Formic acid (pH 2.4, 50 mM), sodium phosphate buffer, ammonium formate and ammonium borate		Intact proteins	Eriksson et al. (2004)
20 mM phosphate buffer pH 2.5	Pluronic F-127	Enzymic digests of insol. Matrix proteins	Miksik et al. (2004)
Diethylenetriamine (DIEN) phosphate buffer		Basic proteins	Corradini et al. (2005)
Ternary nonaqueous buffer: 60/30/10 v/v methanol/acetonitrile/acetic acid	12.5 mM ammonium acetate	Tryptic digests	Assuncao et al. (2005)
Triethanolamine and phosphoric acid, pH 2.5		Microheterogeneity of intact recombinant glycoprotein	Berkowitz and Zhong (2005)
Replaceable cross-linked polyacrylamide (rCPA)			Lu et al. (2005)
MCRB (Moving Chem. Reaction Boundary): weak acidic run buffer with alk. Sample buffer		Basic proteins	Cao et al. (2005)
Carrier ampholytes		Tryptic digests	Busnel et al. (2006)
Tris-phosphate	0.05% polyethyleneimine	Proteins	Sedlakova et al. (2006a)
0.1 M Phosphate pH 2.5	Pluronic F 127	Proteins, peptides, digests	Sedlakova et al. (2006b)
Acid buffers: ammonium acetate, ammonium hydroxyacetate, phosphate	DDAB capillary coating	Basic proteins	Mohabbati and Westerlund (2006)
Borate pH 8.3	D-PEG dedecylpoly(ethylene glycol ether)	Capsid proteins from rhinovirus	Kremser et al. (2006)
Tris-HCl pH 8.2	“Smart aptamer” affinity probes	MutS protein	Drabovich and Krylov (2006)
Tris-borate pH 10	SDS or PEO	Microheterogeneous proteins	Huang et al. (2006)
50 mM Tris-HCl pH 8.5	Artificial gel antibodies	Transferrin	Takatsy et al. (2006)
30 mM ammonium acetate pH 5.5		Mixtures of drugs, peptides, tryptic digests of proteins, biological fluids	Fanali et al. (2006)
MEKC run buffer: 20 mM CAPS, 60 mM sodium cholate, 20% v/v ACN		Urinary CPIII and CPI	Li and Huie (2006)

*Continued*

Buffer	Additives	Analytes/Sample	Reference
0.01 M Tricine, 0.01 M NaCl, 0.01 M sodium acetate, 7 M urea		Intact forms of Alpha-1-acid glycoprotein (AGP)	Lacunza et al. (2006)
20 mM Borax in heavy water	Note: Online CE FTIR detection	Model putrescine proteins	Kulka et al. (2006)
Barium tetraborate 10 mM phosphate Poly ( <i>N,N</i> -dimethylacrylamide)-grafted polyacrylamide (self-coating sieving polymer)	Gold nanoparticles	Tryptic digests Acidic and basic proteins Native proteins	Mendieta et al. (2006) Yu et al. (2006) Zhang et al. (2006)
Tris-phosphate	0.05% (w/v) polyethyleneimine	Proteins	Sedlakova and Miksik (2006)
0.1 M Phosphate pH 2.5	Pluronic F 127	Proteins, peptides, digests	Sedlakova et al. (2006)
1. TRIS-CHES-SDS-Dextran (sieving)		Proteins and biogenic amines from mouse AtT-20 cell line	Chen et al. (2007)
2. TRIS-CHES-SDS (MECC)			
10% acetic acid	0.5% chitosan (high molecular weight) with 0.1% acetic acid	Complex peptide mixtures	Busnel et al. (2007)
100 mM borate pH 8.3	6 mM diaminobutate (DAB)	Transferrin	Bortolotti et al. (2007)
100 mM phosphate	High concentration PDDAC: Poly(diallyldimethylammonium chloride)	Cationic proteins Anionic proteins	Lin et al. (2007)

### A.3.5 Nucleic Acids

Buffer	Additives	Analytes/Sample	Reference
50 mM phosphate, pH 7.0	5% ethylene glycol (v/v)	Oligo dT ladder	Kasper et al. (1988)
1 mM borate, pH 9.1 (CGE)	30% hydrolink (polymerized)	Restriction fragments	
100 mM trizma	Cesium hydroxide	Forensic DNA	McCord et al. (1993)
100 mM boric acid, pH 8.7 (CGE)	0.1 mM EDTA		
	0.5% hydroxyethylcellulose		
29 mM Tris, 68 mM HEPES (pH 7.2); 15 mM Tris, 27 mM MES, 0.5 M EDTA (pH 6.4); 167 mM Tris, 33 mM boric acid (pH 9.0)	0.5% HPMC (pretreatment); 6% short-chain and linear polyacrylamide (SLPA)	Single-stranded DNA	Ren and Ueland (1999)
20 mM TAPS, pH 7.5	7 M urea; 4% HEC	RNA analysis	Saevels et al. (1999)
89 mM Tris-base [pH 8.3], 89 mM boric acid, 2 mM EDTA	4 M urea; 1% PVP	RNA analysis	Khandurina et al. (2002)
20 mM Tris, 10 mM phosphoric acid, pH 7.3	4.5% HPC	DNA analysis/determination of genetically modified organisms	Giovannoli et al. (2004)
50 mM Tris-borate buffer	5% glycerol; 2% methylcellulose	Single-strand conformation polymorphism analysis	Endo et al. (2005)
100 mM TB buffer (pH 8.0)	0.36 µg/mL CTAB; 0.5% PEO	Double-stranded DNA	Lin and Chang (2006)

Buffer	Additives	Analytes/Sample	Reference
50 mM Tris-acetate (pH 8.2)	2 mM MgCl <sub>2</sub> (gel free separation)	SNP analysis	Drabovich and Krylov (2006)
40 mM Tris, 60 mM Mes, and 2 mM EDTA, pH 6.11	1.5% poly( <i>N</i> -isopropylacrylamide) (PNIPAM)	DNA analysis	Yu et al. (2006)
30 mM Trizma® Base, 100 mM TAPS, 1 M EDTA, pH 8.0	7 M urea; 8% PVP or 7% PVP, 1% PDMA	DNA sequencing	Ekstrøm, and Bjørheim (2006)
20 mM Tris-HCl, 2 mM KCl	0.03% Triton X-100	Nucleic acid aptamers	Li et al. (2007)
50 mM sodium bicarbonate, pH 9.0	70 mM SDS	DNA analysis	Hua and Naganuma (2007)
20 mM Tris, 9.5 mM orthophosphoric acid, 2 mM EDTA, pH 7.3 (CGE)	4% HEC	DNA analysis/determination of genetically modified organisms	Sánchez et al. (2007)

## 2.1 INTRODUCTION

Almost any analytical protein application can be accomplished using capillary electrophoresis (CE). CE can be used to characterize protein properties, identify specific protein isoforms, quantify expression levels, study protein interactions with other biomolecules or map the distribution of proteins in one or more analytical dimension. Yet, protein analysis arguably remains the least widely used major CE application. Compared to analysis of nucleotides or small organic compounds, protein analysis by CE has faced greater technical challenges and more persistent competition from alternative separation and assay techniques. Although many protein applications are exquisitely or uniquely accomplished with CE, others are still better achieved using conventional analytical methods (e.g., gel electrophoresis, enzyme-linked immunosorbent assay (ELISA), or column chromatography) or other

advanced technologies (e.g., high-performance liquid chromatography (HPLC), mass spectrometry (MS), or protein microarray). If an investigator has a small number of specific protein applications to perform over and over again, CE's automation and low reagent costs make it a very attractive alternative. If an investigator wants a versatile system that can be used to analyze more than just proteins, opportunities abound on multimode open analytical CE platforms simply by changing the capillary, separation medium, and/or detector. High resolution, versatility, automation, small sample volume requirements, and minimal waste production are the hallmarks of CE for all applications. Poor reproducibility and lack of sensitivity and specificity are traditional weaknesses of CE for protein analysis. The purpose of this chapter is to provide an overview of how CE is used for protein analysis and how it might be used in the future. CE instrument and method development will be strongly influenced by systems biology and the search for biomarkers of complex diseases. Recent technological advances that improve capillary performance and enhance detection of proteins suggest that CE will play a major role in the evolving field of proteomics.

## 2.2 BACKGROUND

Capillary electromigration techniques can be effectively applied for protein analysis in all areas of biology. Basic theoretical principles and applications of CE are discussed here in the context of human biology and disease but are similar whether the analytical focus is plants or other animals. Terminology used to describe the separation of proteins by CE will conform to the recommendations of the Analytical Chemistry Division of the International Union of Pure and Applied Chemistry (IUPAC) [1] except that CE will be used according to tradition as a collective term for all capillary electromigration techniques. Recent progress in the use of CE for a wide variety of protein applications has been documented in a periodic series of reviews by Dolnik and colleagues [2–4]. Other recent reviews specifically related to proteins [5], application of specific CE techniques to proteins and other molecules [6–10], and the use of CE in systems biology and proteomics [11,12] are also recommended.

### 2.2.1 CURRENT STATUS OF CE FOR PROTEIN ANALYSIS

Capillary electrophoresis has found widespread use for protein analysis in the pharmaceutical [13,14] and food science [15–17] industries, primarily for process quality control in determining the purity of natural and synthetic proteins, peptides, and monoclonal antibodies. Dedicated CE instruments are commercially available for clinical diagnostics based on hemoglobin variants or serum and urine proteins [18–22]. Future development of CE in the pharmaceutical, food science, and diagnostic industries appears strongly linked to advances in microchip CE technology and its promise of high-throughput, low-cost analyses [23–25]. CE is not a standard tool in most biology or biochemistry research laboratories. One reason is that competing technologies were already entrenched when CE was first developed. Another is that CE has low UV/Vis detection sensitivity and lacks specificity for analysis of proteins in complex biological matrices. CE is also consistently outperformed by conventional techniques in applications that require fractionation and recovery of proteins for further study [26].

Significant advances have been made in commercial CE instrumentation since the last edition of this book was published. Open analytical systems are more reliable and dedicated microchip systems are commercially available. High-throughput, multicapillary platforms with dedicated proteomic applications are either on the market or nearing final development. Engineering advances include better microfluidics, better optics and electronics, wider range of detection options, and improved software for instrument control and for data processing, analysis and reporting. Newer coated capillaries allow for better control of electroosmotic flow (EOF) and reduce protein–wall interactions in ways that markedly improve the reproducibility and efficiency of CE analyses. The development

of multidimensional assay systems and advances in protein detection by MS and fluorescence has improved the sensitivity and specificity of CE for analysis of proteins in the complex biological matrices that are the targets of proteomic studies. More widespread use of CE for protein analysis might be predicted as biomedical research turns more from the study of individual proteins to large-scale assessment of the human proteome. What role CE will play in the evolving field of proteomics depends on how effectively CE competes with or complements other advanced protein separation technologies, and on how proteomics is applied to the study of complex biological processes.

Some CE techniques are better suited than others for analysis of proteins. A wide variety of applications have been developed for protein analysis by capillary zone electrophoresis (CZE), capillary isoelectric focusing (CIEF), capillary sieving electrophoresis (CSE), and micellar electrokinetic chromatography (MEKC). All of these techniques are excellent for high-resolution analysis of specific polypeptides in uncomplicated matrices, which makes CE ideal for use in process quality control and characterization of purified proteins. CZE and CIEF are also excellent for the analysis of specific proteins in complex biological matrices if the protein or proteins of interest are naturally abundant or readily extracted from biological samples before analysis. Hemoglobin variants, for example, can be directly analyzed in crude hemolysates using commercially available on-capillary detection systems because globins are abundant and do not precipitate at the higher concentrations required for UV/Vis detection. Analysis of less abundant or less soluble proteins often require sample prefractionation, concentration and/or derivatization to enhance detection sensitivity. Like open analytical HPLC platforms, a single multimode open analytical CE platform can be used to accomplish different protein applications depending on the choice of capillary, separation medium and detection system. Capillaries, reagents, and detectors can be readily interchanged, making it simple to switch from one protein application to another. In general, CE offers superior separation efficiency compared to more conventional protein separation techniques when using CZE, CIEF or MEKC. CSE performed on an open analytical CE platform offers relatively fewer advantages over conventional size separation methods beyond those generally characteristic of all CE techniques (i.e., automation, low sample volume requirement, etc.). In contrast, automated microchip CSE represents a significant time- and labor-saving improvement over conventional gel electrophoresis systems but the advantages come at a price. High instrument start-up costs and the need for more advanced operator expertise are obstacles to more widespread CE use as is the fact that CE methods are essentially nonpreparative and fraction collection remains technically challenging.

A significant barrier to the use of CE for protein analysis in many biology and biochemistry research laboratories is the lack of specificity and flexibility provided by conventional polyacrylamide gel electrophoresis, especially when combined with Western blotting. Commercially available reagents and preprepared native, denaturing, isoelectric focusing and two-dimensional (2D) gels offer a wide and usually adequate range of separation efficiencies at relatively low cost per sample, and it requires little expense or expertise to introduce conventional gel electrophoresis into any laboratory. Western blotting is generally as specific as the primary antibody employed, but that functionality is conserved in immunoassays performed by capillary affinity electrophoresis (CAE). A main difference between CAE and Western blotting is that Western blotting is usually performed non-competitively with enzyme-linked secondary antibody detection, and the target protein can be easily changed by switching from one primary antibody to another. Other than the relatively straightforward need to optimally titrate primary and secondary antibody concentrations, most other analytical aspects of Western blotting are consistent regardless of the protein of interest. Moreover, antibodies and reagent kits are widely and inexpensively available commercially. So are gel documentation systems that feature sensitive chemiluminescence and/or phosphorescence detection and software that makes data analysis simple. In contrast, most CAE protein immunoassays are performed non-competitively using fluorescent-labeled primary antibodies or competitively using labeled peptides as competing antigens [27], and it is not as easy to switch from one protein immunoassay to another. Automated immunoassay of specific proteins in a microchip or multicapillary format offers many advantages over traditional Western blotting in terms of separation efficiency and throughput

potential. However, ELISA and protein microarrays [28] competitively offer similar advantages for many protein applications.

A PubMed search of research literature published over the last 10 years using CE as a search term consistently identified approximately 1000 articles during each year of that period. The proportion of articles identified by adding “protein” as a search term was consistently about one-fourth of that total, suggesting sustained interest in CE for protein analysis. Continued evolution of CE immunoassays, microchip platforms and multidimensional systems that incorporate CE with MS and other advanced detection technologies can be expected to increase the use of CE for protein analysis as biomedical research turns its attention from genomics to proteomics and demand for high-throughput protein analysis increases.

### 2.2.2 THE CHALLENGES OF SYSTEMS BIOLOGY AND PROTEOMICS

To study proteins is to study biology, the focus of which is increasingly shifting from individual molecules to systems. Systems biology uses top-down and bottom-up approaches to integrate life science information and better understand the control and operation of biological processes in health and disease [29]. Top-down systems biology is systemic-data driven and identifies molecular interaction networks on the basis of correlated molecular behavior by integrating data from the genome, transcriptome, proteome, and metabolome. Bottom-up systems biology examines the mechanisms through which functional molecular properties arise and constructs detailed mechanistic models of biological processes that can be used to predict system properties. The systems biology approach is more than just a neologistic exercise that combines “-omics” with existing words. It is a conceptual framework that permits consideration of complex systems in a way that begins to encompass the enormous amount of biological variation inherent to living organisms.

Proteomics is the systematic inventory of protein expression levels, posttranslational modifications and interactions with other biomolecules that along with genomics, transcriptomics and metabolomics is an integral part of the systems biology approach. Unlike the relatively static genome, the proteome is a dynamic entity that changes in different physiological states (e.g., health versus disease) and biological compartments (e.g., fluids, cells, tissues, or organisms). The human genome is estimated to contain 30,000–40,000 genes that by alternative splicing or other means code for the production of around 100,000 different proteins [30]. These include enzymes, structural proteins, peptide hormones, molecular transporters, signal transduction elements, transcription activators, and a host of other functionally different proteins. More than two million polymorphic sites are predicted in the human genome [31]. Consequently, many or most of the proteins produced by the human genome exist in multiple primary sequence isoforms in human populations due to allelic polymorphism. Most, if not all, also exist in multiple chemically modified isoforms that are alternatively glycosylated, phosphorylated, methylated, oxidized and/or otherwise enzymatically or nonenzymatically posttranslationally modified at one or more sites on the protein. Since many of the 100,000 proteins produced by the human genome exist as primary sequence isoforms that also differ by how and where they are posttranslationally modified, the actual number of *chemically distinct proteins* in the human proteome is undoubtedly in the order of millions. The sheer magnitude and diversity of the human proteome assures that the probability of any two organisms of the same species having exactly identical proteomes is vanishingly small, as is the probability that any single individual's proteome will be identical in normal and diseased states. Identifying, characterizing, and quantifying chemically distinct proteins in this vast human proteome is the monumental challenge that proteomics presents to analytical science.

Why is it important to accept this challenge? A current and near future priority of biomedical research is to understand and treat complex diseases like diabetes, heart disease, and cancer that have only recently become prevalent sources of morbidity and mortality in human populations. A major goal of systems biology and proteomics is to identify and quantify specific proteins for use as predictive diagnostic and/or prognostic biomarkers of disease [32]. Biomarker discovery is

complicated, however, by the fact that individual response to complex diseases is heritable and highly variable. Sickle cell disease, for example, is caused by a Glu→Val substitution at the sixth position of beta globin in all patients with the disease [33]. But the clinical presentation of sickle cell disease varies from mild to severe, depending on the genetic background of each individual patient [34]. Heritable variation is also observed in human responses to other complex diseases [35,36] and in resistance to drugs used to treat disease [37]. Indeed, remarkably few human traits are truly Mendelian due, in part, to the activities of modifier genes that alter the expression of other genes and obscure regular patterns of inheritance [38,39]. Instead, inheritance of most quantitative traits, including disease risk, is polygenic and attributable to interactions between two or more genes and the environment. As a result, genetic variation and genetic background strongly influence both disease risk and the composition of each individual organism's proteome. Protein expression levels and interactions with other biomolecules are also influenced by environmental factors, like pathogen exposure, nutritional status, or drug intake. Consequently, the types and concentrations of chemically distinct proteins in the human proteome vary widely both between individuals and within individuals over time. The specific challenge that systems biology presents to proteomics is to identify biomarkers of disease within this vast framework of biological variation in the human proteome.

The role CE will play in proteomics will depend in part on how systems biology is applied to biomarker discovery and how biomarkers are applied in the diagnosis and treatment of disease. Given the likelihood that millions of chemically distinct proteins exist in the human proteome, it is clear that comprehensive characterization of an individual organism's entire proteome is beyond the reach of present and near future technology. Given the wide dynamic range of abundance of different proteins in the proteome, and the practical demand for high-throughput, low-cost diagnostic testing, comprehensive characterization of even a limited subset of the human proteome, like the plasma proteome, represents a significant analytical challenge. The estimated dynamic concentration range of proteins in the plasma proteome is  $10^8$ , ranging from 0.5 ng/mL to 50 mg/mL [40]. Even if it were possible to cost-effectively assess all proteins in just the plasma proteome, organizing and understanding the plethora of data produced represents a colossal biomedical and computational challenge because it requires mathematical comparison of the clustering of patterns in proteomic phenotypes (characterized on the basis of the types and concentrations of chemically distinct proteins) with clustering of patterns in clinical phenotypes (characterized on the basis of observable traits or symptoms associated with health and disease). Associating proteomic phenotypes with disease phenotypes is further complicated by the fact that clinical phenotypes of disease can range from mild to severe within and between individuals with the same disease. At present, biomarker discovery appears to be in a sort of Catch-22 situation: biomedical science is technically unable to assess complex disease risk because analytical science does not cost-effectively provide the information needed to discriminate between high and low risk disease phenotypes; but analytical science does not provide this information primarily because biomedical science does not yet know which of the millions of genes, transcripts, proteins and metabolites in an organism are best analyzed in order to characterize normal and disease phenotypes and subphenotypes.

The solution to this situation will require cooperation between clinical and basic scientists and combined expertise in the areas of medicine, biology, chemistry, engineering, and bioinformatics. National and international sample repositories are already being created and categorized to make samples from case controls and subjects with known diseases available for analysis [11]. A plausible top-down approach to biomarker discovery is to develop a general analytical foundation for proteome characterization and later extract functional or diagnostic utility for various proteins on the basis of the results of large-scale systematic data collection [40]. This work is well underway and CE appears poised to be a major contributor, much as it was in the effort to characterize the human genome. A corollary bottom-up approach to biomarker discovery is to comprehensively evaluate narrow proteomic subsets. Characterizing how the levels and functions of a limited number of proteins change in specific cells or specific biochemical pathways associated with disease processes could help differentiate "normal" phenotypes from mild or severe disease phenotypes.

As systems biology progresses toward these goals it is important to emphasize that a range of “normal” human phenotypes exist in part because genotypic and phenotypic variation give human populations the ability to adapt and survive under different environmental and physiological conditions. Furthermore, hereditary risk for mild or severe susceptibility to complex disease is ultimately a function of the interplay between “normal” genetic variation and environmental factors that cause disease. Biochemical and physiological traits often tend to differ in a continuum between individuals in normal populations and within individuals over time or as they progress from normal to diseased states. The fact that phenotypic traits segue almost imperceptibly across a continuum is the ultimate challenge that nature poses to systems biology as it attempts to parse out complex trait patterns associated with normal and disease phenotypes. The advancement of systems biology and proteomics promises to complicate clinical diagnostics due to the increased influx of complex information, but it also holds promise for early detection of complex disease risk and more effective treatment of disease on a case by case basis. The systems biology approach appears indispensable for understanding the clinical heterogeneity of complex diseases, the role of heredity and genetic background in susceptibility to disease, what proteins or metabolites might be effectively used as risk biomarkers for specific diseases, and how biological processes can be manipulated to treat disease. What role CE will play in proteome analysis will depend on how proteomics is applied as part of the systems biology approach. It also depends on how CE instrumentation and method development evolve in competition with other advanced separation technologies whose evolution will also be driven by the demand for more and better information about very complex biological systems and their roles in very complex human diseases.

## 2.3 THEORETICAL ASPECTS

Capillary electromigration techniques can be used to analyze proteins in a wide variety of ways, all of which depend on principles of chemistry and physics as they apply to the movement of proteins in narrow-bore capillaries. Different CE techniques separate proteins on the basis of different protein properties like charge, mass, isoelectric point and/or hydrophobicity. Different CE techniques also use different detector systems and variously employ hydrodynamic, electrophoretic and/or electroosmotic forces for separation and mobilization. The efficiency and specificity of any CE separation is a function of fluid dynamics, electrical field strength, analyte diffusion and other analytical system characteristics that affect peak migration, resolution, and detection. The term *analytical system* is used here to describe the specific CE technique employed and all properties pertaining to its use, including the CE platform, detector type, capillary type and cooling system temperature, separation media composition and properties (e.g., pH, ionic strength, and viscosity), voltage and other run conditions like duration and capillary conditioning. All of these analytical parameters interactively determine how CE can be effectively applied for different protein applications. The sheer number and complexity of interactions make the theoretical aspects of CE for protein analysis difficult to fathom but it is also the reason that proteins can be analyzed by CE in so many different ways, often with distinct advantages over other separation techniques. Many theoretical aspects regarding the electrophoretic separation of molecules by CE are the same for all analytes and are discussed in greater detail elsewhere in this book. Theoretical aspects of CE most important for protein analysis are discussed next.

### 2.3.1 PROTEIN PROPERTIES

Proteins are amino acid polymers (polypeptides) with distinctive charge and shape characteristics that can change depending on their microenvironment. Selection of a specific CE analytical system for a specific protein application depends on the objectives of the separation and how the protein or proteins of interest behave in any particular analytical system. The specificity and selectivity of any CE analytical system depends in part on the physical and chemical properties of the protein itself,

including concentration, amino acid composition, charge, mass, shape, hydrophobicity, absorption and emission characteristics and interactions with other biomolecules. These properties determine how a protein interacts with separation medium constituents and the capillary or other physical components of the analytical system. The Debye–Hückel–Henry theory can be used to mathematically predict the electrophoretic behavior of proteins [41] but often does not apply to predicting protein mobility in CE due to protein interactions with charged constituents of the capillary wall [42]. Predicting protein mobility is also complicated by inter- and intramolecular chemical interactions that influence a protein's physical properties and electrophoretic migration.

How proteins behave in a particular CE analytical system is strongly influenced by the pH (negative log of the hydrogen ion concentration) and ionic strength (concentration of all ions) of the sample and electrolyte solutions. Both markedly influence the charge properties of ionizable functional groups, especially the amino and carboxyl termini and the basic and acidic side chains of amino acids like lysine or glutamate. In general, polypeptides become more negatively charged as pH increases due to progressive deprotonation of acidic carboxyl and basic ammonium groups. As pH increases and hydrogen ion concentrations decrease, carboxyl groups are converted into carboxylate anions ( $\text{R-COOH}$  to  $\text{R-COO}^-$ ) and ammonium groups into amino groups ( $\text{R-NH}_3^+$  to  $\text{R-NH}_2$ ). Decreasing pH (i.e., increasing hydrogen ion concentration) has the opposite effect. The dissociation constants ( $\text{p}K_a$ ) of the  $\alpha$ -carboxyl groups of different amino acids range from about 1.8 for histidine to 2.5 for tryptophan. The  $\text{p}K_a$  of  $\alpha$ -amino groups range from about 8.8 for asparagine to 10.6 for proline. Consequently the carboxyl termini of proteins tend to be negatively charged at pH greater than 2.5 and the amino termini of proteins are positively charged at  $\text{pH} < 8.8$ . The  $\text{p}K_a$  of carboxyl and amino side chains range from about 3.9 for aspartic acid to 12.5 for arginine. The isoelectric point (pI) of a protein is the pH at which the molecule has zero net surface charge, that is, the effective number of positive charges equals the effective number of negative charges. The absolute number of ionizable groups in a specific polypeptide molecule is a function of its primary amino acid sequence. The actual number is a function of (a) pH, (b) the  $\text{p}K_a$  of the ionizable functional groups present, (c) posttranslational chemical modification of ionizable functional groups, and (d) inter- and intra-molecular protein interactions that determine which amino acids are present on the surface of the molecule.

### 2.3.2 CE SEPARATION TECHNIQUES

Capillary electromigration techniques collectively represent a family of related microanalytical methods that effect molecular separations using narrow-bore capillaries and high electric field strengths. Operational differences between different modes of separation are primarily a function of the composition of the electrolyte or buffer solutions and whether coated or uncoated capillaries are used. Because different CE techniques variously employ hydrodynamic, electrophoretic and/or electroosmotic forces to mobilize and separate proteins, peak profiles and separation efficiencies differ between techniques based largely on the relative contributions of these forces. For most separations samples are introduced into the capillary either hydrodynamically using pressure or vacuum, or electrokinetically using voltage. The IUPAC subdivides capillary electromigration techniques into capillary electrophoretic techniques and electrically driven capillary chromatographic techniques while recognizing significant overlap between these two classifications [1]. The CE techniques most commonly used for protein analysis include CZE, CIEF, CSE, and MEKC. CAE is an electrophoretic technique where separation is effected by interaction between an analyte of interest and a specific affinity reagent, for example, a protein-specific antibody that changes the electrophoretic migration of a target protein. Other CE techniques are less frequently used for protein analysis. Capillary isotachopheresis (CITP) is used in conjunction with CZE to automate online sample concentration before analysis. Capillary electrochromatography (CEC) is a special case of capillary liquid chromatography where movement of a mobile phase through a capillary packed or coated with a stationary phase is achieved

by EOF. CEC is also most often used in conjunction with CZE for online analyte concentration or prefractionation.

Smaller proteins move faster in an electric field than larger proteins with similar charge because acceleration is inversely related to mass to charge ratio ( $m/z$ ) at any applied force. Protein separation based on differences in  $m/z$  is the fundamental principle of CZE that uses both electrophoretic and electroosmotic forces to mobilize and separate proteins of interest. Since these two forces can act in opposite directions, directional movement of proteins through the capillary depends on the relative direction and magnitude of each force. CZE is the simplest and easiest CE separation mode to use and can be employed in a wide variety of applications. Anode and cathode electrolyte solutions are usually identical and the efficiency and selectivity of protein separations can be modified simply by adjusting pH and ionic strength. Since the pI of most proteins are between pH 3 and 10, most proteins are positively charged in solutions at pH 3 or below and negatively charged at pH 10 or above. The relationship between the pI of a protein and the pH of the separation medium can be exploited to adjust assay selectivity. CZE performed using electrolyte solutions at low or high pH are nonselective because most proteins will be positively or negatively charged, respectively, and migrate to the oppositely charged electrode when voltage is applied. One reason low pH (e.g., 2.5) phosphate buffer is a popular electrolyte solution for exploratory studies is that essentially all proteins introduced into the anode end of the capillary will be positively charged and migrate toward the cathode in CZE. Another reason is that the internal surfaces of fused-silica capillaries bind less protein at low pH. The down side of low pH buffers includes reduced EOF and longer run times. Higher pH buffers increase EOF but also increase binding of proteins with higher pI to capillary walls such that capillaries with fixed or dynamic coatings are often used for analysis of more basic proteins. More selective CZE separations can be achieved, however, by using electrolyte solutions with pH slightly above or below the pI of the protein or proteins of interest. Under appropriate separation conditions proteins with charge opposite that of the protein of interest will be excluded from the separation. The same principle applies to the pH of sample solutions and selective introduction of proteins into the capillary by electrokinetic injection.

Smaller proteins also move faster than larger proteins when electrophoretically mobilized through media containing a selective physical barrier like polyethylene oxide [43] or dextran [44]. Protein separation based on frictional and other forces influenced by protein mass and hydrodynamic radius is the fundamental principle of CSE. CSE uses fixed or replaceable sieving media to differentially retard migration of proteins or protein complexes with different molecular weights. CSE can be effectively used to determine molecular weight in single or multidimensional analyses, or in mobility shift assays that separate a protein from its complex with an antibody or nucleotide. Capillary gel electrophoresis (CGE) is a special case of CSE performed in capillaries containing cross-linked gels. The use of CGE for protein analysis has declined with the advent of noncross-linked soluble polymers that are replaced between runs and afford more reproducible and reliable CSE separations [45].

CIEF [8,46–52] separates proteins in a pH gradient on the basis of surface charge and is ideal for identification and quantification of protein isoforms since different sequence or posttranslationally modified isoforms of the same protein often have different pI. The pH gradients established by including ampholytes in CIEF separation media progressively range from lower pH regions at the anode to higher pH regions at the cathode when voltage is applied. When sample is introduced into the anode end of the capillary, proteins with higher pI migrate further toward the cathode through higher and higher pH regions. When balance is eventually achieved between positive and negative surface charges proteins become neutral and those with similar pI focus into stationary zones. Proteins with lower pI migrate shorter distances and focus in zones closer to the anode. The protein bands remain focused because diffusional movement in either direction puts the protein into a higher or lower pH region that adds positive or negative charge to the molecule. Addition of charge induces electrophoretic repulsions and attractions that cause the protein to return to a pH region where it either loses or gains protons and becomes neutral again. The focused zones may or may not be fully immobilized, depending on the absence or presence of residual EOF. EOF is

often suppressed in CIEF separations by using neutral coated capillaries and/or including EOF-suppressing compounds in the separation media. Proteins with higher pI have shorter migration times because they have shorter distances to travel when mobilized past a fixed detector placed near the cathode end of the capillary. Migration times are progressively longer for proteins with progressively lower pI. Wide (e.g., pH 3–10) or narrow (e.g., pH 6.7–7.7) range ampholytes are commercially available and can be used alone or in combination to modify selectivity and separation efficiency. Variations in CIEF operating parameters primarily include the use of pressure or electromigration to mobilize focused protein zones past the detector when using fixed window on-capillary detection. Additives like methylcellulose are often included in CIEF separation media to regulate viscosity and flow rates in separations that hydrodynamically mobilize focused protein zones.

Analyte separation based on hydrophobicity is the fundamental principle of MEKC [53–55]. MEKC is a special case of electrokinetic chromatography (EKC) that separates analytes on the basis of a combination of electroosmosis, electrophoresis and interactions between analytes and surfactants or other additives to the electrolyte solution [1]. At sufficiently high concentrations, detergent molecules like sodium dodecyl sulfate (SDS) self-associate in pseudostationary arrangements called micelles, which have hydrophobic inner cores and hydrophilic outer surfaces. Micelles constantly associate and dissociate and have electrophoretic mobility opposite that of normal EOF. During separation, proteins with differing hydrophobicities distribute differently between the hydrophobic inner core and the hydrophilic solution phase. Hydrophilic (polar) proteins that are completely insoluble in the inner core of the micelle migrate at the velocity of EOF. Hydrophobic (nonpolar) proteins that completely associate with the micelle migrate at the velocity of the micelle. Proteins with intermediate levels of hydrophobicity will spend varying amounts of time between the hydrophobic and hydrophilic phases of the separation media and have migration times intermediate to those of the micelle and EOF. Variation in protein hydrophobicity is a function of the relative content of nonpolar (e.g., alanine, glycine, leucine, valine, etc.) and polar (e.g., lysine, arginine, asparagines, glutamine, etc.) amino acids. Because separations are based on hydrophobicity, both charged and neutral proteins can be analyzed by MEKC, which is increasingly used to map one dimension of protein distribution in multidimensional analyses [12,56–59].

### 2.3.3 INSTRUMENTS

No single CE instrument is ideal for all protein applications. Multicapillary instruments have more throughput capacity than single capillary instruments. Some CE instruments have interchangeable detection systems while others do not and are limited to more specific applications. How different CE instruments are used for protein analysis is primarily a function of what detector systems are available for a specific platform, how many and what types of capillaries can be used, sample throughput capacity and the functionality of the system's software for automation of sampling and data collection. Research laboratories at the forefront of CE instrument development use a wide variety of in-house manufactured platforms and software that are not yet commercially available. Most of these incorporate unusual on- or off-capillary detectors into the analytical system or are designed to permit online pre- or postseparation sample treatment or fraction collection. Perhaps the fastest growing segment of advanced instrument development with relevance to proteomics is that of multidimensional systems that analyze proteins on the basis of more than one protein property, that is, charge, mass and/or hydrophobicity [59]. Systems have been developed for protein separation using CE in two dimensions, HPLC in one dimension and CE in the other, or CE followed by MS, which is both a separation and detection technique.

The advent of microfluidic devices like the Agilent 2100 Bioanalyzer (Agilent Technologies, Sanata Clara, CA) has diverse implications for CE-based protein analysis. This commercially available microchip CE platform is a dedicated instrument that uses manufacturer-supplied reagent

kits for the analysis of DNA, RNA and proteins. Analyses are quick (~30 min) and simple with digital control and output that makes it easy to manage and store data. Up to 10 samples can be analyzed simultaneously and the results can be viewed as either electropherograms or gel-like images. The system uses noncross-linked linear polymers, fluorescent protein dye and laser-induced fluorescence (LIF) to separate and detect proteins on the basis of size, and is useful for protein quantification or molecular weight determination. This dedicated analyzer is a feasible alternative to labor intensive conventional electrophoresis methods with advantages superior to that of SDS–polyacrylamide gel electrophoresis (SDS–PAGE) in large part due to automation. One benefit for many biology and biochemistry laboratories is that the system can be used for both proteins and nucleic acids, essentially replacing multiple conventional electrophoresis applications in a single platform. Disadvantages include the inability to recover fractionated proteins and high capital equipment and reagent costs. How microchip systems will be used in proteomic applications will depend on how these systems evolve and their ability to characterize diagnostic subsets of the human proteome.

A relatively limited number of other commercial CE systems is available. Multimode open analytical CE platforms, like those available from Beckman-Coulter (Fullerton, CA) and Agilent Technologies, can perform a wide variety of protein applications because many different separation modes and detection systems can be used. Sebia Electrophoresis (Norcross, GA) and Beckman-Coulter manufacture dedicated platforms and reagent kits for automated clinical analysis of hemoglobin and/or plasma and urine proteins. Convergent Biosciences (Toronto, Canada) markets a CIEF system for whole-column image detection (WCID) of proteins. The systems biology demand for faster, more specific and more sensitive protein analysis has encouraged new companies to enter the CE instrument market with systems specifically designed for proteomic applications. Cell Biosciences (Palo Alto, CA) is developing a dedicated CIEF system specifically for immunodetection of proteins. The instrument is reportedly capable of analyzing 96 samples in 8–12 h and could replace Western blotting for use in some protein applications, especially for analysis of low abundance proteins in an automated format. CombiSep (Ames, IA) manufactures a high-throughput, multicapillary instrument capable of determining the molecular mass of proteins in 96 samples in 30 min [60].

#### 2.3.4 CAPILLARIES

Poor between-run analytical reproducibility has been a major impediment to the wider use of CE in protein applications. Variable capillary performance continues to be the single most important source of analytical variation. Uncoated fused-silica capillaries from different manufacturers or different production lots from the same manufacturer can have significantly different chemical properties. The internal surfaces of uncoated fused-silica capillaries chemically interact with proteins directly and with components of electrolyte solutions in ways that markedly influence protein recovery, mobility and separation efficiency. The need for consistent starting conditions for each analytical run is one reason uncoated capillaries are typically rinsed with sodium hydroxide and/or other regenerating solutions between analytical runs. Capillaries are also usually rinsed between runs with separation media in an effort to establish a reproducible internal chemical equilibrium.

The single most important capillary property influencing protein analysis is the charge characteristics of the internal surface which can be positively charged, neutral or negatively charged. The charge properties of the capillary wall depend on the pH and chemical composition of the electrolyte solution and whether the capillary is uncoated or chemically modified. The surface silanol groups of uncoated fused-silica capillaries are negatively charged at pH > 2 and are progressively deprotonated at higher pH. The negatively charged wall attracts a layer of hydrated cations from the electrolyte solution that move toward the cathode when an electric field is applied. This generates the EOF characteristic of many CE separations, which greatly influences the resolution and efficiency of protein separations. When it exists, EOF is always in the direction of the electrode with the same charge

as the capillary surface. EOF in uncoated fused-silica capillaries is progressively higher at higher pH and decreases with increasing ionic strength. Protein–wall interactions in uncoated fused-silica capillaries also increase at higher pH, which can decrease protein recovery and degrade capillary performance.

Because the surface of a fused-silica capillary is chemically reactive it can be chemically modified to better control, minimize, or even reverse surface charge. Many of the problems associated with protein analysis in uncoated fused-silica capillaries have been largely overcome by the development of methods to chemically modify the internal surface. Chemical modification produces more consistent starting conditions between analytical runs and decreases protein–wall interactions. Coated capillaries are particularly useful for the analysis of basic proteins, that is, proteins with greater positive charge, because basic proteins bind more readily to the negatively charged surface of uncoated fused-silica capillaries. Typical coating materials include polyacrylamide, polyvinyl alcohol, polyethylene glycol, polyvinylpyrrolidone, polyamines, and cationic detergents. Capillaries with covalently-attached (fixed) coatings that are acidic, neutral, basic, hydrophobic, or hydrophilic are commercially available. The performance of capillaries with fixed coatings can deteriorate over time and the capillaries must be replaced periodically due to degradation of the coating material or accumulation of proteins or other foreign matter that corrupts the quality of the separation. Problems encountered with fixed coatings can be overcome somewhat by the use of “dynamic” coatings where the coating agent is applied internally before a separation and then is stripped and replaced between runs. Coating reagents like polyamines or cationic detergents bind to negatively charged fused-silica capillaries and create a positively charged internal surface with reverse EOF (directed toward the anode). MicroSolve Technology Corporation (Eatontown, NJ) markets a family of quality-controlled CE reagents (CElixir) that includes multiple electrolyte solutions with a variety of pH that have been optimized for use with different dynamic coating solutions.

Because low abundance proteins can be difficult to detect by absorption spectroscopy, light transmittance and path length are important properties that also must be considered in capillary selection. Although most capillaries used for protein analyses are constructed of fused-silica, borosilicate glass, quartz, Teflon and other materials are also infrequently used (quartz transmits ultraviolet light better than glass at wavelengths used for protein detection). The internal cavities of most CE capillaries are round but rectangular capillaries have also been used [61]. Typical internal diameters range from 2 to 100  $\mu\text{m}$ . Optical path length and detection sensitivity both increase with diameter but separation efficiency is usually better in narrower capillaries. Most capillaries have an opaque polyimide coating on the outside that provides tensile strength and limits breakage. For analytical systems using on-capillary spectrophotometric detection, the polyimide coating is usually removed by heating or with acid to create a window through which light will pass. Transparent external coatings that provide tensile strength and also optically transmit light have also been developed but are not widely used. Modified capillaries with extended light paths (e.g., bubble- or z-shaped) have been developed to increase detection sensitivity, which can be especially important for low abundance proteins. The utility of capillaries with extended light paths for protein analysis has diminished somewhat with the expanded use of protein-specific derivatizing agents and fluorescence detection.

### 2.3.5 SEPARATION MEDIA

Individual electrons normally cannot pass through solutions from one electrode to another. Instead, the electrons are carried between electrodes in solution by electrolytes that make protein electrophoresis possible. When a capillary is placed between two separated vials of electrolyte solution and voltage is applied, chemical reactions occur that consume electrons and generate negative ions at the cathode and also produce electrons and generate positive ions at the anode. As negative and positive charge builds up at the cathode and anode, respectively, ions in the electrolyte solutions and sample move through the capillary toward the oppositely charged electrode. This neutralizes

charge differences between the electrolyte vials and allows continued electron flow through the electrodes and charged molecule flow through the capillary. Conducting multiple analytical runs without replacing electrolyte solutions can lead to ion depletion, especially when using low ionic strength electrolyte solutions and small volume reservoirs.

As previously noted, the pH and ionic strength of electrolyte solutions markedly influence the charge and migration of proteins due to their effects on both the protein and the internal surface of the capillary. EOF is positively related to pH and inversely related to ionic strength. Although higher ionic strength electrolyte solutions can suppress ionic interactions between charged proteins and ionized silanol groups, they can also generate excessive heat at high voltages that may surpass the cooling capacity of the analytical system. Overheating can alter the stability of proteins, corrupt capillary coatings and degrade the quality and reproducibility of CE separations. CZE often uses the same simple electrolyte solution (e.g., phosphate or borate) at both the anode and cathode ends of the capillary. Other separation techniques use more complex electrolyte solutions that are buffered or contain additives that (a) selectively or nonselectively modify proteins to alter their charge or conformation (e.g., affinity reagents or detergents), (b) selectively or nonselectively modify proteins to increase signal strength (e.g., fluorescent antibodies or nonspecific derivatizing agents), or (c) selectively impede the mobility of proteins through the capillary on the basis of their size, shape, or hydrophobicity (e.g., linear polymers or micelles).

### 2.3.6 DETECTION

Various types of detectors are commonly or uncommonly used for protein analysis in CE analytical systems. In all cases, detection is based on characteristic properties of the protein or proteins of interest in their modified or unmodified state. Most commercial platforms use on-capillary absorption or fluorescence spectrophotometers that measure light as it passes transversely through the lumen of the capillary at a fixed narrow window through which analytes sequentially pass during electromigration. In contrast, WCID systems monitor absorbance or fluorescence of all proteins simultaneously over the entire length of the capillary [62,63]. WCID is ideal for use with CIEF because it eliminates band distortions caused by mobilization of narrow focused protein zones. WCID systems are also advantageous for real time on-capillary study of dynamic processes like biomolecular interactions or how proteins migrate under different analytical conditions. In-house constructed CE platforms use a variety of less common on- and off-capillary detection systems (Chapter 9). These include UV/Vis or fluorescence detection using unusual optical systems, polarization, total internal reflection, correlation spectroscopy, and multiphoton excitation. Electrochemical or amperometric CE detectors measure analyte concentrations on the basis of change in current caused by oxidation or reduction of chemical reactants or products at an electrode [64]. Kuijt et al. [65] demonstrated the use of quenched phosphorescence for CE peptide detection using separation media containing 1-bromo-4-naphthalenesulfonic acid whose phosphorescence and background signal is quenched by electron transfer from peptide amino groups at higher pH.

Absorption spectroscopy using ultraviolet or visible light is the detection system most commonly used in CE protein applications. Most commercially available UV/Vis CE detectors use narrow band filters to limit transmittance to specific wavelengths but multiwavelength diode array detectors are also available. Choice of wavelength for UV/Vis protein detection depends on the abundance of the protein of interest and the absorption characteristics of the protein, capillary and electrolyte solution. Nearly all proteins absorb light at 214 and 280 nm due to molecular absorption of electromagnetic energy at these wavelengths by peptide bonds and aromatic amino acids, respectively. Absorbance at any given protein concentration is usually greater at lower UV wavelengths but many separation media constituents, like some ampholytes used in CIEF, also absorb low-frequency UV light and can interfere with detection. The absorption characteristics of naturally-occurring protein prosthetic groups can be used to increase detection specificity for some proteins. Hemoglobin variants, for example, are usually detected by absorbance at 415 nm because the attached heme groups absorb light

energy at this wavelength and thus impart some degree of detection specificity. Proteins containing aromatic amino acids like tryptophan, tyrosine, and phenylalanine absorb electromagnetic energy when excited at wavelengths between 250 and 300 nm and naturally fluoresce at wavelengths between 300 and 400 nm. Native fluorescence detection can be used to enhance analytical specificity for proteins with high aromatic amino acid content [66–68].

The obligatory use of narrow-bore capillaries in CE limits permissible optical path lengths. This makes on-capillary UV/Vis absorption spectrophotometry relatively insensitive for analysis of low abundance proteins or when conventional detection systems are used for native fluorescence applications. Optical path length is of less concern when using high-intensity fluorescence detection. Fluorescence spectroscopy measures luminescence generated when molecular absorption of a photon induces the emission of another photon with a longer wavelength. The use of derivatizing agents to enhance the sensitivity of fluorescence detection has greatly expanded the utility of CE for some protein applications [27,69]. LIF detectors using argon ion (488 nm) laser sources have been available for some time on commercial multimode open analytical CE platforms. Fluorescein isothiocyanate (FITC) and other fluorescein derivatives are often used with argon ion lasers because fluorescein has absorption and emission maxima at 490 and 514 nm, respectively. Other high-intensity, monochromatic excitation sources are also used for CE fluorescence detection, including other laser sources and less expensive UV light-emitting diodes [66,67].

The need for greater detection sensitivity and the availability of a wider range of high-intensity excitation wavelength options have combined to promote development and use of novel fluorophores for derivatization of a variety of analytes [70]. Derivatizing agents are used to nonspecifically label carboxyl, amine or sulfhydryl groups of proteins or peptides. Examples include FITC and Cy3.5 [71], 3-(2-furoyl)quinoline-2-carboxaldehyde (FQ) [56,57,72], *o*-phthalic dicarboxaldehyde/beta-mercaptoethanol [66], monobromobimane [73], dipyrrometheneboron difluoride (BODIPY) [74], and MitoTracker Green [75]. Fluorophores are classified as either fluorescent or fluorogenic depending on their emission properties [69]. Fluorescent derivatizing agents emit photons when excited regardless of their binding state while fluorogenic agents only fluoresce when bound to their target. Background fluorescence produced by fluorescent derivatizing agents can limit fluorescence detection sensitivity.

The number of derivatization sites on a protein and the chemical nature of the selected derivatizing agent can influence protein speciation and quantification [69,76]. For example, lysine is a primary target for many derivatizing agents and most proteins have one or more lysine residues. Modification of lysine amino groups or other ionizable functional groups by uncharged derivatizing agents can alter protein surface charge and electrophoretic mobility. Incomplete labeling of ionizable functional groups can produce multiple fluorescent species of the same protein each with different charge properties. Incomplete labeling can also corrupt the relationship between fluorescence signal strength and protein concentration thus jeopardizing accurate quantification. Cationic amine derivatizing agents can be used to apply a fluorescence tag to a protein while maintaining its charge characteristics, but all cationic fluorophores are fluorescent rather than fluorogenic and produce background signal that can obscure signals of interest [69]. Proteins of interest that are not readily separated from contaminating proteins are difficult to specifically detect using nonspecific fluorescence labeling techniques in one-dimensional CE analyses. Selectivity and sensitivity can both be enhanced by the use of analyte-specific fluorescence labeling like that afforded using fluorescent antibodies [27,77–79] or when using fluorescent proteins or peptides as competing antigens [80] in CAE applications.

MS is increasingly the detection method of choice for many proteomic applications because it provides high sensitivity detection and information about protein structure (Chapter 8). Conventional two-dimensional SDS–PAGE has traditionally been the workhorse off-line separation system used in conjunction with MS for the study of proteins [12]. An investigator can run a 2D gel, use an automated spot-cutting system to collect a sample separated in two property dimensions by pI and molecular weight, then process and analyze the sample using a variety of single or tandem MS techniques, or HPLC-MS. Samples can also be analyzed directly using reversed phase, ion exchange

or other HPLC-MS technique. Coupling CE with MS permits high efficiency protein separation based on one or more protein properties in an automated format that eliminates post-separation sample handling. CZE is most commonly combined with MS using soft ionization methods due to the simplicity and compatibility of many CZE electrolyte solutions. However, the process of transferring separated proteins from the capillary outlet to the mass spectrometer still presents obstacles to more widespread CE-MS use due to issues related to solvent compatibility and the placement of the CE electrode at the CE-MS interface. The amount of sample that CE can deliver to the MS also remains a major limitation for CE-MS detection of low abundance proteins. Greater detail regarding the advantages and disadvantages of CE-MS for protein analysis is provided in Chapter 8 and recent reviews [6,59,81,82].

### 2.3.7 SAMPLE PREPARATION AND FRACTION COLLECTION

Proteins that are abundant in complex biological matrices or have unique spectral properties can be readily detected and quantified with little or no sample preparation. Little sample preparation may also be needed to analyze proteins in less complicated matrices or where the protein of interest is effectively separated from all potential contaminants. However, many proteins are present in biological samples at concentrations that are lower than the limit of detection of many CE analytical systems. If fluorescence derivatization is not compatible with the desired application, analysis of low abundance proteins may require sample pretreatment to concentrate the protein or proteins of interest or remove interfering compounds. Pre-analytical sample concentration or fractionation can be performed on- or off-column. If sample availability and volume is not severely limited, the same off-line methods commonly used to concentrate or fractionate samples for HPLC or gel electrophoresis can be used to treat samples for CE analysis. Dilute samples can be concentrated by ultrafiltration or reconstituted after lyophilization. Buffer exchange by ultrafiltration or dialysis can be used to remove salts or other compounds that may interfere with a separation. A variety of common off-column fractionation methods from affinity chromatography to acid precipitation can be used to select specific proteins or remove interfering proteins with similar charge, size or hydrophobicity. Development of advanced robotic instruments for automated sample treatment using a variety of different modalities makes off-column sample pretreatment an increasingly feasible option for high-throughput CE protein analysis. CE techniques like CITEP or CAC are frequently used for on-column sample pretreatment to concentrate or fractionate proteins before separation, which can be particularly useful in CE-MS for automated detection of low abundance proteins.

Fraction collection by CE is possible but difficult to accomplish in yields sufficient for further study of separated proteins even when using CE methods that are considered preparative. CE is consistently outperformed by other protein separation techniques when it comes to preparative operation or fraction collection for post-separation analysis [26]. Because CE sample injection volumes are very low, the concentrations of separated proteins eluting from the capillary are also very low. Typical CE injection volumes are usually < 50 nL and only nanogram quantities of specific proteins are isolated with each analytical run. Peaks from multiple CE runs can be pooled to increase sample recovery but consistent fraction collection requires highly reproducible run to run separations and accurate prediction of post-detector elution from the capillary. Fraction collection can be performed by adsorption of analytes to moving blotting membranes as they exit the capillary [83]. Inclusion of magnetic beads coated with immobilized antibodies represents an innovative new approach to on-column fraction collection [84]. CE fraction collection is desirable because CE is often able to separate analytes that cannot be resolved by other techniques and because CE separation in free solution often allows preservation of analytes in their native form. A key advantage to preparative CE compared to preparative HPLC is that analyses can be performed using very small sample volumes like those available from single cells.

## 2.4 PRACTICAL APPLICATIONS

This section details characteristic examples of protein analysis by CZE, CSE, CIEF, and MEKC. The selected examples were chosen to demonstrate some of the more important theoretical aspects of protein separation by each of these techniques while also highlighting the application of CE for characterization of protein properties, isoform identification, use in mobility shift assays, and multidimensional protein analysis. Table 2.1 lists recent references for specific proteins analyzed by different CE methods and show how CE analysis of proteins can be used in a variety of biological applications.

## 2.5 ANALYSIS OF PROTEIN PROPERTIES BY CZE AND CSE

Information about a protein's physical and chemical properties can help determine its biological function and can be useful in a bottom-up approach to understanding a biological system. The biological activities and binding properties of proteins are strongly influenced by the type and number of ionizable functional groups that are available to participate in chemical reactions with other molecules. Information about a protein's size, shape, and hydrophobicity can also be used to help deduce transport properties, compartmental distribution or other biological characteristics.

CZE separates proteins in narrow-bore capillaries under the combined influence of electrophoretic and electroosmotic forces. Electrophoretic mobility is a function of charge and frictional forces and thus distinguishes proteins with different mass to charge ratios ( $m/z$ ). Analysis of protein ladders by Sharma and Carbeck [85] elegantly demonstrates the fundamental theoretical principles that permit the separation of proteins by CZE. In these experiments, net charge and hydrodynamic radius ladders were prepared from purified lysozyme. Positively charged functional groups were progressively chemically modified to produce a range of molecules with precisely defined charge and shape characteristics. Figure 2.1 is an idealized schematic showing how charge and radius ladders are synthesized and the net effects of progressive derivatization of one or more functional groups on a protein's charge, hydrodynamic radius and electrophoretic mobility.

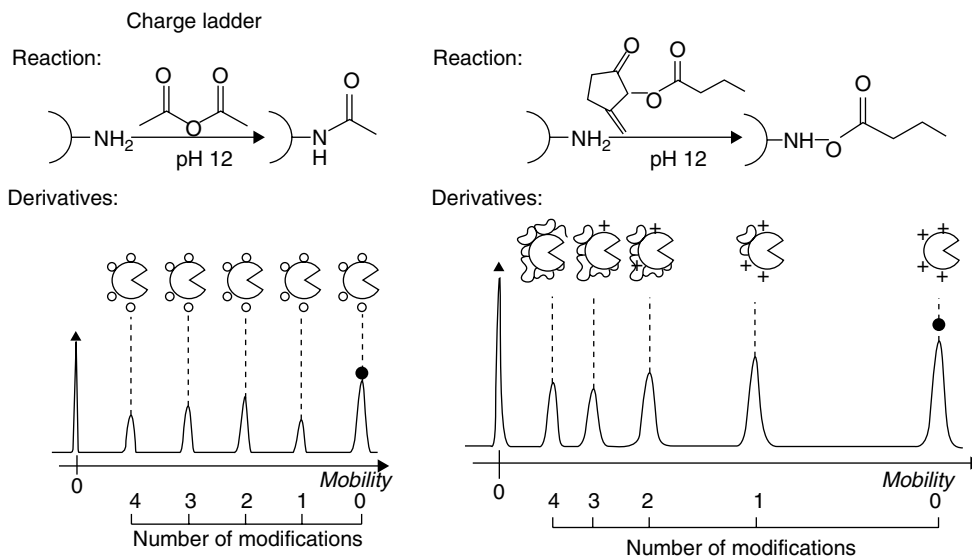

To study purified lysozyme from chicken egg white (EC 3.2.1.17, 14.3 kDa, 6 lysine residues, pI 10.9) the authors produced a charge ladder by chemically derivatizing primary amines ( $\text{RNH}_2$ ) at pH 12 with acetic anhydride. Two radius ladders were produced by derivatizing the same amines with two different sizes of polyethylene glycol *N*-hydroxysuccinimide ester (PEG-NHS, with 2 or 5 kDa PEG chains). The products of multiple reactions were combined to produce complete ladders in a single sample since single reactions did not always produce all derivatized forms. The high lysine ( $\text{p}K_{\text{a}} = 10.5$ ) content of unmodified lysozyme makes it a very basic protein that is positively charged at the hydrogen ion concentration of the separation media (pH 8.4). Because the protein would be expected to bind to the negatively charged surface of an uncoated fused-silica capillary the internal surfaces of the capillaries used in these experiments were coated with a cationic polymer to reverse internal surface charge and reduce protein-wall interactions. Because the internal surface charge of the capillary was the reverse of normal, EOF was also the reverse of normal, that is, toward the anode instead of the cathode, and the separations were conducted in reverse polarity where samples were introduced at the cathode end of the capillary with the detector oriented toward the anode.

Under the conditions of these experiments, electroosmosis is a more or less uniform directional force toward the anode on all proteins in the sample. In contrast, positively charged protein molecules are electrophoretically attracted to the cathode and move in a direction opposite that of EOF at rates inversely related to  $m/z$ . Electrophoretic mobility toward the cathode is inversely related to  $m/z$  because increasing positive charge increases electrostatic attraction while increasing mass increases frictional forces that retard velocity. When electroosmotic force is greater than the opposing electrophoretic force, a protein will migrate in the direction of the detector. Migration times will therefore be greater for proteins with higher electrophoretic mobility (lower  $m/z$ ) because the difference between electroosmotic and electrophoretic forces increases as electrophoretic mobility increases.

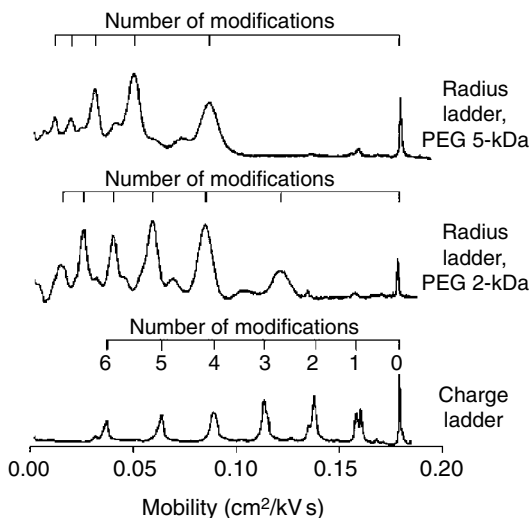

**FIGURE 2.1** Schematic illustration of the synthesis of protein charge and radius ladders and their characterization by CZE. Ladders are synthesized by the partial modification of primary amino groups on a protein. Charge ladders are produced using acetic anhydride and radius ladders are produced using PEG-NHS esters. The rungs of a charge ladder contain proteins that differ incrementally only in net charge from those in neighboring peaks and are thus equally spaced. The rungs of a radius ladder contain proteins that differ in both net charge and hydrodynamic radius from those in neighboring peaks. (From Sharma U, Carbeck JD. *Electrophoresis* 2005;26:2086–91. With permission.)

Figure 2.2 shows the effect of progressive derivatization of lysozyme amino groups with acetic anhydride or PEG-NHS on electrophoretic mobility. Mobility was empirically calculated for each observed peak as  $\mu = (L_T L_D / V) ((1/t_{nm}) - (1/t_x))$ , where  $L_T$  is the total length of the capillary,  $L_D$  is the length of the capillary to the detector window,  $V$  is the applied voltage,  $t_{nm}$  is the migration time of a neutral marker, and  $t_x$  is the peak migration time. The constant influence of electroosmotic force on peak migration is accounted for by including the migration time of the neutral marker in the equation. Since all variables besides  $t_x$  are constants in each analytical run,  $1/t_x$  decreases as peak migration time increases and the difference between  $1/t_{nm}$  and  $1/t_x$  increases. Consequently, peak mobility is greater for molecules with lower  $m/z$  and longer migration times.

The precisely defined charge and shape characteristics of the lysozyme molecules in the charge and radius ladders clearly demonstrate these principles. In both types of ladders, unmodified lysozyme had the highest positive charge and the lowest  $m/z$  so it also had the longest migration times and highest calculated peak mobility. In the charge ladder, progressive neutralization of charged lysozyme amino groups by incremental addition of acetic anhydride progressively decreased charge but had little influence on the mass of the molecule. Consequently, the magnitude of the increase in  $m/z$  was approximately equal with each additional amino group modification as evidenced by the even distribution of the differently charged peaks. In contrast, incremental addition of either size PEG-NHS to lysozyme amino groups progressively increased hydrodynamic radius but also decreased charge. Since both mass and charge were modified with each additional amino group modification, the increase in  $m/z$  was disproportional as evidenced by the unequal peak spacing of lysozyme molecules with different numbers of PEG-NHS-modified amino groups.

Separation of purified lysozyme molecules with varying but well-defined charge and mass properties clearly demonstrates the theoretical aspects of how proteins are separated on the basis of these characteristics by CZE. It shows that electroosmotic force must be considered in all separations and

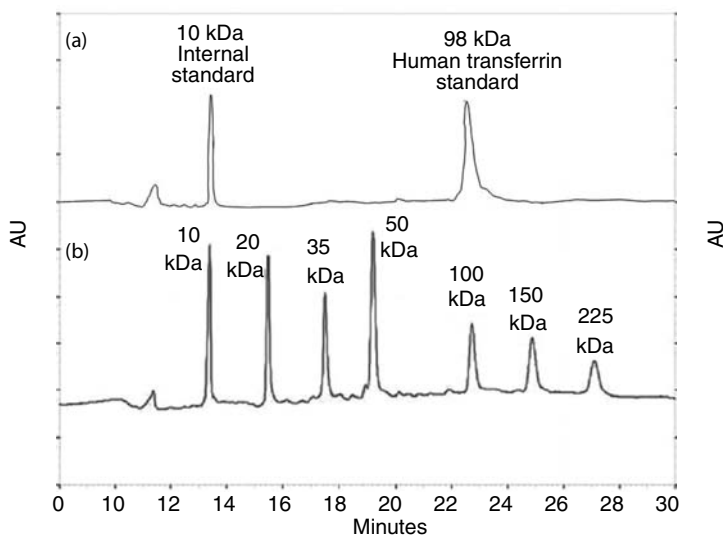

**FIGURE 2.2** Analysis of lysozyme charge and radius ladders by CZE. The analytical system included a Beckman-Coulter P/ACE MDQ instrument operated in reverse polarity at 20 kV with UV detection at 214 nm and capillary cooling at 25°C. Derivatized lysozyme molecules with different hydrodynamic radii and/or charge or were separated by CZE on the basis of  $m/z$  using a positively charged, 60 cm long (50 cm to detector) by 50  $\mu\text{m}$  ID fused-silica capillary (cationic polymer poly-(diallyldimethylammonium chloride) was applied to suppress adsorption of lysozyme). Separation media contained 25 mM Tris and 192 mM glycine (pH 8.4, ionic strength 7.9 mM). The bottom panel shows peak mobility for the charge ladder constituents while the upper two panels show peak mobility for the two radius ladders. (From Sharma U, Carbeck JD. *Electrophoresis* 2005;26:2086–91. With permission.)

can be modified to tailor separations based on the pI of the protein of interest. It also shows how electrophoretic mobility increases with protein charge and decreases with increased mass/hydrodynamic radius. Besides aptly demonstrating the principles of CZE, protein charge and radius ladders can be applied in a variety of practical ways. Sharma and Carbeck [85] used lysozyme radius ladders to measure partitioning of different sized molecules in polymer hydrogels and also suggested that radius ladders can be used to measure the effects of hydrodynamic size on the transport properties of a protein. Ebersold and Zydney [86] used CZE and myoglobin charge ladders to quantify electrostatic interactions between proteins and membranes during ultrafiltration.

Like CZE, CSE also separates proteins in narrow-bore capillaries under the combined influence of electrophoresis and electroosmosis (if present) but markedly increases the influence of frictional forces by including sieving polymers in the separation media. Since frictional force is largely a function of protein mass and shape, CSE primarily separates proteins on the basis of molecular weight if charge differences between proteins are normalized by addition of detergent. SDS-PAGE is the analytical technique most commonly used to determine protein molecular weight in most biology and biochemistry research laboratories. Size exclusion HPLC and MS can also accomplish this task with varying degrees of sensitivity, specificity, and automation.

Betgovargez et al. [58] produced a multidimensional profile of the human serum proteome and used CSE to map one dimension of protein distribution by molecular weight. Their approach is characteristic of how CE techniques can be incorporated in multidimensional analyses for proteome characterization—in this case, by first using an off-line 2D chromatographic system before analysis of the resulting fractions by both CSE and CIEF. Figure 2.3 was selected for inclusion in this section because it very clearly demonstrates the use of CSE for molecular weight determination. In this figure, upper panel shows the electropherogram obtained from a sample containing purified transferrin supplemented with a 10 kDa internal standard and lower panel shows the electropherogram obtained

**FIGURE 2.3** Protein molecular weight determination by CSE. The analytical system included a Beckman-Coulter ProteomeLab PA 800 operated in reverse polarity at 15 kV with photo diode array UV detection at 220 nm and capillary cooling at 25°C. SDS-treated proteins were separated by CSE on the basis of molecular weight using a negatively charged, 30.2 cm long (20.2 cm to detector) by 50  $\mu$ m ID uncoated fused-silica-capillary. The separation media included a formulation of polymers optimized for separation of proteins over a wide molecular weight range that is marketed in a kit as part of the system. Analysis of purified transferrin is shown in the upper panel while molecular weight standards are shown the lower panel. (From Betgovargez E, et al. *J Biomol Tech* 2005;16:306–10. With permission.)

from a molecular weight standard containing eight different proteins with known molecular weights (10–225 kDa). Because all samples were treated with SDS, which was also included in the separation media, all proteins were negatively charged and CSE was performed in reverse polarity with the detector toward the anode. SDS also normalizes charge effects on proteins such that separation was a function of molecular weight rather than native  $m/z$  and smaller proteins moved more rapidly through the sieving media than larger proteins.

The molecular weights of unknown proteins in test samples can be determined using a calibration curve calculated on the basis of the relationship between the log of the molecular weight standards and  $1/\text{mobility}$ . CSE can be performed under denaturing or nondenaturing conditions using replaceable soluble polymers or fixed cross-linked polymers. CSE can be used to determine molecular weight, for direct quantification of abundant proteins in uncomplicated matrices, or for quantitative analysis by immunoassay where bound and free antibodies are identified and quantified on the basis of differences in molecular weight.

### 2.5.1 IDENTIFICATION OF BETA GLOBIN ISOFORMS BY CIEF

Allelic polymorphism in a specific gene can produce nearly identical proteins with primary sequences that differ by one or more amino acids. Primary sequence isoforms can be readily separated by CIEF on the basis of their pI if the amino acid substitution changes the surface charge of the protein. Similarly, enzymatic or nonenzymatic posttranslational chemical modification of ionizable protein functional groups can produce chemically distinct isoforms of the same protein with detectably different surface charge and pI. Analysis of hemoglobin by CIEF is an excellent example of how this technique can be applied for the identification and quantification of a family of related proteins that represent a concise subset of the human proteome. Members of this family include many primary

sequence isoforms associated with monogenic diseases but also includes posttranslationally modified isoforms whose chemical composition reflects the concentrations of metabolomic constituents and disease status. The principles and approach used to evaluate primary sequence and posttranslationally modified beta globin isoforms described below can be applied to the study of other proteins, only not as easily since hemoglobin is unusually amenable to one-dimensional analysis by CIEF due to its high abundance, high solubility, and the UV/Vis detection specificity afforded by the attached heme groups.

Hemoglobin is a tetrameric oxygen transport protein composed of two mixed pairs of alpha and beta globin subunits. Hemoglobin tetramers readily dissociate into  $\alpha\beta$  dimers that migrate as a unit when analyzed by most charge-based separation techniques [33]. Polymorphism and mutation in globin genes are responsible for the synthesis of hundreds of different primary sequence isoforms of both alpha and beta globin, including the beta globin isoforms responsible for the anemia associated with sickle cell disease and hemoglobin C disease. The most prevalent (normal) beta globin isoform has a glutamic acid residue at position 6 ( $\beta\text{Glu6}$ ), which imparts negative surface charge to the  $\alpha\beta$  dimer at  $\text{pH} > 4.1$  due to deprotonation of its carboxyl side chain. Sickle beta globin has a valine residue at the same beta globin position ( $\beta\text{Val6}$ ) which does not have an ionizable functional group and thus imparts no additional negative or positive charge regardless of  $\text{pH}$ . The C beta globin isoform has a lysine residue at the same beta globin position ( $\beta\text{Lys6}$ ), which imparts positive surface charge to the  $\alpha\beta$  dimer at  $\text{pH}$  less than  $\sim 10.5$  due to protonation of its amino side chain.

Homozygous sickle cell disease and heterozygous S/C disease are hereditary hemoglobinopathies prevalent among persons of African ancestry. Figure 2.4a demonstrates the application of CIEF in my laboratory for diagnosis of congenital human hemoglobinopathies [87,88] using  $\text{pH} 6.7\text{--}7.7$  ampholytes. The sample shown in the figure was prepared for use as a hemoglobin pI standard by pooling erythrocyte hemolysates from multiple subjects that were homozygous or heterozygous for globin alleles that produce normal, sickle and/or C beta globin isoforms. The figure shows that  $\alpha\beta$  dimers containing the more positively charged C beta globin isoform ( $\alpha\beta^{\text{Lys6}+}$ ,  $\text{pI} = 7.44$ ) eluted first, followed by  $\alpha\beta$  dimers containing the more neutral sickle beta globin isoform ( $\alpha\beta^{\text{Val6}}$ ,  $\text{pI} = 7.21$ ), followed in turn by  $\alpha\beta$  dimers containing the more negatively charged normal beta globin isoform ( $\alpha\beta^{\text{Glu6-}}$ ,  $\text{pI} = 6.97$ ). The peak between  $\alpha\beta^{\text{Val6}}$  and  $\alpha\beta^{\text{Glu6-}}$  contains fetal hemoglobin where gamma globin replaces beta globin in the hemoglobin dimer ( $\alpha\gamma$ ,  $\text{pI} = 7.06$ ). Multiple sequence variations between gamma and beta globin are responsible for the pI difference between  $\alpha\gamma$  and  $\alpha\beta$  dimers. The proportions of different hemoglobin variants present in a sample can be determined on the basis of peak area at 415 nm. Excellent peak resolution and capacity for automated peak identification based on calculated pI make CIEF a highly effective analytical method for quantitative analysis of primary sequence globin isoforms.

CIEF can also be used for quantification and identification of posttranslationally modified hemoglobin isoforms. Virtually all human beta globin isoforms have a cysteine residue at position 93 ( $\beta\text{Cys93}$ ) whose sulfhydryl group ( $\text{pK}_a \sim 8.4$ ) participates in nitric oxide transport.  $\beta\text{Cys93}$  also nonenzymatically forms a mixed disulfide with glutathione *in vivo* under conditions of oxidative stress; one physiological role of glutathione is to protect protein sulfhydryl groups from irreversible oxidation. The mixed disulfide formed between  $\beta\text{Cys93}$  and glutathione is called S-glutathionyl hemoglobin and has been recommended for use as a biomarker of oxidative stress [89–92]. The sample shown in Figure 2.4b was prepared *in vitro* from erythrocytes obtained from a patient with homozygous sickle cell disease, and consequently, only the sickle beta globin isoform and  $\alpha\beta^{\text{Val6}}$  dimers were present. A proportion of the dimers were converted into S-glutathionyl hemoglobin by disulfide exchange *in vitro* with glutathione disulfide (oxidized glutathione). Glutathione is a tripeptide (Glu–Cys–Gly) that is negatively charged at  $\text{pH} > 4.1$  due to deprotonation of the carboxyl side chain of its N-terminal glutamic acid. When the mixed disulfide is formed between  $\beta\text{Cys93}$  and the glutathione cysteine residue, the  $\alpha\beta^{\text{Val6}}$  dimer acquires negative charge that lowers its pI, increases its migration time and produces a new peak ( $\alpha\beta^{\text{Val6,Cys93-SG}}$ ,  $\sim 40\%$  of total hemoglobin based on peak area at 415 nm) that was not detected in the untreated hemolysate. Naturally occurring

**FIGURE 2.4** Analysis of primary sequence and posttranslationally modified beta globin isoforms by CIEF. The analytical system included a Beckman-Coulter P/ACE MDQ instrument operated in normal polarity at 30 kV with UV/Vis detection at 415 nm and capillary cooling at 20°C. Hemoglobin  $\alpha\beta$  dimers with different beta globin primary sequences or chemical modifications were separated by CIEF on the basis of pI using a neutral, 31 cm long (21 cm to detector) by 50  $\mu$ m ID fused-silica capillary (DB-1, coated with dimethylpolysiloxane to suppress EOF). Hemolysates were prepared by adding 10  $\mu$ l of erythrocytes to 200  $\mu$ l of hemolyzing reagent (10 mM KCN, 5 mM EDTA) and pressure injected at the anode for 10 s at 1.0 psi. Separation media contained 0.375% methylcellulose and 2% pH 6.7–7.7 ampholytes in deionized water. Cathode solution was 80 mM borate, pH 10.25. Anode solution was 100 mM phosphoric acid in 0.375% methylcellulose. Voltage was applied without pressure for 3 min before focused zones were mobilized past the detector using pressure at 0.5 psi with constant voltage. Samples were (a) mixed hemolysate containing Hbs C, S, F and A; (b) hemolysate containing HbS and S-glutathionyl HbS; (c) hemolysate from a patient with diabetes and elevated glycated hemoglobin.

S-glutathionyl hemoglobin levels *in vivo* measured by MS or ion exchange HPLC are estimated to be <3% of total hemoglobin in normal individuals and up to ~9% in patients undergoing peritoneal dialysis [89,91,92].

Enzymatic and nonenzymatic protein glycation are posttranslational biochemical processes that also occur naturally in many cells. Attachment of sugars to specific serine, asparagine, and hydroxylysine residues is under strict enzymatic control and serves a multitude of biological functions, such as facilitating protein secretion or prolonging protein survival in the circulatory system [33]. In contrast, nonenzymatic glycation is a concentration- and oxidation-dependent condensation reaction between protein amino groups and the carbonyl groups of aldehydes, ketones, and reducing sugars, also known as the “browning” or Maillard reaction. Nonenzymatically glycosylated proteins initially form Schiff bases that can chemically rearrange to form Amadori products that can rearrange further to form advanced glycation end (AGE) products that disrupt normal protein function and play an important role in the etiology of vascular complications associated with diabetes and other chronic diseases [93]. Glycated hemoglobin levels increase in proportion to mean blood glucose that remains elevated in diabetes patients with poor metabolic control. Glycated

hemoglobin measurements (including HbA1c) are widely used to clinically monitor metabolic status and therapeutic success in diabetes patients.

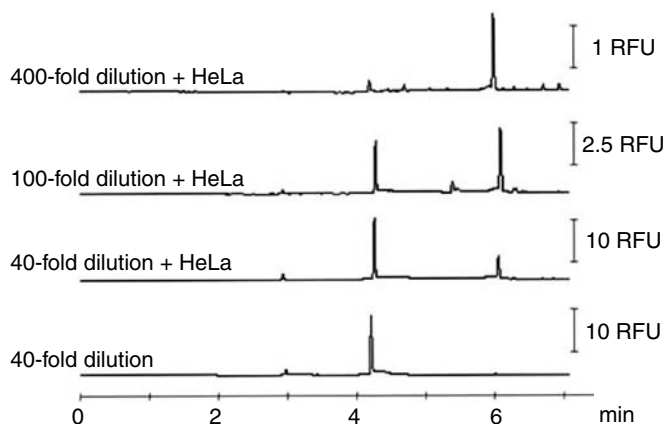

The *N*-terminal valine of beta globin ( $\beta$ Val1) is particularly susceptible to nonenzymatic posttranslational chemical modification by glucose, glycolytic intermediates, and glucose oxidation/fragmentation products. Chemical modification of the  $\beta$ Val1  $\alpha$ -amino group inhibits its protonation and lowers both the  $pK_a$  of the  $\alpha$ -amino group and the pI of hemoglobin  $\alpha\beta$  dimers. Glucose and other molecules react with other alpha and beta globin amino groups but glycation at these sites apparently does not alter the surface charge of  $\alpha\beta$  dimers [33], probably because the charge on these groups is not significantly altered by glycation at pH optimal for separation by charge-based separation techniques. The sample shown in Figure 2.4c was prepared from erythrocytes obtained from a patient with type 1 diabetes and elevated glycated hemoglobin levels. The larger of the two major CIEF peaks ( $\alpha\beta^{\text{Glu6-}}$ ) contains  $\alpha\beta$  dimers that are not posttranslationally modified in ways that alter pI, for example, on  $\beta$ Val1. The smaller peak ( $\alpha\beta^{\text{Glu6-,Val1-Glucose}}$ ,  $\sim 15\%$  of total hemoglobin) with longer migration time contains  $\alpha\beta$  dimers with lower pI that are posttranslationally modified on  $\beta$  Val1 by glucose and other biomolecules.

These examples show how CIEF can be used to identify and quantify a family of sequence and posttranslationally modified beta globin isoforms based on pI. They also show how oxidative stress and hyperglycemia both influence the speciation of hemoglobin into a variety of chemically distinct isoforms that differ by how and where they are posttranslationally modified. Because hemoglobin is nonenzymatically modified by compounds like glutathione and glucose, isoform levels measured by CIEF reflects the concentrations of these and other metabolites and can be used to quantitatively assess a narrow subset of the human proteome that provides diagnostic information in a more or less bottom-up approach to biomarker discovery. Comprehensive assessment of the hemoglobinome, if you will, holds promise for identifying normal and disease risk phenotypes because beta globins are posttranslationally modified in characteristic patterns associated with characteristic patterns in disease phenotypes, that is, oxidative stress and diabetes. Many other proteins also undergo similar nonenzymatic and/or enzymatic posttranslational modifications with glutathione, glucose and other metabolites. Assessment of posttranslationally modified protein isoforms, especially long-lived proteins like collagen where modifications accumulate irreversibly, could provide information about both the proteome and the metabolome since the chemically distinct protein isoforms present are a function metabolite exposure over time.

### 2.5.2 SP 1 MOBILITY SHIFT ASSAY BY CAE

Capillary affinity electrophoresis is often used to enhance selectivity or study binding interactions between proteins and other biomolecules. CAE applications rely on the principle that the electrophoretic mobilities of bound and unbound forms of a protein of interest differ and can be identified and quantified by CE, most often using CZE or CSE. One example is electrophoretic mobility shift assays, which are used to study protein–protein, protein–antibody, or protein–DNA interactions. A study by Ronai et al. [94] demonstrated the advantages of a CE mobility shift assay (CEMSA) for analysis of SP 1 binding capacity based on affinity between SP 1 and a fluorescent-labeled synthetic oligonucleotide. SP 1 is a sequence-specific DNA-binding protein that plays an important role in the transcriptional regulation of many genes. Figure 2.5 demonstrates the principle of the assay using a fluorescent DNA probe and HeLa nuclear extracts that contained SP 1. In this example, DNA probes were prepared from the 5' upstream regulatory region of the human dopamine D4 receptor (DRD4) gene by polymerase chain reaction (PCR) amplification using fluorescein labeled primers. The probes (at 40-, 100-, or 400-fold dilutions) were then incubated with or without HeLa nuclear extract and analyzed by CE with fluorescence detection.

The  $m/z$  of the free DNA probe was lower than that of the DNA–protein complex and consequently had greater electrophoretic mobility and shorter migration time when analyzed by CZE. The analysis was performed in normal polarity but with the detector window closer to the inlet

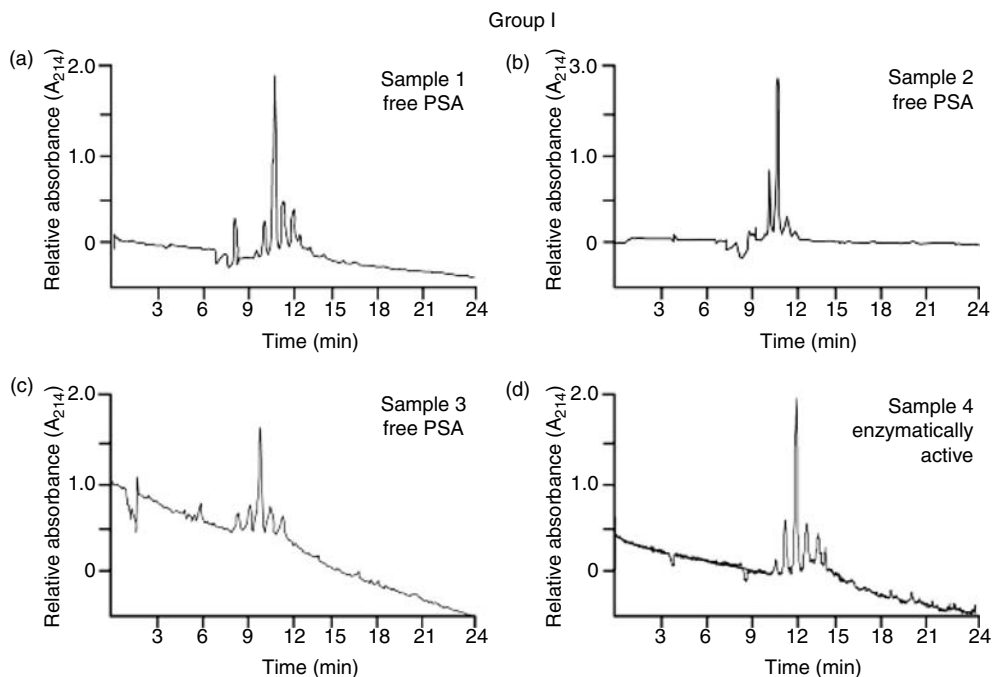

**FIGURE 2.5** SP 1 capillary electrophoresis mobility shift assay (CEMSA). The analytical system included a Beckman-Coulter P/ACE MDQ instrument operated in normal polarity at 200 V/cm with laser-induced fluorescence detection (488 nm excitation, 520 nm emission) and capillary cooling at 20°C. Free DNA (~4.2 min) and DNA–protein complex (~6 min) were separated by CZE based on *m/z* using a neutral coated, 50 cm long (10 cm to detector) by 50  $\mu$ m ID fused-silica capillary. Separation media (TBE buffer) contained 89 mM Tris HCl, 89 mM boric acid, and 2 mM disodium EDTA, pH 8.3. Samples containing various dilutions of fluorescein labeled DNA probe with or without a fixed amount of HeLa nuclear extract (containing SP 1) were pressure injected for 5 s at 3 psi. (From Ronai Z, et al. *Curr Med Chem* 2004;11:1023–9. With permission.)

(10 cm) in order to shorten the migration time while still using a longer capillary (50 cm total length) and high voltage. The proportion of DNA–protein complex present was a function of the relative concentrations of the DNA probe and nuclear extract. In the absence of HeLa nuclear extract (bottom electropherogram), a single large peak was observed at about 4.2 min representing the unbound (free) DNA probe. Addition of HeLa nuclear extract with the same 40-fold dilution of the same DNA probe (second electropherogram from the bottom) resulted in the appearance of a second peak at approximately 6 min representing the SP 1–DNA probe complex. Decreasing the concentration of the DNA probe while holding the concentration of HeLa extract constant (top two electropherograms) resulted in a proportional increase of bound vs. free DNA probe. Competition assays using nonfluorescent DNA probes with the consensus SP 1 binding sequence or a mutated version of the consensus sequence showed that the effect of the HeLa extract was specific for SP 1. The authors used this CEMSA to show that Sp 1 binding to the DRD4 gene was influenced by the number of SP 1 binding 120 base pair repeat sequences present in the highly polymorphic 5' upstream regulatory region.

### 2.5.3 ANALYSIS OF FREE PROSTATE-SPECIFIC ANTIGEN ISOFORMS BY CAPILLARY ZONE ELECTROPHORESIS

Prostate-specific antigen (PSA) is a single-chain glycoprotein that belongs to the kallikrein family of serine proteases [95]. Overproduction of PSA, for example, in prostate hyperplasia, cancer or prostatitis, causes more of the protein to enter the circulatory system such that serum PSA can be used as a biomarker for prostate-related diseases. PSA has one known glycosylation site that is chemically modified by a diantennary N-linked oligosaccharide that itself can vary on the basis of the presence or absence of fucose, one or two sialic acids, or the glycan content of fucose and *N*-acetyl-d-galactosamine. Free PSA thus exists as chemically distinct posttranslational isoforms. Genetic variants of PSA have also been reported. In addition, PSA in serum binds to several serine protease inhibitors, including  $\alpha$ 1-antichymotrypsin,  $\alpha$ 2-macroglobulin and  $\alpha$ 1-antitrypsin. Consequently, PSA in serum exists as both free PSA and complexed PSA, primary sequence

**FIGURE 2.6** Analysis of PSA heterogeneity by CZE. The analytical system included a Model 310 Thermo Capillary Electrophoresis Crystal CE instrument operated in normal polarity at 25 kV with UV detection at 214 nm. Free PSA isoforms were separated on the basis of  $m/z$  using a 60 cm long by 50  $\mu\text{m}$  ID fused-silica capillary. Separation media contained 20 mM sodium borate, 5 mM 1,3-diaminopropane, pH 8.0. Samples were pressure injected for 3 s at 200 mbar. Panels (a)–(d) show the separation of PSA isoforms in purified PSA obtained from four different commercial vendors.

isoforms, and in posttranslationally modified isoforms. Free PSA isoforms were previously reported to have pI between 5.7 and 7.2. Characterization of all structural variants/isoforms is important since modification may differentially modulate PSA biological activity and serve as biomarkers of disease.

Donohue et al. [95] developed a CZE method for the analysis of PSA and compared the profiles of seven commercially available purified PSA products. Since different manufacturers use different proprietary methods to produce purified PSA for research use, their goal was to evaluate the heterogeneity of commercially available PSA. The capillary used in these experiments was dynamically coated by adding 1,3-diaminopropane to the buffer as an EOF modifier to enhance glycoprotein separation and reproducibility. Figure 2.6 shows the heterogeneity observed in four of the seven samples analyzed. Four to seven peaks were observed with one dominant peak in each case representing 51%–70% of the total free PSA (complexed forms and genetic variants are not expected in purified samples). The dominant peak in the sample shown in panel c was not the same as the dominant peaks in panels a and b on the basis of peak retention time, which had intra-assay and interassay relative standard deviations of 0.6% and 5.0%, respectively. The author suggested that the dominant peak is most likely fucosylated disialylated diantennary PSA as demonstrated by other investigators using LC-MS. The majority of the lower-abundance isoforms had longer migration times indicating that these species are more electronegative and likely attributable to alteration of the oligosaccharide structure. Since the profiles of all seven commercially available samples differed, the authors concluded that variation in purification methods strongly influence the isoform composition and heterogeneity of purified PSA products.

#### 2.5.4 ANALYSIS OF HISTONE H1.5 ISOFORMS BY OFFLINE MULTIDIMENSIONAL RPHPLC-CZE

The fundamental subunit of chromatin is the nucleosome core, which consists of DNA wrapped around an octamer of core histones [96]. H1 histones are linker histones associated with the core histone–DNA complex and with the linker DNA between adjacent nucleosomes. Histone H1 phosphorylation is a function of the cell cycle, lowest in G<sub>1</sub> phase, rising during S and G<sub>2</sub>, and reaching a maximum in M phase. H1 phosphorylation appears to be involved in chromatin decondensation, destabilizing chromatin structure, and weakening binding to DNA. Individual H1 subtypes differ in their degree of phosphorylation during the cell cycle.

To better understand H1 phosphorylation, Sarg et al. [96] incorporated CZE in a multidimensional analysis to show that human lymphoblastic T-cells have unambiguous site specificity for histone H1 phosphorylation. Human lymphoblastic T-cells were synchronized in culture and labeled with <sup>32</sup>P. Lyophilized perchloric acid cell extracts containing <sup>32</sup>P-labeled H1 histones (~500 μg) were first separated by reversed phase HPLC (RP-HPLC) on a Nucleosil 300-5 C4 column. Figure 2.7a shows that H1.5, the main component histone and the most highly phosphorylated during interphase and mitosis, was clearly separated from residual histones H1.2, H1.3, and H1.4. The extent of H1.5 phosphorylation was then determined by analyzing the H1.5 fraction by CZE (Figure 2.7b), which identified four peaks representing nonphosphorylated (p0), monophosphorylated (p1), diphosphorylated (p2), and triphosphorylated (p3) H1.5. A similar H1.5 sample pretreated with alkaline phosphatase showed only two peaks, a large p0 peak and a smaller p1 peak but no p2 or p3, confirming the identity of the phosphorylated isoforms. Phosphate groups are negatively charged such that their addition to H1.5 decreases surface charge and alters *m/z*.

#### 2.5.5 ONLINE MULTIDIMENSIONAL PROTEIN ANALYSIS BY CSE-MEKC

Multidimensional separation of proteins based on more than one physical property can greatly expand the number of proteins that can be qualitatively or quantitatively identified among the complement of proteins present in any proteomic compartment. The process can be automated by coupling multiple HPLC, CE and/or MS systems in a variety of hybrid/hyphenated combinations. Interfacing any two analytical systems online, even two different CE techniques, requires the use of compatible buffers/electrolytes and transfer of protein-containing fractions from the outlet of the first dimension to the inlet of the second dimension [59]. For complex biological samples, multidimensional analyses can be quantitative if MS is used but is at best semi-quantitative if based on absorbance or derivatized fluorescence intensity across a landscape of intersecting dimensional coordinates (e.g., pI vs. molecular weight). Compared to HPLC, CE provides exceptionally high separation efficiency but is also uniquely suited for analysis of proteins in single cells due to the very low sample volume requirement.

Harwood et al. [56] used CSE and MEKC to map protein distribution in single mouse embryos in two dimensions based on size and hydrophobicity (Figure 2.8). Although CE can be used to inject, lyse, and analyze whole cells completely online [68,69,77,97], mouse embryos are relatively large (~75 μm) and would require the use of greater diameter capillaries where Joule heating might compromise separation efficiency. Embryo extracts were therefore prepared off-line and protein and nonprotein primary amines were nonspecifically labeled with 3-(2-furoyl)quinoline-2-carboxaldehyde (FQ) before analysis by CSE-MEKC. Over 100 mouse embryo components were identified with fluorescence intensities over 10 times greater than the standard deviation of the background fluorescence.

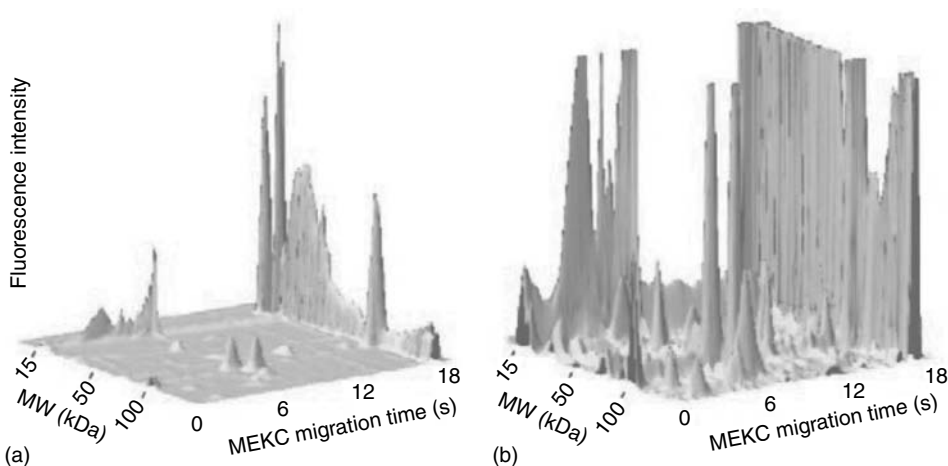

On average, mouse embryos contained about 27 ng of protein each and yielded approximately 1 μL of lysate. In this study, approximately 3 nL (90 pg of protein or 0.3% of total protein) was injected such that analytical reproducibility could be tested on the basis of the results of multiple analyses. Data collection and processing were performed using in-house developed software that

**FIGURE 2.7** Isoform analysis of phosphorylated H1 histone by multidimensional HPLC-CZE. Panel (a) shows the separation of H1 histones by RP-HPLC on a Nucleosil 300-5 C4 column. Panel (b) shows the separation of the H1.5 RP-HPLC fraction by CZE. The CE analytical system included a Beckman-Coulter P/ACE 2100 instrument operated in normal polarity at 12 kV with UV detection at 200 nm and capillary cooling at 25°C. Nonphosphorylated (p0) and mono-, di-, and tri-phosphorylated (p1, p2, p3) H1.5 isoforms were separated on the basis of  $m/z$  using a 57 cm long (50 cm to detector) by 75  $\mu\text{m}$  ID untreated fused-silica capillary. Separation media contained 0.1 M sodium phosphate, 0.02% hydroxypropylmethylcellulose, pH 2.0. Samples were injected for 2 s. (From Sarg B, et al. *J Biol Chem* 2006;281:6573–80. With permission.)

produced gel-like images or landscape images like those shown in Figure 2.8. Each analytical run consisted of approximately 200 cycles where fluorescence intensity was measured between 0 and 17 s as 200 different CSE fractions were analyzed by MEKC. The reproducibility of the separations in replicate analyses were determined in the first and second dimensions by comparing cycle number and seconds, respectively, for 50 sample constituents with the highest fluorescence intensities. The average standard deviations were 4.7 cycles and 0.30 s in the CSE and MEKC dimensions, respectively.

This example shows that CSE-MEKC can separate and detect over 100 different cellular components in a single mouse embryo and could potentially be used to semiquantitatively compare protein expression levels in individual cells from a heterogeneous cell population. Though nonspecific, the use of fluorescence derivatization and detection greatly increased the sensitivity and dynamic range

**FIGURE 2.8** 2D CSE-MEKC separation of proteins in a single mouse embryo. The analytical system included an in-house constructed multidimensional CE system operated in reverse polarity with postcolumn laser-induced fluorescence detection in a sheath-flow cuvette (473 nm excitation, 580 nm emission). Both CSE and MEKC separations used 20 cm long by 30  $\mu\text{m}$  ID fused-silica capillaries dynamically coated with EoTrol LN (Target Discoveries, Palo Alto, CA) to stabilize normal EOF. Samples were injected at the inlet of the CSE capillary for 5 s at 11 kPa using negative pressure. CSE was performed at 1000 V/cm in separation media containing 100 mM Tris, 3.5 mM SDS and 5% dextran polymer (513 kDa) at pH 8.7. Analytes were transferred sequentially into the second capillary where MEKC was performed at 900 V/cm in separation media containing 100 mM CHES, 100 mM Tris and 15 mM SDS at pH 8.7. The net electric field across the first capillary was held at 0 V/cm during analyte separation in the second capillary, a process that was repeated for approximately 200 cycles where each cycle was composed of a 1 s transfer and a 17 s separation in the second dimension. Data collection and processing were performed using in-house developed software that can produce the landscape images shown here at full scale (a) or ten-times expanded scale (b). (From Harwood MM, et al. *J Chromatogr A* 2006;1130:190–4. With permission.)

of protein detection. Multidimensional resolution was better than that attainable in a single CE dimension, and was perhaps similar to that attainable using conventional 2D SDS–PAGE. However, analyzing the protein content of embryos by conventional methods like 2D SDS–PAGE and tandem MS requires pooling extracts from many cells in order to acquire enough sample for analysis. Such results only reflect average protein expression levels rather than expression levels in individual cells as described in the example presented here.

Proteomic analysis of individual cells or specific tissues has important implications for diagnosis of disease since comparing normal and diseased cells can help identify proteomic phenotypes characteristic of disease. For example, Kraly et al. [98] used CSE-MEKC to analyze tissue homogenates from esophageal and stomach biopsy samples collected from patients with Barrett’s Syndrome. They identified 18 features from the homogenate profiles as biogenic amines and amino acids that differed in diseased and normal tissues. The results suggest that two-dimensional CE might be useful for rapid characterization of endoscopic and surgical biopsies for this and other diseases.

## 2.6 CONCLUDING REMARKS

The probability that all chemically distinct proteins in the vast human proteome will be identified and characterized any time soon is vanishingly small. However, research and development toward this goal can only improve the quality and quantity of proteomic data that is available and the ability of biomedical science to use that information to improve the human condition. CE appears poised to play a significant role in the collection of proteomic data for use in both top-down and bottom-up

systems biology approaches to biomarker discovery. Electrophoresis in narrow-bore capillaries is capable of extremely high efficiency protein separations based on one or more protein properties. Some of the application examples included in this chapter show how one-dimensional CE techniques can be used to identify and quantify specific protein isoforms or study their physical properties. Other examples show how CE can be used in multidimensional analyses to separate proteins on the basis of multiple physical properties. The efficiency of multidimensional protein separations is approaching the scale needed for relatively comprehensive analysis of the more abundant proteins present in discrete proteomic compartments like the plasma proteome or individual cell proteomes. Many of the reproducibility, sensitivity and specificity issues traditionally associated with analysis of proteins in a capillary format have been overcome by technological advances in CE instrument and method development. MS is and will likely remain the detection method of choice for most microanalytical protein separation techniques due to its high degree of sensitivity and selectivity; characteristics that one-dimensional CE techniques often lack when it comes to protein analysis.

Commercial availability of CE-MS analytical systems has opened the door for high efficiency, multidimensional protein analysis to those who can afford it. Commercialization of multidimensional systems that combine multiple CE techniques, or CE with HPLC, could lead to even greater ability to separate, identify and quantify proteins in complex biological samples. However, multidimensional map coordinates of the distribution of proteins based on charge, size, and/or hydrophobicity provide relatively low quality data because complex biological samples simply contain too many proteins with similar multidimensional properties. Proteomic phenotyping based on limited protein information can only be used to divide individuals in a population into relatively indistinct groups and provides little or no mechanistic information. Higher quality proteome data quantifies specific proteins, as many as possible, and can be used to quantitatively group individuals on the basis of discrete patterns in the proteomic distribution of chemically distinct proteins.

Understanding and classifying biological variation in the vast human proteome is a major undertaking and a challenge that nature and systems biology have presented to biomedical and analytical science. Capacity to cost-effectively and simultaneously profile the concentrations of many chemically distinct proteins in selected proteomes is what biomedical science most urgently needs for biomarker discovery and management of complex diseases. By design or by good fortune, analytical systems for protein analysis by CE are well-positioned to advance in both bottom-up and top-down approaches to the collection of proteomic data. High-throughput microchip and multicapillary CE instruments, and high-resolution multidimensional systems that incorporate CE, can greatly expand both the quantity and quality of protein data that can be acquired. What remains to be determined is how well CE will compete with other advanced protein separation technologies or assay techniques whose development will also be influenced by the emergence of systems biology and biomarker discovery as driving forces in the evolution of analytical instrumentation.

## ACKNOWLEDGMENT

The author would like to thank Dr. Mark Richards for his kind and considered review of the manuscript for this chapter.

## 3.1 INTRODUCTION

Electrophoresis is a separation technique based on the migration of the analyte in a solution under the influence of electric field. In electrophoretic separation it is essential for the analyte to be charged or ionic. The migration velocity of the analyte is primarily depends on the charge and the size of the analyte under a homogeneous electric field but it can also be modified by several chemical or physical interactions between the analyte and the electrophoretic media including additives or

**FIGURE 3.1** Schematic illustration of the principle of MEKC.

polymer networks. Neutral molecules were not considered to be separated by electrophoresis until micellar electrokinetic chromatography (MEKC) was developed by Terabe et al. in 1984 [1]. The idea using ionic micelles in electrophoresis was suggested by Nakagawa in 1981 as described by Terabe et al. [1]. The neutral analyte will gain an apparent electrophoretic mobility when it is incorporated into the ionic micelle and will migrate at the same velocity as the micelle under electrophoretic conditions. Since the distribution equilibrium of the analyte between the micelle and the surrounding aqueous phase can be quickly established, the apparent electrophoretic mobility or migration velocity is directly related to the distribution coefficient. The more the analyte is incorporated, the higher the mobility. The analyte also migrates by electroosmotic flow (EOF) under capillary electrophoresis (CE) conditions, although EOF does not contribute to the separation at all. Thus, the migration time in MEKC is a function of electrophoretic velocity of the micelle, distribution ratio, and EOF velocity. A schematic principle of MEKC is shown in Figure 3.1, where EOF is stronger than the electrophoretic migration of the anionic micelle and hence the anionic micelle migrates toward cathode at a retarded velocity. The neutral analyte migrates at the velocity between EOF velocity and that of the micelle and the migration velocity depends on how much fraction of the analyte is incorporated into the micelle. It should be noted that there is optimum distribution of the analyte to the micelle for good separation, that is, totally incorporated analyte by the micelle or free from the micelle cannot be separated by MEKC. MEKC introduced the chromatographic principle into CE by adding ionic micelles into the electrophoretic solution. MEKC is a branch of CE and extended significantly the applicability of CE to a wide range of analytes, particularly small molecules. Since MEKC also belongs to a chromatographic technique, it is familiar for most chromatographers to design separation conditions.

MEKC can be easily performed just by adding ionic micelles to the electrophoretic solution or background electrolyte solution in capillary zone electrophoresis (CZE), which is the simplest separation mode of CE, without any instrumental modification. The ionic micelle added to the background solution (BGS) is called pseudostationary phase because it plays a role as stationary phase in chromatography, although it migrates inside the capillary. It should be noted that micelles are classified as a pseudophase because the micelles exist only in equilibrium with surfactant molecules in solution and cannot be isolated. The idea of separation of neutral analytes by electrophoresis was extended to the use of other pseudostationary phases such as microemulsions, liposomes, charged cyclodextrins (CDs), dendrimers, charged polymers, and so forth, and the technique can be generally named as EKC [2].

Although MEKC has been widely accepted as a CE technique for the separation of neutral analytes, it is also a powerful technique in improving selectivity of charged analytes in CE. MEKC is almost 25 years old and popular among separation scientists as pointed out by a large number of papers published, more than 2600 by 2005 [3], and coverage of the technique in the first edition of this handbook. Therefore, this chapter does not describe much about the fundamental characteristics of MEKC but the main target is to give the guiding principles for full availability of the technique.

There are many books, book chapters, or review articles on fundamental MEKC [4–11]. In particular, online sample preconcentration techniques are becoming popular in CZE to improve concentration detection sensitivity and so are in MEKC, which will be introduced rather in detail. Although it is generally stated that CE requires minimal amounts of sample (certainly true), it should be mentioned that the volume of sample solution required is much greater than that actually introduced into the capillary because the injection end of the capillary must be dipped into the sample solution—this is typically at least a few microliters.

## 3.2 BACKGROUND

### 3.2.1 INSTRUMENTATION

No special modification of conventional CE instrumentation is required to perform MEKC. However, the micellar solutions, prepared by dissolving a surfactant into a buffer solution, have higher electric conductivity than the conventional CZE buffers and the current is usually high in MEKC. Therefore, care must be taken to apply voltages that avoid excessive current (e.g., preferably less than 50  $\mu\text{A}$ ). Otherwise, the separation efficiency will be deteriorated due to high Joule heating. Temperature of capillary should be controlled higher than the Krafft point of the surfactant, which is the temperature where the surfactant solubility increases rapidly with an increase in temperature. Krafft points change depending on the solution, for example, the Krafft point of sodium dodecyl sulfate (SDS) is 15°C in pure water, but it will be lower in buffer solutions.

Native fused-silica capillary with an inside diameter (ID) of 50 or 75  $\mu\text{m}$  is generally used in MEKC. To suppress EOF acidic conditions are employed. The use of surface-treated capillaries, such as polyacrylamide or neutral coating, is effective to suppress EOF. Charged surface coating such as successive multiple ionic layer (SMIL) coating [12] increases EOF even under acidic conditions or reverses the direction of EOF. For example, the capillary is first coated with polybrene after rinsing the surface followed by the coating with dextran sulfate, producing stable negatively charged surface even at low pH. An additional third coating of polybrene produces stable positively charged surface.

Photometric detectors are the most popular in CE instruments including diode array detectors. Laser-induced fluorescence (LIF) detection and electric conductivity detectors are also popular. LIF is particularly sensitive and powerful for detecting low concentration analytes. However, most analytes are not natively fluorescent and some derivatizations are necessary. Conductivity detector is useful for the detection of non-ultraviolet (non-UV) absorbing analytes such as inorganic ions or fatty acids. Both LIF detection and conductivity detectors are commercially available and easy to interface with conventional CE instruments. Electrochemical detectors are also useful for selective high-sensitivity detection. Several techniques have been developed to circumvent the problem of strong effects of electrophoretic field on electrochemical detection, but despite this, commercial electrochemical detectors are not used extensively.

### 3.2.2 MASS SPECTROMETRIC DETECTION

Mass spectrometry (MS) is becoming an indispensable detection method in every separation analysis. High-performance liquid chromatography (HPLC)-MS is now a practical and robust technique with electrospray ionization (ESI) or atmospheric pressure chemical ionization (APCI) interface to generate analyte ions directly from the liquid phase. The same instrument can be utilized for CE-MS with minor modifications. Since the liquid flow rate is significantly different between HPLC and CE, some modifications are necessary; to keep the supply of the liquid to ESI interface a sheath liquid is added through the coaxial ESI spray nozzle, which is also helpful to keep electrical connection for CE run. A mixture of methanol and water-containing acetic acid or formic acid is usually used as a sheath liquid at a flow rate around few  $\mu\text{L}/\text{min}$  in the positive ESI mode. The ESI voltage and CE voltage are simultaneously applied at the spray nozzle but the CE current and ESI current are not the same and the mismatch may cause some troubles interrupting current due to bubble formation

or unstable CE current. It is preferable to maintain the BGS at a low conductivity to minimize the current mismatch. In some instruments, the spray nozzle can be grounded, thus solving the problem. Since the presence of a high concentration of salts adversely affect the ionization efficiency in ESI, volatile electrolytes such as ammonium formate or acetate are widely employed in CE buffer, which minimizes contamination of the ion source. However, addition of the surfactant to BGS is essential in MEKC, and most surfactants are nonvolatile contaminating the interface, and strong electrolytes reduce the ionization efficiency in ESI. Several techniques have been developed to circumvent this problem: partial-filling technique, reverse migration of the micelle, or the use of volatile surfactant. The partial-filling technique is very effective for avoiding entrance of nonvolatile surfactant into the ion source [13–17], but it is not a mature technique for MEKC-MS as of yet. Other techniques are less popular and will not be introduced here. The more effective procedure for MEKC-MS is to perform conventional MEKC with nonvolatile surfactant and electrolytes, noting that concentrations of SDS and inorganic electrolytes are to be kept low (20 and 10 mM, respectively) [18,19]. Atmospheric pressure photoionization (APPI) interface is a promising interface for MEKC, where up to 50 mM SDS can be used [20].

### 3.2.3 CHEMICALS

#### 3.2.3.1 Surfactants

Although a large number of surfactants are commercially available, limited numbers of surfactants are widely utilized in MEKC. SDS is the most popular because it has many advantages over other surfactants—specifically, it has high stability, relatively low Krafft point, low UV absorbance, high solubilizing capability, and high quality reagent is readily available. Among several different surfactants frequently used in MEKC, bile salts such as sodium cholate and sodium deoxycholate, and cetyltrimethylammonium bromide or cetyltrimethylammonium chloride (CTAB or CTAC) are also useful to obtain different selectivity from that obtained with SDS. The effect of surfactant structures on selectivity will be discussed later. The concentration of the surfactant must be higher than critical micelle concentration (CMC), above which the surfactant forms micelles. The CMC of SDS is 8 mM in water, but it will be lower (e.g., down to 3 mM) in buffer solutions. In most applications, SDS concentrations are between 10 and 50 mM, but even 100 mM can be employed if the applied voltage does not cause excessive current. Different surfactants will provide different selectivity for separation and, hence, surfactant choice is a means of selectivity manipulation. The mixed micelle, which consists of two or more surfactants, can provide different selectivity in separation; in particular, the mixed micelle between an ionic and a nonionic surfactant is considered of value because selectivity is closely related to the surface structure of the micelle. Some surfactants such as bile salts and amino acid derived surfactants are chiral and can be used for enantiomers separations.

#### 3.2.3.2 Additives

As will be discussed later, selectivity can be manipulated by changing several parameters in addition to using different surfactants. The choice of additives to modify distribution equilibrium can follow the analogy to reversed-phase HPLC. Water miscible organic solvents such as methanol, acetonitrile, 2-propanol, and so forth, used as mobile phase modifiers in reversed-phase HPLC, are also effective in MEKC. For hydrophobic or less water-soluble analytes, the organic solvent addition is useful to reduce the distribution of the analyte to the micelle. The content of the organic solvents are usually less than 30% to avoid the dissociation of the micelle. However, much higher concentration can be used for separation, although it is not certain that the micelle is still stable. It should be noted that the addition of the organic solvent to BGS affects viscosity; in particular, methanol or 2-propanol addition increases viscosity significantly, and EOF is accordingly decreased because EOF mobility is inversely proportional to viscosity. The addition of hydrophobic solvent may change the micellar structure

even if the concentration is low; for example, 1-butanol or 1-propanol may partly be incorporated into the micelle as a cosurfactant, which causes a change in selectivity. Another advantage of the use of an organic solvent is that the adsorption of the analyte on the capillary wall is minimized.

Cyclodextrins (CDs) are useful additives in MEKC to reduce the distribution of the analyte to the micelle, improving the separation of highly hydrophobic analytes. CD addition can also change selectivity, particularly for aromatic isomers. Since CDs are chiral, CD addition makes enantiomer separation possible, and this is particularly useful for the separation of neutral enantiomers. In most applications,  $\beta$ -CD or  $\gamma$ -CD is used at relatively high concentrations (e.g., 10–40 mM). The surfactant molecule may be included into the cavity of the CD and, therefore, the inclusion complex formation constant between the analyte and CD may be different from that observed in the absence of the surfactant. Ion-pair reagents are useful in MEKC in a manner analogous to that in reversed-phase HPLC for the separation of ionic analytes. However, the mechanism is slightly different between MEKC and HPLC, because the micelle is charged [21]. A high concentration of urea [22] or glucose [23] can be used to improve the separation of highly hydrophobic analytes or to change selectivity.

### 3.2.3.3 The Electrophoresis (Separation or Running) Solution

The micellar solution prepared by dissolving an ionic surfactant into a buffer solution is used as a “running” solution in MEKC. Popular buffer solutions often used to prepare the micellar solution are phosphate, borate, or tris(hydroxymethyl)aminomethane (Tris). It is well known the pH of the buffer significantly affects the EOF; that is, EOF is almost completely suppressed below pH 2, low at  $\sim$ pH 5 and strong (and relatively constant) above pH 7 when a native capillary is employed. The concentration of buffer electrolytes is usually 20–50 mM, and while higher concentrations give higher buffer capacity, this generally generates high current in addition to the contribution of the ionic surfactant to conductivity. It should be noted that the counter ion of the ionic surfactant is exchanged by the counter ion of the buffer electrolyte and, consequently, the character of the micelle may be changed. The use of potassium-containing electrolytes must be avoided when using SDS because potassium dodecyl sulfate has a higher Krafft point at room temperature, and the surfactant will be precipitated out.

### 3.2.4 OPERATING CONDITIONS

No special care is needed to perform MEKC compared with the CZE operation described in Chapter 1. The difference between the two techniques is only the electrophoretic solution or running solution. The current tends to be higher in MEKC, requiring a more frequent replenishment of the running solution to avoid the pH change in running solution associated with buffer depletion. When a cationic surfactant such as CTAB is employed, the direction of EOF is reversed and regeneration of the surface needs to be accomplished through sufficient rinsing of the capillary. It should be noted that CTAB in the anodic vial will generate bromine by electrolysis which ultimately contaminates the running solution.

## 3.3 THEORETICAL ASPECTS

### 3.3.1 RETENTION FACTOR AND RESOLUTION EQUATION

The migration behaviors of the analyte, the micelle marker, and the EOF marker are shown in Figure 3.2a, where the corresponding electropherogram is also shown (Figure 3.2b). The EOF marker migrates at the velocity of EOF and the micelle at the velocity of difference between EOF and the electrophoretic velocity of the micelle, which is in the opposite direction of EOF. The neutral analyte migrates at the velocity between the two extremes: the analyte is assumed to be equally distributed between the micelle and the aqueous phase in Figure 3.2. EOF mobility is assumed to be

**FIGURE 3.2** Schematic illustration of the migration behavior in MEKC. (From Terabe, S. et al., *Anal. Chem.*, 57, 834, 1985. With permission.)

4/3 times larger than electrophoretic mobility of the micelle in absolute values or the migration time of the micelle,  $t_{mc}$ , is four times longer than that of the EOF marker,  $t_0$ . The EOF marker is free from the micelle throughout the progress and methanol is often used as a marker. Although methanol does not absorb UV, it can be detected due to the fluctuation of the reflective index inside the capillary. Sudan III or IV is often used as a micelle marker, because it is assumed to be totally incorporated into the micelle. Some cationic hydrophobic compounds such as quinine sulfate can be employed as an SDS marker, because quinine interacts strongly with the SDS micelle due to electrostatic and hydrophobic interaction.

The retention factor,  $k$ , can be defined as

$$k = \frac{n_{mc}}{n_{aq}}, \quad (3.1)$$

where  $n_{aq}$  and  $n_{mc}$  are the amount of the analyte in the aqueous phase and that incorporated into the micelle. It can be calculated from the migration times  $t_R$  of the analyte,  $t_0$ , and  $t_{mc}$  as follows [1]:

$$k = \frac{t_R - t_0}{t_0 (1 - t_R/t_{mc})}. \quad (3.2)$$

The resolution equation in MEKC can be given by [24]

$$R_s = \frac{\sqrt{N}}{4} \left( \frac{\alpha - 1}{\alpha} \right) \left( \frac{k_2}{1 + k_2} \right) \left( \frac{1 - (t_0/t_{mc})}{1 + (t_0/t_{mc}) k_1} \right), \quad (3.3)$$

where  $N$  is the number of theoretical plates and  $\alpha$  is the selectivity factor equal to  $k_2/k_1$ , which is assumed to be larger than 1, where  $k_2$  and  $k_1$  are retention factors of analyte 1 and analyte 2, respectively. Equations 3.2 and 3.3 are similar to those of the conventional chromatography but different due to the limited migration time window for the analyte between  $t_0$  and  $t_{mc}$ . The last factor (parameter) in right-hand side of Equation 3.3 is not part of the conventional resolution equation, and is ascribed to the change in effective capillary length utilized for separation. In other words, the micelle is not stationary in the capillary but migrates during the separation process, which makes the length of the micelle interacting with the analyte in the capillary shorter than the physical length

by the distance the micelle migrates during  $t_R$ . We may define this parameter as the migration time window contribution, although the last factor becomes null when EOF is absent or the micelle is stationary. The effect of each factor in Equation 3.3 is briefly discussed below for reasonable optimization of MEKC separation.

### 3.3.1.1 Number of Theoretical Plates

Column efficiency, expressed as the number of theoretical plates ( $N$ : plate numbers), has been shown to be as high as 100,000–200,000 in MEKC. The most important factor contributing to the plate height is the longitudinal diffusion as in CZE—the shorter the migration time, the higher plate number. Since the diffusion coefficient of the micelle is usually one order lower than that of the small molecule, higher plate numbers can be expected for analytes having larger retention factors or those more incorporated into the micelle. The next important factor to be considered is extracolumn effects; in particular, the injection sample volume or sample plug length. In general, the sample plug length should be restricted to less than 1% of the capillary length unless sample preconcentration occurs. The use of a longer capillary alleviates the large volume injection problem, although the plate number is not proportional to the capillary length, as in other CE modes. It should be noted that if the initial sample zone length is minimal, extremely high efficiency can be expected. Temperature effects are not serious if current is lower than 50  $\mu\text{A}$ , and it should be noted that the adverse effects on efficiency often observed are due to the sample adsorption on the capillary wall. Thorough rinsing of the capillary or an addition of a small amount of organic solvent may solve the problem. If the plate number is lower than 100,000, care must be taken to identify the reason of low efficiency; overloading of the sample or adsorption of the analyte on the capillary wall should be considered.

### 3.3.1.2 Selectivity Factor

As in chromatography, selectivity factor is the most important parameter in optimizing the separation. Since the micelle corresponds to the stationary phase in chromatography, the selection of the surfactant is of primary importance. SDS is a good initial choice and, if not successful, bile salts or CTAB/CTAC should be the second choice. If other surfactants are available, they may be tested. However, the number of different surfactants available for MEKC is rather limited and, hence, the selection of additives to modify selectivity should be considered when expected separation is not obtained by changing the surfactant. Some of the additives suggested above should be considered, as well as the use of mixed micelles. In MEKC, the efficiency is much higher than that of HPLC, the minimum  $\alpha$  that provides successful separation may be as low as 1.02.

### 3.3.1.3 Retention Factor

The retention factor is contained in the third (retention factor) and fourth (migration time window) parameter in Equation 3.3. Therefore, the optimum  $k$  value,  $k_{\text{opt}}$ , that gives the maximum value for the product of third and fourth parameters is a function of  $k$ ,  $t_0$ , and  $t_{\text{mc}}$ , and given by [25]

$$k_{\text{opt}} = \sqrt{t_{\text{mc}}/t_0}. \quad (3.4)$$

When SDS is used under neutral or alkaline conditions in native or uncoated capillary, the value  $t_{\text{mc}}/t_0$  is usually 3–4 and the retention factor should be adjusted to about 1.7–2.0. Since the retention factor is related to the surfactant concentration by [24]

$$k = \frac{KV_{\text{mc}}}{V_{\text{aq}}} \cong K\bar{v}(C_{\text{sf}} - c_{\text{mc}}), \quad (3.5)$$

where  $K$  is the distribution coefficient of the analyte between the micelle and the aqueous phase,  $V_{mc}$  and  $V_{aq}$  are volume of the micelle and the aqueous phase, respectively,  $\bar{v}$  partial specific volume of the micelle, and  $C_{sf}$  is the surfactant concentration. Equation 3.5 suggests that  $k$  is nearly proportional to the surfactant concentration; this means that the phase ratio  $V_{mc}/V_{aq}$  is adjusted by changing the surfactant concentration. Therefore, the optimization of  $k$  is straightforward provided that the specific volume and CMC are known; the  $\bar{v}$  value for an SDS micelle is about 0.85 mL/g. Even if these values are not known, it is easy to adjust  $k$  by increasing or decreasing the surfactant concentration considering the linear dependence of  $k$  on  $C_{sf}$ .

### 3.3.1.4 Migration Time Window

The EOF velocity is difficult to control precisely and depends on the surface charge on the inside wall of the capillary. If the wall is negatively charged, EOF is cathodic and vice versa. The factors affecting EOF are described above. In general, if the EOF velocity is decreased, the migration time window becomes wide and the resolution will be improved at the expense of migration time. The detailed discussion on the effect of EOF on resolution is published by Zhang et al. [26].

### 3.3.2 INTERACTION MECHANISM BETWEEN THE MICELLE AND THE ANALYTE

Three types of interaction mechanisms are known between the micelle and the analyte as shown in Figure 3.3: (1) incorporation of the analyte into the hydrophobic core, (2) adsorption of the analyte on the surface or on the palisade layer, and (3) incorporation of the analyte as a cosurfactant. Highly hydrophobic and nonpolar analytes such as aromatic hydrocarbons will be incorporated into the core of the micelle. The selectivity may not be very different among long alkyl-chain surfactants for this class of analyte but the distribution coefficient will be increased with longer alkyl-chain surfactants. Thus, selectivity will not be altered significantly for nonpolar hydrophobic analytes, even when different surfactants are used. However, bile salts may provide substantially different selectivity in comparison with long-alkyl chain surfactants, even for nonpolar hydrophobic analytes.

Most analytes are considered to be incorporated by the micelle on the surface or on the palisade layer [Figure 3.3a (1)] or partly incorporated into the core at the hydrophobic group and on the surface at the polar group [Figure 3.3a (2)]. Therefore, the polar group of the surfactant significantly affects selectivity. The palisade layer will be much different in mixed micelles consisting of an ionic and a nonionic surfactant and, hence, selectivity will be significantly different from the single surfactant micelle (Figure 3.3b).

**FIGURE 3.3** Schematic illustration of micellar solubilization. (a) Ionic micelle and (b) mixed micelle of ionic and nonionic surfactants interacting (1) with the hydrophobic core, (2) on the surface, (3) as a cosurfactant, and (4) with nonionic surface. (From Terabe, S., *Anal. Chem.*, 76, 240A, 2004. With permission.)

The interaction mechanism between the micelle and the analyte or chemical selectivity in MEKC has been investigated by several groups. Linear solvation energy selectivity relationship (LSER) can be utilized, where structural descriptors such as size, dipolarity, and hydrogen-bonding capabilities are employed to evaluate their contribution to interaction (retention factor) using many different types of solutes and different surfactants [27]. As expected, the molecular size or hydrophobicity causes the strongest positive interaction due to unfavorable energy term for the formation of properly sized cavity in the solvent system for solute accommodation. The second most important term in most MEKC systems is the solute hydrogen bond acceptor capability, but this interaction negatively affects the interaction. Since hydrophobicity affects the interaction almost equally among different MEKC systems, fine tuning in selectivity is performed by the hydrogen bond acceptor capability or basicity of the solute or acidity of the surfactant. Similar conclusions have been obtained by other groups [28–30].

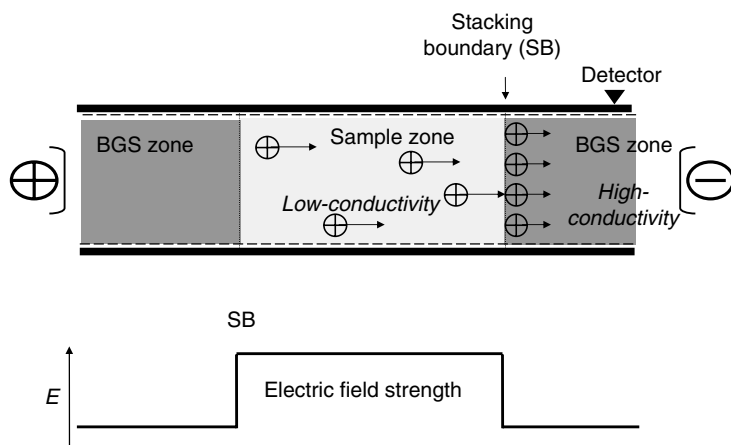

### 3.3.3 ONLINE SAMPLE PRECONCENTRATION

Poor concentration detection sensitivity in CE is a serious problem in almost all CE modes. The main reasons are due to the small amount of sample introduced into the capillary and a short optical path length for photometric detectors. To solve the problem, three major solutions are available: sample pretreatment such as solid-phase extraction (SPE), the use of high sensitivity detectors such as LIF, and the implementation of online sample preconcentration techniques. In addition, extended path length cells such as bubble cell or Z-type cell are commercially available for photometric detection, enabling a 3- to 10-fold enhancement in sensitivity. Most online sample preconcentration techniques are designed not to require any modification of the instrument and to be compatible with any detection methods because the concentration of the sample is increased prior to separation. Several techniques have been developed: transient isotachopheresis (t-ITP), field-enhanced (amplified) sample stacking, sweeping, and dynamic pH junction. The sample zone injected as a much longer plug than normal can be focused to the length less than that of the normal injection. These techniques are based on the migration velocity change of the analytes, between the sample solution zone and BGS, and the analyte must have an electrophoretic *mobility even if it is apparent mobility*. Among these methods, t-ITP and dynamic pH junction are applicable only to ionic or ionizable analytes. Therefore, field-enhanced sample stacking and sweeping are the main techniques described.

#### 3.3.3.1 Field-Enhanced Sample Stacking

The principle of the technique is simple and is based on the fact that the electrophoretic migration velocity is proportional to the field strength. Thus, the sample solution is prepared in a lower conductivity solution than that of the BGS; then the analyte ion migrates rapidly in the sample zone when an electric field is applied. The analyte ion quickly migrates until it reaches the boundary between the sample zone and the BGS zone, where the migration velocity decreases upon entering the BGS zone due to low electric field as shown in Figure 3.4. The larger the difference in electric fields between the sample zone and BGS, the higher the focusing efficiency. However, it is noteworthy that EOF velocity is also proportional to the field strength, but the liquid flow by EOF must be homogeneous throughout the capillary. That is, if the EOF velocity in the two zones is mismatched, mixing of the two zones at the boundary must occur, which can seriously deteriorate the concentration efficiency. Therefore, it is desirable to suppress EOF when online sample stacking is performed. There are several techniques based on the same principle introduced by Chien and Burgi [31].

In principle, field-enhanced stacking is a technique for the concentration of charged analytes using discontinuous solutions in the capillary. Neutral analytes are not concentrated by this method because they do not have electrophoretic mobility. However, by utilizing charged micelles, an apparent electrophoretic mobility can be imparted to a neutral analyte according to the principles of MEKC. As in conventional field-enhanced sample stacking, sample solutions are prepared in a

**FIGURE 3.4** Schematic illustration of the principle of field-enhanced sample stacking.

low electrical conductivity solution, with or without adding micelles, and a conventional micellar solution is used as the BGS. When the sample solution is prepared without the micelle, the analyte is incorporated by the micelle that enters the sample zone from the BGS zone when voltage is applied. The analyte having a high  $k$  that will induce extensive incorporation into the micelle can be efficiently concentrated by field-enhanced stacking because it is apparently highly charged. It should be noted that the micellar concentration is low in the sample zone even if the sample solution contains the micelle, because the migration velocity of the micelle in the sample zone is faster than that in the BGS. As described in Chapter 1, there are two sample injection techniques amenable to field-enhanced stacking: pressurized/hydrostatic injection and electrokinetic injection. With either technique, an EOF suppressed condition will yield a higher concentration efficiency. Larger amounts of sample can, therefore, be injected by electrokinetic injection, while with pressurized injection the sample, volume is limited to that substantially less than the capillary volume. In summary, either injection method will yield a maximum concentration efficiency of less than 100-fold under favorable conditions [32,33].

### 3.3.3.2 Sweeping

Sweeping is an online concentration technique developed for MEKC where the neutral analyte is efficiently concentrated [34,35]. The principle of sweeping is shown in Figure 3.5 under suppressed EOF conditions. Sweeping seems similar to field-enhanced sample stacking but the difference is that no field enhancement in the sample zone is required in sweeping with a field strength equal to or lower [36] than that of BGS. The sample solution is prepared devoid of the micelle but at a conductivity similar to that of BGS (acidic to suppress EOF) and injected hydrodynamically as a long plug (Figure 3.5a). When the voltage (negative for anionic micelle such as SDS) is applied, the micelle enters the sample zone and collects analytes at the front end of the entering micellar zone (Figure 3.5b) until the front end reaches the original boundary between the sample zone and the BGS (Figure 3.5c). The original sample matrix migrates at the velocity of the micelle and the micelle vacancy zone migrates ahead of the swept sample zone (Figure 3.5c). The length of the swept analyte zone is given by [34]

$$l_{\text{sweep}} = l_{\text{inj}} \left( \frac{1}{1+k} \right), \quad (3.6)$$

**FIGURE 3.5** Schematic illustration of the principle of sweeping under suppressed EOF conditions. The sample solution is prepared devoid of the micelle and BGS is the micellar solution. (a) Sample injection as a long plug. (b) Start of sweeping by application of a voltage. (c) End of sweeping and start of MEKC separation.

where  $l_{\text{sweep}}$  and  $l_{\text{inj}}$  are lengths of the sample zone after and before the end of sweeping, respectively. According to Equation 3.6, to obtain high concentration efficiency,  $k$  should be maximized. It should be noted that  $k$  in Equation 3.6 is the value in the sample matrix; that is, it is different from that in BGS. Therefore, the additive to BGS such as an organic solvent or CD used to improve resolution should not be added to the sample matrix. The zone length of the swept zone of a hydrophobic analyte was extremely narrow as observed when the sweeping process was traced with the peak shape of the sample zone at different positions in the microchannel [37]. Under favorable conditions, 64 cm of 70 cm of effective capillary length was filled with a dilute sample solution and 6 cm of 70 cm was used for the MEKC separation, yet good separation and high efficiency was obtained because the sample zone length after sweeping was very narrow and the time spent for the separation was short. EOF is not related to the sweeping mechanism, but higher concentration efficiency was obtained under suppressed EOF conditions [35]. Consequently, sweeping gives high concentration efficiency with improvements in detection sensitivity on the order of 1000-fold greater than the conventional injection/separation.

Although sweeping is an online sample preconcentration technique for neutral analytes, charged analytes, or ions can be more efficiently concentrated if the micelle employed has a polarity opposite to that of the analyte, because the retention factor will be large due to a strong electrostatic interaction. Therefore, the SDS micelle is convenient for concentrating cationic analytes, while cationic micelles (e.g., CTAB) are suitable for anionic analytes such as aromatic sulfonates or carboxylates [38]. Sweeping is effective in other EKC modes that use pseudostationary phases such as charged CDs, microemulsions, and so forth. In addition, the sweeping principle is applicable to online concentration of metal ions and sugars by utilizing an in-capillary complexation reaction, sweeping of metal ions by ethylenediaminetetraacetic acid (EDTA) [39], or sweeping of sugars (*cis*-diols) using borate ions [40].

As mentioned before, when pressure-based sample injection is employed, the maximum injection volume must be less than the effective length of the capillary. At least 10% of the effective capillary length must remain available for separation. To inject a larger sample volume, electrokinetic injection must be employed. In most online sample preconcentration techniques, the maximum amount that can be injected without loss of separation efficiency is certainly less than the capillary volume. However, with a large volume sample injection under cathodic EOF conditions in SDS MEKC, a sample devoid of the micelle can be continuously electrokinetically injected for a volume equivalent to seven times the capillary volume without significant loss of separation efficiency under favorable

conditions. Here, the analyte in the sample is continuously concentrated when it reaches the swept zone [41].

### 3.3.3.3 Combination of Different Preconcentration Methods

A combination of the different online sample preconcentration techniques enables much higher concentration efficiency or simultaneous concentration of different types of analytes. First, cationic (or anionic) analytes can be electrokinetically injected for an extensive period of time to cause overloading. Second, the long preconcentrated sample zone resulting from the injection can be further concentrated by sweeping using anionic (or cationic) micelle. This combination of field-enhanced sample injection (FESI) and sweeping is termed cation-selective (or anion-selective) exhaustive injection-sweeping (CSEI/ASEI-sweeping) and can generate extraordinarily high concentration efficiency with close to a million-fold increase in sensitivity, enabling the analysis of samples with analytes present in as low as parts per trillion (ppt) levels [42,43].

Dynamic pH junction is a technique suitable for online sample preconcentration of weakly acidic or basic compounds, with the principle based on the change in electrophoretic velocity between that of the ionized and neutral state of the analyte [44]. The sample solution is prepared in an acidic medium for the acidic analyte with the BGS a basic buffer having a pH higher than the  $pK_a$  of the analyte. When electrophoretic process begins, the acidic sample zone is titrated by the alkaline BGS and the pH of the sample zone increases, causing deprotonation of the analyte. The ionized analyte migrates toward the anode against the EOF and focuses at the boundary of pH change. The technique is very effective for the selective concentration of acidic or basic analytes having a range of  $pK_a$  values. When the sample contains both neutral and weak acidic compounds, the combination of sweeping and dynamic pH junction is a useful online sample preconcentration method. For example, with urine or plasma containing a combination of riboflavin, flavin mononucleotide (FMN), and flavin adenine dinucleotide (FAD), an enhancement in detection sensitivity of more than 1000-fold was observed for these analytes by dynamic pH junction-sweeping with the sample diluted in a 75 mM phosphate buffer pH 6.0 (and BGS of 140 mM borate) because almost neutral riboflavin was concentrated by sweeping and other FMN and FAD were concentrated by dynamic pH junction simultaneously [45].

## 3.4 PRACTICAL APPLICATIONS

More than 2000 articles involving “MEKC” have been published since 1990 according to Zare [3]. Therefore, it is impossible to survey all papers to determine which provide the best practical applications of MEKC—consequently, only few practical applications have been arbitrarily selected by the author for inclusion here. For more detailed examples, it is recommended that the reader consult more comprehensive reviews [7,46–48] or relevant chapters of a recently published book [6].

### 3.4.1 PHARMACEUTICAL ANALYSIS

MEKC is probably most widely accepted in pharmaceutical analysis and several review articles have detailed these applications [49–53]; therefore, only a few recent publications are introduced here. In addition, the reader may refer to Chapter 4 in this book contributed by Altria and colleagues.

As mentioned above, MS is becoming an indispensable detection technique, in particular, for the detection and identification of impurities in drugs. An ESI has been successfully interfaced between MEKC and a single quadrupole or ion-trap MS instrument using a running solution containing 20 mM SDS and 10 mM sodium phosphate buffer (pH 7.5) without any devices to avoid SDS and inorganic electrolytes from entering into the MS ion source [18]. In this report, it was demonstrated that sub- $\mu\text{g/mL}$  levels of mebeverine and related compounds could be detected in full-scan mode, while

**FIGURE 3.6** Extracted-ion chromatograms obtained during MEKC–ESI-MS of a heat-treated solution of ipratropium (1 mg/mL) using a BGE containing 10 mM sodium phosphate (pH 7.5), 20 mM SDS, and 12.5% acetonitrile. Capillary length, 57 cm. Peaks:  $m/z$  332, ipratropium;  $m/z$  184 and  $m/z$  314, degradation products. (From Mol, R., et al., *J. Chromatogr. B*, 843, 283, 2006. With permission.)

detection limits are in the 10–50 ng/mL range when selected ion monitoring was applied. It was also shown that 0.1% (w/w) levels of potential impurities in mebeverine could be detected in full-scan MS. The technique was also successfully applied to the analysis of a galantamine sample containing a number of related impurities [19]. Two degradation products were detected and identified by MS/MS scan in a heat-stressed ipratropium sample as shown in Figure 3.6.

In the pharmaceutical industry, rapid developments and validations of suitable methods for assessment of purity, potency, and stability of new drug substances and drug products are critical to providing appropriate data for early project development decisions. For example, a simple, fast, and selective MEKC method for the simultaneous assay of ketorolac tromethamine and its identified related impurities in both the drug substance and coated tablets was developed by Orlandini et al. [54]. To optimize separation conditions, a response surface study was performed. Flufenamic acid (FL) and tolmetin (TL) were chosen as internal standards to quantify ketorolac tromethamine and the impurities, respectively. The optimized BGS consisted of a mixture of 13 mM boric acid and phosphoric acid (equal mixture), adjusted to pH 9.1 with 1 M sodium hydroxide, containing 73 mM SDS. Optimal temperature and voltage were 30°C and 27 kV. Under these conditions, all compounds were resolved in about 6 min as shown in Figure 3.7. The related substances could be quantified up to the 0.1% (w/w) level. Method validation was performed by evaluating selectivity, robustness, linearity and range, precision, accuracy, detection sensitivity, and quantification limits, as well as system suitability for drug substances/drug product and a satisfactory method performance was obtained.

### 3.4.2 CLINICAL AND BODY FLUID ANALYSIS

Development of the analytical separation methods for biomarker discovery and metabolite research is an important domain for the early detection of certain diseases, as well as in pharmaceutical investigations. Recent applications of MEKC and CZE in the field of urinary biomarkers have been summarized by Iadarola et al. [55]. Most target analytes are present in body fluids at low concentrations and, consequently, high sensitivity analysis is essential. The use of high sensitivity detectors or implementation of online sample concentration techniques is essential. Sample pretreatment is also critical in the analysis of body fluids for cleaning up and concentrating the target analytes, and for this several techniques are available.

Direct injection of plasma samples in MEKC was first reported by Nakagawa et al. [56]. Determination of cefotaxime (C) and its deacetylated metabolite (DA) in human plasma were investigated by direct injection of plasma in both CZE and MEKC [57]. MEKC was shown to be superior with regard to simplicity, rapidity, precision, and sensitivity relative to CZE. In MEKC, plasma samples spiked with C, DA, and theobromine (as internal standard) were directly injected after dilution with water, and analyzed using a phosphate buffer (pH 8.0) containing 165 mM SDS as a running solution. The interday precision ( $n = 4$  days) was 1.49% in RSD when theobromine was used as internal standard. A satisfactory interday precision between slopes was also obtained with MEKC, even without the use of an internal standard (RSD = 4.38%). Detection limits ( $S/N = 3$ ) were about 1 mg/L in plasma for C and DA. The advantage of MEKC is due to the fact that SDS solubilizes the proteins, and this liberates the drugs from protein-binding sites. The SDS-protein complexes migrate with the micelles and, thus, do not interfere with the detection of the analytes.

An MEKC-sweeping technique for the simultaneous determination of flunitrazepam and its major metabolites, 7-aminoflunitrazepam and *N*-desmethyflunitrazepam, was reported by Huang et al. [58]. The optimized conditions involved a running solution of 25 mM borate (pH 9.5) containing 50 mM CTAB and 30% methanol (v/v) with a 60 cm (50 cm to the detector)  $\times$  50  $\mu\text{m}$  ID capillary and sample injected as a 151-mm plug. The limits of detection were 13.4, 5.6, and 12.0 ng/mL for flunitrazepam, 7-aminoflunitrazepam, and *N*-desmethyflunitrazepam, respectively, and the sensitivity enhancement for each compound was within the range of 110- to 200-fold. The method was applied

**FIGURE 3.8** Sweeping MEKC electropherogram of a spiked urine sample. Peak identification: 1, 7-aminoflunitrazepam; 2, flunitrazepam; 3, *N*-desmethyflunitrazepam. Analyte concentration: 0.3  $\mu\text{g}$  spiked in a 3-mL urine sample before SPE extraction. Conditions: capillary, 60 cm long (50 cm to detector), 50  $\mu\text{m}$  ID; running solution: 25 mM borate buffer (pH 9.5) containing 50 mM CTAB and 30% methanol (v/v), conductivity 7.28 mS/cm; sample matrix: 25 mM borate buffer (pH 9.5); applied voltage: -25 kV; UV detection at 240 nm. (From Huang, C.-W., et al., *J. Chromatogr. A*, 1110, 240, 2006. With permission.)

to a spiked urine sample in combination with SPE — an example of electropherogram is shown in Figure 3.8.

Ewing's group has developed ultramicro separation technique using CE with an electrochemical detector and a narrow bore capillary of 13  $\mu\text{m}$  ID. They applied the technique to the separation of amine metabolite in the fruit fly, *Drosophila melanogaster*, and 14 biogenic amines and metabolites were successfully resolved by MEKC using 25 mM borate buffer (pH 9.5) containing 50 mM SDS and 2% 1-propanol [59]. Flies were snap-frozen in a liquid nitrogen bath, the separated fly heads treated to yield a 3  $\mu\text{L}$  sample solution that could be analyzed for biogenic amines as shown in Figure 3.9. Quantitative results were, for example, 37.2, 311.0, 142.0, 79.5, 732.8 fmol ( $1 \times 10^{-15}$  mol) per fly head of a wild-type *Drosophila*, for tyramine, octopamine, *N*-acetyloctopamine, dopamine, and *N*-acetyldopamine, respectively. MEKC with electrochemical detection gave limits of detection as low as 3.4 amol for octopamine, and made the technique useful for volume-limited sample analysis.

Kennedy's group used microdialysis sampling to monitor extracellular dopamine concentration in the brains of rats. The dialysate, mixed online with 6 mM naphthalene-2,3-dicarboxaldehyde and 10 mM potassium cyanide in a reaction capillary, was periodically analyzed by MEKC at 90-s intervals [60]. The MEKC system consisted of a 10  $\mu\text{m}$  ID, 369  $\mu\text{m}$  OD, and 16 cm (14.5 cm to the detector) capillary, 30 mM phosphate buffer (pH 7.4) containing 6.5 mM SDS and 2 mM 2-hydroxypropyl- $\beta$ -CD, with LIF detection using the 413-nm line of a 14-mW diode-pumped laser, and an electric field of 850 V/cm. The detection limit for dopamine was 2 nM when sampling by microdialysis. The separation capability of the developed method is illustrated in Figure 3.10 where

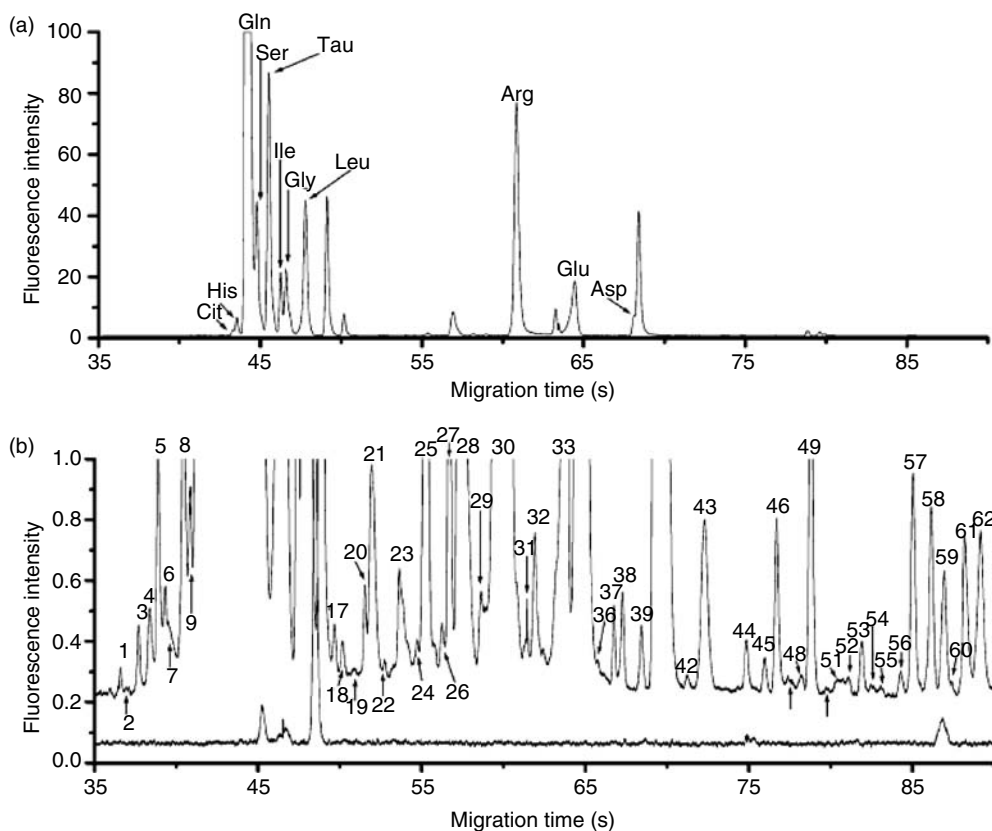

**FIGURE 3.9** MEKC-EC separation of a *Drosophila* head homogenate. (a) Enlargement of 5.5–9 min highlighting dopamine (1), *N*-acetyloctopamine (3), octopamine (5), *N*-acetylserotonin (6), and *N*-acetyldopamine (7). (b) Enlargement of 9–11 min emphasizing peaks for 4-dihydroxyphenylalanine (9) and catechol (11). (c) Enlargement of 11–15 min showing tyramine (12). (d) Comparison of Canton-S (wt) and *iav*<sup>1</sup> *Drosophila* head homogenates highlighting the internal standard catechol (11) and tyramine (12). Conditions: running solution, 25 mM borate buffer (pH 9.5) containing 50 mM SDS and 2% 1-propanol; capillary, a fused silica capillary of 148  $\mu\text{m}$  OD and 13  $\mu\text{m}$  ID, 50 cm long; Field strength, 333 V/cm. The working electrode was held at +750 mV vs. a Ag/AgCl reference electrode. (From Paxson, T.L., et al., *Anal. Chem.*, 77, 5349, 2005. With permission.)

the basal dopamine concentration in dialysates collected from the striatum of anesthetized rats was  $18 \pm 3$  nM ( $n = 12$ ).

### 3.4.3 FOOD ANALYSIS

Applications of CE techniques to food analysis is rapidly increasing and recent progresses have been reviewed [61,62]—a detailed discussion of this topic can be found in Chapter 30 by Vargas and Cordoba. The analysis of food components or nutrients does not require high sensitivity but does

**FIGURE 3.10** Sample electropherogram collected from the striatum of an anesthetized rat illustrating peak capacity of the method. (a) Full scale plot with amino acids identified by migration time matching marked. (b) Expanded scale for electropherogram collected from control samples (derivatization reagents sampling artificial cerebral spinal fluid *in vitro*, lower trace) and *in vivo* samples (upper trace) at 10-fold higher gain illustrating smaller peaks detected. Fluorescence units are equivalent in the plots. Peaks that were consistently observed *in vivo* and not observed in control samples were counted. Numbers for off-scale peaks are not shown. Peak 55 is dopamine. (From Shou, M., et al., *Anal. Chem.*, 78, 6717, 2006. With permission.)

require good resolution, in particular for the analysis of plant nutrients; however, for the analysis of contaminants or agrochemical residues, high sensitivity is essential in combination with sample pretreatments.

The catechin content of tea is often analyzed by CE techniques. Matcha is a special powdered green tea used in the Japanese tea ceremony and catechins contained in it have been quantified by MEKC [63]. MEKC conditions are conventional; a 50  $\mu\text{m}$  ID bubble capillary of 77 cm effective length, 25 mM phosphate buffer (pH 7.0) containing 20 mM SDS, applied voltage of 27 kV, and detection at 200 nm. Water and methanol extracts of matcha were compared with water extracts of a popular green tea. An electropherogram of matcha extract is shown in Figure 3.11. The concentration of epigallocatechin gallate (EGCG) available from drinking matcha is 137-times greater than the amount of EGCG available from China Green Tips green tea, and at least three times higher than the largest value reported in the literature for other green teas.

The residue analysis of pesticides or herbicides in food is an important social concern. The contents of these agrochemicals are very low and the sample preparations are time consuming and labor intensive. Therefore, development of simple, inexpensive, and efficient total analysis system is urgently needed. The analysis of pesticides in fruits and vegetables was described by Juan-García

**FIGURE 3.11** Electropherogram of a matcha tea sample prepared in deionized water using the traditional Japanese method. Conditions: capillary, 80.5 cm (77.0 cm effective length), 50  $\mu\text{m}$  ID with bubble (three times extended path length); running solution, 25 mM phosphate buffer (pH 7.0) containing 20 mM SDS; applied voltage, 27 kV; detection, at 200 nm. Peak identification: (1) caffeine, (2) catechin, (3) epigallocatechin, (4) epigallocatechin gallate (EGCG), (5) epicatechin, (6) epicatechin gallate, and (7) internal standard (4-amino-2-hydroxybenzoic acid). (From Weiss, D.J. and Anderton, C.R., *J. Chromatogr. A*, 1011, 173, 2003. With permission.)

et al. [64] using SPE and stir-bar sorptive extraction (SBSE), in combination with MEKC. The recoveries obtained by SPE ranged from 40% to 106% with RSD from 10% to 19%, whereas the SBSE method was associated with recoveries in the 12–47% range with RSDs of 3–17%. It is noteworthy that the limits of quantification were much better by SPE (0.2–0.5 mg/kg depending on the processed sample amount) than those obtained by SBSE (1 mg/kg for each compound). MEKC conditions using 75 mM sodium cholate in 6 mM tetraborate buffer (pH 9.2) was employed and exemplary electropherograms are shown in Figure 3.12, where pesticide residues in lettuce were analyzed.

### 3.4.4 ENVIRONMENTAL ANALYSIS

Most target analytes in environmental analysis are low in concentration, although the amount of sample is not very limited. As a result, CE is not an ideal technique for environmental analysis. A combination of a sample pretreatment such as SPE or liquid–liquid extraction, and online sample preconcentration is clearly necessary here. There are several review articles published on the topic [65–67] and a detailed discussion of this topic can be found in Chapter 31 by Tonin and Tavares.

Determination of pesticides in water has been performed by automatic online SPE in combination with MEKC [68]. A  $\text{C}_{18}$  solid-phase minicolumn was used for the preconcentration, allowing a 12-fold enrichment (as an average value) of the pesticides from fortified water samples. MEKC was performed with 10 mM phosphate buffer (pH 9.5) containing 60 mM SDS and 8% acetonitrile. Pesticides mixtures spiked in water were detected down to a concentration of 50  $\mu\text{g/L}$  in less than 13 min as shown in Figure 3.13.

**FIGURE 3.12** Electropherograms of SPE extracts from 15 g sample of (a) lettuce that contains pyriproxyfen at 0.2 mg/kg sample and (b) lettuce sample spiked with the pesticides at 0.5 mg/kg levels. Peak identification: (1) flutriafol, (2) cyproconazole I, (3) cyproconazole II, (4) myclobutanil, (5) tebuconazole, (6) acrinathrin, (7) bitertanol, (8) fludioxonil, and (9) pyriproxyfen. MEKC conditions: capillary, 75  $\mu\text{m}$  ID  $\times$  57 cm (50 cm to the detector); running solution, 6 mM sodium tetraborate (pH 9.2) containing 75 mM sodium cholate; detection, 214 nm. (From Juan-García, A., et al., *J. Chromatogr. A*, 1073, 229, 2005. With permission.)

**FIGURE 3.13** Electropherograms of an unspiked and spiked river water sample (0.25  $\mu\text{g/mL}$ ). MEKC conditions: capillary, 75  $\mu\text{m}$  ID  $\times$  47 cm; running solution, 10 mM phosphate buffer (pH 9.5) containing 60 mM SDS and 8% acetonitrile; detection, 226 nm. (From Hinsmann, P., et al., *J. Chromatogr. A*, 866, 137, 2000. With permission.)

### 3.5 METHODS DEVELOPMENT GUIDELINES

Introductory conditions for initial MEKC separations of neutral or weakly ionizable analytes are provided in Table 3.1 [4]. The choice of the running solution is rather arbitrary, but a weakly alkaline borate buffer is recommended because the electrophoretic mobility of the borate ion is rather low and, thus, the current can be kept low. The sample solution can be prepared in any solvents provided

**TABLE 3.1**  
**Suggested Standard Operating Conditions**

Capillary	50–75 $\mu\text{m}$ ID $\times$ 20–50 cm (to the detector) uncoated fused silica capillary
Running solution	50 mM SDS in 50 mM borate buffer (pH 8.5–9.0) or 50 mM phosphate buffer (pH 7.0) (use sodium salts)
Applied voltage	10–25 kV (keep current below 50 $\mu\text{A}$ )
Temperature	25°C or ambient
Sample solvent	Water or methanol (other water miscible organic solvents are usable)
Sample concentration	0.1–1 mg/mL (lower concentrations are acceptable if detectable)
Injection method	Hydrodynamic or siphoning at anodic end
Injection volume	Less than 1% of the capillary length
Detection	Absorbance at 200–210 nm (higher wavelengths are possible if detectable)

Source: Modified from Table 3 of Terabe, S., *Micellar Electrokinetic Chromatography*, Beckman, Fullerton, 1992.

they are miscible with water. However, water-rich solution is advisable if the analyte is water soluble. When the sample contains high concentrations of an organic solvent, each peak may split due to incomplete mixing of the sample solution with the running solution. When online sample preconcentration is to be utilized, the sample solution must be optimized for each concentration technique. For a preliminary run, a relatively high concentration of the analyte will be favorable for easy detection. The separation time depends on the EOF velocity and effective capillary length (length to the detector) but under the conditions listed in Table 3.1 the migration time of the micelle may be less than 20 min.

When a preliminary run shows insufficient separation, several parameters may need to be adjusted in order to obtain optimized separation [9]. First, estimate the retention factors of analytes by Equation 3.1 using measured  $t_0$  and  $t_{\text{mc}}$ . Should measuring the  $t_{\text{mc}}$  prove to be nontrivial due to the difficulty observing the micelle marker peak, simply assume  $t_{\text{mc}}$  is four times longer than  $t_0$ . If  $k$  values are between 0.5 and 10,  $k$  values should be optimized—alternatively, adjust to about 2 by changing the micelle (or surfactant) concentration. If  $k$  values are too high ( $k > 10$ ), several options are available; decrease the micelle concentration by adding an organic solvent (methanol or acetonitrile), add a CD, or use another surfactant (e.g., a bile salt). If  $k$  values are too small ( $k < 0.5$ ), limited options are available; increase surfactant concentration if the analyte is neutral, add an ion-pairing reagent (a tetraalkylammonium salt for anionic analytes and an alkanesulfonate for cationic analytes) or use cationic surfactant such as CTAB instead of SDS if the analytes are anionic.

If optimum  $k$  values do not provide acceptable resolution, further tuning may be required; the use of additives such as organic solvents or CDs may be needed, or the use of alternate surfactants may prove effective. The selection of additives is extensive, but it is recommended that addition of a low concentration of an organic solvent be trialed initially. If the unresolved analytes have closely related structures, addition of a CD derivative may prove effective. There are many different CD derivatives available, but simply  $\beta$ -CD or  $\gamma$ -CD can be tested initially. Further tuning can be performed by selecting other CD derivatives (e.g., sulfated) if necessary. Another choice is the modification of the micelle by using mixed micelles, in particular, addition of a nonionic surfactant such as Brij-35 or Tween 60, adding cosurfactants such as 1-propanol or 1-butanol, or by adding an organic counter ion such as tetraalkylammonium salts for SDS.

The above-mentioned guideline describes practical procedures based on the migration behavior [9]. Computer-assisted modeling, predictions, and multifactor optimization strategy are proposed based on physicochemical models describing the migration behavior for ionizable analytes [69–71]. Other than the factors mentioned above, several experimental parameters that include temperature, applied voltage, buffer concentration, pH, and so forth affect resolution and many parameters can

be altered in a manner that provides a fine tuning via statistical approaches, using fitting procedures of polynomial equations (chemometrics). There are several techniques reported to optimize MEKC separation conditions. It is beyond the scope of this chapter to describe chemometric techniques in detail, and only some references are mentioned [72–76]. Although the approaches based on statistical designs are helpful to find the optimum values for many parameters, they should not be used as a black box system [77]. Analysts need to play a crucial role in optimizing separation conditions by carefully considering separation models.

### 3.6 CONCLUDING REMARKS

Most fundamental characteristics on MEKC were investigated by mid-1990s and, hence, this chapter is not much different from that in second edition of the book [78] in fundamental theory and major procedures. New parts of the chapter are mainly MS detection, online sample preconcentration, and new applications. Unlike a decade ago, MEKC is now a mature technique in CE arsenal, and while a few new, innovative MEKC-related techniques may not arise, applications of MEKC is likely to be widely expanded—this is certainly true in the bioanalytical fields and in the ever-expanding microscale separations including those in microfabricated devices. Although MEKC is considered to be suitable for the separation of small molecules, it is also useful for the separation of large molecules such as peptides and proteins, and applications to large molecules will certainly be explored more extensively in the future. The latest progress in MEKC has been recently reviewed [79].

One of the issues that still remains unsolved in MEKC is the improvement in reproducibility in quantitative analysis, including migration time and peak height or peak area—a problem that is not characteristic of MEKC only, but general to every CE technique. To verify the validity of the MEKC method, intercompany cross-validation exercises have been performed and the results have shown acceptable method performance in terms of relative migration time precision [80]. While reproducible EOF is an issue, it is so in every CE separation modes (except for gel electrophoresis); however, MEKC has more parameters to consider to maintain acceptable reproducibility. First, some characteristic issues in MEKC are discussed to improve quantitative results. CMC and distribution coefficient are both temperature sensitive: an increase in temperature causes an increase in CMC and, hence, a decrease in the micellar concentration, which reduces the retention factor. On the other hand, an increase in temperature causes a decrease in distribution coefficient and, hence, the retention factor. Therefore, the temperature increase will significantly decrease the retention factor from the viewpoint of CMC and distribution coefficient. It is well known that an increase in temperature reduces viscosity of the running solution in any CE mode, which increases both electrophoretic and EOF velocities, reducing the migration time. Thus, temperature and migration time have an inverse relationship where a decrease in migration time accompanies an increase in temperature, and the effect will be larger in MEKC than in CZE. Consequently, temperature must be controlled with diligence in MEKC, relative to other CE modes, in order to obtain high reproducibility. To maintain a low current is also a good strategy, particularly since MEKC usually produces a higher current than CZE due to the addition of the surfactant. A compromise is, therefore, necessary between high Joule heating and fast separation time. It should be noted that an added bonus with the use of micelles is that they may prevent analyte adsorption on the capillary wall, which may contribute to good reproducibility.

Minimizing the temperature effects discussed above could be obtained with the use of polymer micelles or polymer surfactants [81–83], whose CMC is zero, and even in nonaqueous solvent, the micelle is stable. Although several polymer surfactants are commercially available, no such surfactant is widely accepted, probably because SDS, CTAB, or CTAC, and bile salts are superior to polymer surfactants as the pseudostationary phase in MEKC. Although microemulsion electrokinetic chromatography (MEEKC) is not discussed in this chapter but covered in Chapter 4 by Altria and colleagues, a similar optimization strategy to that in MEKC applies to MEEKC [84–86]. Since

microemulsion (oil-in-water or o/w) consists of four components, surfactant, oil (organic solvent), cosurfactant, and buffer, available parameters for optimizing selectivity are more extensive than that in MEKC. For most analytes, the choice of the surfactant is most important because the surface of the microemulsion affects significantly selectivity as in the case of micelles. For nonpolar hydrophobic analytes, the choice of the organic solvent is effective but conditions that confer stability to the microemulsion limit the range of organic solvent composition. An advantage of MEEKC over MEKC is the ability to vary the migration time window by changing the concentration of SDS in microemulsion [84]. It should be noted that the composition of microemulsion tends to change with evaporation of the organic solvent, particularly noteworthy if a volatile organic solvent such as hexane is used as the core oil.

Finally, the author would like to emphasize that, although MEKC gives similar separation selectivity to that observed with reversed-phase HPLC, the choice of selectivity manipulations are more versatile and separation efficiency is much higher than that of HPLC. Detection sensitivity, in terms of concentration, has been considered inferior to that of HPLC, but sensitivity is not an issue if high sensitivity detectors are implemented or if online sample preconcentration is employed. One more important feature of MEKC, as a mode of CE, is the ability to use small amounts of sample and almost no need of organic solvents. Therefore, the basis for the apparent lower popularity of MEKC in industrial routine analysis is, at least partially, because CE techniques are not widely accepted among those who are engaged in industrial analysis based largely on the popular HPLC platform. However, it is strongly encouraged that the instrument companies explore the development new CE instruments that are more user-friendly and easy to operate.

## 4.1 INTRODUCTION

The use of capillary electrophoresis (CE) as an analytical technique has become more widespread and popular in recent years and has established itself as a method of choice for many applications. The ability to analyze small ions and organic molecules has made it the mainstay in many industries such as the food and beverage, biotechnology, and pharmaceutical industries, many of which have incorporated CE into their research as well as their quality assurance (QA) and quality control (QC) departments.

Pharmaceutical analysis is dominated by high-performance liquid chromatography (HPLC) with thin layer chromatography (TLC) and gas chromatography (GC) also used to a lesser extent, as their quantitative abilities are not widespread as HPLC. CE, however, is becoming a more widely used technique and is recognized by several regulatory authorities as a reliable routine analytical technique. Although CE was initially heralded for its high speed and low sample volume, resolving power, and versatility, the technique is also valuable because it is quantitative, can be automated, and can separate compounds that have been traditionally difficult to handle by HPLC. Qualitative analysis is also possible by capillary electrophoresis-mass spectrometry (CE-MS).

The small sample volumes required by CE can be an advantage over HPLC if sample supply is limited, for example, in drug discovery, however, with short path lengths using traditional ultraviolet (UV) detection methods, the technique can suffer from low sensitivity. A number of solutions to this problem have been introduced including "Bubble Cell" by Agilent, which increases the path length at the point of detection. A "High Sensitivity Detection Cell" also by Agilent improves detection sensitivity 10-fold over normal capillaries. Other detection methods such as "Laser-Induced Fluorescence Detection" (LIFD) and CE-MS also give better sensitivity and have led to CE being on a par with HPLC for many pharmaceutical applications and indeed CE is superior to HPLC for many separations.

The advantages of CE for pharmaceutical analysis include its speed and cost of analysis, reductions in solvent consumption, and disposal and the possibility of rapid method development. CE also offers the possibility of using a single set of operating conditions for a wide range of separations that can improve laboratory efficiency. CE instruments can be coupled to a variety of detector types including mass spectrometers, indirect UV detectors, LIFD's, and low UV wavelength detectors.

Separation efficiencies achieved by CE can be an order of magnitude better than competing HPLC methods, which highlights the potential resolving power of CE for complex and difficult separations, which is a valuable advantage in pharmaceutical analysis. The use of an open tubular capillary improves resolution relative to that of packed HPLC columns by eliminating the multiple path term ( $A$ ) in the following Van Deemter equation. CE reduces plate height further by also eliminating the mass transfer term ( $Cu_x$ ) that comes from the finite time needed for solutes to equilibrate between the mobile and stationary phases in liquid chromatography (LC). This stationary phase is absent in CE [1] [with the exception of micellar electrokinetic chromatography (MEKC) and

microemulsion electrokinetic chromatography (MEEKC) where a “pseudo-stationary phase” forms part of the separation mechanism, these CE modes will be discussed later in the chapter].

$$\text{van Deemter equation for plate height } H = A + \frac{B}{u_x} + \frac{C}{u_x},$$

where  $A$  is the multiple path term which is zero for CE capillaries,  $B/u_x$  is the longitudinal diffusion term and is the only contributor to band broadening in CE, and  $C/u_x$  is the equilibration time (mass transfer) term also zero for CE.

High-speed separations are possible with CE, sometimes as quick as a matter of seconds. Because of this it is an ideal technique for “high-throughput” analyses such as forensic testing, DNA sequencing, and, in particular, screening of candidate drug compounds. Multiplexed CE instruments can be used to perform multiple parallel separations, dramatically increasing sample throughput. For example, the “CombiSep cePRO 9600™” utilizes multiple capillaries and can perform 96 separations in parallel.

An important aspect of CE for pharmaceutical analysis is its ability to separate all molecules of pharmaceutical interest such as small and large synthetic and natural drugs, proteins and peptides, oligonucleotides, carbohydrates and polysaccharides, inorganic ions, and so forth.

This chapter will look at the use of CE for pharmaceutical analysis and will include descriptions of the various modes of CE and their suitability for quantitative and qualitative analysis of pharmaceutical compounds. Practical applications of CE for the analysis of pharmaceuticals will be covered, these applications include drug assay, impurity determination, physicochemical measurements, chiral separations, and the analysis of small molecules. A section covering the approach to CE method development for pharmaceutical analysis will include guidelines to selecting the best mode of CE for an intended separation. Extensive data will be provided on successful pharmaceutical separations with references to extra source material for the interested reader. This chapter will provide a comprehensive and up to date view of the role and importance of CE for the analysis of pharmaceuticals and will provide the reader with practical information and real data that will help them to decide if CE is suitable for an intended separation.

## 4.2 BACKGROUND

In the 1930s, Tiselius developed the first electrophoretic apparatus to perform separations based on differential migration rates in an electrical field. Up until the early 1980s, most of the research carried out using this technique was by biochemists and molecular biologists on the separation, isolation, and analysis of proteins and other biological macromolecules. Since its introduction in the 1980s [2–5] and with the appearance of commercial instruments for performing analytical electrophoresis on a microscale in capillary columns, CE has become established as a fast, reliable, and highly efficient alternative and complementary method to LC. While CE can perform separations that may be difficult by traditional LC methods and provides different migration patterns, combined use of these two techniques can be a powerful analytical tool for the pharmaceutical analyst. Over the past number of years since the early 1990s, there have been many review papers [6–12] and books [13,14] published concerning CE for pharmaceutical analysis. Since the first applications of CE to pharmaceutical analysis by Altria and Simpson [15] in 1987, the number of reports of CE for a range of pharmaceutical applications now is in hundreds and the number of pharmaceutical compounds analyzed by CE is far greater [13]. There have also been a number of specialized reviews of CE for pharmaceutical analysis including chiral CE [16–20], CE with electrochemical detection [21] and conductivity detection [22], LIFD [23], CE coupled with electrospray-ionization MS (CE-ESI-MS) [24], and CE determination of acid dissociation constants [25].

When deciding on the optimum CE conditions for an intended separation, the pharmaceutical analyst must take a different approach to that of the analyst using HPLC techniques. The vast range

of HPLC methods routinely used for pharmaceutical analysis would lead the liquid chromatographer to use literature databases and pharmacopoeia methods along with his/her own experience to decide on initial HPLC conditions. Properties such as sample solubility, log  $P$  values, sample polarity, stationary phase characteristics, and mobile phase compositions, among others, all are important to the LC analyst when deciding on the initial chromatographic conditions and can be easily obtained for most applications. The CE analyst, however, must consider the problem separation in a different manner. The depth of knowledge and literature associated with CE method development is in its infancy when compared to LC. As CE is an electro-driven separation technique, the approach to method development must look at factors such as compound  $pK_a$  data, functional groups, electrolyte pH, and applied voltage. Compound solubility will also determine which mode of CE is applicable to the required separation. CE method development guidelines will be given more consideration in a later section of this chapter.

### 4.3 THEORETICAL ASPECTS (ELECTROPHORETIC MODES)

There are several electrophoretic modes that can and have been used to analyze pharmaceuticals. Each mode offers different possibilities to the CE analyst and the choice of CE mode is the first step when developing a separation method. The mode of CE that best suits the sample to be analyzed must be decided. Some questions that the analyst must ask include are all of the components to be separated soluble in an aqueous electrolyte; are the components charged, neutral, or both; are physicochemical measurements available for the analytes, that is,  $pK_a$  and/or log  $P$  values; what are the properties of the sample matrix; and so forth. This section will provide the reader with a brief introduction to the various modes of CE, which have been utilized for pharmaceutical analysis and give tips on deciding the mode and detection method for an intended separation/analysis. The detailed theoretical aspects of each CE mode are too broad to be covered in this chapter so the reader will be directed to other sources for more in depth theory.

#### 4.3.1 FREE SOLUTION CAPILLARY ELECTROPHORESIS

Free solution CE (FSCE) or capillary zone electrophoresis (CZE), as it is sometimes called, is the simplest and one of the most widely used forms of CE and involves the use of buffered aqueous solutions as the carrier electrolytes. FSCE is principally used to separate charged, water-soluble analytes and separations rely principally on the pH-controlled dissociation of acidic groups or the protonation of basic functions on the solute. These ionic species are separated based on differences in their charge-to-mass ratios. For example, basic drugs are separated at low pH as cations while acidic drugs are separated as anions at high pH. In FSCE all neutral compounds are swept, unresolved, through the detector together. Under the influence of an applied electric field, sample ions will move toward their appropriate electrode. Cations migrate toward the cathode and anions toward the anode. The speed of their movement toward the electrode is governed by their size and number of appropriate charges. Smaller molecules with a large number of charges will move more quickly than larger or less charged compounds. The speed of movement, known as the electrophoretic mobility, is characteristic of each solute. The mobility of a species can also be changed by complexing the ion as it migrates along the capillary. For example, additives such as cyclodextrins (CDs) can be used to complex with drug enantiomers to achieve chiral separations. The presence of an electroosmotic flow (EOF) allows the separation and detection of both cations and anions within a single analysis, as above pH 7 the EOF is sufficiently strong to sweep anions to the cathode regardless of their charge.

There are a number of variables in FSCE that can be used in the optimization of FSCE methods. These include the operating pH, electrolyte type and concentration, capillary dimensions, temperature, and injection volume. Electrolyte additives such as ion-pair reagents and chiral substances can also be employed in order to manipulate selectivity.

As the majority of pharmaceutical compounds are basic, the highly polar nature of these compounds can make separating them complex by LC methods. Ion-pairing reagents and column regeneration is often necessary to reduce nonspecific ionic interactions in the LC column. With CE, these highly functional groups can be exploited to enable separation. These basic drugs and their impurities can be separated using FSCE in two ways. First, at low pH, the capillary surface is essentially neutral resulting in a suppression of the EOF in the capillary and the protonated analytes migrate toward the detector with little or no influence from the EOF. The second and less desirable method is to use an amine inner capillary surface to repel cationic interactions within the capillary wall, which allows separation over a wide pH range. Using a low pH phosphate buffer, Hudson and coworkers [26] reported the use of FSCE to analyze over 500 basic pharmaceutical compounds.

To separate mixtures of acidic and basic drugs (or any cationic and anionic species), FSCE at high pH can be used [27]. At pH 7 or greater, the EOF generated by the applied current is sufficiently strong to sweep anions to the detector. Analyte migration time is dependent on solute charge type and density, strongly cationic species migrate first while small highly charged anions attempt to migrate against the EOF and are detected last. Neutrals will not be resolved and migrate with the EOF. Readers who require a more detailed description of the theoretical aspects of FSCE will find a number of books dealing with the subject [28–31]. A review paper by Smith and Evans [32] outlines the use of FSCE in pharmaceutical and biomedical analysis.

#### 4.3.2 NONAQUEOUS CAPILLARY ELECTROPHORESIS

Nonaqueous CE (NACE) is used for the separation of water-insoluble or sparingly soluble pharmaceuticals. NACE employs electrolytes composed of organic solvents and has been successfully utilized [33–38]. NACE is also useful for the resolution of water-soluble charged solutes as the selectivity obtained can be different to aqueous-based separations. The viscosity and dielectric constants of organic solvents can have an effect on both sample ion mobility and the level of EOF. Resolution, efficiency, and migration times are critically affected by the nature of the organic solvent, the electrolyte composition, its concentration, and temperature. Because of their different physical and chemical properties (viscosity, dielectric constant, polarity, autoprotolysis constant, etc.), methanol and acetonitrile are the most frequently used solvents for NACE. In particular, methanol–acetonitrile mixture containing 25 mM ammonium acetate and 1 M acetic acid is considered to be the appropriate electrolyte solution for the separation of a large variety of basic drugs [39]. The low currents present in NACE not only allow the use of higher electrolyte salt concentrations and higher electric field strengths but also the sample load can be scaled-up by employing capillaries with wider inside diameter. In addition, an effective sample introduction to a mass spectrometer, in terms of volatility, surface tension, flow rate, and ionization can be expected to further extend the use of NACE [40]. NACE exploits the vastly different physicochemical properties of organic solvents to control EOF and analyte migration. The ability of organic solvents to accept protons from the silanol groups of the capillary wall appears to play an important role in the development of an EOF. Although an EOF may not be required or may be completely undesired in a few electromigration capillary techniques, it plays a significant role in separations in free solution CE. However, the purity of the solvents may affect the EOF as they may contain foreign ionic species. The velocity of EOF is higher in pure solvents than in electrolyte solutions, which may be beneficial when fast liquid transport is desired. Salt-free solvents may also be advantageous in mass spectrometric detection [40].

One of the most attractive features of organic solvents is that their physical and chemical properties differ widely, both from each other and from water. Accordingly, simply changing the organic solvent or varying the proportions of two solvents can achieve selectivity manipulation in NACE.  $pK_a$  values in organic solvents can be significantly different from those in water allowing separations that are difficult to achieve in aqueous electrolytes. It has been shown that all solvents in which a measurable EOF is developed in the capillary are either amphiprotic or aprotic solvents. In addition

to self-dissociation, amphiprotic solvents act as proton donors or acceptors if there are other proton donors or acceptors in the separation system. However, there are differences in their proton donor and acceptor capabilities. Methanol, similar to water, has an equal tendency to donate and accept protons, but basic amide-type solvents are worse proton donors than proton acceptors. Aprotic solvents, such as acetonitrile, can only accept protons. Inert solvents are capable of neither autoprotolysis nor donation–acceptance of protons to a considerable extent, which makes them less suitable for NACE [40].

A number of review papers have been published which look at detection methods [41], selectivity manipulation [42], and pH of the background electrolyte [43] in NACE. This mode of CE has been reported to be used for a range of pharmaceutical separations; separation of a number of opium alkaloids [44], a mixture of cationic drugs [45], a range of tropane alkaloids [46], a range of beta-blockers [47], tricyclic antidepressants [37], and different basic drugs [48]. NACE has also been used to separate polar acidic and basic drugs [49] and to perform chiral separation of pharmaceutical amines [50].

### 4.3.3 MICELLAR ELECTROKINETIC CHROMATOGRAPHY

Micellar electrokinetic chromatography (MEKC) was developed by Terabe et al. [4], and combines the separation mechanism of chromatography with the electrophoretic and electroosmotic movement of solutes and solutions for the separation of constituents in a sample. This mode of CE is covered in detail in Chapter 3 by Terabe, and utilizes surfactant micelles as a “pseudo-stationary phase” in the carrier electrolyte. Surfactants are molecules with detergent properties, which are composed of a hydrophilic water-soluble head group and a hydrophobic water-insoluble hydrocarbon chain group [e.g., sodium dodecyl sulfate (SDS),  $\text{CH}_3-(\text{CH}_2)_{11}-\text{O}-\text{SO}_3^- \text{Na}^+$ ]. When anionic surfactant molecules are present in a solution at a concentration above their critical micelle concentration (CMC) they aggregate to form negatively charged micelles. These are generally spherical in shape with the hydrophilic head groups oriented in the aqueous buffer and the hydrocarbon chains in the centre. Figure 4.1 shows the arrangement of the molecules to form a micelle.

MEKC uses the same instrument set-up as in conventional CE and uses uncoated capillaries. When a water-insoluble hydrophobic compound is added to a micellar solution, it partitions into the core of the micelle and is solubilized. Conversely, if a water-soluble hydrophilic compound is added to the solution it will solubilize in the aqueous phase and will not partition into the micelle. Neutral compounds of intermediate water solubility will partition between the aqueous phase and the micelle core and the extent of the partitioning depends on the hydrophobicity of the compound. When high pH micellar solutions are used as the carrier electrolyte in CE, the negatively charged micelles migrate in the opposite direction to the EOF but the more powerful EOF carries them to the cathode,

**FIGURE 4.1** The arrangement of surfactant molecules when a micelle is formed. Depending on the surfactant, surfactants will form micelles with different numbers of molecules (Aggregation Number, AN). In the case of SDS its AN is 62 and its CMC is 8.27 mM.

through the detector. Very water-soluble solutes will remain in the aqueous phase and will separate due to differences in their electrophoretic mobilities. Solute, which are completely solubilized by the micelle, will migrate and reach the detector at the same time as the micelle. The main advantage in employing MEKC is that uncharged neutral compounds will partition between the aqueous phase of the electrolyte and the micelle and will separate based on the difference in micelle/water partitioning and migration times are proportional to their micelle/water partition coefficients,  $\log P_{mw}$ .

The composition of the micellar buffer solution can be changed in many ways in order to optimize the separations. The nature of the surfactant, that is, charge and concentration, the use of additives such as organic solvents, urea, and CDs can be altered in order to manipulate the separation of an analyte mixture. Books by Pyell [51] and Baker [31] dedicate chapters to more detailed discussions of MEKC theory and practice. Review papers by Pappas et al. [52], Molina and Silva [53], and Pyell [54] also cover many MEKC applications and development options.

#### 4.3.4 MICROEMULSION ELECTROKINETIC CHROMATOGRAPHY

Microemulsion electrokinetic chromatography (MEEKC), first presented in 1991 by Watari [55], is an extension of MEKC and is probably the most versatile mode of CE that offers the possibility of highly efficient separations of both charged and neutral solutes with a wide range of water solubilities. The range of pharmaceutical applications of MEEKC has grown rapidly in recent years with chiral analysis, pharmaceutical assay, impurity determination, and  $\log P$  measurements among the most common. MEKC and MEEKC differ in the type of pseudostationary phase used, as discussed in the previous section, MEKC electrolytes consist of micellar solutions while MEEKC electrolytes are composed of microemulsions, with solutes partitioning between the microemulsion droplets and electrolyte buffer.

Microemulsions are optically clear, thermodynamically stable suspensions of <10 nm diameter droplets of an immiscible liquid dispersed in another liquid, usually oil droplets in an aqueous continuous phase. These are referred to as oil-in-water (O/W) microemulsions and are the most commonly used in MEEKC applications; however, water-in-oil (W/O) microemulsions have also been used for MEEKC analysis of pharmaceuticals [56,57]. The microemulsion droplets are stabilized by the presence of a surfactant, for example, SDS, which was described in Section 4.3.3. The hydrocarbon chain of the surfactant resides in the oil droplet while the hydrophilic head remains in the aqueous phase, which reduces the interfacial tension at the oil–water interface. By incorporating a cosurfactant (usually a short chain alcohol), which bridges the oil–water interface in a manner similar to the surfactant, the interfacial tension is reduced further to almost zero resulting in a thermodynamically stable system. This arrangement is shown in Figure 4.2. SDS, an anionic surfactant, is the most commonly used surfactant in MEEKC and results in a negatively charged droplet. The aqueous continuous phase of the microemulsion usually contains additives, for example, pH buffers and/or ion-pair reagents, CDs, or organic modifiers to provide optimum separation conditions.

The separation mechanism in MEEKC is similar to that in MEKC where solutes are separated by both electrophoretic mechanisms in the capillary and by chromatographic interaction between the microemulsion droplets and the aqueous phase. Similar to MEKC, hydrophobic solutes favor inclusion in the oil droplet while hydrophilic solutes will favor the aqueous phase, neutral solutes will be separated according to differences in their oil/water partitioning coefficients ( $\log P_{ow}$ ) and migration times can be directly related to a neutral solutes  $\log P$  value. Generally, high pH buffers such as phosphate or borate are used in MEEKC and when a voltage is applied across the capillary, these buffers generate a high EOF toward the cathode end of the capillary. The negatively charged oil droplets attempt to migrate through the capillary to the anode but the EOF sweeps them through the capillary to the cathode. If charged solutes interact with the charged droplet this will also influence their migration time. Separation, therefore, is dependent on solute size, charge, and hydrophobicity, which allows the separation of neutral components.

**FIGURE 4.2** Schematic representation of an o/w microemulsion droplet.

MEEKC is the most versatile mode of CE for pharmaceutical analysis and offers many advantages over MEKC. It can be applied to a wider range of solutes than MEKC as solutes can penetrate the surface of a microemulsion droplet more easily than a more rigid micelle and offers greater separation capability for water-insoluble compounds [58]. MEEKC has been found to provide superior separation efficiency than MEKC, probably due to improved mass transfer between the microemulsion droplet and the aqueous phase [59]. MEEKC also provides a larger separation window, the size of which can be controlled and therefore offers greater separation capability for hydrophobic compounds [58,60]. Owing to the unique ability of microemulsions to solubilize water-soluble and water-insoluble, charged and neutral compounds, MEEKC is particularly suited to performing complex pharmaceutical separations. The many variables and operating parameters involved in MEEKC provide a large number of method development options for difficult pharmaceutical separations. Other advantages of utilizing MEEKC include the potential elimination or reduction in sample preparation steps resulting in rapid analysis times for difficult water-insoluble samples. This is due to the solubilizing power of microemulsions for water-soluble and water-insoluble compounds. Samples can be simply dissolved in the microemulsion and injected directly onto the capillary with little or no pretreatment. This was demonstrated by Broderick et al. [56] and Altria et al. [57] when utilizing W/O MEEKC for the analysis of a number of pharmaceutical preparations and sunscreen lotions. As the microemulsion droplets are less than 10 nm in diameter and optically transparent, they are very well suited to the use of low wavelength detection. This can be advantageous when detecting analytes with weak chromophores or when the sample matrix interferes with detection at higher wavelengths. This was demonstrated by McEvoy et al. [61] when detecting ibuprofen at 190 nm using O/W microemulsion liquid chromatography (MELC). Many reports have been published detailing the use of MEEKC for pharmaceutical applications and there have been a number of review papers [62–66] written, which describe further examples of MEEKC applications and advancements in method development with descriptions of operating parameter effects. An application-based research paper by Altria [58] highlights the suitability of MEEKC for a broad range of pharmaceutical applications. Readers can also find detailed theoretical aspects of MEEKC in a paper by Watari [66] and *Electrokinetic Chromatography* by Pyell [51].

#### 4.3.5 CAPILLARY ELECTROPHORESIS-MASS SPECTROMETRY

Capillary electrophoresis-mass spectrometry combines the short analysis time and high separation efficiency of CE with the molecular weight and structural information from the MS to provide a

powerful tool that can be utilized to quantify unknown compounds and impurities. Currently, ESI serves as the most common interface between CE and MS, as it can produce ions directly from liquids at atmospheric pressure, and with high sensitivity and selectivity for a wide range of analytes of pharmaceutical significance. It can also be applied to the detection of a wide range of analytes without derivatization and gives the information necessary to determine the structural formula of the analytes of interest.

The most common detection technique in CE is on-column UV absorbance detection, which can be applied to most pharmaceutical applications as most organic compounds display some UV absorbance. A drawback of UV detection is its relatively low sensitivity due to the short optical path length of the capillary detection window. The marriage of CE and MS instrumental analytical techniques results in an extremely powerful and highly sensitive tool for the separation, identification, and characterization of a wide range of molecules, especially pharmaceuticals. Smith et al. [67] first introduced CE-MS in 1988 and since then there has been an increased utility of CE-MS in pharmaceutical analysis. A chapter covering the coupling of CE to MS [51] describes in more detail the interfacing of the two methods, in particular electrokinetic chromatography-MS (EKC-MS). A number of CE-MS reviews have also been published [67–74], which cover the many applications of this technique and deal with operational, development issues, and quantification [69].

#### 4.3.6 MULTIPLEXED CAPILLARY ELECTROPHORESIS

The demand for high-throughput analytical methods to support the evolution of parallel synthetic technologies in drug discovery applications has led to the development of multiplexed CE to characterize libraries of compounds and alleviate backlogs in the discovery process. Multiplexed or parallel analysis is achieved in CE through the use of instruments containing bundles (arrays) of capillaries. The capability to use the same instrument to analyze multiple samples simultaneously, and the diverse separation conditions that are possible, allows rapid turnaround times. In the past 10 years, multiplexed CE instruments have become commercially available with a number of companies such as CombiSep, Beckman Coulter, and Genteon offering multiplexed systems with up to 384 capillaries coupled to laser-induced fluorescence (LIF) and UV detectors. Applications of multiplexed CE in pharmaceutical analysis include physicochemical profiling [76–78], chiral analysis [79–81], and organic reaction monitoring [82]. In a recent paper, Marsh and Altria [83] reported the use of multiplexed CE for the measurement of  $\log P$  and  $pK_a$  values, tablet assay, and impurity determination. While still in its infancy, the use of multiplexed CE in pharmaceutical applications shows clear advantages over traditional screening techniques. The ability to analyze multiple samples or vary experimental conditions in parallel offers a unique and powerful tool for drug discovery. Multiplexed CE has a broad range of high-throughput applications spanning the pharmaceutical, fine chemical, agrochemical, and biotechnology industries. The multiplexed CE format provides the flexibility to simultaneously vary separation conditions to speed method development processes. As this CE approach is relatively new, there are few sources of literature dedicated to the topic. The papers previously mentioned [76–84] cover the use of multiplexed CE for various pharmaceutical applications and give brief discussions of method development and instrumentation. A review paper by Pang et al. [85] gives more detailed information about the instrumentation and a wider range of applications.

### 4.4 METHODS OF DETECTION

Detection methods for CE analysis are as diverse as those used for HPLC. The most widely used detection methods used in CE include ultraviolet/visible (UV/Vis) absorbance, LIF, mass spectrometry, conductivity, amperometry, radiometric, and refractive index. When deciding which detection method is best suited to an intended application, the analyst must first know if the compounds to be separated can be detected using a certain type of detector, that is, does the analyte have a chromophore,

does it fluoresce, and so forth. If selective detection is desirable then choosing a detector that will only detect the compound of interest or classes of compound may be required, especially if components reach the detector simultaneously. Should quantitative and detailed qualitative data be required, then mass spectrometric detection would be the method of choice. The same criteria for detectors in HPLC apply in CE including sensitivity, selectivity, linear range, and the ability to provide qualitative data.

This section will only discuss the most common detection methods used for CE analysis of pharmaceuticals, that is, UV/Vis absorbance, LIFD, mass spectrometry, and electrochemical detection. In the tables of applications, the method of detection is indicated for each application. This should aid the interested reader and provide information on detector suitability for intended applications.

#### 4.4.1 UV/VIS ABSORBANCE

UV/Vis absorbance is by far the most common detection mode utilized in CE analysis of pharmaceuticals. This is mainly due to the fact that most pharmaceutical compounds are organic in nature and contain one or more chromophores, which leads the analyst to choose this detection method first. This reason along with the fact that UV/Vis detectors are the most common detectors in the majority of laboratories and are easily coupled to the CE instrumentation has led to UV/Vis detection being the usual method of choice in CE analysis of pharmaceuticals. The most advantageous type of UV/Vis detectors are diode array detectors (DADs), which utilize multiple wavelength detection to acquire spectral data that allows purity determination and some peak identification. A drawback of UV/Vis detection for CE analysis is the reduction on concentration sensitivity compared to its use in HPLC. With absorbance detection, minimum detectable concentrations in CE are 10–100 times higher than in HPLC, this is due to the lower path length of the cell. With CE the path length is the inner diameter of the capillary, which is typically 50–100  $\mu\text{m}$ , compared to path lengths of 10 mm for HPLC detectors.

Sensitivity can be enhanced through the use of larger inner diameter capillaries; however, larger capillary diameters produce a higher current, which leads to joule heating and separation efficiency decreases dramatically when the capillary diameter is increased above 100  $\mu\text{m}$ . There have been a number of approaches to enhance sensitivity by increasing the path length without increasing the inner diameter of the capillary. Moring et al. [85] used a “z-cell” with a 3 mm capillary section for path length, which gave a 10-fold increase in sensitivity. Tsuda et al. [86] used a 1000  $\mu\text{m}$  path length “rectangular capillary” to increase sensitivity, however, their application is limited by commercial availability and cost. Wang et al. [87] used a “multireflection cell” to effectively increase the path length more than 40-fold and reported a 40-fold increase in peak height compared to a single pass cell. A “bubble cell” can also be used to increase the path length by only increasing the diameter of the capillary where the light beam goes through it. This was demonstrated by Heiger [88] who reported a threefold increase in peak height when using a 50  $\mu\text{m}$  ID capillary with a 150  $\mu\text{m}$  “bubble.” Some manufacturers supply specialized detection cells such as Agilent's high sensitivity detection cell, which provides a 10-fold increase in sensitivity and an extended linear range.

#### 4.4.2 LASER-INDUCED FLUORESCENCE DETECTION

Laser-induced fluorescence is the optical emission from molecules that have been excited to higher energy levels by absorption of electromagnetic radiation. Laser-induced fluorescence detection (LIFD) can be regarded as the most sensitive optical detection technique to be coupled to CE with sensitivity proportional to the intensity of emitted light. The main advantage of fluorescence detection compared to absorption measurements is the greater sensitivity achievable because the fluorescence signal has a very low background. Intense light is available from the laser and this light can be efficiently focused into the narrow channel of the capillary in the detection window. LIFD is not a

universal detection method and solutes must possess native fluorescence or must be able to be derivatized to generate a fluorophore. The pharmaceutical analyst, when deciding on the suitability of LIFD to their separation must consider this. There are several commercially available LIF detectors designed for use with CE. Beckman Coulter offers a dual wavelength LIF detector that works with a 488 nm ( $\text{Ar}^+$  laser) and a 633 nm (HeNe laser). The Picometrics ZETALIF detector is a single wavelength excitation LIF detector which is a modular design and can be used externally to the CE instrument. Picometrics also offer another commercial detector, which can be used inside a cassette of any CE instrument.

A number of publications are available that describe the theoretical aspects of LIFD [51,89], which will provide the reader with a more detailed coverage of this topic. A number of reviews have also been published which cover the use of CE-LIF detection for the analysis of a range of compounds including pharmaceuticals [90–94]. Zhang et al. [94] also show the use of wavelength-resolved LIFD for quantitative and semi-qualitative analysis of target solutes.

#### 4.4.3 MASS SPECTROMETRIC DETECTION

Section 3.5 covered briefly the use of CE-MS for pharmaceutical applications. The suitability of CE-MS to pharmaceutical applications is due to its appeal as a universal and selective detector, which provides very good sensitivity. Significantly, CE-MS can provide quantitative data and where required, conclusive qualitative information.

#### 4.4.4 ELECTROCHEMICAL DETECTION

The two types of electrochemical detection used most often in CE are amperometry and conductivity. Although not as widely used in pharmaceutical CE as UV/Vis or LIFD, these methods are used when alternative detection methods are not suitable, that is, solutes lack chromophores, fluorophores or if sensitivity is poor using optical detection methods. Amperometric detection measures the current that results from oxidation or reduction of electroactive solutes at a working electrode surface. Oxidation occurs when an electron is transferred from a solute molecule to the working electrode in the amperometric cell, during oxidation the charge on the solute increases. Reduction occurs when electron transfer is in the opposite direction, from the working electrode to the solute molecule, and the charge on the solute is reduced. Oxidation and reduction of the solutes is caused by a potential being applied across a supporting electrolyte between a working and reference electrode. The current that flows through the working electrode is proportional to the number of electron transfers taking place, and therefore to the concentration of the solute. A review by Lui et al. [95] gives a more detailed account of amperometric detection in CE. A number of recent applications of amperometric detection for CE analysis of pharmaceuticals include determination of the hydrolysis rate constants and activation energy of aesculin [96] and analysis of acyclovir [97]. The basis of conductivity detection is the change in electrical conductivity of a solution when an ionic solute is introduced into it. A conductivity detector has two electrodes in the cell and a high frequency alternating current is applied to the electrodes. The buffer from the capillary flows between the electrodes and when an ionic solute comes into the cell it decreases the electrical resistance of the solution, thereby increasing the electrical conductivity. The measured conductivity is proportional to the concentration of the solute. As only ionic solutes cause a change in conductivity, this method cannot be used with MEKC or MEEKC for the detection of separated neutral solutes. As with amperometry, there have been relatively few applications of conductivity detection for pharmaceutical analysis by CE, compared to optical detection methods. Bowman et al. [98] used this technique for the analysis of small amines in pharmaceuticals. Readers are encouraged to consult reviews by de Silva [99], Baldwin [100], Holland and Leigh [101], and Wang and Fang [102] who discuss in more detail electrochemical detection in CE analysis.

**TABLE 4.1**  
**Features and Limits of Detection of CE Detection Methods**

Detection Method	Detection Requirements	Selective	Universal	Qualitative	On-column Detection	Approximate LOD (Molarity)
UV/Vis absorbance	<ul style="list-style-type: none"> <li>• Chromophore groups</li> <li>• Absorb UV above 190 nm</li> </ul>	Yes	No	Some, using DADs	Yes	$10^{-5}$ – $10^{-7}$
LIF	<ul style="list-style-type: none"> <li>• Fluorophore groups</li> <li>• Derivatized to contain fluorophores</li> </ul>	Yes	No	No	Yes	$10^{-13}$ – $10^{-16}$
MS	<ul style="list-style-type: none"> <li>• No special requirements</li> </ul>	Yes	Yes	Yes	No	$10^{-8}$ – $10^{-10}$
Amperometry	<ul style="list-style-type: none"> <li>• No special requirements</li> </ul>	Yes	No	No	No	$10^{-7}$ – $10^{-10}$
Conductivity	<ul style="list-style-type: none"> <li>• Solutes need to be charged</li> </ul>	No	Yes	No	No	$10^{-7}$ – $10^{-9}$

#### 4.4.5 SELECTING THE MOST SUITABLE DETECTOR

When deciding which detection method is most suitable to an application, the pharmaceutical analyst needs some fundamental information about their sample and also the analytical requirements. The main points to be considered when choosing a detection method are sensitivity and selectivity requirements and the ability to provide qualitative information. If these requirements are known then the list of available detectors is reduced. Knowledge of the chemical structure of target analytes is indispensable when choosing an appropriate detector as information about chromophore and fluorophore groups, solute charge, molecular weight, and so forth narrows the options available to the analyst. Table 4.1 lists the most common detectors as discussed in this section and shows the limits of detection, detection requirements, and so forth for each type that will aid in detector selection. Readers are encouraged to consult reviews by Xu et al. [92] and Swinney and Bornhop [103], which cover CE detectors in more detail.

#### 4.5 SELECTING THE MOST SUITABLE MODE OF CE

As previously discussed in Sections 3.1 through 3.5, the various modes of CE offer various possibilities to the pharmaceutical analyst. Depending on the complexity of the sample, the nature of its components, and the intended application, the nature of pharmaceutical analytes varies enormously from highly water-soluble compounds to species only soluble in pure organic solvents. Each of these modes of CE will provide various advantages and disadvantages for the separation and detection of different classes of compounds. FSCE is well reported for many pharmaceutical assays and impurity determinations, mainly for water-soluble and some water-insoluble acidic and basic compounds. NACE is suited to the separation of highly water-insoluble charged compounds and the volatile nature of the solvents used makes it ideal for coupling to a MS. NACE also offers different selectivity to FSCE for the separation of pharmaceuticals [45,46]. For complex separations, MEEKC is the method

of choice as it gives the analyst more method development options, it has a wider application range than MEKC and unlike FSCE and NACE, this mode of CE will separate both charged and neutral compounds. The use of W/O MEEKC has shown applicability of this method for the analysis of highly water-insoluble compounds in hydrophobic matrices without the need for lengthy sample pretreatment or expensive organic solvents [56,57]. For rapid screening, enantiomeric separations and physicochemical measurements of pharmaceuticals, multiplexed CE has been used [77–85]. The main pharmaceutical application areas of CE are chiral separations, pharmaceutical assay, impurity determinations, physicochemical measurements, and the analysis of small molecules and ions. Each of these areas will be discussed in the next section and a selected number of applications will be detailed in tabular form showing the mode of CE used. As the numbers of applications are too numerous to be included in this chapter, sources of further applications will be cited for the interested reader.

## 4.6 PHARMACEUTICAL APPLICATIONS OF CAPILLARY ELECTROPHORESIS

Since the first application of CE to pharmaceutical analysis in 1988 [15], the number of reports describing the analysis of numerous different pharmaceutical compounds and formulations by CE has expanded to be in the hundreds. Lunn [13] has covered in detail the CE separation methods for over 700 pharmaceutical compounds taken from hundreds of publications. The objective of this applications section is to provide the reader with an introduction to the main pharmaceutical application areas with examples of successful separations including sources of comprehensive reviews for each area. Within each application area there may be more specialized applications (e.g., chiral MEEKC) for enantiomeric separations and some aspects may be cross-linked with other applications or detection methods to comprehensively cover the topic of this chapter. Sources of extra reading material in the form of review papers will be cited where relevant.

### 4.6.1 CHIRAL PHARMACEUTICAL ANALYSIS

Chiral analysis has become one of the most studied areas of CE, as it is a powerful analytical tool for separating chiral compounds, which is of major importance in pharmaceutical applications. The two most important analytical techniques used in chiral separations still are LC and CE, followed by GC and capillary electrochromatography (CEC). Compared to other techniques, CE has several advantages, the high resolving power, and low consumption of sample, solvent, and chiral selector. In method development, the chiral selector is added to the background electrolyte instead of using a range of expensive chiral LC columns. Chiral CE provides high flexibility in choosing and changing types of selectors. The possibility of low wavelength UV detection for CE also allows the separation and detection of analytes with poor chromophores, which are difficult to detect by UV/high-performance liquid chromatography (UV/HPLC).

This section will look at recently developed chiral selectors and chiral CE separating techniques. Readers are referred to papers by Rizzi [104] and Gubitz and Schmid [105], which deal with the fundamental aspects and principles of chiral CE. A book dedicated to CE for chiral analysis by Chankvetadze [106] covers a number of aspects of chiral CE including the use of chiral metal complexes, macrocyclic antibiotics, crown ethers, and chiral MEKC. Review papers by Gubitz and Schmid [107], Hoogmartens and coworkers [16], and Amini [108] cover recent applications of chiral CE. The following paragraph gives a very brief introduction to the basic theory of chiral CE separations.

At low pH, basic drugs are positively charged and their migration toward the cathode can be retarded by a chirally selective complexing agent, resulting in the separation of enantiomers of differing affinity for the agent. This principle has been demonstrated for the resolution of chiral basic

drugs using CDs as a chiral selector [109]. At high pH, chiral acidic drugs are negatively charged and migrate against the EOF toward the anode. Neutral chiral selector agents are swept along the capillary with the EOF toward the detector; thus, complexation reduces the migration time of the drug and results in enantioseparation [110].

There are many types of chiral selectors that have been applied to the separation of enantiomers by CE, but the most common are native and derivatized CDs. Other chiral selectors, which have been applied to CE separations, include natural and synthetic chiral micelles, crown ethers, chiral ligands, proteins, peptides, carbohydrates, and macrocyclic antibiotics [105,111–114]. A review by Blanco and Valverde [114] describes the separation capabilities of various chiral selectors and provides criteria for their choice in terms of molecular size, charge, and the presence of specific functional groups or substructures in the analytes.

Chiral CE using mass spectrometric detection has also been utilized for detailed qualitative analysis of pharmaceuticals, a review by Shamsi [115] covers the various modes of CE-MS including the use of neutral CDs for FSCE-MS and MEKC-MS.

#### 4.6.1.1 Cyclodextrins

Native and derivatized CDs are employed routinely for enantiomeric separations. These naturally occurring carbohydrates have a bucket-like shape, which allows analytes to become included into the CD cavity by complexation. The migration time of the analytes is dependent on their mobilities and degree of interaction with the CD. Enantiomeric separations are brought about by the difference in the stabilities of the complexes formed between each enantiomer and the CD molecule. The chiral hydroxyl groups around the rim of the CD can interact enantioselectively with chiral analytes, which can fit into the CD cavity, leading to the separation of enantiomers with differing binding constants. There are three types of CDs,  $\alpha$ ,  $\beta$ , and  $\gamma$ , each differing in the number of glucose units they are composed of.  $\beta$ -CDs are the least soluble in water but their solubility can be improved by the addition of urea to the background electrolyte. Because enantioselection is based on the formation of inclusion complexes between the CD host and the chiral solute, the type of CD chosen is a major factor for achieving efficient resolution of enantiomers. Recent reviews [20,117] have covered the background to the use of CDs in chiral CE. Systematic approaches to the development of chiral CE methods using sulfated CDs for the separation of acidic, basic, neutral, and zwitterionic species have also been reported [118,119]. Systematic method development approaches for several selected compounds were performed by modifying method parameters, such as the concentration of the chiral selectors, buffer pH, type of organic modifiers, buffer type, temperature, and applied voltage. Many practical aspects were also discussed through several specific examples in order to demonstrate how to develop and validate a precise, sensitive, accurate, and rugged separation. Perrin et al. [75] studied the robustness of enantiomeric separations of acidic, basic, and neutral compounds using highly sulfated CDs in a low pH phosphate buffer with short-end injection. An eight-factor experimental design was used to study the robustness of chiral separations of propranolol (basic), praziquantel (neutral), and warfarin (acidic). These factors included electrolyte pH, CD and electrolyte concentration, capillary temperature, and applied voltage. Results showed that control of pH is critical, especially for the separation of acidic enantiomers while CD concentration changes did not adversely affect the robustness of the separations.

#### 4.6.1.2 Crown Ethers

Crown ethers have been developed and synthesized for use in Chiral CE. Kuhn et al. [119] first utilized chiral crown ethers for the enantiomeric separation of drugs and amino acids in 1992. Since then there have been a number of applications of these chiral selectors in CE analysis, 18-crown-6 tetracarboxylic acid [18C6H(4)] is to date, the only chiral crown ether that has been used for chiral

CE separations and forms complexes with chiral analytes in a way similar to CDs, based on differences in complex formation energies. Two new 18-crown-6 diaza derivatives were investigated as chiral selectors [120]. These derivatives did not show any chiral selectivity toward the investigated analytes, they could serve well as an additive to improve the chiral resolution in combination with CDs.

#### 4.6.1.3 Macrocyclic Antibiotics

Although CDs and their derivatives are present in the majority of chiral CE applications, the use of macrocyclic antibiotics can be observed with increasing frequency [121,122]. The number of macrocyclic antibiotics utilized for chiral CE has now exceeded 10 and includes four main groups: glycopeptides, polypeptides, ansamycins, and aminoglycosides (although this group is not always considered as macrocyclic). Thanks to their macrocyclic structure and the diversity in chemical groups, they exhibit a variety of interactions (inclusion, electrostatic, hydrogen bond, hydrophilic-lipophilic, or other Van der Waals bond type), which enables them to achieve high chiral resolution with a wider range of analytes (acidic or basic, with large or small molecular sizes, etc.) [124]. Macrocyclic antibiotics are enantioselective for positively charged solutes using ansamycins and enantioselective for anionic compounds using the glycopeptides. Within a given class of antibiotics such as the glycopeptides, enantioselectivity may also be altered by use of micelles, uncoated vs. coated capillaries, or manipulation of operating parameters such as pH or organic modifiers. In a review paper, Aboul-Enein and Ali [123] describe the chemistry of these antibiotics, the effect of chromatographic conditions on enantioselectivity, the mechanism of resolution, the applications and limitations of the compounds in LC and CE.

#### 4.6.1.4 Oligo- and Polysaccharides

Apart from CDs, many other linear and cyclic oligo- and polysaccharides have been used as chiral selectors [127] (e.g., monosaccharides as D-glucose, D-mannose, or polysaccharides as dextrans, dextrans, and many others). Park et al. [125] used highly sulfated cyclosophoraoses, the sulfated derivatives of chiral unbranched cyclic  $\beta$ -(1 $\rightarrow$ 2)-D-glucans, and successfully used them to separate five basic chiral drugs. These derivatives exhibited higher resolution than the original cyclosophoraoses. Another new charged polysaccharide, *N*-(3-sulfo, 3-carboxy)-propionylchitosan, was studied by Budanova et al. [126]. This appeared to have a different chiral recognition mechanism from the charged polysaccharides. The use of polysaccharides combined with CDs has also been reported [128].

#### 4.6.1.5 Proteins

A protein or glycoprotein consists of amino acids or amino acids and sugars, both of which are chiral. Therefore, proteins have the possibility to discriminate between the enantiomers of a chiral molecule. CE methods using proteins as the immobilized ligands or running buffer additives are attractive for the separation of enantiomeric mixtures. Although separation efficiencies by CE are generally somewhat higher than those obtained with HPLC, chiral CE methods based on proteins have a disadvantage of low efficiencies in addition to low loadability. Proteins such as bovine serum albumin (BSA) and human serum albumin (HSA) and several additional proteins have been used as chiral selectors in CE. Reviews by Haginaka [111] and Millot [129] provide a more in-depth coverage of recent chiral CE separations using proteins as chiral selectors. Although proteins display very good chiral discrimination for pharmaceutical enantiomers, their high background UV absorbance limits their usefulness in chiral CE. More can be gleaned on protein analysis by CE from Chapter 2 by Hempe.

#### 4.6.1.6 Chiral MEKC

Enantiomeric separation by MEKC involves the addition of a chiral surfactant or a chiral selective agent to the background electrolyte. A number of selectors have been used in chiral MEKC including crown ethers and CDs. These selectors are usually used in combination with chiral or achiral micelles, for example, CD modified MEKC (CD-MEKC) [130]. MEKC usually utilizes negatively charged micelles formed from anionic surfactants such as SDS, which constitutes the pseudostationary phase. The separation is achieved by differential partitioning of analytes between the pseudostationary phase and the bulk aqueous phase. Chiral surfactants used for chiral MEKC separations include natural surfactants (bile salts, amino acids, and glucose), monomeric synthetic surfactants, and polymeric surfactants [131–133]. Chiral separation in MEKC is affected by the affinity of the enantiomers toward the micelles and the concentration of the micellar phase, which depends on the aggregation properties of the chiral surfactants or chirally modified surfactants. Dobashi et al. [131] first reported the use of chiral mixed micelles to obtain optical separation of enantiomers in 1989 and since then, there have been many reports on enantiomer separations by MEKC. Otsuka and Terabe [134] has reviewed the use of natural and synthetic chiral surfactants in MEKC, in a review by Ha et al. [16], recent applications, and aspects of chiral MEKC are covered in more detail.

#### 4.6.1.7 Chiral MEEKC

Chiral separation by MEEKC was first demonstrated in 1993 [135] using (2*R*,3*R*)-di-*n*-butyl tartrate as a water immiscible chiral selector in the microemulsion electrolyte that successfully separated ephedrine enantiomers. Chiral MEEKC offers increased method development flexibility, the ability to custom tune chiral resolution through the increased method development options, and unique solubility capabilities for both analytes and additives when compared to typical capillary electrophoretic techniques. Chiral MEEKC offers the possibility to simultaneously determine drug enantiomers of more than one compound along with chemical impurities/additives. Importantly, the greatest advantage of this technique is the ability to separate more hydrophobic racemic components for which CE is not currently a preferred methodology. Only in recent years, more research into this area of chiral separations has been carried out by Pascoe and Foley [136], Mertzman and Foley [137,138], and Zheng et al. [139] among others. Chiral separations in MEEKC can be achieved by utilizing a number of chiral agents such as a chiral surfactant dodecoylcarbonylvaline (DDCV) [136], chiral alcohols as cosurfactants [139], a combination of both of these chiral components [140], and the use of CDs in CD modified MEEKC as the only chiral agent and in combination with both SDS and DDCV as surfactants [137]. Although no literature in the form of reviews and few books are dedicated to chiral electrokinetic chromatography (MEKC and MEEKC), Pyell [51] includes a chapter dealing with enantiomer separations by electrokinetic chromatography. There are a number of reviews by Ha et al. [16], Marsh et al. [63], and Huie [64], which cover these subjects in some detail and give examples of recent applications.

#### 4.6.1.8 Pharmaceutical Applications of Chiral CE

Chiral selectors are routinely used in industry for a wide variety of applications and there have been many reports published describing their use in CE for the enantiomeric separations of pharmaceutical compounds. A quick search of scientific databases will yield a far greater number of publications dealing with chiral CE than is possible to cover in this chapter; however, Table 4.2 contains a selection of such applications and details of carrier electrolytes used. Readers are referred to review papers [16,63,64,116,107,141–144], which comprehensively cover recent chiral applications of CE and provide more detailed theory about chiral separations and detection methods.

**TABLE 4.2**  
**Selected Chiral Separations of Pharmaceuticals**

Application	Chiral Selector	Mode	References
Enantiomeric purity methods for three pharmaceutical compounds	A range of $\alpha$ -, $\beta$ -, and $\gamma$ -cyclodextrins, highly and singly sulfated	FSCE	[153]
Evaluation of chiral purity of frovatriptan	Sulfobutyl ether $\beta$ -cyclodextrin	FSCE	[154]
Chiral separation of four fluoroquinolone compounds	Hydroxypropyl- $\beta$ -cyclodextrin	FSCE	[155]
Chiral separation of bupivacaine enantiomers	Human serum albumin	FSCE	[156]
Chiral separations of a range of pharmaceuticals	Sulfated $\beta$ -cyclodextrin ( $\beta$ -CD-(SO <sub>4</sub> <sup>-</sup> ) <sub>4</sub> )	NACE	[157]
Dopa enantiomers	(+)-(18-crown-6)-2,3,11,12-tetracarboxylic acid	FSCE	[147]
Chiral separation of <i>N'</i> -nitrososornicotine in tobacco	Hydroxypropyl- $\beta$ -cyclodextrin	FSCE	[145]
Enantioseparation of <i>erythro</i> -mefloquine and its analogues	Heptakis-(2,3, 6-tri- <i>O</i> -methyl)- $\beta$ -CD Heptakis-(2,3-di- <i>O</i> -methyl-6-sulfo)- $\beta$ -CD Randomly sulfated $\beta$ -CD	FSCE	[158]
Enantioseparation of nine racemic arylglycine amides	Highly sulfated $\beta$ -cyclodextrin	FSCE	[159]
Enantioseparation of basic pharmaceutical compounds	Sulfated cyclodextrins	FSCE	[160]
Enantiomeric separation of compounds containing primary amine groups	(+)-(18-crown-6)-2,3,11,12-tetracarboxylic acid	CE-MS	[161]
Separation of 4 diastereomers of an antiviral agent with 2 chiral centers	Highly sulfated $\alpha$ , $\beta$ , and $\gamma$ -CDs	FSCE	[162]
Separation of ( <i>R</i> -(-) and <i>S</i> -(+) citalopram) in tablets	Carboxymethyl- $\gamma$ -cyclodextrin (CM- $\gamma$ -CD)	FSCE	[205]
Lisuride bulk substance	Acidic electrolyte with the addition of gamma-cyclodextrin ( $\gamma$ -CD)	FSCE	[206]
Identification and quantification of <i>cis</i> -ketoconazole impurity in tablets and gel	Heptakis-(2,3, 6-tri- <i>O</i> -methyl)-beta-cyclodextrin	CE-MS	[207]
Separation of omeprazole enantiomers	40 mM phosphate, pH 2.2, 30 mM $\beta$ -CD, and 5 mM sodium disulfide	FSCE	[208]

#### 4.6.1.9 Examples of Chiral CE and Validated Methods

*N'*-nitrososornicotine (NNN) is a nitrosamine found in cured tobacco and is believed to be one of the main carcinogenic constituents of tobacco. Racemic NNN is present as (*R*) and (*S*) enantiomers and it is known that (*S*)-NNN undergoes more 2' hydroxylation than (*R*)-NNN. For rapid and efficient enantiomeric separation of this nitrosamine, McCorquodale et al. [145] developed a simple CE method, employing a citric acid buffer with hydroxypropyl- $\beta$ -CD (HP- $\beta$ -CD). Separation was achieved in 4 min.

A nonaqueous chiral CE method was developed and validated by Olsson et al. [146] for the enantiomeric separation of omeprazole an antiulcer drug and its metabolite 5-hydroxyomeprazole. Heptakis-(2,3-di-*O*-methyl-6-*O*-sulfo)- $\beta$ -CD (HDMS- $\beta$ -CD) was chosen as the chiral selector in an

**FIGURE 4.3** Enantiomeric separation of (a) omeprazole and 5-hydroxyomeprazole at a concentration of 1 mM and (b) omeprazole and 5-hydroxyomeprazole at a concentration of 1 and 3 mM, respectively, using 30 mM HDMS- $\beta$ -CD, 1 M formic acid, 30 mM ammonium acetate, 25 kV, 5 s injection at 50 mbar, capillary and tray temperature 16°C. (From Olsson J., et al., *J. Chromatogr. A*, 1129, 291–295, 2006.)

ammonium acetate buffer acidified with formic acid in methanol. The separation is illustrated in Figure 4.3.

The addition of a chiral crown ether [(+)-(18-crown-6)-2,3,11,12-tetracarboxylic acid] to the background electrolyte allowed Blanco and Valverde [147] to separate the enantiomers of benserazide and determine the enantiomeric purity of Dopa (3,4-dihydroxyphenyl-alanine). Levodopa is the main active ingredient in the pharmaceutical formulation Madopar<sup>®</sup>, which is used to treat Parkinson's disease, while dextradopa causes unwanted side effects. The dextradopa impurity was clearly resolved from the main peak and determined to be 0.5%.

The validation criteria for chiral CE methods are similar to those employed for the validation of chiral HPLC methods and include limits of detection, detector linearity, recovery, precision, and robustness. A number of validated chiral CE methods have been reported, as described previously Olssen et al. [146] developed and validated a chiral NACE method for the enantiomeric determination of an antiulcer drug and its metabolite. Enantiomeric determination of a local anesthetic, ropivacaine in a pharmaceutical formulation showed the required limit of quantification of 0.1% of the impurity [148]. Jimidar et al. [149] reported a validated CE method for the chiral separation of an Alzheimer's treatment, galantamine hydrobromide, using an  $\alpha$ -CD chiral selector and the method was successfully included in a New Drug Application. Song et al. [150] achieved a LOD of 0.05% for the undesired enantiomer of an M3 agonist using a highly sulfated  $\gamma$ -CD in a low pH buffer. Other validated chiral CE methods are also cited [151,152].

#### 4.6.2 PHARMACEUTICAL ASSAY

Assay of pharmaceutical substances and formulated products is one of the most important and regulated activities in the pharmaceutical analysts laboratory. Regulatory authorities require strict validation standards to show that analytical assay methods are robust, accurate, repeatable, and suitable for their intended purpose. In the pharmaceutical industry, HPLC has dominated most analytical assay determinations and it is well established as the method of choice in most laboratories. In addition, pharmacopoeia monographs specify HPLC and titrimetric methods for the majority of pharmaceutical assays. To date, CE is not used extensively in QC work despite displaying excellent efficiencies, resolution, asymmetry factors, and signal-to-noise ratio. This is mainly due to the fact that CE can suffer from insufficient sensitivity and repeatability to control impurities in pharmaceutical substances at the levels required. These issues have been addressed somewhat with sensitivity

improvements being reported through the use of alternative detection techniques such as mass spectrometry and LIFD and the use of high sensitivity detection cells for UV detection. When conducting CE analyses, the electrophoretic conditions inside the capillary can sometimes vary slightly between injections, which can lead to greater variability in peak migration times. Poor injection precision due to the very small volumes injected can also cause variations in peak areas. A number of approaches can be made to overcome these problems. Migration times and peak areas can be calculated relative to an internal standard, which leads to improvements in repeatability [164]. Greater migration time reproducibility can also be achieved by applying the separation voltage across the capillary for a very short time prior to injection and separation [165]. The factors affecting CE reproducibility and efforts to address the problem have been covered in more detail by Shihabi and Hinsdale [166], Schaeper and Sepaniak [167], and Mayer [168]. Many factors are involved in reproducibility. Some of these, such as temperature control, voltage control, and sample injection precision, are inherent in the design of the instrument. Other factors, such as the quality of the reagents used and the manner in which the instrument is programmed and operated, are completely in the hands of the user. These two factors, the quality of the instrument and the quality of the operation, are both required in order to achieve reproducible results. A commercially available capillary treatment system of proprietary buffers and rinse solutions has been shown to improve CE repeatability as the capillary is coated with a bilayer of surfactants ensuring that the surface coverage and the EOF is consistent between injections and between capillaries [169]. Figure 4.4 highlights the consistency of the EOF when using the buffer coating system compared to a standard phosphate buffer when using a capillary composed of 19 different channels. In Figure 4.4a, the peaks in the channels have different speeds and the separation is poor while Figure 4.4b shows a single peak due to a consistent EOF in each channel, which makes the peaks move at the same speed.

There is a time lag before new analytical methods such as CE are accepted by regulatory authorities in the submission dossiers for new medicines and pharmaceutical substances. Regulatory authorities are, however, beginning to recognize CE with general monographs appearing in the BP, EP, and Japanese Pharmacopoeia using CE for identification tests. For example, a test for related substances of levocabastine hydrochloride by MEKC has been included in the British Pharmacopoeia 2005 [163].

One of the major advantages of using CE as an alternative to HPLC methods for pharmaceutical assay is the relatively small solvent consumption, that is, milliliters of CE electrolyte compared to liters of HPLC mobile phase, increased efficiency, reduced analysis time, and the possibility of fewer sample pretreatment steps. The ability to quantify a range of sample types using a single set of CE conditions is another strong feature and can contribute to considerable savings in analysis and system setup times. This is particularly true when using multiplexed CE systems where high sample throughput is possible. The merits of using CE compared to HPLC for pharmaceutical analysis will be discussed in more detail in a later section.

Some recent examples of pharmaceutical assay by CE include a MEEKC method for the determination of folic acid in tablets giving a precision of  $<1.2\%$  relative standard deviation (RSD) and recovery of  $99.8 \pm 1.8\%$  at three concentration levels [170]. Lehmann and Bergholdt [171] developed and validated a high-precision CE method for the main component assay of ragaglitazar, which met the acceptance criteria that are set for HPLC main component assays. In a separate study, Jamali and Lehmann [172] used a FSCE method to analyze ragaglitazar and its counterion arginine in active pharmaceutical ingredients (APIs) and low dose tablets. The method was suitable for the assay and identification of ragaglitazar and arginine, chiral purity of ragaglitazar, and the purity of ragaglitazar, with percentage recovery found to be 101–106% for ragaglitazar and 101–125%. Pajchel et al. [173] used a phosphate buffer supplemented with SDS to develop a selective and precise assay method for quantitative determination of benzylpenicillin, procaine, benzathine, and clemizole. The separation is shown in Figure 4.5.

A number of validated CE methods for pharmaceutical assay have been reported; a selection of recent methods along with the mode of CE used and the run buffer are shown in Table 4.3.

**FIGURE 4.4** Separations on a multibore capillary using phosphate buffer or Celixir buffer. (a) Separation using phosphate buffer: 50 mM phosphate 2.5, multibore capillary  $19 \times 25 \mu\text{m}$  channels, 27 cm long,  $130 \mu\text{A}$ , +5 kV,  $30^\circ\text{C}$ , detection at 200 nm, sample salbutamol 1 mg/mL, 1 s injection. (b) Separation using Celixir buffer: 50 mM phosphate 2.5, multibore capillary  $19 \times 25 \mu\text{m}$  channels, 27 cm long,  $90 \mu\text{A}$ , +5 kV,  $30^\circ\text{C}$ , detection at 200 nm, sample salbutamol 1 mg/mL, 1 s injection. Multibore capillary  $19 \times 25 \mu\text{m}$  channels, 27 cm long, +5 kV,  $30^\circ\text{C}$ , Elixir buffer pH 2.5,  $90 \mu\text{A}$ , 200 nm. (From Altria K.D., *J. Pharm. Biomed. Anal.*, 31, 447–453, 2003.)

### 4.6.3 IMPURITY PROFILING OF PHARMACEUTICALS

Impurities in pharmaceuticals are the unwanted chemicals that remain with the APIs, or develop during formulation, or upon aging of both the API and formulated pharmaceutical product. The presence of these unwanted chemicals even in small amounts may influence the efficacy and safety of the pharmaceutical products. Impurity profiling (i.e., the identity as well as the quantity of impurity in the pharmaceuticals) is another important aspect of the pharmaceutical analysts work and must meet strict regulatory requirements. The different pharmacopoeias, such as the British Pharmacopoeia (BP) and the United States Pharmacopoeia (USP) have tests for related substances incorporated into most monographs for pharmaceutical compounds and formulations. In addition, The International Conference on Harmonization (ICH) has published guidelines on impurities in new drug substances [190]. Impurity profiling is generally carried out by HPLC and cross-correlated with other

**FIGURE 4.5** Electropherogram of benzylpenicillin and procaine, benzathine, and clemizole. Buffer phosphate–borate (pH 8.7), supplemented with 14.4 g/L SDS. Detection wavelength was 214 nm. Separations were performed in 60 cm (52 cm effective length)  $\times$  75  $\mu$ m ID fused-silica capillary coated with polyimide (AccuSep capillaries, Waters) thermo regulated at 25°C, with voltage of 18 kV applied (current about 140  $\mu$ A). Hydrodynamic injection by gravity-driven siphoning 10 s. P, procaine; B, benzathine; C, clemizole; BP, benzylpenicillin; MEOH, methanol (EOF marker). (From Pajchel G., et al., *J. Chromatogr. A*, 1032, 265–272, 2004.)

chromatographic methods such as TLC or an alternative HPLC method. The overriding requirements in impurity determination methods are that all likely synthetic and degradative impurities are resolved from the main compound and these can be quantified at 0.1% and lower levels. This quantification is possible using commercial CE instrumentation with standard capillaries. The structural impurities of a drug will often possess similar structural properties of the main component, which makes achieving resolution of the compounds challenging. The high separation efficiencies and different separation mechanism of CE often allows easier resolution of the main component and related substances than when using HPLC or TLC. The ability to easily alter separation parameters and the applicability of one CE method to a range of compounds can make CE a cheaper and more rapid complementary method to LC methods. Because LC and CE utilize different separation mechanisms, the analyst can have a high degree of confidence in the cross-correlation of agreeable results.

Various modes of CE have been used for impurity determination with CE. Hansen described the comparison of CZE (FSCE), MEKC, MEEKC, and NACE for the determination of impurities in bromazepam [193] and found that NACE provided the best technique for the poorly water-soluble compounds with impurities determined to be 0.05%. Chiral CE methods can be used to determine enantiomeric impurities [191]. Readers are referred to a paper by Sokolies and Koller [192] describing method development for chiral purity testing in CE. FSCE is the most widely used as most drugs and impurities are acidic or basic. Low pH buffers are used for basic drug impurities and high pH buffers for acidic compounds.

**TABLE 4.3**  
**Selected Validated CE Methods for Pharmaceutical Assay**

Application	Buffer	Mode	References
Determination of sertaconazole in pharmaceutical preparations	20 mM phosphate + 40% acetonitrile	FSCE	[174]
Development and validation of a quantitative assay for raloxifene	20 mM acetate (pH 4.5)	FSCE	[175]
Analysis of atorvastatin calcium using capillary electrophoresis and microchip electrophoresis	25 mM sodium acetate (pH 6)	FSCE	[176]
Determination of ibuprofen and flurbiprofen	20 mM <i>N</i> -(2-acetamido)-2-aminoethanesulfonic acid (ACES) with 20 mM imidazole and 10 mM alpha-cyclodextrin of pH 7.3	FSCE	[177]
Separation and quantification of fibrate-type antihyperlipidemic drugs	1/15 M phosphate buffer (pH 10)	FSCE	[178]
Simultaneous determination of six angiotensin-II-receptor antagonists.	60 mM phosphate (pH 2.5)	FSCE	[179,180]
Simultaneous analysis of four atypical antipsychotics	55 mM phosphate 15 mM SDS (pH 6.5)	MEKC	
Determination of cyclizine hydrochloride in tablets and suppositories	80 mM sodium phosphate buffer (pH 3.5)	FSCE	[181]
Simultaneous determination of six corticosteroids in commercial pharmaceuticals	50 mM phosphate (pH 2.3)	FSCE	[182]
Simultaneous determination of penicillin G, procaine, and dihydrostreptomycin in veterinary drugs	Borate buffer containing sodium cholate and sodium deoxycholate	MEKC	[183]
Quantitative analysis of quinolizidine alkaloids in Chinese herbs	0.08 M borate (pH 8)	FSCE	[184]
Simultaneous determination of four tricyclic antidepressants	1% acetic acid, 50 mM ammonium acetate, 20% acetonitrile in methanol	NACE	[185]
Analysis of benzodiazepines	50 mM ammonium acetate, 1 M acetic acid in acetonitrile	NACE	[37]
Determination of fluoxetine and its main metabolite norfluoxetine in human urine	Ceofix™ Buffer system, using dynamically coated capillaries	CE-MS CE-MS <sup>2</sup> CE-DAD	[187]
Determination of heroin, basic impurities, and adulterants with capillary electrophoresis	7:3 methanol–acetonitrile containing 15 mM ammonium acetate	NACE	[186]
Determination of various benzylpenicillin salts	Celixir™ Buffer capillary coating system plus added cyclodextrins	FSCE	[188]
Simultaneous determination of ingredients in a cold medicine by CD-MEEKC	Phosphate–borate buffer supplemented with SDS 14.4 g/L	MEKC	[173]
Folic acid in tablets	0.81% pentane, 6.61% 1-butanol, 2% 2-propanol, 4.47% SDS, 86.11% 10 mM sodium tetraborate, 3 mM 2,6-di- <i>O</i> -methyl-beta-CD	MEEKC	[189]
	0.5% ethyl acetate, 1.2% butanol, 0.6% SDS, 15% propanol, 82.7% 10 mM tetraborate (pH 9.2)	MEEKC	[170]

A method was developed and validated using a low pH buffer for the determination of ranitidine and potential related impurities in bulk drug and formulations [194]. This method gave detection limits of 0.03% diamine, 0.04% oxime, 0.1% Bis, and 0.24% nitroacetamide but importantly, it detected a number of peaks, which were not resolved by either HPLC or TLC.

High pH buffers such as phosphate or borate are employed in the analysis of acidic components. At high pH, acidic components migrate against the EOF, thus maximizing mobility differences. A high pH borate buffer of 9.2 was developed and validated for the determination of homotaurine as an impurity in calcium acamprosate by FSCE, detection limits of between 0.01% and 0.15% homotaurine were reported [195]. A high pH CE method was used to quantitatively profile the chloromethylated, monomethylated, and hydroxylated impurities of a new compound (LAS 35917). The CE method allowed the quantification of the impurities at levels of 0.04–0.08% of the parent drug, while HPLC failed to resolve the impurities [196].

MEKC and MEEKC have the unique capability to separate both charged and neutral substances and have been employed for the quantification of a number of pharmaceutical compounds and related impurities. A MEKC method was developed and validated for the determination of didanosine, an anti-HIV treatment, which was separated from 13 of its potential impurities [197]. A simple, fast, and selective MEKC method was used for the determination of ketorolac tromethamine and its known impurities in 6 min and gave a quantification limit of 0.1% for impurities [198]. MEEKC is similar to MEKC in its ability to separate and quantify charged and neutral compounds (see Sections 3.3 and 3.4) and has been used to a lesser extent for impurity studies than MEKC, mainly due to the relatively recent introduction of this mode of CE. Future impurity profiling should see an increased utilization of MEEKC methodology. Further to the determination of ketorolac and its impurities using MEKC, Furlanetto et al. [199] used a mixture design in the optimization of a MEEKC method for the same analysis, complete resolution of the analytes was obtained in 3 min. Wen et al. [200] utilized MEEKC to simultaneously separate 17 species of heroin, amphetamine, and their basic impurities and adulterants in under 10 min. Readers are referred to a review by Hilhorst et al. [204] covering impurity profiling of drugs by CE. Some application-based papers will also provide the reader with more information on profiling by CE-MS [201,202] and CE-LIFD [203] (see also Table 4.4).

#### 4.6.4 PHYSICOCHEMICAL PROFILING

During the early phase and later phase of drug development, knowledge of physicochemical properties of pharmaceutical compounds is important in order to predict their bioavailability and blood-brain barrier distribution to help in formulation design and drug delivery. Physicochemical properties such as acid dissociation constant ( $pK_a$ ), octanol–water partition-coefficient ( $\log P_{ow}$ ), solubility, permeability, and protein binding are closely related to drug absorption, distribution, metabolism, and excretion. About 30% of drug candidate molecules are rejected due to pharmacokinetic-related failures [220]. When poor pharmaceutical properties are discovered in development, the costs of bringing a potent but poorly absorbable molecule to a product stage can become very high. Fast and reliable *in vitro* prediction strategies are needed to filter out problematic molecules at the earliest stages of discovery. In drug discovery, there can be a vast number of compounds requiring physicochemical screening mainly because of the high volumes of syntheses that can be carried out by combinatorial chemistry. Consequently, there is a need for rapid and reliable methods of physicochemical profiling to maintain high throughput and efficiency. CE is a simple, versatile, automated, and powerful separation technique and widely applied in physicochemical profiling for pharmaceuticals. It has advantages over traditional potentiometric, spectrophotometric, chromatographic, and other methods, as CE requires very small amounts of sample and can measure compounds with impurities and low aqueous solubility. The advent of multiplexed CE instruments for physicochemical measurements can allow for the simultaneous analysis of up to 96 separate compounds using just

**TABLE 4.4**  
**Pharmaceutical Impurity Applications**

Application	Buffer	Mode	References
Heroin and its basic impurities	100 mM DM- $\beta$ -CD in Celixir reagent B (pH 2.5); 100 mM HP- $\beta$ -CD in Celixir reagent B (pH 2.5); 103.2 mM SDS, 50 mM phosphate–borate (pH 6.5)	FSCE	[188]
Separation of penicillin V and its impurities	SDS 20.0 g/L (69 mM) and pentanesulfonic acid sodium salt 2.2 g/L adjusted to pH 6.3	MEKC	[209]
Ranitidine hydrochloride and related substances	190 mM trisodium citrate (pH 2.6)	FSCE	[194]
Aminopyridines and related substances	50 mM phosphate buffer (pH 2.5)	FSCE	[210]
Homotaurine as an impurity in calcium acamprostate	40 mM borate (pH 9.2)	FSCE	[195]
New substance (LAS 35917)	60 mM tetraborate (pH 9.2)	FSCE	[196]
5-Aminosalicylic acid and its major impurities	120 mM CAPS buffer (pH 10.2), 65 mM SDS, 55 mM TBAB, 5% MeOH	MEKC	[211]
Ketorolac tromethamine and its known related impurities	13 mM boric acid, phosphoric acid (pH 9.1) with 1 M sodium hydroxide, 73 mM (SDS), 90.0% 10 mM borate, 2.0% <i>n</i> -heptane, 8.0% SDS/ <i>n</i> -butanol in 1:2 ratio	MEKC MEEKC	[198,199]
Vancomycin and related impurities	120 mM Tris-phosphate buffer (pH 5.2) containing 50 mM CTAC	MEKC	[212]
Ximelagatran thrombin inhibitor and related substances in drug substance and tablet formulation	Phosphate buffer (pH 1.9), 22% (v/v) MeCN, 11 mM hydroxypropyl $\beta$ -CD	FSCE	[213]
Penicillin and related impurities	20 mM ammonium acetate (pH 6.5) In aqueous and nonaqueous electrolyte	FSCE and NACE	[214]
<i>N</i> -acetylcysteine and its impurities	100 mM borate (pH 8.40)	FSCE	[215]
Ciprofloxacin and its impurities	Phosphate buffer (pH 6.0), 0.075 M pentane–1-sulfonic acid Na salt	FSCE	[216]
Metacycline and its related substances	160 mM sodium carbonate + 1 mM EDTA (pH 10.35), 13% v/v MeOH	FSCE	[217]
Loratadine and related impurities	100 mM H <sub>3</sub> PO <sub>4</sub> (pH 2.5), 10% acetonitrile	FSCE	[218]
Rofecoxib and photodegradation impurities	25 mM borate, 15 mM SDS, 10% acetonitrile	MEKC	[219]
Galantamine impurities by CE-MS	50:25:25 (v/v/v) 100 mM ammonium acetate/acetonitrile/methanol	CE-MS	[202]

*Abbreviations:* CAPS, 3-(Cyclohexylamino)-1-propanesulfonic acid; CTAC, cetyltrimethylammonium chloride; EDTA, ethylenediaminetetraacetic acid; TBAB, tetrabutylammonium bromide.

one instrument [76–79], which can offer huge savings in time costs compared to the more traditional methods mentioned previously. In a review paper by Jia [221], the principles and applications of CE in profiling various physicochemical properties are covered.

Of the physicochemical properties mentioned previously in this section, only capillary electrophoretic measurements of  $pK_a$  and  $\log P_{ow}$  values will be covered here as they have received the most attention in physicochemical profiling by CE.

**FIGURE 4.6** Dependence of the effective mobilities of a monovalent compound (LY334370) on pH. Arrow indicates the pH equal to the  $pK_a$ . (From Caliaro G.A., Herbots C.A., *J. Pharm. Biomed. Anal.*, 26, 427–434, 2001.)

#### 4.6.4.1 $pK_a$ Measurements

The majority of pharmaceutical compounds are either acidic or basic and are therefore ionizable. Other physicochemical properties, such as lipophilicity and solubility, are  $pK_a$  dependent; therefore,  $pK_a$  is one of the fundamental parameters of a drug molecule. The  $pK_a$  determination of acids and bases by CE is based on measuring the electrophoretic mobility of charged species associated with the acid–base equilibria as a function of pH. The detailed theory of  $pK_a$  and  $\log P_{ow}$  measurements is beyond the scope of this chapter and readers are referred to a review by Jia [221], which describes in more detail the theoretical aspects of physicochemical profiling by CE methods including FSCE, NACE, MEKC, and MEEKC.

The  $pK_a$  values of pharmaceutical compounds can be determined from migration time data obtained by running the compound with free solution CE electrolytes at a range of pH values. The mobility of the solute at each pH can be calculated from its migration time and the EOF (measured against a neutral marker such as methanol), and a plot of mobility versus pH can be constructed (see Figure 4.6). The  $pK_a$  value can be calculated mathematically or obtained from the plot.

The  $pK_a$  values of water-insoluble and sparingly soluble compounds can be determined by NACE using methanol as the background electrolyte [48], or a 50% methanol/water electrolyte as used by de Nogales et al. [226] for the measurements of acid dissociation constants of several hydrophobic drugs. The most common method for  $pK_a$  measurements, however, is FSCE (see Table 4.5).

CE instruments are highly automated and can be used for high-throughput applications, particularly with the use of capillary array instruments. CE compares favorably to other methods of  $pK_a$  measurements [48] and unlike titration methods, precise information of sample concentration is not required as only analyte mobilities are used to calculate dissociation constants by CE. Sparingly soluble compounds are easily analyzed and only very small amounts of material are required, which is useful for screening of newly synthesized compounds where only small quantities may exist or where the molecules are present in only very small amounts. By using a “sample stacking” technique along with pressure assistance and short-end injection for rapid analysis, Wan et al. [224] were able to successfully measure the  $pK_a$  values of pharmaceutical compounds with concentrations as low as  $2 \mu\text{M}$ . Techniques commonly used for  $pK_a$  measurement such as potentiometric or UV-Vis spectroscopy do not differentiate between the analyte of interest and any other degradant or impurity present, which can cause problems if the analyte is not highly pure or unstable in solution. Because CE is a separating technique, it can measure the  $pK_a$  values of impure or unstable compounds where electrolyte purity is not essential. This was demonstrated by Ornskov et al. [225] where a CE method of  $pK_a$  measurement was used successfully for a set of labile drug compounds that were unstable in solution. Determining the EOF intensity during  $pK_a$  measurements may be time consuming,

**TABLE 4.5**  
**Selected CE Applications for  $pK_a$  Measurements**

Application	Buffer	References
$pK_a^*$ values of 21 basic drugs with aliphatic or aromatic amino groups	pH* range 4.9–9.7 Methanol and sodium acetate buffer + acetic acid	[48]
Medium-throughput $pK_a$ of 48 pharmaceutical compounds—acidic, basic, and multivalent	pH range 2.5–11.0 Electrolytes of 0.1 M ionic strength composed of phosphate, acetate, and borate buffers adjusted to required pH with phosphoric, acetic, or boric acid or NaOH Pressure-assisted CE at 2 psi	[227]
Rapid $pK_a$ screening of 26 acidic, basic, and multivalent pharmaceuticals	pH range 2.5–11.0 Electrolytes of 0.05 M ionic strength composed of 0.5 M phosphate and 1 M acetate buffers mixed to obtain required pH PACE at 25 mbar, “short-end” injection	[224]
$pK_a$ determination of labile drug compounds	PH range 2.0–12.0 Electrolytes of 0.05 M ionic strength composed of 1 M phosphate, 0.1 M borate, and 1 M acetate buffers mixed and adjusted with phosphoric acid, acetic acid, and NaOH to obtain required pH “Short-end” injection	[225]
2-Amino-2-oxazolines (antihypertensive agents)	pH 4.77–9.69	[228]
Cephalosporins (antibiotics)	pH 2.0–9.0	[229]
$pK_a$ determination of $^{99m}$ Technetium radiopharmaceuticals	pH range 1.3–6.6 50 mbar PACE Citric acid adjusted with NaOH	[230]
Dissociation constants of anthrocyclines (antibiotics)	Phosphoric acid, disodium phosphate, and monosodium phosphate (pH 4.20–8.20)	[231]
Dissociation constants of cytokinins (phytohormones)	Phosphate and acetate buffers of ionic strength 0.015 M (pH 1.5–6.0)	[232]
Determination of $pK_a$ values Dihydrofolate reductase inhibitors	pH 2.1–4.5 50 mM phosphate buffer adjusted with phosphoric acid/NaOH	[233]
Quinolones (antibacterial)	pH 2.0–11.0	[234]
Dissociation constants of amino- and guanidinopurine nucleotide analogs and related compounds by CZE	pH 3.50–11.25, ionic strength (25 mM)	[235]
Determination of $pK_a$ values with dynamically coated capillaries	Dynamic capillary coating	[236]
$pK_a$ of organic bases in aq. acetonitrile (0–70%, v/v)	pH range 4.76–9.5 Tris, ethanolamine and acetate buffers	[237]
$pK_a$ of <i>N</i> -imidazole derivative aromatase inhibitors	pH range 3.88–9.16 25 mM phosphate buffer adjusted with triethylamine	[238]

especially at a low pH. Geiser et al. [236] overcame this drawback by using a dynamic capillary coating procedure to increase the EOF and thus to reduce the analysis time. In addition, this coating procedure enhanced migration time stability. Table 4.5 lists selected recent applications of CE to the measurement of dissociation constants.

#### 4.6.4.2 Log $P_{ow}$ Measurements

Hydrophobic interaction (or liquid–liquid partitioning) of pharmaceutical compounds in the body plays a significant role in partitioning of drugs into lipid bilayers of biomembranes, bioavailability, and pharmacokinetics. As with  $pK_a$  values, liquid–liquid partition coefficient measurements are extremely important during drug discovery, screening, and formulation processes. Solute hydrophobicity is usually expressed by the octanol–water partition coefficient ( $\log P_{ow}$ ) that is defined as the ratio of the concentrations of a species in the two phases at equilibrium. A number of methods to measure  $\log P_{ow}$  are available including the shake flask method, potentiometric titration, and liquid chromatographic separation methods [241] and extensive data collections of  $\log P_{ow}$  values can be found in literature [239,240]. CE techniques using pseudostationary phases in the background electrolyte, that is, MEKC and MEEKC, allow the measurement of  $\log P_{ow}$  values because of the partitioning of solutes between the MEKC micelle and microemulsion droplet (MEEKC). Early work using MEKC showed that the extent of solutes partitioning with micelles was related to the solutes solubility [242,243], the rise in popularity of MEEKC, however, demonstrated its applicability to a wider range of solutes and this technique has been used extensively in  $\log P_{ow}$  measurements. Examples of using MEEKC for  $\log P_{ow}$  measurements are cited [78,244,245]. MEEKC review papers by Hansen [62], Marsh et al. [63], and Huie [64] comprehensively cover the many applications in this area of physicochemical profiling.

Using MEEKC, the compounds solubility is assessed by bracketing it with neutral marker compounds of known  $\log P_{ow}$  values, which are used to create a calibration graph of  $\log P_{ow}$  against time or  $\log k$  (log of the retention factor) (see Figure 4.7). The  $\log P_{ow}$  of the analyte of interest can be calculated by its migration time or retention factor using the graph. The higher the compounds  $\log P_{ow}$  value, the more it partitions into the microemulsion droplet and the longer it takes to migrate. Table 4.6 contains a number of selected CE applications for  $\log P_{ow}$  measurements, the interested reader should consult recent reviews [62–64], which contain a comprehensive collection of all recent physicochemical measurements by CE.

#### 4.6.5 ANALYSIS OF SMALL MOLECULES AND IONS (PHARMACEUTICAL)

The separation and detection of small organic and inorganic ions is an important activity in the pharmaceutical industry. CE is routinely used for ion analysis in the pharmaceutical industry for a number of applications, these include counterion determination, stoichiometry, salts, and excipients in drug formulations. Most pharmaceutical molecules are charged and are commonly manufactured

**FIGURE 4.7** Plot of  $\log P$  against the retention factor ( $\log k$ ) from MEEKC on a dynamically coated capillary column for compounds of varied structure. (From Poole S.K., et al., *J. Chromatogr. B*, 793, 265–274, 2003.)

**TABLE 4.6**  
**Selected Log *P* Measurements Using MEKC and MEEKC**

Application	Buffer	Mode	References
Neutral and weakly acidic compounds using dynamically coated capillary columns	SDS (1.4% w/v), <i>n</i> -butanol (8% v/v) and <i>n</i> -heptane (1.2% v/v) in 90 mL acidic buffer	MEEKC	[246]
Determination of octanol–water partition coefficients of 80 pesticides	2.16% SDS (w/w), 0.82% heptane (w/w), 6.49% 1-butanol (w/w) in 0.05 M sodium phosphate–0.1 M borate at pH 7	MEEKC	[245]
Estimation of octanol–water partition coefficients of anticancer platinum(II)-complexes	Heptane/SDS/butanol in phosphate buffer at pH 7.4	MEEKC	[247]
Log <i>P</i> <sub>ow</sub> measurement using multiplexed MEEKC	6.61% (w/v) 1-butanol, 0.81% (w/v) <i>n</i> -heptane, 3.31% (w/v) SDS, 800 mL of 68 mM CAPS buffer (pH 10.3)	MEEKC	[248]
Neutral and basic compounds by microchip MEEKC	2% w/v SDS, 1.2% v/v <i>n</i> -heptane, 8% v/v 1-butanol, 50 mM CAPS (pH 10.4)	MEEKC	[249]
Neutral pharmaceuticals	25 mM borate buffer (pH 8.5), 20–150 mM SDS	MEKC	[242]
Neutral pharmaceuticals and steroids	0.05 M phosphate, pH 7 (pH 9 for steroids), 80 mM sodium cholate, 100 mM SDS or 100 mM CTAB	MEKC	[250]
Determination of drug in phospholipids	50 mM phosphate buffer (pH 7.4) containing different concentrations of sodium cholate C (50, 60, 80, 125 mM)	MEKC	[251]

with a counterion, commonly a metal cation for acidic drugs and an ionic salt or small organic acid for basic drugs. During development of a new drug, a range of different counterions may be synthesized to compare pharmaceutical properties such as solubility, stability, and crystallinity of the different salts. The ratio of the drug to counterion is known as the drug stoichiometry and this needs to be characterized analytically. The typical stoichiometry is a 1:1 drug–counterion mixture; however, frequently 2:1 and 1:2 compositions are manufactured depending on the ionic nature of the drug and/or counterion. There is a clear analytical need to quantify drug counterion levels to demonstrate that the correct salt version has been manufactured and that the required stoichiometry can be reliably achieved batch-to-batch when the final drug salt has been selected. The counterion of basic drugs includes inorganics such as sulfate and chloride or organic acids such as maleate, fumarate, acetate, or succinate. Cations analyzed involve a range of metal ions including Na<sup>+</sup>, K<sup>+</sup>, Mg<sup>2+</sup>, Ca<sup>2+</sup>, and simple low molecular weight amines. These analytes possess little or no chromophore, which generally necessitates use of indirect UV detection. However, some larger anionic counterions such as benzoates and simple organic acids can possess sufficient UV activity to allow direct UV detection. Alternatively, metal ions may be complexed “on capillary” to form metal chelates that can then be detected by direct UV measurement. Alternative detection methods such as conductivity detection have also been used [268] to detect potassium counterion and other inorganic cationic impurities in pharmaceutical drug substances.

Popular techniques for the analysis of small ions include ion-exchange chromatography and flame atomic absorption spectrometry but CE is becoming more popular for such applications due to its simplicity and speed of method development and analysis, elimination of the need for specialized columns, high resolving power, and simple sample treatment steps (typically, the sample just needs to be diluted in the background electrolyte and injected onto the capillary). Commercial ion analysis

**FIGURE 4.8** Electropherogram of 20 common amino acids. 50 mM Ethanesulfonic acid, pH 2.8; applied voltage, 30 kV; injection time, 10 s. Peaks: 1 = Lys; 2 = Arg; 3 = His; 4 = Gly; 5 = Ala; 6 = Val; 7 = Ser; 8 = Ile; 9 = Leu; 10 = Thr; 11 = Asn; 12 = Met; 13 = Gln; 14 = Trp; 15 = Glu; 16 = Phe; 17 = Pro; 18 = Tyr; 19 = Cys. (From Fritz J.S., *J. Chromatogr. A*, 884, 261–275, 2000.)

kits are available that contain predefined method conditions, reagents and buffers that simplify method development and allow analysis times of 2–10 min, comparing favorably to ion-exchange chromatography methods.

Pharmaceutical excipients such as SDS or alginic acid can be analyzed as raw materials or when present in formulations [263]. Kelly et al. [252] developed a reliable quantitative CE method for the determination of SDS in a cefuroxime axetil pharmaceutical preparation. Separation of amino acids can be troublesome and complicated using HPLC methods as they first need to be derivatized to provide a chromophore for detection. Performing these separations using CE and low pH electrolytes, however, can be relatively simplistic as lower detection wavelengths of 185 nm can be used to detect zwitterionic amino acids, which become cations at low pH. A background electrolyte of 50 mM ethanesulfonic acid (pH 2.8) was used to resolve a number of amino acids, which were detected at 185 nm without any sample pretreatment [253], as shown in Figure 4.8.

Simple organic acids often possess chromophores, which makes direct UV detection possible, even at low wavelengths. CE can measure the presence of small ion contaminant impurities in drug substances. For example, an NACE method with indirect UV detection was used to monitor ammonium ion contaminant in pharmaceutical preparations with a limit of detection of 50 ppb [254]. A number of reviews have been published that will provide the reader with a comprehensive coverage of the status of CE for the analysis of ions and small molecules, including detection methods, quantification, and stoichiometric determinations [8,9,11,253,255,256]. Table 4.7 shows some recent analysis applications of CE for ion analysis.

## 4.7 METHOD DEVELOPMENT AND VALIDATION

As with any other analytical technique developing a CE method involves some basic steps. As a general guide to method development, the following items should be considered: the objectives of the intended separation, instrumental requirements, sample characteristics, sample pretreatment, data handling, and reporting. The objectives may be straightforward and require the detection and quantification of a single charged compound of which there is much information available and separation can be achieved using simple aqueous buffers. They may be more complex and require the separation, identification, and quantification of a number of charged and neutral components,

**TABLE 4.7**  
**Selected CE Applications for the Analysis of Small Molecules and Ions**  
**(Pharmaceutical)**

Application	Electrolyte	References
<i>Anions—indirect detection</i>		
SDS levels in tablets	3–10 mM barbital buffer, pH ~9	[252]
Determination of Br, Cl, and SO <sub>4</sub> as impurities in calcium acamprosate	10 mM potassium chromate + 1 mM borate, pH 9.15	[257]
Acetate counterion in an antifungal lipopeptide	4.0 mM 4-hydroxybenzoic acid, myristyltrimethylammonium bromide, as an EOF modifier	[258]
Sodium acetate in antisense oligonucleotides	Phthalate, myristyltrimethylammonium bromide type EOF modifier	[259]
Drug inorganic counter ion determination	Chromate, tetradecyltrimethylammoniumbromide (TTAB)	[260]
Drug organic acid counter ion determination	Phthalate, 4-morpholineethanesulfonic acid (MES), tetradecyltrimethylammoniumbromide (TTAB)	[261]
Anion screening for drugs and intermediates	Chromate, myristyltrimethylammonium bromide type EOF modifier	[262]
<i>Anions—direct detection</i>		
Quantitative determination of alginic acid in pharmaceutical formulations	12.5 mM borate/boric acid buffer (pH 8.3)	[263]
Determination of residual Br in excess of chloride for local anaesthetic analysis	60:40 MeCN:methanesulfonic acid buffer (pH 1.3)	[264]
Arginine counterion determination for ragaglitazone	10:90 ACN:(2% SB-β-CD and 0.7% DM-β-CD in 25 mM phosphate buffer, pH 8.0)	[172]
<i>Cations—indirect detection</i>		
Ammonium ion impurities	NACE method, imidazole	[254]
Ca, Li, K, and Na counterions of glycosaminoglycans	4-Aminopyridine buffer (pH 9)	[265]
Ca in calcium acamprosate drug substance	10 mM imidazole containing 1 mM tetrabutylammonium sulfate (pH 4.5)	[266]
Sodium in drug substance	Imidazole, formic acid	[267]
Quarternary amine residues in drug substance	Quinine, THF	[267]
Piperazine in pharmaceutical drug substances	50 mM benzylamine (pH 8.7)	[269]
<i>Cations—direct detection</i>		
K counterion and inorganic cationic impurities of pharmaceutical drug substances by conductivity detection	30 mM creatinine, 30 mM acetic acid, 4.5 mM 18-Crown-6	[268]

which may be only possible using MEKC or MEEKC. The compound of interest may be present in a number of isomeric forms, which requires chiral selectors added to the background electrolyte or may be present in trace quantities as degradation products or impurities, which require separation and quantification with high sensitivity. Other items to be considered when deciding the objectives are as follows: do all of the sample components need to be separated/quantified/identified and what

is the sample matrix. Identifying these goals helps to determine the instrumental requirements. For example, if qualitative analysis is required then a DAD or MS detector will be required. To achieve lower limits of detection, LIFD or UV sensitivity enhancement techniques may be used. The characteristics of the sample and sample matrix are helpful in selecting the mode of CE. If the sample and/or sample matrix is water insoluble, then NACE, MEEKC may be the CE mode of choice. Data handling depends on the type of the intended analysis, quantitative or qualitative and whether internal or external standardization is used for quantification. If the analyst possesses enough knowledge and experience of CE separations, he/she may be able to decide on initial CE conditions and optimize the separation from there. This, however, is not always the case particularly as the in-depth knowledge and experience of pharmaceutical analysis by CE is not as widely established as it is for other separation methods such as HPLC, TLC, and GC. Once the analyst identifies the separation objectives, a literature search of published reports to find sources of developed and/or validated methods for the same or similar separations should be carried out. A variety of literature sources are available. Sources of reviews and publications for each application area, CE mode and detection method described in this chapter are cited toward the end of each individual section to direct the reader to relevant literature sources. A number of tables of selected applications are also presented. Lunn [13] provides detailed method information for several hundred applications. In addition to searching published application literature, a number of commercial CE instrument and consumable manufacturers and suppliers offer generic and sample methods for a range of applications. Beckman Coulter, for example, has published a generic method development strategy for chiral CE, previously published in *LCGC Europe* [283].

Developing a method involves selecting and optimizing a number of variables

- *Mode of CE*: as discussed previously the mode of CE must suit the separation.
- *Capillary*: fused-silica capillaries are the standard type used. Capillary length will affect the speed of separations. Small internal diameter capillaries allow higher electric field strengths to be applied resulting in more efficient separations. Typically, capillaries of 50  $\mu\text{m}$  inner diameter and 0.5–1 m in length are used.
- *Capillary conditions*: these are affected by the capillary pretreatment reagents (e.g., NaOH) or dynamic capillary coating systems to achieve better reproducibility.
- Applied voltage and operating current.
- Injection mode and volume.
- Capillary temperature.
- *Detector*: as discussed previously, the detector type is governed by quantitative/qualitative and suitability requirements.
- *Buffer composition*: this is one of the most important variables to consider, as the type of compounds to be analyzed will dictate the pH, polarity, concentration, additives, and so on of the buffer.

A number of books and reviews provide a more detailed insight and coverage of the operating parameters of CE and their effects in method development, such as those mentioned above. This chapter does not have the scope to cover these in detail and readers are encouraged to consult the publications [13,14,34–37].

If there are no previous published methods for a particular pharmaceutical compound or class of compound then evaluation of some of the properties and functionalities must be considered to determine the initial method conditions. If  $\text{pK}_a$  data are available for the solute of interest and other species that need to be resolved then an appropriate electrolyte pH can be selected. If the compound is present as a racemic mixture then selection of an appropriate chiral selector can be made based on the compounds functional groups and other chiral separation applications. For basic compounds, a 50 mM phosphate ( $\text{Na}_2\text{HPO}_4$ ) buffer adjusted to pH 2.5 with phosphoric acid, in a standard capillary with an applied voltage of +20 kV and UV detection at 200 nm is a good starting point.

Samples should be dissolved in an appropriate solvent at a concentration of  $\sim 1 \text{ mg ml}^{-1}$ . This set of operating conditions is appropriate for a wide range of basic compounds. Additional optimization can be achieved using additives such as CDs, ion-pairing reagents, and organic solvents.

For the separation of acidic compounds, the buffer can be replaced with a 15 mM borate solution with a natural pH  $\sim 9.3$ . The same operating parameters as those used for the separation of basic compounds can be used to separate a wide range of acidic drugs and buffer additives similar to those used for basic separations can be used.

For the separation of neutral compounds using MEKC, 15 mM  $\text{Na}_2\text{HPO}_4$  containing 50 mM SDS as the micellar electrolyte can be employed. Using different surfactants such as bile salts can help if the solutes are particularly water insoluble. Optimization can be carried out by adjusting the surfactant concentration and type, adding organic solvents, ion-pairing reagents, CDs, and so forth. Reviews by Pappas et al. [52], Molina and Silva [53], and Pyell [54] discuss MEKC operating parameters and applications in detail.

MEEKC offers more selectivity options than MEKC and can be used to separate a wider range of solutes. Owing to the composition of the microemulsion electrolytes, MEEKC can be used for more complex separations of water-soluble, water-insoluble, charged and neutral compounds, particularly where water-insoluble matrices are involved. A standard O/W microemulsion composed of 3.3% SDS, 0.8% octane, 6.6% butanol in 10 mM borate with fused-silica capillaries are used for most applications and this is a good starting point for any intended MEEKC separation. With a range of buffer additives available such as organic modifiers, CDs, ion-pairing reagents along with the various microemulsion parameters, MEEKC offers a wider selection of optimization choices than any other form of CE for pharmaceutical analysis. The background theory and operating parameters of MEEKC have been reviewed by Altria [58,270,271] and Klampfl [272], which detail the effects of each microemulsion and instrument variable on separation selectivity.

#### 4.7.1 METHOD OPTIMIZATION USING EXPERIMENTAL DESIGN

Although the approach to CE method development is similar to HPLC methods, the number of variables involved can sometimes make the optimization of separation conditions a difficult task. This is particularly true when dealing with MEKC and MEEKC where pH, nature, and concentration of the surfactant, buffer, and organic modifiers combined with instrument variables such as applied voltage, temperature, and injection volume all have a great influence on solute separation. Ideally, a method should be optimized to find the best separation conditions in as short a time as possible with the minimum number of experiments. Statistical experimental design is a powerful tool to quantify the effect of one or more variables on a set of measured responses. It provides a methodological framework for changing operating parameters simultaneously by the help of experimental designs. These approaches involve the smallest possible number of useful experiments and provide maximum information. The use of experimental design strategies for CE methods involving univariate (studying one factor at a time) and multivariate (studying multiple factors simultaneously) techniques has evolved as a rapid method development and optimization option. Multivariate techniques are probably the least time consuming and are recommended. Multivariate (chemometric) experimental designs have been reviewed by Altria et al. [273] and Sentellas and Saurina [274,275]. Veuthey and Rudaz [276] have also covered the use of statistical and chemometric tools for pharmaceutical analysis. The use of artificial neural networks (ANNs) in separation science has also been reviewed [277]. Pyell [51] includes a detailed chapter containing many examples of experimental work (MEKC and MEEKC) using experimental design.

#### 4.7.2 METHOD VALIDATION GUIDELINES FOR PHARMACEUTICAL APPLICATIONS

Validation of pharmaceutical CE methods requires similar considerations to those examined during HPLC validation procedures. A useful guide for method validation in analytical chemistry is the

Eurachem guide [285], which discusses when, why, and how methods should be validated. However, for the pharmaceutical industry, the main reference source is the *ICH Guidelines* [286], which provides recommendations on the various characteristics to be tested for the most common types of analytical procedures developed in a pharmaceutical laboratory. The main characteristics of any analytical method to be tested are specificity, linearity, accuracy, precision, solution stability, limits of detection and quantification, and robustness. Specific aspects should be considered for a CE method including method transfer between instrument manufacturers, reagent purity and source, electrolyte stability, capillary treatment and variations in new capillaries, and buffer depletion. Fabre and Altria [284] discuss CE method validation in more detail and include a number of examples of validated CE methods for pharmaceutical analysis. Included in Table 4.3 are a number of validated pharmaceutical assay methods.

## 4.8 COMPARISON OF HPLC, GC, AND CE FOR PHARMACEUTICAL ANALYSIS

As HPLC is the most widely used pharmaceutical analysis technique among current chromatographic methods, a short comparison of HPLC and CE should be very informative to the reader. Some comparisons will also be made to GC. This section will illustrate the advantages, disadvantages, and complementary natures of HPLC and CE.

The range of CE applications in pharmaceutical analysis is at least as extensive as that of HPLC. Adopting CE testing provides several distinct advantages, including faster analysis and method development, lower consumable expenses, and easier operation. All of these factors are important in pharmaceutical separations where high throughput is becoming ever important. The disadvantages of CE are not to be forgotten; they include poorer injection precision (hence the need to incorporate internal standards) and the limited number of staff members who are trained and experienced in using CE compared with the number who are competent with HPLC. The highly complementary nature of the two techniques is a valuable tool for the pharmaceutical analyst where “cross-validation” using the two methods can give a high degree of confidence in results.

### 4.8.1 EFFICIENCY

As solute peaks in HPLC and GC chromatograms are integrated and measured in the same way as peaks in CE electropherograms, direct comparisons of peak efficiency for each method is possible. Typical CE capillary dimensions are 30–100 cm long (although when using “short-end injection” the effective length can be reduced further) with internal diameters of between 50 and 100  $\mu\text{m}$  and can generate  $\sim 400,000$  theoretical plates, compared to  $\sim 150,000$  plates for a typical wall coated open tubular GC column 0.18 mm internal diameter and 20 m long. HPLC, however, can generate at best 30,000 plates for a typical 150 mm C18 column. The main reason for the higher efficiency possible in CE compared to HPLC is that the solutes move through the column with a “plug” or flat flow profile, while they move through HPLC columns with a “laminar flow” profile. The other reasons for higher plate numbers in CE are the absence of multipath and longitudinal diffusion and slow equilibration of the solute in the capillary. Turbulent flow, often associated with GC columns, is also absent from CE capillaries due to the electrodriven nature of the EOF.

### 4.8.2 SAMPLE TYPES

Similar to HPLC, CE is well suited for the analysis of both polar and nonpolar compounds but unlike HPLC columns, the same capillary can be used for most CE applications, that is, chiral separations, small ions, and so forth. Sample preparation for CE analyses is straightforward and usually requires sample dissolution in the buffer or water, sometimes with the addition of a small volume of organic

solvent to help dissolve the solute. CE buffers can be used over a wider pH range than HPLC mobile phases, as most HPLC columns can only be used within a specified pH limits without damaging the column.

### 4.8.3 SAMPLE VOLUME

Relatively small sample volumes are required for CE analyses compared to HPLC and GC, only a few nanoliters are injected compared to microliters used in GC and HPLC. This is due to the small volumes of the capillaries, typically 0.98  $\mu\text{l}$  for a 50 cm  $\times$  50  $\mu\text{m}$  ID capillary. This is advantageous when only limited amounts of the sample is available.

### 4.8.4 SENSITIVITY

As mentioned in Section 4, detection limits in CE are generally poorer than HPLC or GC due to the narrow detection path length for UV/Vis detection and the nanoliter injection volumes. Various approaches to improve CE sensitivity such as the use of LIFD detectors, low wavelength detection, and so forth have been covered in Section 4.4. Some comparisons of CE and HPLC sensitivity for pharmaceutical analysis are illustrated in Table 4.8.

### 4.8.5 PRECISION

Because of the small injection volumes used in CE, peak area reproducibility is poorer than HPLC. The use of high sample concentrations and internal standards makes CE precision values more comparable to HPLC. The precision of solute migration times can also suffer because of variations within the capillary between injections, affecting the EOF. This can be alleviated by careful preparation of buffers and samples and the use of dynamic capillary coating systems.

**TABLE 4.8**  
**Comparisons of Recent HPLC and CE Applications**

Application	Method	Analysis Time	LOD	Precision RSD%	References
Determination of four parabens in cosmetics	HPLC	21 min	0.02–0.05	0.41–1.14	[279]
	CE	16 min	$\mu\text{g ml}^{-1}$ 0.16–0.21 $\mu\text{g ml}^{-1}$	0.77–2.17	
Determination of glycyrrhizic acid in pharmaceutical preparations	HPLC	7 min	n/a	0.9–1.7	[287]
	CE	15.5 min	n/a	3.2–4.0	
Stereoselective analysis of carvedilol in serum	HPLC	27 min	1 ng ml <sup>-1</sup>	n/a	[280]
	CE	15 min	50 ng ml <sup>-1</sup>	n/a	
Determination of ketoconazole in drug formulations	HPLC	3 min	HPLC = 2.5 times	1.91	[281]
	CE	5 min	less than CE	2.95	
Determination of diazepam in pharmaceutical tablets	HPLC	4.9 min	1.44 $\mu\text{g ml}^{-1}$	0.98	[282]
	CE	4.1 min	4.24 $\mu\text{g ml}^{-1}$	1.62	

#### 4.8.6 ANALYSIS TIMES

Typical analysis times for both HPLC and CE are between 5 and 30 min. With CE, however, a number of options are available to shorten analysis times; pressure-assisted CE where an external pressure is applied to the capillary in conjunction with the EOF helps speed up separations. Short-end injection, where the sample is introduced into the detector end of the capillary can also reduce analysis times, these methods were demonstrated by Mahuzier et al. [278]. A shorter capillary can also be used to achieve shorter analysis times. As discussed in Section 4.3.6, the use of multiplexed or capillary array CE instruments can provide the pharmaceutical laboratory with the capability to conduct multiple analyses simultaneously, offering a significant advantage in terms of time and cost savings. This is particularly advantageous where the screening of large numbers of new pharmaceutical compounds is required due to combinatorial organic synthesis in drug discovery.

#### 4.8.7 REAGENTS AND CONSUMABLES

This area provides CE with many advantages over HPLC methods for a number of reasons. Owing to the applicability of the same CE instrumentation and capillaries to a wide range of applications only the buffer composition needs to be changed, whereas a variety of normal and reversed-phase, chiral and ion-exchange, and so forth HPLC columns are available with a wide range of packing material for different classes of compounds and separations. CE capillaries are also only a fraction of the cost of HPLC columns, particularly chiral columns, which can cost in excess of 1200, a standard fused-silica capillary that costs a few euro can be used with milligrams of a chiral selector to perform the same separation. Relatively small amounts of buffers and reagents are used in CE, milliliters compared to liters for HPLC mobile phases. This offers significant cost savings for both the purchase and disposal of expensive chemicals.

As discussed in Section 4.3.6, the use of multiplexed CE instruments can provide the pharmaceutical laboratory with the capability to conduct multiple analyses simultaneously, offering a significant advantage in terms of time and cost savings.

### 4.9 CONCLUSIONS

Capillary electrophoresis has been shown as a suitable analytical method for a wide range of pharmaceutical applications, indeed for principal applications such as pharmaceutical assay, physicochemical measurements, and chiral analysis CE can be superior to HPLC in terms of speed and range of method development options, cost efficiency, speed of analysis, ease of use, selectivity, peak efficiency, and the possibility of implementation of a single set of method conditions for the analysis of several different samples. The various advantages of CE have been highlighted which include low cost of consumables, speed of analysis, the use of standard instruments and capillaries for most applications, high-throughput analysis using capillary array instruments, superior efficiency, and low wavelength detection. The main disadvantages of CE are its poor sensitivity due to the narrow detection path length using UV/Vis detection methods and poor injection precision. Measures to improve detection limits include more sensitive detection methods such as LIFD, while CE-MS offers the possibility of highly sensitive qualitative analysis. Quantitative methods such as the use of internal standards serve to improve injection precision to levels approaching that of HPLC.

The various modes of CE available for pharmaceutical analysis means that effectively all types of drug compounds can be separated using standard instrumentation, that is, charged, neutral, polar and nonpolar, large and small molecules, and counterions. MEKC and MEEKC have been shown to be particularly suitable for the separation of complex mixtures of both charged and neutral compounds, in particular MEEKC, which can be applied to a wider range of solutes of a broadly varying water solubility using both W/O and O/W microemulsions as the carrier electrolyte.

The range of pharmaceutical applications of CE is very extensive with hundreds of reports published and this chapter only serves to give a brief introduction to each application area with tabulated examples of proven methods. Many validated methods are cited which indicate the usefulness of CE in the analytical laboratory, indeed the use of CE in pharmaceutical laboratories is now very widespread and regulatory authorities have begun to accept CE for a number of new drug product submissions. CE identification tests in general monographs for drug substances have been included in the British and European Pharmacopoeia.

CE is regularly used to provide complementary information to HPLC or other methods as well as being a technique of choice for certain applications. As further research is carried out and the use of CE becomes more widespread in pharmaceutical laboratories, the use of CE is certain to become more popular and possibly take over from traditional analytical methods such as HPLC and titrimetric techniques for routine testing of pharmaceuticals.

## 4.10 DEDICATION

To the memory of Johnny McEvoy, a great man who left us with many great memories.

## 5.1 INTRODUCTION

Capillary electrochromatography (CEC) is a hybrid of capillary electrophoresis (CE) and capillary high-performance liquid chromatography (HPLC). As such, it has been characterized by some as exhibiting the best of both technologies and by others as a composite of the worst attributes of both—the reality lies somewhere between the extremes. Shifting fortunes and interest in CEC are well represented in Figure 5.1, which illustrates a best estimate of the number of publications on the topic over the past decade. What is evident is (1) a boom attributable to the promise of highly efficient liquid phase chromatographic separations and (2) a decline in interest due to practical issues such as the irreproducibility of electroosmotic flow (EOF) (also a factor in the limited market impact of CE)

**FIGURE 5.1** A bar chart showing the number of publications on the topic of CEC per year for the last decade.

and a rediscovery of ultra high pressure liquid chromatography (UPLC). It is possible that there will be a resurgence of interest arising at least in part from the growth of microchip-based separations technology. CEC is a good fit on the microfluidic platform owing to its compatibility with small-pore-size monolithic media and fine particulate packings (due to the lack of backpressure limitations in the absence of pressure-driven bulk flow), its relative independence from mechanical valves and pumps, the inherent ease of miniaturizing electrical and electronic components, and its facility to be interfaced to other chip-based unit operations such as solid phase extraction, filtration, optical spectroscopic detection, and electrochemistry. This chapter describes the basic theoretical concepts and operational principles of CEC. The discussion is intended to provide sufficient background on CEC instrumentation, the principles of CEC operation, and on the range of applications of CEC to equip the reader to employ CEC in the laboratory.

## 5.2 THEORY

Capillary electrochromatography is a hybrid separation method that couples CE with HPLC. It combines the high separation efficiency that capillary zone electrophoresis (CZE) offers with the wide range of parameters that can be manipulated in HPLC, particularly the wide range of stationary phases from which to choose. Subsequently, CEC has become a powerful technique that has gained interest in the last few years.

### 5.2.1 ELECTROSMOTIC FLOW

Capillary electrochromatography utilizes an electric field rather than a pressure gradient to propel the mobile phase through a packed bed. High efficiencies can be achieved in CEC mainly because of the use of EOF. The flow profile of EOF is pluglike, unlike the parabolic flow of pressure-driven HPLC, making for less dispersion and therefore higher efficiency than pressure-driven separations under otherwise identical conditions. Another benefit of EOF is that it generates no pressure drop, thus, small diameter packings (0.5–2  $\mu\text{m}$ ) can be used, thereby further enhancing efficiency. In CEC, separations are generally carried out using aqueous buffers with organic modifiers in fused-silica capillaries of 25–100  $\mu\text{m}$  internal diameter (i.d.) packed with small particles (<5  $\mu\text{m}$ ) in an applied electric field.

**FIGURE 5.2** Flow profiles of EOF and laminar flow.

**FIGURE 5.3** Schematic representation of the electrical double layer at a negatively charged capillary wall.

CEC was first introduced more than 30 years ago (1974) when Pretorius et al. [1] first demonstrated the use of EOF to drive a mobile phase through a liquid chromatography (LC) column. Pretorius used 75–125  $\mu\text{m}$  particles in a 1-mm i.d. glass tube and was able to show that band broadening with EOF was considerably smaller than with pressure-driven flow. In 1981, Jorgenson and Lukacs [2] further proved the principle of electrically driven chromatography using small-diameter particles in fused-silica capillaries. Although the efficiencies were relatively low ( $\sim 60,000$  plates  $\text{m}^{-1}$ ), they were able to separate 9-methylanthracene from perylene on a 170- $\mu\text{m}$  i.d. capillary packed with 10- $\mu\text{m}$  reverse-phase packing material. The work that finally resurrected the interest in CEC, however, was pioneered by Knox and Grant [3] in 1987 and 1991 with their theoretical and practical approach that demonstrated the practical feasibility of CEC.

The stark contrast of EOF to the parabolic laminar flow profile generated by an external pump used in HPLC is shown in Figure 5.2. The flat profile of EOF originates in the evenly distributed charge on the capillary wall, or packing material surface, at which an electrochemical double layer is formed. On application of a longitudinal potential, a shear plane develops and ions, their solvation layer, and adjacent species slip toward the outlet with a uniform velocity cross section. This contrasts with pressure-driven flow, as in HPLC, in which frictional forces at the column walls lead to laminar flow profile. That yields broad peaks due to the dispersive nature of the broad range in flow velocities. With a flat profile, zone broadening is minimized, leading to high separation efficiencies in CEC. The uniform EOF velocity (in channels  $\sim 0.1$  to  $\sim 150$   $\mu\text{m}$  in diameter) is independent of the channel width.

To understand the generation of EOF inside the capillary, Stern's model, as presented in Figure 5.3, is discussed. The inner wall of a fused-silica capillary possesses ionizable silanol groups on the surface. In a buffer filled capillary, these silanol groups dissociate to give the capillary wall a negative charge ( $\text{SiO}^-$ ). This is centered by cations from the buffer solution, giving rise to an

electrical double layer. The layer of ions closest to the surface is called the “Stern layer” and is essentially rigid or immobile. A more diffuse layer is formed distal to the Stern layer and is known as the “Gouy layer.” This mobile layer is rich in cations and decays into the bulk liquid. The double layer is formed at the capillary wall and the surface of the particulate packing material.

The formation of this electrical double layer gives rise to a potential that falls off exponentially as a function of distance from the capillary surface. This zeta potential ( $\zeta$ ) has values ranging from 0 to 100 mV. The distance between the Stern layer and a point in the bulk liquid at which the potential is 0.37 times the potential at the interface between Stern and diffuse layer is defined as the thickness of the double layer ( $\delta$ ).

The equation describing  $\delta$  (the thickness of double layer) g [3] is

$$\delta = [\varepsilon_r \varepsilon_0 RT / 2cF^2]^{1/2}, \quad (5.1)$$

where  $\delta$  is the thickness of double layer,  $\varepsilon_r$  the dielectric constant or relative permittivity of the eluent,  $\varepsilon_0$  the permittivity of a vacuum,  $R$  the universal gas constant,  $T$  the absolute temperature,  $c$  the molar concentration, and  $F$  the Faraday constant.

Solving Equation 5.1, for a monovalent electrolyte at a concentration of 0.001 M in water ( $\varepsilon_r = 80$ ), the thickness of the electrical double layer would be 10 nm, and at a concentration of 0.1 M it would be 1 nm for the eluent/sorbent and eluent/capillary wall interfaces.

The zeta potential (at the shear plane) is dependent on  $\delta$  and the charge density  $\sigma$  [4]

$$\zeta = \frac{\delta \sigma}{\varepsilon_0 \varepsilon_r}. \quad (5.2)$$

The relationship between the EOF linear velocity ( $u_{eo}$ ) and  $\zeta$  is given by the Smoluchowski equation

$$u_{eo} = \frac{\varepsilon_0 \varepsilon_r \zeta E}{\eta}, \quad (5.3)$$

where  $E$  is the electric field strength and  $\eta$  is the viscosity of the solvent.

It is now apparent that the EOF depends upon the surface charge density, the field strength, the thickness of the electrical double layer, and the viscosity of the separation medium, which in turn is dependent upon the temperature. In a packed capillary, the vast majority of the total surface area is contributed by the packing material, thus it is reasonable to approximate the surface charge density of the system (both the capillary wall and the packing) using the value for the sorbent.

When a voltage is applied longitudinally along the capillary, cations in the diffuse (Gouy) layer are free to migrate toward the cathode, carrying the bulk solution with them. The result is a net flow in the direction of the cathode.

A main factor affecting electroosmotic mobility is buffer pH. EOF will be significantly greater at high pH compared to low pH. At high pH (pH > 9), silanols on the capillary surface are completely ionized and thus, EOF mobility is at its greatest. At low pH (pH < 4), however, the ionization of silanols is low and the EOF mobility is nearly insignificant. The ionic strength of the buffer will also affect mobility.

A solute's apparent or effective mobility ( $\mu_x$ ) takes into account both its individual electrophoretic mobility ( $\mu_{ep}$ ) and EOF mobility ( $\mu_{eo}$ ):

$$\mu_x = \mu_{ep} + \mu_{eo}. \quad (5.4)$$

Under “normal” polarity with a fused-silica capillary, samples are introduced at the anode and EOF migrates toward the cathode. In this case, cations have positive  $\mu_{ep}$ , neutrals have zero  $\mu_{ep}$ , and

**FIGURE 5.4** Schematic representation of (a) CZE and (b) CEC inside a capillary column. (From Knox, J.H. and Grant, I.H., *Chromatographia*, 26, 329, 1988. With permission.)

anions have negative  $\mu_{ep}$ . In other words, cations migrate faster than the EOF and anions migrate more slowly than the EOF, whereas neutrals migrate with the same velocity as the EOF. Thus, to determine EOF velocity experimentally, a neutral and chromatographically unretained marker can be injected into the capillary under a given set of conditions. Often, acetone is used as a marker in reversed-phase CEC. By measuring the time that it takes for the neutral unretained marker to reach the detector, EOF can be determined on the basis of the distance traveled.

As discussed above, the origin of EOF is the electrical double layer that exists at the interface of a charged surface in contact with an electrolyte solution, as in the case of CZE (Figure 5.4a). In a capillary packed with silica particles, the surface of both the capillary wall and of the particles are negatively charged owing to the dissociation of silanol groups (Figure 5.4b). Again, the surface areas of silica-based packing materials are much greater than that of the capillary wall, thus most of the EOF is generated by the surface silanol groups of the packing material. When an axial electrical field is applied to the column, ions in the diffuse section of the double layer migrate towards the cathode moving the bulk solution by viscous drag.

Looking back at Equation 5.3, in an open tubular (OT) capillary with thin double layer and in the absence of significant polarization,  $\zeta$  is the zeta potential of the wall  $\zeta_w$ , and is defined as potential on a hypothetical surface of shear close to the tube wall. For porous/nonporous packing particles that are nonconducting,  $\zeta$  is zeta potential at the particle surface  $\zeta_p$ .

For OT fused-silica capillaries, the  $\zeta$  potential has been determined to be between 20 and 120 mV depending on the pH. The potential  $\zeta$  in capillaries made of polymeric materials (i.e., polytetrafluorethylene, polyethylene, or polyvinylchloride) ranges from 0 to 60 mV at pH 6.0 and 10, respectively. The potential  $\zeta$  of C18 derivatized particles can be assumed to be in the same range as that of polymeric materials [5]. Figure 5.5 shows the EOF velocities versus the electric field strength measured for a C18 packing material (CEC Hypersil, C18, 3  $\mu\text{m}$ ). Depending on the surface charge of the packing materials and the pH of the buffer, linear flow rates of as much as 2.5  $\text{mm s}^{-1}$  can be achieved in a 35-cm long column.

### 5.2.2 ZONE BROADENING: CEC VERSUS HPLC

Electroosmotic flow-driven chromatography yields higher separation efficiencies than HPLC because of the use of small particles and reduction of plate heights as a result of the plug-flow profile.

**FIGURE 5.5** Plot of EOF velocity vs. the applied electric strength. Conditions: 250 (335) mM  $\times$  0.1 mM CEC Hypersil C18, 2.5  $\mu$ m, 80% ACN/20% MES 25 mM pH 6, 10 bar pressure applied to both ends of capillary, 20°C. (Reprinted from Landers, J.P, *Handbook of Capillary Electrophoresis*, 2nd ed., CRC Press, FL, 1997, Chapter 5. With permission.)

The linear velocity in a pressure-driven system is given by the following equation described by Knox and Grant [3]:

$$u = \frac{d_p^2 \Delta p}{\Phi \eta L}, \quad (5.5)$$

where  $u$  is the linear velocity,  $d_p$  the particle diameter,  $\Phi$  the flow resistance parameter for packed columns,  $\Delta p$  the pressure drop across the column,  $L$  the column length, and  $\eta$  the viscosity of the solvent.

On the other hand, the linear velocity through a packed capillary under an applied electric field is given by the Smoluchowski equation, as discussed above in Equation 5.3.

By comparing the two Equations 5.3 and 5.5, it can be seen that the linear velocity  $u$  is proportional to  $d_p^2$  in a pressure-driven system while it is independent of the particle diameter in an electrically driven system. Since plate height values are generally lowered as a result of using small diameter particles, it is possible in electrically driven systems to use very small diameter packing materials and still maintain high linear velocities to yield rapid and very efficient separations.

Since electromatography uses a stationary phase just like in conventional LC, the principles of band broadening in CEC and LC are similar. The plate height can be expressed using a modified Van Deemter equation:

$$H = Ad_p \left[ \frac{ud_p}{D_m} \right]^{1/3} + \frac{B}{u} + \frac{Cud_p^2}{D_m}, \quad (5.6)$$

where A, B, and C are constants, and  $D_m$  is the diffusion coefficient.

The A term refers to eddy diffusion that arises from the different flow paths the solute molecules may traverse through the packed bed. Band broadening occurs because molecules in different flow streams are moving at different velocities. Solute molecules move faster (on average) in wider paths than they do in narrow paths. This term is much more significant in a pressure-driven system, where the flow rate varies from one channel to another, while in an electrically driven system like CEC, the contribution of the A term to zone broadening is significantly lower, because of the closely matched velocities between the channels (in the absence of electrochemical double layer overlap). The C term represents the contribution to the plate height resulting from resistance to mass transfer between the mobile phase and the stationary phase. The effect is greater as the mobile phase velocity increases

**FIGURE 5.6** Schematic representation of (a) electroosmotic and (b) pressure-driven flow in a CEC packed column. (From Knox, J.H. and Grant, I.H., *Chromatographia*, 26, 329, 1988. With permission.)

owing to the diminished equilibration time. Just as the use of small diameter particles reduces the A term contribution to zone broadening, the C term contribution can be minimized by using smaller packing materials.

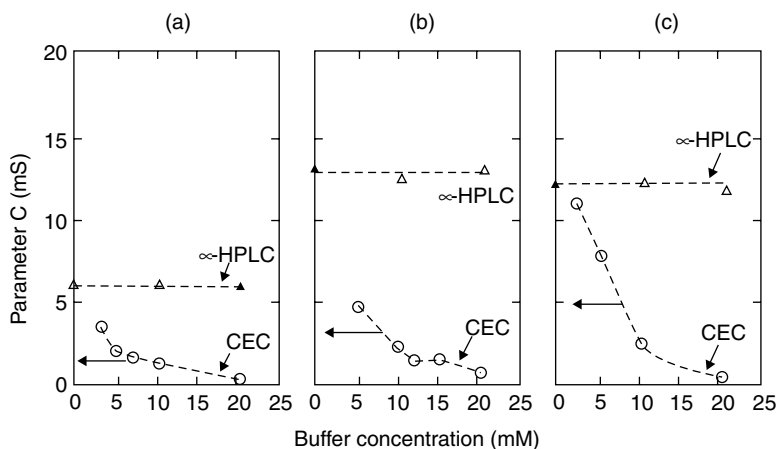

In a recent study by Horváth and coworkers [6], band broadening between electrically driven and pressure-driven flows in several packed capillaries were examined. Their results suggested that detection and injection contributions to band spreading are negligible. The experimental data were examined and fitted to the simplified Van Deemter equation to evaluate the eddy diffusion (A) and the mass transfer (C) parameters of each mode of flow:

$$H = A + \frac{B}{u} + Cu. \quad (5.7)$$

As expected, their column studies showed that the A term was much smaller in CEC than in HPLC. This was attributed to the plug-like EOF flow profile in CEC as shown in Figure 5.6. This results in reduced multipath dispersion effects by a factor 2–4. The C term in HPLC was shown to be greater than for CEC using packing materials with pore sizes  $\geq 300 \text{ \AA}$ , but was not observed in packing materials with average pore size of  $80 \text{ \AA}$ . This was attributed to the absence of EOF transport through the pores of the particles because of double layer overlap. The intraparticle resistance to mass transfer contribution to plate height,  $H_i$ , was evaluated using

$$H_i = \left[ \frac{\theta(k_0 + k + k_0k)^2 d}{30 k_0(1 + k_0)^2(1 + k)} \right] \frac{D_{\text{eff}}}{D_{\text{app}}} \frac{\mu d}{D_m}, \quad (5.8)$$

where  $\theta$  is the tortuosity of the support,  $d$  is the diameter of particle,  $D_m$  is the diffusivity of the solute in the mobile phase,  $\mu$  is the interstitial mobile phase velocity,  $k$  is the retention factor,  $D_{\text{eff}}$  is the effective molecular diffusivity in the pores, and  $D_{\text{app}}$  is the apparent diffusivity for transport in the porous particle by diffusion and by intraparticle convective transport. The retention factor,  $k$ ,

**FIGURE 5.7** C term vs. the concentration of electrolyte in solution evaluated for HPLC and CEC. (Reprinted from Wen, E., et al., *J. Chromatogr. A*, 855, 349–366, 1999. With permission from Elsevier.)

is given by

$$k = \frac{\varepsilon_i(1 - \varepsilon_i)}{\varepsilon_\theta}, \quad (5.9)$$

where  $\varepsilon_i$  is the intraparticle porosity and  $\varepsilon_\theta$  is interstitial porosity. Figure 5.7 shows how the C term can be reduced by intraparticle EOF for large particles. It was also shown that the contribution of the C term is reduced as the concentration of electrolytes in solution is increased.

In an additional study on the differences of zone broadening in CEC versus HPLC, Dittmann and coworkers modified the Horvath model for HPLC to account for the effects of EOF [3,7].

$$H = H_{\text{disp}} + H_{e,\text{diff}} + H_{i,\text{diff}} + H_{t,\text{diff}} + H_{\text{kin}}, \quad (5.10)$$

where  $H_{\text{disp}}$  is the plate height increment due to the axial dispersion of the solute in interstitial space,  $H_{e,\text{diff}}$  is the plate height increment resulting from film resistance at the particle boundary,  $H_{i,\text{diff}}$  is the plate height contribution from interparticle diffusion,  $H_{t,\text{diff}}$  is the plate height contribution of transchannel mass transfer, and  $H_{\text{kin}}$  is the plate height contribution from the interaction between the solute and the stationary phase. The sources of band broadening from  $H_{e,\text{diff}}$ ,  $H_{i,\text{diff}}$ , and  $H_{\text{kin}}$  are shown in Figure 5.8 [8]. In Equation 5.10, height equivalent to a theoretical plate (HETP) is expressed as the sum of independent terms that contribute to zone broadening. In a packed column, dispersion in the axial direction is expressed as

$$H_{\text{disp}} = H_{a,\text{diff}} + H_{\text{eddy,diff}}, \quad (5.11)$$

where  $H_{a,\text{diff}}$  is the plate height contribution arising from static diffusion in the axial direction, and  $H_{\text{eddy,diff}}$  is the plate height contribution due to the differences in axial transport velocity (eddy diffusion).

In Equation 5.10, it is assumed that the contributions of all individual terms are independent of flow profile except for the  $H_{\text{eddy,diff}}$  and  $H_{t,\text{diff}}$  terms. Because of the plug-like flow velocity profile, the contribution of transchannel diffusion is much smaller in an EOF-driven system (Figure 5.6). The contribution of transchannel diffusion to the total HETP in a packed column is very small owing to the small channel diameter; approximately one-sixth of the particle diameter. Flow velocity in the channels between particles determines the magnitude of the eddy diffusion term contribution. In

**FIGURE 5.8** Sources of dispersion in liquid chromatography. (Reprinted from Bartle, K.D. and Myers, P., *J. Chromatogr. A*, 916, 3–23, 2001. With permission from Elsevier.)

a pressure-driven system velocity varies with the diameter of the channels, while in an electrically driven system, flow velocity is largely independent of the width of the channel. Therefore, solutes exchanging between one channel and another do not usually experience a difference in flow velocity as they would in a pressure-driven system, resulting in much lower dispersion.

### 5.3 COLUMNS

The packing in a CEC column plays the key role of providing sites for the sorptive interactions (as in HPLC) as well as supporting EOF. The development of both particulate packings having properties tuned for CEC, and alternative column technologies such as monoliths, is emerging rapidly.

CEC columns are generally made of fused-silica tubing, usually packed with the appropriate stationary phase. Today, the most commonly used CEC columns have i.d. of 100  $\mu\text{m}$  or less, with 50 and 75  $\mu\text{m}$  i.d. being the most popular. The stationary phase is retained in the column by two frits. Column designs can be categorized into two major types: OT columns and packed structures, which include packed columns, monolithic columns, and microfabricated structures (open or continuous beds). Packed capillary columns are most commonly used, as has been demonstrated in numerous papers [9–11]. They can be subdivided into three different categories: columns packed with particles, columns with continuous beds fabricated *in situ* creating a rod-like monolithic structure, and columns with immobilized or entrapped particulate materials.

#### 5.3.1 OPEN TUBES

Open tubular CEC (OTCEC) is similar to CE, with the exception of having a stationary phase attached on the wall of the fused-silica capillary. OT columns offer some advantages over packed capillaries [9]. OT columns with inner diameters of 10  $\mu\text{m}$  or less can generate plate height lower than those for packed columns with the same i.d. The limited band broadening in OT columns results from the absence of packing material and end frits. The small diameter OT column also allows a faster separation with higher field strength without causing significant Joule heating. The drawbacks of

FIGURE 5.9 Schematic of capillary packing procedure.

OTCEC columns include difficulties associated with sample injection volume (due to the extremely small loading capacity) and detection. Because of the low nL to pL sample size range, and the small i.d. and therefore path length, optical detection can be difficult. This has restricted the growth of application of OTCEC.

### 5.3.2 PACKED COLUMNS

Capillary electrochromatography capillaries are usually packed with 3–5  $\mu\text{m}$   $\text{C}_{18}$  or  $\text{C}_8$  packing materials. A packed column typically consists of two parts, a packed and an OT section as illustrated in Figure 5.9. The preparation of these columns includes the fabrication of retaining frits within a capillary and the packing of small diameter particles into narrow-bore capillaries. The retaining frits are typically made by filling a small section of the column with silica, then, sintering to produce two porous plugs. After this temporary frit is formed, stationary phase is slurry packed into the column at high pressure. Once packed, a second retaining frit is sintered in place with a heating element, and the excess stationary phase is flushed out by applying pressure in the reverse direction. Packed columns provide higher column capacity than the OT columns. Most columns for CEC have been packed with reversed-phase materials.

Both these steps, fritting and packing, present technical difficulties and therefore reproducibility remains problematic. The use of retaining frits in fabricating a packed column presents several issues. The fabrication of frits causes the removal of the protective polyimide coating and causes the column to be fragile at the frit. Nonreproducibility in manufacturing the frits is also another drawback of this approach. Moreover, the heat applied in the process of making the frits changes the characteristics of the packing materials at the frits. The difference in surface chemistry leads to bubble formation at the interface between the frits and the unpacked segments of the capillary. These limitations have led to the development of various alternative approaches.

### 5.3.3 MONOLITHIC COLUMNS

Fritless monolithic columns, which emerged during the last decade [4,12–19], have proven to be a viable alternative to packed capillaries for CEC. They are prepared by *in situ* polymerization to form a continuous rod-like porous bed, thereby, eliminating the difficulties encountered with packed columns. The porous monoliths can be either in rigid structures [12,16,19–31] or soft gels [4,13,24,32–38]. Monolithic columns have special characteristics and present several advantages, mainly in the ease of their preparation [39–41]. These advantages include the following: (1) the polymerization process is simple and can be performed directly within the confines of a capillary or a microfluidic chip, thus avoiding the problems related to both frit formation and packing; (2) columns of virtually any length and shape can be fabricated; (3) the polymerization mixture can be prepared using a wide variety of monomers, allowing a nearly unlimited choice of

**FIGURE 5.10** Schematic representation of the preparation of a monolithic column. (Reprinted from Svec, F., et al., *J. Chromatogr. A*, 887, 3–29, 2000. With permission from Elsevier.)

both matrix and surface chemistries; and (4) the polymerization process can be easily controlled, which enables optimization of the porous properties of the monolith, and consequently the flow rate and chromatographic efficiency of the system. Studies conducted by Luo and Andrade [42] suggest that continuous polymeric beds with submicron channels may be the ideal packing structure for CEC. With greatly reduced geometric tortuosity and more favorable EOF, this approach should simplify column technology and alleviate other problems associated with CEC (i.e., bubble formation) [43].

Polymeric monolithic columns have been widely developed and successfully applied for CEC. As can be seen in Figure 5.10 [44], the preparation of a monolithic porous polymer sorbent is a simple and straightforward process. The steps consist of (1) modification of the capillary wall in order to provide functional groups on the surface that will participate in the subsequent polymerization process; (2) filling the capillary with the homogeneous polymerization mixture consisting of the monomers, initiator, and porogenic solvent; (3) initiation of polymerization thermally or by exposure to ultraviolet (UV) radiation to obtain a rigid monolithic porous polymer; and (4) the removal of unreacted components, such as the porogenic solvents and any other soluble compounds that remain in the polymer.

As mentioned before, a large number of available monomers with a wide variety of functionalities are available giving unlimited choices of surface chemistry. They may be used directly for the preparation of polymer monoliths and some are shown in Figure 5.11.

### 5.3.3.1 Molecularly Imprinted Polymer Sorbents for CEC

Molecularly imprinted polymers (MIPs) are tailor-made materials able to selectively recognize an analyte. These stationary phases have been successfully employed in CEC, particularly when a high degree of selectivity is required. The first applications of MIPs were as stationary phases in affinity chromatography [45,46]. Extensive peak broadening and tailing, however, were observed, especially for the more retained compound (usually the template). It was reported that this was due to the heterogeneity of binding sites, in terms of both affinity and accessibility, and different association and dissociation kinetics.

The use of MIPs for CEC gained considerable interest, most likely owing to the need for a highly effective liquid-based separation system with unique selectivity for predetermined molecular species in a miniaturized format. This is especially attractive since CEC is known to have more efficiency than conventional HPLC, and thus CEC-mode separations should lead to improved performance of imprinted polymers compared to that achieved in conventional LC.

**FIGURE 5.11** Selection of (a) monomers with functional groups, (b) cross-linkers, (c) charged monomers for EOF generation, and (d) chemical initiators used for the preparation of polymer monolithic columns.

The first requirement for MIP-CEC is therefore the adaptation of the molecular imprinting technology to the capillary format. This is not a simple task and the straightforward approach taken from HPLC experiments by packing irregular MIP particles to prepare MIP sorbents presented some technical difficulties in the capillary format. Thus, most approaches have reported the synthesis of MIP stationary phases within the confines of the capillary column. This monolithic format is attractive but deceptively challenging. While laborious packing procedures, such as frit making as well as bulk polymerization of MIP with subsequent crushing and sieving steps, are avoided, other challenges abound.

The first attempt to adapt MIPs to capillary columns was reported using an *in situ* dispersion polymerization, which involved the formation of about 10  $\mu\text{m}$  sized agglomerates of 0.5–4  $\mu\text{m}$  particles [47]. These MIP capillaries were imprinted against *L*-phenylalanine anilide, pentamidine, and benzamidine. The results showed low selectivity of these columns and only pentamidine showed

**FIGURE 5.12** Schematic illustration of (a) covalent and (b) noncovalent imprinting procedures.

a pH-dependent retention that might originate from imprinting. Despite the poor performance of these columns, this work is of high importance in indicating the feasibility of synthesizing MIPs *in situ*.

As shown in Figure 5.12, the preparation of MIPs includes the polymerization of suitable monomers around a template in the presence of an appropriate cross-linker and solvent (porogen). Following polymerization, the template molecule is removed to leave cavities complementary in size, shape, and chemical functionality to the analyte. Accordingly, the polymer should be able to selectively rebinding the target analyte.

Two main approaches are used to produce MIPs: the noncovalent [48] and the covalent [49] approach. In the covalent approach (Figure 5.12a), the functional monomer is covalently bonded to the template molecule before polymerization. When polymerization is complete, the covalent bonds between the template molecule and the polymer are cleaved and the template molecule is extracted. The resulting imprint is then able to recognize and rebinding the imprinted analyte *via* reversible covalent bonds. However, this technique suffers from lack of generality owing to the difficulties of finding suitable monomers.

A more general technique is the noncovalent approach. So far, only the noncovalent imprinting technique has been used for the preparation of MIP phases for CEC. In the noncovalent approach, monomers interact with the template molecule *via* hydrogen bonding, ionic bonding, Van der Waals forces, hydrophobic effects, and so forth. The noncovalent imprinting technique has been dominant because of its generality and simplicity. A broad range of species have been imprinted during the past several years [50]. Figure 5.12b shows the procedure for preparation of an MIP using the noncovalent approach.

With the noncovalent approach, the selectivity of the MIP can be altered by optimizing the types and quantities of functional monomers, cross-linking monomers and solvents used. Careful selection of a porogenic solvent is necessary in order to produce a polymer with enough porosity to assure good permeability. The degree of cross-linking is also important in achievement of stability of the template–monomer complex during polymerization, and will also affect polymer porosity.

Figure 5.11 shows some of the most common monomers, cross-linkers, and initiators used for the preparation of monolithic MIPs.

### 5.3.3.2 Particle Entrapment

In the entrapped monolithic column approach, particles are immobilized inside the capillary column in a sol-gel matrix [14,16,17,19,51] or by sintering the particles with heat [25] instead of using retaining frits. The entrapment approach eliminates the problems associated with retaining frits in conventional packed columns. Moreover, column longevity improves significantly because the problems caused by the failure of frits can be avoided.

Columns fabricated via the sintering method have reproducible separations with  $\sim 125,000$  plates  $m^{-1}$ . The column preparation involves packing the capillary with silica particles (premodified with the desired stationary phase), a washing step, drying with nitrogen gas, and a two-step heat treatment at different temperatures (120°C and 360°C). To reintroduce stationary phase that might have been damaged during the process, *in situ* resilanization is required. The multistep fabrication and stationary phase reattachment process can be time consuming.

There are two means of immobilizing particles in sol-gel matrix. One is to prepare a sol-gel solution (typically a mixture containing alkoxysilanes, ethanol, and hydrochloric acid), followed by addition of particulate materials containing the stationary phase to form a suspension. The suspension is introduced into the column by vacuum or pressure, and then dried to result in an immobilized packed bed. Studies have shown that columns prepared using this method generate  $\sim 80,000$  plates  $m^{-1}$ . Fabrication of these columns is problematic owing to irreproducibilities in the finished products.

The second approach to particle entrapment is to introduce the solution sol gelled after the column has been packed. Chirica and Remcho [16] used high pressure to slurry pack the column. Tang et al. [20,27,51] used supercritical CO<sub>2</sub> to pack the column. After packing, the sol-gel solution was forced into the column and dried. If temporary retaining frits are used, they are eliminated after drying. These methods generated columns with efficiencies of  $\sim 125,000$  plates  $m^{-1}$ . In comparison to the “one-step” method, less entrapment matrix is required and higher reproducibility and homogeneity were noted.

## 5.4 DEVELOPING A CEC METHOD

Developing a CEC method can seem like a daunting task, but by focusing on some key items and understanding how they are interrelated, the process can become reasonably straightforward. The easiest path is of course to find and use a preexisting method. These may be found by either conducting a literature search or contacting a column manufacture. If a method cannot be located, then the analyst will need to take into consideration: the sorbent, separation buffer, organic modifiers, temperature, and voltage. Table 5.1 is a compilation of CEC applications by compound class, suitable stationary phase, particle size, and reference where the method can be found, and may serve as a good starting point.

### 5.4.1 SORBENTS

One item to consider when developing a new method is that there are many capillary columns available to the consumer, and even though the stationary phases may be similar there will be variations in EOF and selectivity between them. This effect was studied by Dittmann and Rozing [201] for five reverse-phase sorbents anchored onto silica particles. Figure 5.13 shows the EOF variation for five C18 stationary phases from the work conducted by Dittmann and Rozing. Since variations in EOF exist between different columns with similar stationary phases, it is important to be aware that methods may need to be modified when using a column that is different in even a seemingly minor way than the one used in creating the original method.

### 5.4.2 SEPARATION BUFFER

Proper selection of a separation buffer is crucial because it will help resist changes in pH, is used to dissolve the sample, will mitigate the interactions between the sample and bonded phase, affect the EOF, and is the electrical connection between the cathode and anode when voltage is applied during a separation. There are some important features of the separation buffer that must be considered: pH, ionic strength, and organic modifiers. Of these, pH and ionic strength will be covered in this section, and organic modifiers will be discussed separately.

**FIGURE 5.13** Separation of PAHs on five reversed-phase C18 stationary phases. Column 250 (335) mm  $\times$  0.1 mm, 3  $\mu$ m, mobile phase 80% ACN 20% 50 mM Tris-HCl, pH 8, 20 kV, temperature 20°C, 10 bar pressure applied to both ends of capillary, 20°C. Samples were not identical but all contained (1) thiourea, (2) naphthalene, and (3) fluoranthene. (Reprinted from Dittmann, M.M. and Rozing, G.P., *J. Microcol. Sep.*, 9, 399, 1997. With permission.)

The separation buffer in the column and inlet/outlet vials should also be replaced—ideally after each run—to prevent buffer depletion. Buffer depletion occurs as the cation and anion components of the buffer migrate toward cathode and anode respectively during a run. Over time, the concentration of anions at the cathode and cations at the anode will be reduced. This reduction of ions will also occur within the buffer in the column itself. When this occurs to an extreme, major performance degradation is the result.

#### 5.4.2.1 pH

In selecting a separation buffer, the sample to be dissolved must be considered first. It is important to consider the  $pK_a$ s of the components of the sample as the pH will determine whether the sample components are charged or neutral. Euerby et al. [121] showed that by changing buffer pH, and using a 25-cm effective length 3- $\mu$ m particle size Hypersil phenyl stationary phase, the migration order of some of the barbiturates in their mixture changed when the pH was increased from 6.1 to 7.8, owing to a change in analyte ionization state. For biological samples the pH is not only important in dictating the charge of the analyte, but also critical in preventing sample denaturation.

EOF is also pH dependent. For example, in columns having silica support particles, ionizable silanols will cause these columns to exhibit a more pronounced dependency of EOF on pH than do other columns. The silanols begin to ionize at pH 2 and will continue to ionize progressively (based on the regiospecificity of a given silanols'  $pK_a$ ) until approximately pH 8–9, at which point the preponderance of silanols are fully ionized. The zeta potential will therefore increase, and it is for this reason that the electroosmotic velocity increases with increasingly alkaline solutions.

**FIGURE 5.14** Effect of mobile phase pH on the linear velocity of the EOF. Comparison of CEC Hypersil C18 (◆), C8 (●), and phenyl (▲) packing materials. (Reprinted from Euerby, M.R., et al., *J. Microcol. Sep.*, 11, 305, 1999. With permission.)

Euerby et al. [121] demonstrated that the linear velocities for three different commercially available columns increased with rising pH, as shown in Figure 5.14. These Agilent columns were packed with Hypersil C18, Hypersil C8, and Hypersil phenyl.

A possible solution to the low electroosmotic velocity encountered with standard reverse-phase columns is to use a mixed-bed column. A mixed-bed column contains both normal-phase (NP) and reverse-phase (RP) components, and when working at lower pH regions the NP component will yield EOF from the surface charge associated with the anionic or cationic NP sorbent. Tang and Lee [20] compared electroosmotic velocity over the pH range of 2–9 for reverse-phase and mixed-bed columns; both columns were sol–gel bonded continuous-bed columns. The reverse-phase column contained an ODS1 stationary phase whereas the mixed-bed column was an ODS/SCX mixture. They noted that the mixed-bed column exhibited a nearly constant EOF for the entire pH range studied, unlike the reverse-phase column that continually increased as the pH climbed. These findings are shown in Figure 5.15.

#### 5.4.2.2 Ionic Strength

Another variable to be optimized is the ionic strength of the separation buffer. The ionic strength not only determines the buffering capacity of the buffer being used, but also affects EOF and Joule heating.

From Equation 5.3, it seems that there is no relation between EOF velocity and double layer thickness, but there is a direct relation to the zeta potential. To find the relation between EOF and ionic strength, Equation 5.1 must be substituted into Equation 5.2 to obtain

$$\zeta = \frac{[(\epsilon_0 \epsilon_r RT / 2F^2 cz^2)^{1/2}] \sigma}{\epsilon_0 \epsilon_r}. \quad (5.12)$$

Thus the zeta potential will have an inverse relation to the square root of the electrolyte concentration. Likewise, it can be seen that EOF velocity will be dependent on the inverse square root of the ionic strength of the electrolyte.

**FIGURE 5.15** Plots of EOF velocity vs. mobile phase pH for sol-gel bonded continuous-bed columns. Conditions: 25/34 cm  $\times$  75  $\mu$ m i.d. continuous-bed columns containing sol-gel bonded ( $\square$ ) 3  $\mu$ m, 80  $\text{\AA}$  ODS1, and ( $\Delta$ ) 3  $\mu$ m, 80  $\text{\AA}$  ODS/SCX; 70: 25: 5 (v/v/v) ACN/H<sub>2</sub>O/50 mM phosphate buffer; 5 kV  $\times$  2 s injection; 30 kV applied voltage; 0.3 mM thiourea used as EOF marker. (Reprinted from Tang, Q. and Lee, M.L., *J. High Resol. Chromatogr.*, 23, 73, 2000. With permission.)

Heating is also a concern when working with high ionic strength buffer solutions. As the ionic strength of the solution is increased, the current will likewise increase. Utilizing the following equation for estimating Joule heating ( $Q$ )

$$Q = E^2 \Lambda c, \quad (5.13)$$

where  $E^2$  is the voltage gradient,  $\Lambda$  is molar conductivity of the electrolyte, and  $c$  is the electrolyte molar concentration, it can be determined that heating will increase by raising the molar conductivity of the electrolyte. The changes brought on by heating will be discussed in more detail in Section 5.4.4.

### 5.4.3 ORGANIC MODIFIER EFFECTS

The effect of organic modifiers such as acetonitrile (ACN), ethanol, isopropanol, methanol, and tetrahydrofuran on CEC separations is quite complicated. Organic modifiers added to an aqueous buffer can increase the solubility of neutral and nonpolar compounds, but at the same time yield some EOF effects in concert with changes in retention factors.

Addition of a modifier will alter the viscosity of the run buffer depending on its interactions with the aqueous buffer. According to Equation 5.3, there is an inverse relation between electroosmotic velocity and solution viscosity, and therefore, the electroosmotic velocity will change accordingly when a modifier is used. In addition, the dielectric constant of the buffer solution will change with increasing organic solvent concentration, which will affect the zeta potential inversely thus altering EOF.

An example of addition of organic modifiers decreasing EOF was presented by Kanitsar et al. [202] for the effect of various organic additives on the separation of three carboxylic acids. Separation buffers consisting of 15% v/v solvent to pH 6.0, 25 mM KH<sub>2</sub>PO<sub>4</sub> and 0.75 mM TTAB buffer were used in conjunction with benzyl alcohol, as the neutral marker, for EOF determination. For the

**FIGURE 5.16** Effect of the ACN content on EOF mobility in CEC. Electropak phenyl column, EP-75-40-3-PH [40 cm packed (47 cm total) 75  $\mu\text{m}$  i.d.]; electrolyte: Tris HCl (pH 8)–ACN mixture (ionic strength 5 mM); temperature: 25°C; applied voltage: +20 kV; UV detection: 220 nm; electrokinetic injection: 4 s (+10 kV); EOF marker: thiourea. (Reprinted from Cahours, X., et al., *J. Chromatogr. A*, 845, 203–216, 1999. With permission from Elsevier.)

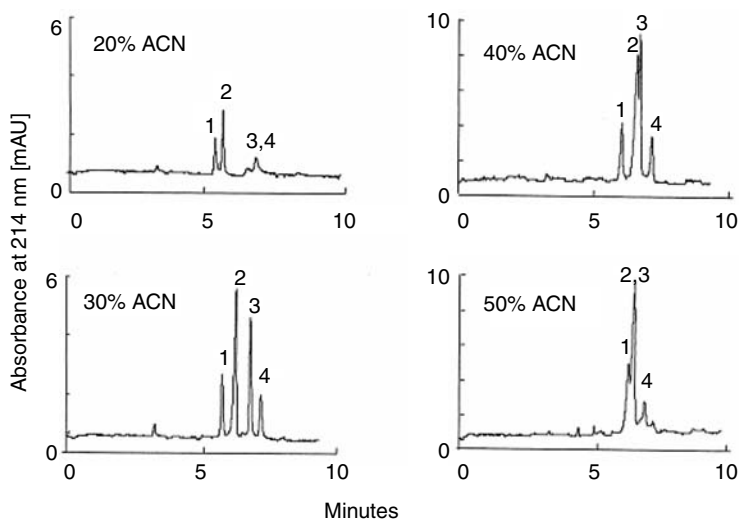

solvent systems studied, the respective EOF values were determined to be  $4.03 \times 10^{-4} \text{ cm}^2 \text{ V}^{-1} \text{ s}^{-1}$  for water,  $2.71 \times 10^{-4} \text{ cm}^2 \text{ V}^{-1} \text{ s}^{-1}$  for ethanol,  $2.56 \times 10^{-4} \text{ cm}^2 \text{ V}^{-1} \text{ s}^{-1}$  for 1-propanol,  $2.29 \times 10^{-4} \text{ cm}^2 \text{ V}^{-1} \text{ s}^{-1}$  for ACN,  $2.24 \times 10^{-4} \text{ cm}^2 \text{ V}^{-1} \text{ s}^{-1}$  for methanol, and  $0.69 \times 10^{-4} \text{ cm}^2 \text{ V}^{-1} \text{ s}^{-1}$  for ethylene glycol. An example of increasing EOF was given by Cahours et al. [166] for addition of ACN to a 5 mM, pH 8 Tris–HCl buffer. They noticed a 17% increase in EOF velocity when the ACN percentage was increased from 30% to 80%, and a plot of their findings is shown in Figure 5.16.

As with HPLC, organic modifiers will of course affect interactions between analytes and the stationary phase. With reverse-phase materials, addition of an organic modifier to a buffer will lower the partition coefficient of an analyte. At an appropriate concentration, it is possible to optimize the partition function for a given analyte and tune the retention factor ( $k'$ ). Zhang et al. [91] showed that by increasing the percentage of ACN in their mobile phase that the retention times of four proteins separated by RPCEC were not altered significantly. What they did notice, however, is that as the ACN percentage was increased a reduction in retention attributed to chromatographic interactions occurred, and at a sufficiently high ACN percentage the separation was largely electrophoretic in nature. Electrochromatograms for this separation showing ACN percentages in the range of 20%–50% are given in Figure 5.17.

The organic modifier/buffer species and organic modifier/surface interactions are not fully understood, and as such there is no easy way to summarize the effect of organic modifiers on EOF. These effects are specific to a given stationary phase/buffer species/buffer concentration combination, and therefore experimentation and optimization are required.

#### 5.4.4 INFLUENCE OF TEMPERATURE

Joule heating leads to zone spreading and both qualitative and quantitative irreproducibility; to attenuate Joule heating the column is housed in a temperature-controlled environment. Unregulated

**FIGURE 5.17** Effect of ACN concentration in the eluent on the separation of four proteins. Column, 39 cm (effective length 29 cm)  $\times$  50  $\mu$ m i.d., fused-silica capillary with porous methacrylic monolith having tertiary amino functions; mobile phase, ACN (% v/v) in 60 mM aqueous sodium phosphate, pH 2.5; applied voltage,  $-25$  kV; detection, 214 nm; sample: (1) ribonuclease A, (2) insulin, (3)  $\alpha$ -lactalbumin, and (4) myoglobin. (Reprinted from Zhang, S., et al., *J. Chromatogr. A*, 887, 465–477, 2000. With permission from Elsevier.)

Joule heating leads to a cycle of increased resistivity and increased heating. In the worst case scenario, the buffer will heat until ultimately out-gassing occurs. Most of the CE instrumentation available today is equipped with heating or cooling capability, but when dealing with a homebuilt system temperature control should be considered.

EOF velocity will also be changed by fluctuations in temperature. With an increase in temperature the EOF velocity will increase, owing to a decrease in the viscosity of the buffer system in accordance with Equation 5.3. Zhang et al. [203] showed that an increase in temperature from 25°C to 55°C increased the velocity of the EOF as shown in Figure 5.18. Also, the kinetics of partitioning of analytes between the stationary and mobile phases will be more rapid which can aid in minimizing band broadening effects.

#### 5.4.5 VOLTAGE

As with any other separation method, the ultimate goal of developing a method is to have the shortest analysis time that affords the desired resolution between sample components. In CEC, reduced analysis times can be gained by working at higher voltages because of the linear relation between applied voltage and both electrophoretic and electroosmotic velocity. One concern about working with elevated voltages is that there is increased possibility of excessive Joule heating. Li and Remcho [204] demonstrated the linear relationship between field strength and the EOF velocity using acetone as an unretained neutral marker in a packed Nucleosil C18 column (shown in Figure 5.19) for 3, 5, and 7  $\mu$ m particles.

#### 5.4.6 SUMMARY

There are numerous variables that can be altered in developing a CEC method, and the vast majority of them are interrelated. This contributed greatly to the decline in interest in CEC in the late 1990s. For example a change in buffer pH may change EOF, the charge state of an analyte, and

**FIGURE 5.18** Plots of the EOF mobility, measured with DMSO as the unretained neutral marker, against the reciprocal absolute temperature. Mobile phase (■) 10% ACN, (□) 20% ACN, (○) 30% ACN in 60 mM sodium phosphate buffer, pH 2.5; temperature, 25°C; applied voltage, -30 kV; detection, 214 nm. Column, 40 cm (effective length 30 cm)  $\times$  75  $\mu\text{m}$ , fused silica with styrenic monolith having quaternary ammonium functions. (Reprinted from Zhang, S., et al., *J. Chromatogr. A*, 914, 189–200, 2001. With permission from Elsevier.)

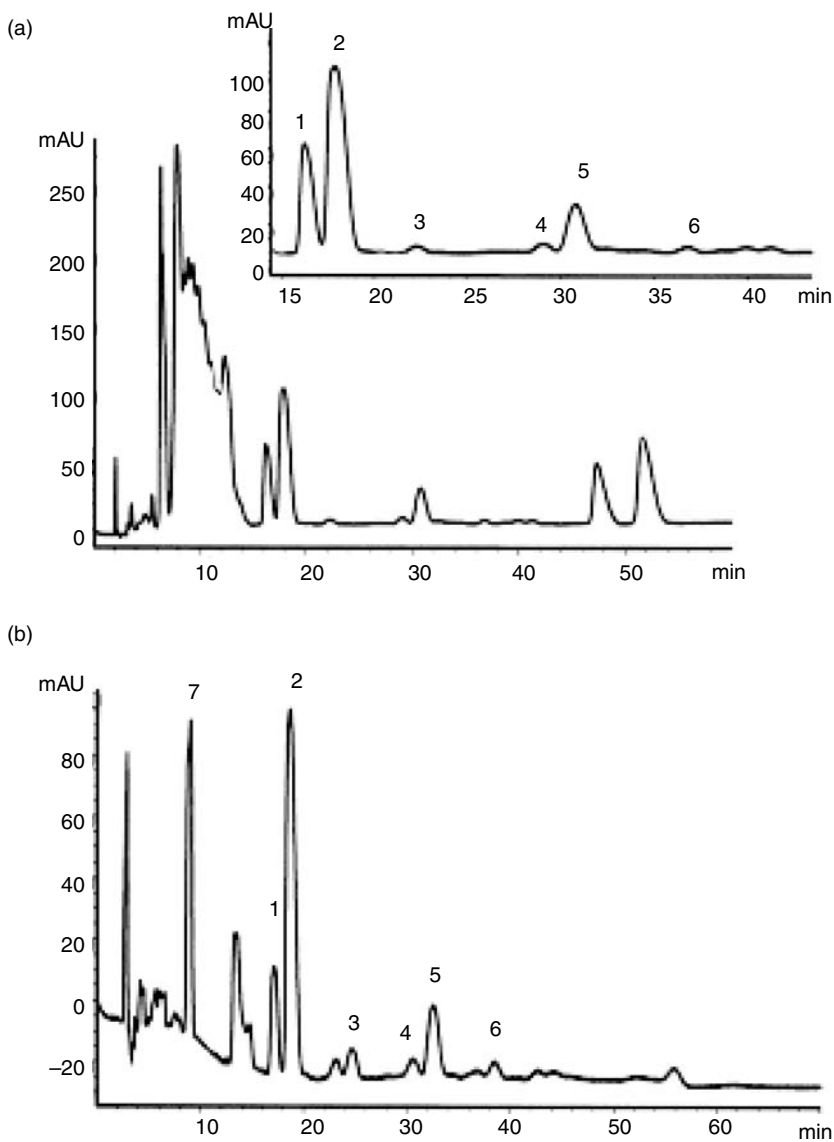

**FIGURE 5.19** Linear velocity as a function of field strength for 3-, 5-, and 7- $\mu\text{m}$ -diameter Nucleosil C18 particles. (Reprinted from Li, D.M. and Remcho, V.T., *J. Microcol. Sep.*, 9, 389, 1997. With permission.)

its partitioning behavior. The ionic strength of a mobile phase can also change the EOF, and current will increase as salts are added to the system. If the current is sufficiently high (owing to the mobile phase ionic strength) heating effects may be encountered, which can lower the partition coefficients of analytes and the mobile phase viscosity, and may ultimately lead to bubble formation. Therefore, it is important to consider how a change in one component of the method can alter other components.

## 5.5 APPLICATIONS

Capillary electrochromatography can be an effective separation tool for a wide range of sample types, as evidenced in Table 5.1. In this section, examples of separations utilizing CEC will be highlighted.

**FIGURE 5.20** CEC of (a) pyrethrin dip and (b) flea and tick mist. Conditions: MeCN-25 mM Tris-THF (55:35:10, pH 9). (1) Cinerin II, (2) pyrethrin II, (3) jasmolin II, (4) cinerin I, (5) pyrethrin I, (6) jasmolin I, and (7) piperonyl butoxide. (Reprinted from Henry, C.W., et al., *J. Chromatogr. A*, 905, 319–327, 2001. With permission from Elsevier.)

A CEC separation of insecticidal pyrethrin esters was accomplished by Henry et al. [63]. Here it was shown that it is possible to identify pyrethrin esters (cinerin I, pyrethrin I, jasmolin I, cinerin II, pyrethrin II, and jasmolin II) in a commercially available pyrethrin dip and flea and tick mist (Figure 5.20). The column inner and outer diameters were 100 and 350  $\mu\text{m}$ , respectively, and the total and effective lengths were 33 and 25 cm, respectively. The column was packed with 3  $\mu\text{m}$  particle size Hypersil C18. The mobile phase was composed of 55:35:10, pH 9, ACN-25 mM Tris-tetrahydrofuran. Other parameters were an applied voltage of 30 kV, column temperature of 25°C, and UV detection at 254 nm.

**FIGURE 5.21** Separation of estrogenic compounds: (1) estriol, (2) estradiol, (3) equiline, and (4) estrone. (a) With pCEC-CIS-MS: 80 bar and +15 kV applied, (b) pCEC-CIS-MS: 80 bar and +5 kV applied, and (c) CHPLC-CIS-MS: 80 bar applied. (Reprinted from Rentel, C., et al., *Electrophoresis*, 20, 2329, 1999. With permission.)

An example of a separation of estrogens (estriol, estradiol, equiline, and estrone) with pressurized CEC (pCEC) was shown by Rentel et al. [132]. Capillaries with inner diameters of 100  $\mu\text{m}$  and outer diameters of 360  $\mu\text{m}$  were used. The GROM-SILODS-0 AB packing material used had a particle size of 3  $\mu\text{m}$ . Detection of the estrogenic analytes was accomplished with coordination ion spray mass spectrometry (CIS-MS). Other experimental parameters were: pH 9, 4 mM ammonium acetate in 5:95 water-ACN mobile phase, applied pressure of 80 bar, and applied voltage of 15 (Figure 5.21a) and 5 kV (Figure 5.21b).

Tricyclic antidepressants were analyzed by Vallano et al. [179] via an MIP-CEC separation. In this separation, doxepin, imipramine, amitriptyline, trimipramine, and clomipramine were separated from the template molecule nortriptyline (Figure 5.22). The capillary inner diameter and total length were 100  $\mu\text{m}$  and 33 cm, respectively, and the total length of the monolithic bed was 22.5 cm. The eluent was 92:2 ACN: 10 mM sodium acetate pH 3.0 to which 0.02% trifluoroacetic acid and 0.015% triethylamine (TEA) (v/v) was added. A constant applied voltage of 30 kV was utilized.

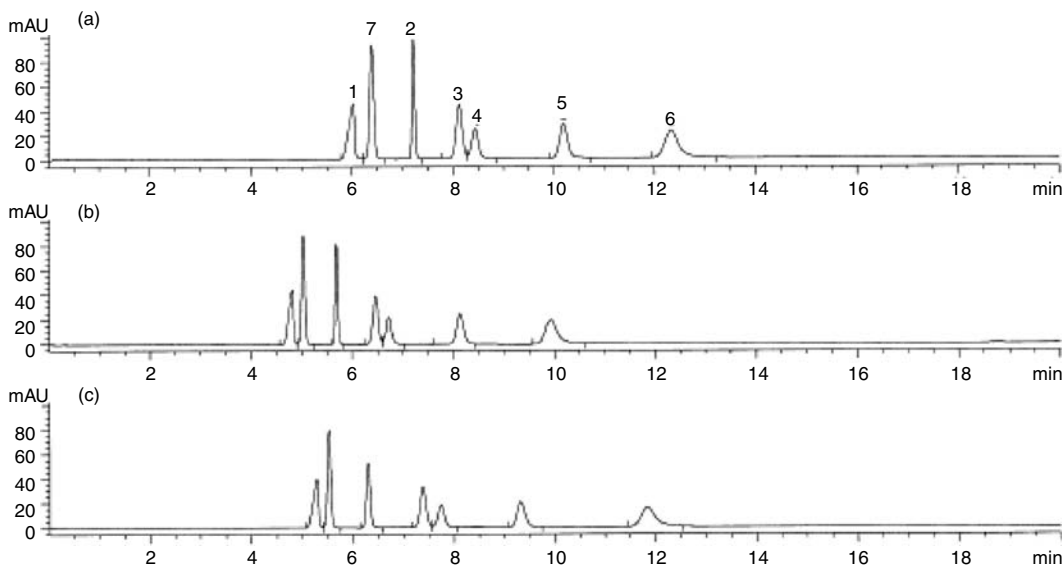

CEC has also been used to successfully separate nucleotides. For example, Helboe and Hansen [115] separated cytidine, uridine, inosine, guanosine, thymidine, adenosine, and thiourea, with a CEC Hypersil C18 column. Column specifics are as follows: particle size of 3  $\mu\text{m}$ , inner diameter of 100  $\mu\text{m}$ , and bed length of 25 cm. The mobile phase was 98% 5 mM acetic acid, 3 mM TEA, pH 5: 2% ACN. Figure 5.23, shows the optimization of temperature and voltage, 25°C and 20 kV for 5.4A, 25°C and 25 kV for 5.4B, and 20°C and 25 kV for 5.4C. Nucleotides were also examined by Cahours et al. [114]. Figure 5.24 illustrates the effect ionic strength has on the migration order of adenosine (A), cytidine (C), guanosine (G), uridine (U), and thymidine (T), and thiourea, an EOF marker. For this separation, the column dimensions were 27 cm total length  $\times$  75  $\mu\text{m}$  inner diameter.

**FIGURE 5.22** MIP-CEC separation of a simulated combinatorial library consisting of several tricyclic antidepressants. Conditions: capillary i.d. 100  $\mu\text{m}$ ; Ltot: 33 cm; Lbed: 22.5 cm; eluent: ACN: 10 mM Na acetate pH 3.0 (98:2) with 0.02% trifluoroacetic acid and 0.015% TEA (v/v); voltage +30 kV constant; injection: +2 kV, 2 s; column temperature: 50°C. (Reprinted from Vallano, P.T. and Remcho, V.T., *J. Chromatogr. A*, 887, 125-135, 2000, with permission from Elsevier.)

The effective length of the column was 20 cm and it was packed with 3  $\mu\text{m}$  Phenyl Hypersil. The separation temperature and voltage were 20°C and 20 kV, respectively, and the detection wavelength was 254 nm. The electrolyte was composed of pH 5 acetic acid/ammonia-ACN (95/5), and the ionic strengths used were 10 and 5 mM, respectively.

Pharmaceuticals have also been separated by CEC. Taylor and Teale [148] conducted gradient CEC separations of drug mixtures. In their study, a mixture of corticosteroids consisting of triamcinolone, hydrocortisone, prednisolone, cortisone, methylprednisolone, betamethasone, dexamethasone, adrenosterone, flucortolone, and tramcinolone acetonide was examined. This mixture was separated using a 3- $\mu\text{m}$  Hypersil ODS. The packed length, length to detection window, and total length of this column were 30, 30.1, and 42 cm, respectively. The applied voltage was 30 kV, and the detection wavelength used was 240 nm. Gradient elution was used as follows: initially, 5 mM ammonium acetate in ACN–water (17:83) for the first 3 min, then for 15 min; the ACN concentration was ramped to 38% and kept constant for the remainder of the analysis. The flow rate for this analysis was 10  $\mu\text{L min}^{-1}$  for the first 3 min, and was then elevated to 100  $\mu\text{L min}^{-1}$ . This separation is shown in Figure 5.25.

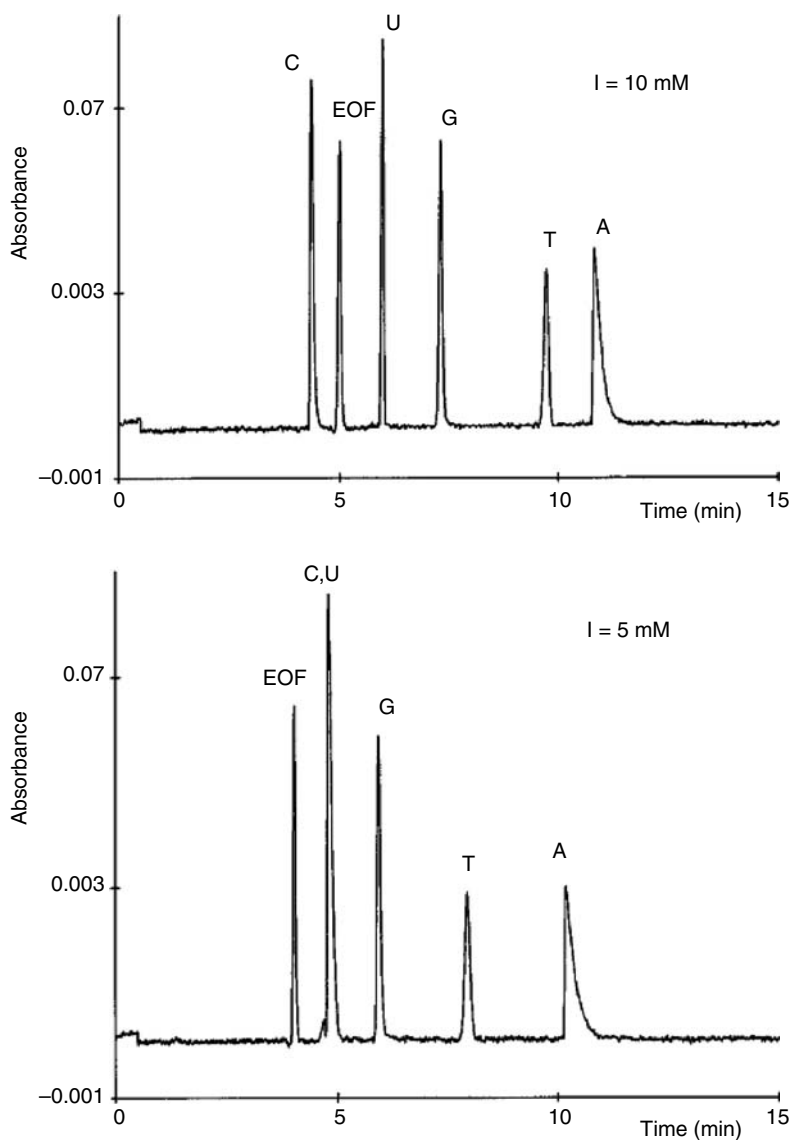

**FIGURE 5.23** Final optimization of temperature and voltage. Order of peaks: (1) cytidine, (7) thiourea, (2) uridine, (3) inosine, (4) guanosine, (5) thymidine, and (6) adenosine. Conditions: injection, 10 kV for 3 s; 25 cm  $\times$  100  $\mu$ m column (CEC Hypersil C<sub>18</sub>, 3  $\mu$ m); mobile phase (5 mM acetic acid, 3 mM TEA, pH 5)–ACN (92:8, v/v). (a) 25°C and 20 kV; (b) 25°C and 25 kV; and (c) 20°C and 25 kV. (Reprinted from Helboe, T. and Hansen, S.H., *J. Chromatogr. A*, 836, *J. Chromatogr. A*, 315–324, 1999. With permission from Elsevier.)

An example of a CEC analysis of an illicit drug was shown by Lurie and collaborators [134]. In this study, a standard mixture of seven cannabinoids was separated, and this test mixture was then compared with concentrated hashish and marijuana extracts (Figure 5.26). The cannabinoid standards used were cannabigerol (CBG), cannabidiol (CBD), cannabinol (CBN),  $\Delta$ -9-tetrahydrocannabinol (d9-THC),  $\Delta$ -8-tetrahydrocannabinol (d8-THC), cannabichromene (CDB), and  $\Delta$ -9-tetrahydrocannabinolic acid (d9-THCA-A), with dimethyl sulfoxide (DMSO) as the neutral marker. A Hypersil C18 column (3  $\mu$ m  $d_p$ ) was used. The column inner diameter was 100  $\mu$ m and had a total length of 49 cm, and the effective length was 40 cm. UV detection was conducted at 210 nm. The run buffer was 75% ACN and 25% 25 mM phosphate buffer pH 2.57. The applied voltage was 30 kV, and the column temperature was kept at 20°C.

Carbohydrate separations too have been accomplished using CEC. Such an example was presented by Zhao and Johnson [106], where they studied sucralose and related carbohydrates, as shown in Figure 5.27. The 100  $\mu$ m inner diameter column was packed with 3  $\mu$ m ODS particles, had a total bed length of 25 cm, and a total length of 33 cm. During each run, an external pressure of six bars was applied to the inlet and outlet vials to eliminate bubble formation. The compounds were detected at 195 nm for this experiment. Different mobile phase compositions were studied, and for Figure 5.28 the eluent was: 35:65 ACN/4 mM borate (Figure 5.28a), 30:70 ACN/4 mM borate, and 25:75 ACN/4 mM borate. For the three runs shown in Figure 5.28, the applied voltage was 15 kV. Note that sucralose was successfully separated from related compounds A and B, a system peak, and ethyl acetate (EA) traces from compound A.

Clearly, CEC is a flexible and efficient separation technique that, with careful attention in method development, is capable of addressing analytical needs across a broad spectrum of sample types.

**FIGURE 5.24** Effect of the ionic strength on the migration order of nucleosides in CEC. Column: 27 cm  $\times$  75  $\mu$ m i.d., bed length 20 cm, packing: 3  $\mu$ m Phenyl Hypersil; electrolyte: acetic acid/ammonia (pH 5)/ACN (95/5); temperature: 20°C; applied voltage: +20 kV; UV detection: 254 nm; electrokinetic injection: 4 s (+10 kV); nucleoside concentration: 50 ppm. (Reprinted from Cahours, X., et al., *J. High Resol. Chromatogr.*, 23, 138, 2000. With permission.)

## 5.6 CONCLUSIONS

What does the future hold for CEC? It is impossible to predict the path the technique will follow. It is of course unlikely that it will ever enjoy the great breadth of application of HPLC and GC. That said, it is entirely possible that the technique will find one or more niches in which it will thrive. Likely areas of application include: field-portable, low-cost, chip-based analytical instruments; disposable components in medical diagnostic/assay devices; and consumables for clinical diagnostic tools.

**FIGURE 5.25** CEC-UV chromatogram (240 nm) of a mixture of 10 corticosteroids ( $100 \mu\text{g mL}^{-1}$ ) using a linear gradient elution program. Voltage = 30 kV, HPLC injection volume =  $10 \mu\text{L}$ , flowrate =  $10 \mu\text{L min}^{-1}$  for 3 min then increased to  $100 \mu\text{L min}^{-1}$ . Gradient program = initial: ammonium acetate, 5 mM, in ACN-water (17:83), held for 3 min then ramped to 38% acetonitrile at 15 min and maintained to end of run. Column = Hypersil ODS,  $3 \mu\text{m}$ , 42 cm total length, 30 cm packed length, 30.1 cm to window, (1) triamcinolone, (2) hydrocortisone and prednisolone coeluting, (3) cortisone, (4) methylprednisolone, (5) betamethasone, (6) dexamethasone, (7) adrenosterone, (8) fluocortolone, and (9) triamcinotone acetonide. CEC is a technique that must compete in an increasingly crowded field of technologies, yet it has a sufficient quantity of positive attributes—detailed in this chapter—to be worthy of consideration. It will be intriguing to see where this road leads.

## 6.1 INTRODUCTION

Since Francis Crick and James Watson discovered the double helical structure of deoxyribonucleic acid in 1953 [1], which finding—with the understanding of the basic rules of inheritance suggested by Gregor Mendel in the nineteenth century—became the theoretical basis of contemporary genetic studies, there has been an urgent need for rapid, precise, sensitive, and high-throughput analysis of nucleic acids. In the mid-1960s, electrophoresis-based methods employing polyacrylamide and agarose gels were rapidly developed; however, these were fairly time-consuming and labor-intensive techniques. The use of gels as sieving matrices for DNA electrophoresis was necessary to provide and appropriate anticonvective media and to make electric field mediated separation of nucleic acid

molecules size based. Please note that the constant linear charge density of DNA chains results in practically equal charge-to-mass ratio for the different lengths oligo- and polynucleotide molecules. Slab gels are still widely used in DNA analysis in spite of the fact that they are not quantitative, they lack online detection option and the analysis usually takes a long time. The next generation of DNA separation techniques transpired in the late 1980s by the application of capillaries to electrophoresis. This resulted in higher separation speed, as the large surface area-to-volume ratio allowed effective Joule heat dissipation (i.e., higher voltages could be applied) [2]. In the past two decades, capillary electrophoresis (CE) became a powerful separation technique featuring automation, ease of use, and high efficiency. Novel detection methods, such as laser-induced fluorescence (LIF), increased the sensitivity of the technique, thus advancing low-level DNA analysis from small amount of samples. The next big step toward large-scale and automated DNA analysis was the introduction of low viscosity so-called replaceable sieving polymer networks, which provided much higher flexibility compared with high viscosity cross-linked gels [3].

Capillary gel electrophoresis (CGE) also shed light to the possibility of miniaturization (lab-on-a-chip), as microfluidic devices can be manufactured similar to that of semiconductor chips, and existing CE methods can be readily transferred from the capillary to microchip electrophoresis [4]. Thanks to the rapid technical developments of CE in the past 15 years [5], the identification of the three billion base pair of the human genome was completed well ahead of schedule [6,7] enabling new high-throughput genomics based approaches to be manifested in biomedicine, especially in clinical diagnostics.

## 6.2 BACKGROUND

Slab gel electrophoresis is a well established and still very popular separation method for nucleic acid analysis. Polyacrylamide and agarose are the most frequently used matrices for horizontal and vertical slab gel electrophoresis [8]. DNA fragments can be detected after the separation either by the application of a fluorescent dye, such as ethidium bromide, or by autoradiographic techniques. Besides the traditionally used slab gel electrophoresis, analysis of DNA molecules in the beginning of the twenty-first century is also based on high-performance liquid chromatography (HPLC) and CE. Liquid chromatography partitions analytes between a very hydrophobic stationary phase and a relevant mobile phase. As the diffusion characteristic of the analyte is an important issue, electrophoresis is advantageous over HPLC when large molecules, such as longer DNA fragments, are separated. The mass transport of DNA molecules is slow in the HPLC mobile phase, resulting in increased band broadening. In CGE this does not represent a problem. CE instrumentation is also less complex and capillaries are cheaper than HPLC columns. A good critical comparison of the two methods is described in Reference 9.

Slab gels feature the benefit of separating multiple samples simultaneously in multilane format; however, the emergence of multicapillary array instruments prevailed over this advantage [10]. Today, mostly 96 capillary units (ABI, Molecular Dynamics) but even 384-capillary array electrophoresis instruments (Genteon) are commercially available, allowing high-throughput analysis primarily for industrial sequencing and genotyping laboratories. As these instruments are quite expensive and the change of a single damaged capillary represents a major issue (i.e., in most instances replacement of the entire array), smaller molecular diagnostic laboratories cannot afford to use them. Microchip-based units (Agilent, Biorad) or small cartridge-based multicapillary systems (eGene) with fluorescence-based nucleic acid detection represent a good alternative to slab gel electrophoresis for smaller molecular biology or clinical laboratories. In the past few years several reviews have been published on DNA separation by CE discussing theoretical issues, separation matrices and detection modes [11–16], and genetic diagnostic [17–23] and forensic applications [24,25].

## 6.3 THEORETICAL ASPECTS

### 6.3.1 ELECTROPHORETIC MIGRATION OF NUCLEIC ACIDS

Applying a uniform electric field ( $E$ ) to an oligo- or polynucleotide molecule with a net charge of  $Q$ , the electrical force ( $F_e$ ) is defined as

$$F_e = QE. \quad (6.1)$$

In a gel or polymer network solution, a frictional force ( $F_f$ ) acts in the opposite direction

$$F_f = f \left( \frac{dx}{dt} \right), \quad (6.2)$$

where  $f$  is the translational friction coefficient and  $dx$  and  $dt$  are the distance and time increments, respectively. Differences in shape, size, and overall charge of the solute molecules result in variances in electrophoretic mobilities providing the basis of the electrophoretic separation. Under steady-state conditions,  $F_e$  and  $F_f$  are counterbalanced, thus the solute migrates with a steady-state velocity of  $v$

$$v = \frac{dx}{dt} = \frac{EQ}{f}. \quad (6.3)$$

The electrophoretic mobility ( $\mu$ ) is defined as the velocity per unit field strength

$$\mu = \frac{v}{E}. \quad (6.4)$$

Retardation of the solute molecules in gel-filled or polymer-filled capillaries is a function of the separation matrix concentration ( $P$ ) and its physical interactions with the molecules subject to electromigration is defined by the retardation coefficient ( $K_R$ )

$$\mu_{\text{app}} = \mu_0 \exp(-K_R P), \quad (6.5)$$

where  $\mu_{\text{app}}$  is the apparent electrophoretic mobility and  $\mu_0$  is the free solution mobility of the analyte (i.e., with no sieving matrix) [8].

When the average pore size of the matrix is in the same size range as the hydrodynamic radius of the migrating analyte molecule, the classical sieving theory applies (Ogston regime) [26,27], that is, at constant polymer concentration the retardation coefficient ( $K_R$ ) is an apparent logarithmic function of the molecular weight (MW) of the migrating analyte [28]:

$$\mu \sim \exp(-MW). \quad (6.6)$$

In this instance, the so called Ferguson plots [29] cross each other at zero gel concentration.

The Ogston theory assumes that the migrating solute behaves as an unperturbed spherical object with comparable size to the pores of the gel. However, DNA molecules can migrate through polymer networks with pores significantly smaller than their size [30] by the phenomenon referred to as reptation, suggesting “snakelike” motion for large biopolymers through the much smaller gel pores [31–33]. The reptation model implies an inverse relationship between the size (MW) and the mobility of the analyte molecules as shown in the following equation:

$$\mu \sim \frac{1}{MW}. \quad (6.7)$$

At extremely high electric field strengths, reptation turns into biased reptation and the resulting mobility of the analyte is described by

$$\mu \sim \left( \frac{1}{MW} + bE^a \right), \quad (6.8)$$

where  $b$  is a function of the mesh size of the sieving matrix, the charge, and segment length of the migrating DNA molecules, and  $1 < (a) < 2$ .

### 6.3.2 EFFICIENCY AND RESOLUTION

In CGE one of the major contributors to band broadening, besides the injection and detection extra column effects, is the longitudinal diffusion of the solute molecules in the capillary tube [34]. The theoretical plate number ( $N$ ) is characteristic of column efficiency

$$N = \mu \frac{E \cdot \ell}{2D}, \quad (6.9)$$

where  $\mu$  is the electrophoretic mobility,  $D$  is the diffusion coefficient of the solute in the separation gel-buffer system, and  $\ell$  is the effective column length.

Resolution ( $R_s$ ) between two peaks can be calculated from the differences of their electrophoretic mobilities ( $\Delta\mu$ ) [35]

$$R_s = 0.18 \cdot \Delta\mu \sqrt{\frac{E \cdot \ell}{D \cdot \mu}}, \quad (6.10)$$

where  $\bar{\mu}$  is the mean mobility of the sample components of interest. As one can see, Equations 6.9 and 6.10 suggest that higher applied electric field and lower solute diffusion coefficient would result in higher separation efficiency ( $N$ ) and concomitantly higher resolution ( $R_s$ ). One of the limiting factors is the so-called Joule heat ( $Q_j$ ), generated by the applied power ( $P = V \times I$ ) [2]

$$Q_j = \frac{P}{r^2 \cdot I \cdot L}, \quad (6.11)$$

where  $I$  is the current,  $L$  is the total column (electrode to electrode) length, and  $r$  is the inside radius of the capillary. Owing to the temperature dependence of electrophoretic mobility, efficient temperature control during CE separation is important in order to attain good reproducibility. Modern, automated CE instruments are equipped with effective liquid- or air-cooling systems to address temperature change-related problems.

## 6.4 PRACTICAL APPLICATIONS OF CAPILLARY ELECTROPHORESIS ANALYSIS OF DNA MOLECULES

### 6.4.1 POLYMERASE CHAIN REACTION PRODUCT ANALYSIS

#### 6.4.1.1 Mutation Detection and Polymorphism Studies

Polymerase chain reaction (PCR) is an *in vitro* DNA replication and amplification technique that revolutionized nucleic acid analysis [36]. It enables small amount of nucleic acid molecules to be exponentially amplified (i.e., to generate enough material for their analysis and sequencing). PCR is a commonly used technique in biomedical, molecular biology, and clinical diagnostics laboratories

accommodating a variety of tasks, such as detection of hereditary diseases, identification of genetic fingerprints, diagnosis of infectious diseases, cloning of genes, and paternity testing. Electrophoresis is a crucial part of this method (except in case of real-time PCR) and CE—especially combined with LIF—more and more replaces classical electrophoretic techniques in many fields.

The first research groups to investigate the utility of CE for PCR product and in general for DNA analysis were Brownlee's and Karger's in the late 1980s [37–39]. In the years, novel high-resolution polymer networks and capillary coatings were developed and CE conditions were optimized for better DNA separation performance [12,40–42]. At the present time, many DNA-related applications are still being reported by using similar conditions and capillaries. In this section, we list a few examples from several important reports on PCR-based methods that greatly helped the fields of molecular genetics. Chromosome 18q allelic loss has been reported to have prognostic significance in stage II colorectal carcinoma. Erill et al. [43] have developed a robust and reliable fluorescent and multiplex PCR assay to analyze five microsatellite markers for the allelic loss at the long arm of chromosome 18. Amplicon detection and evaluation was accomplished by an ABI 310 Genetic Analyzer (Applied Biosystems).

The most frequently used methods for DNA length polymorphism analysis usually consists of two major steps. First is the amplification of the genome region of interest followed by electrophoresis-based separation of the resulting fragments. Hyytia-Trees et al. [44] developed a subtyping method for Shiga toxin-producing *Escherichia coli* O157 strains, which was based on the analysis of several variable number of tandem repeats in the bacterial genome. PCR products were sized using a multicapillary electrophoresis-based sequencing system (CEQ™8000; Beckman Coulter) with the following conditions: injection at 2.0 kV after 15 s and separation at 6.0 kV after 60 min.

One of the largest groups of genetic polymorphisms is referred to as single nucleotide polymorphisms (SNPs), which were conventionally detected by restriction fragment analysis. This method is based on the cleavage of molecules by sequence-specific endonucleases. Interrogation of the size of the resulting DNA fragments is usually electrophoresis separation based. The C677T mutation of the methylenetetrahydrofolate (*MTHFR*) gene is a nutrient-oriented, “eco” genetic mutation, which is associated with elevated levels of homocysteine and an increased risk for coronary heart disease. Sell and Lugenwa [45] reported on an automated assay by means of the Hinf I RFLP to detect this mutation. The resulting restriction fragments were analyzed on an ABI PRISM 310 single capillary-based Genetic Analyzer.

Allele-specific PCR is another very popular genotyping method and is also referred to as amplification refractory mutation system. The technique is based on the utilization of an allele-specific primer as its 3' end hybridizes to the SNP site followed by amplification using a DNA polymerase that lacks 3' exonuclease activity. Amplification in this case occurs only if the primer sequence perfectly matches with the template sequence. Carrera et al. [46] describe refractory mutation system analysis of point mutations by CE. The first application of a multiplex multicolor assay for the simultaneous detection of three of the most frequent mutations related to hereditary haemochromatosis was presented by Gomez-Llorente et al. [47]. One of the described methods was allele-specific PCR and CE analysis of the amplified products that enabled easy, rapid, unambiguous, and high-resolution discrimination between wild-type and mutant alleles. Fluorescently labeled products were analyzed on an ABI PRISM 310 Genetic Analyzer using POP-4 polymer and fused-silica capillaries of 47-cm length and 50- $\mu$ m diameter [47].

Ligase detection reaction (LDR) developed by Barany [48] provides an elegant technique for multiplexed typing of SNPs, deletions, and insertions. It utilizes the ability of the DNA ligase to preferentially seal adjacent oligonucleotides hybridized to a target DNA with perfect complementation at a nick junction. In their paper, Thomas et al. [49] reported on the use of CE and microchip electrophoresis format for detecting single base mutations in selected gene fragments with high diagnostic value in colorectal cancer using LDR. The electrophoretic separations were carried out for the single-stranded DNA products generated by allele-specific ligation assay to screen for a single base mutation in the *K-ras* oncogene. Various separation matrices were investigated in CGE.

LDR products (44 and 51 bp) were analyzed by a cross-linked polyacrylamide gel (5%T/5%C) in approximately 45 min having a 1000-fold molar excess of the LDR primers (25 bp). Interestingly, when linear polyacrylamide gels were used, these same fragments could not be detected because of significant electrokinetic bias during the electrokinetic injection process.

Another frequently used genotyping technique is based on primer extension. In this method, the 3' end of the applied primer anneals just before the SNP site as the first step of a quasi-minisequencing reaction, which is carried out using dideoxy-ribonucleotide triphosphate terminators. For detection purposes, either the primers or the dideoxy nucleotide terminators are labeled by an appropriate fluorophor. Another version of this technique is allele-specific primer extension, which also represents a good method of choice for efficient genotyping. This technique is based on the sequence specific extension of two allele-specific primers that differ at their 3' end defining the allele. Single base extension (SBE) assay—next to allele-specific PCR—was used for the detection of three mutations related to hereditary haemochromatosis [47]. ABI PRISM 310 Genetic Analyzer using POP-4 polymer and fused-silica capillaries of 47-cm length and 50- $\mu\text{m}$  diameter was applied for separation.

Brazill and Kuhr [50] presented a model system to show possible advantages in combining SBE technique with CGE and electrochemical detection (Figure 6.1). An electrochemically labeled primer, with ferrocene acetate covalently attached to its 5' end, was used. The complementary dideoxynucleotide (ddNTP) extended the primer by a single nucleotide and the reaction mixture

**FIGURE 6.1** CGE coupled to sinusoidal voltammetric detection of SBE product. Separation capillary: 25- $\mu\text{m}$  ID/25-cm length; Coating and separation medium: POP-4. Separation conditions: injection: 6 s at  $-4$  kV; Separation voltage:  $-4$  kV. The SV detection employed a 21 Hz sine wave scanning from  $-200$  mV to  $800$  mV versus Ag/AgCl. Both of the time courses shown in this figure are from the second harmonic or 42 Hz. The solid trace is from the injection of the successful SBE utilizing ddATP terminator. The first peak corresponds to migration of the unextended primer, whereas the late-eluting peak corresponds to the extended product. The dotted trace represents the control reaction utilizing ddCTP. (From Brazill, S.A. and Kuhr, W.G., *Anal Chem*, 74, 3421, 2002. With permission.)

was subsequently separated by CGE in a 25-cm-long fused-silica capillary filled with POP-4 sieving medium. The ferrocene-tagged fragments were detected with sinusoidal voltammetry.

Heteroduplex analysis is another very useful approach to analyze known or unknown genetic variations. The method is based on the differential migration of heteroduplex DNA molecules (formed between a wild-type gene segment and the corresponding homologous segment containing an induced mutation or a naturally occurring SNP), compared to the corresponding homoduplex in nondenaturing polyacrylamide gel. Heteroduplexes migrate slower than their corresponding homoduplexes due to their quasi open configuration surrounding the mismatched bases. Heteroduplex analysis is usually carried out by slab gel electrophoresis, CE, or denaturing HPLC (dHPLC); however, it can also be performed by microchip electrophoresis. Kozłowski et al. [51] demonstrated the influence of a number of parameters on the electrophoretic properties of DNA duplexes such as temperature, presence of glycerol, capillary length, as well as polymer (GeneScan) concentration, and evaluated their contribution to the overall analysis time. Their study was carried out on an ABI 310 apparatus equipped with argon-ion laser. The time required for the detection of two typical *BRCA1* gene deleterious mutations by heteroduplex analysis could be significantly decreased through careful optimization of analysis conditions. The effect of different silanizing reagents, polymeric coatings, and polymer networks were investigated for detecting DNA mutations in the *BRCA1* gene via heteroduplex analysis by Landers' group [52]. Figure 6.2 shows the results of analyzing one heterozygous *BRCA1* mutant using capillaries coated with different silanizing reagents and polymers and how they compare with commercial coated capillaries. In general, the electroosmotic flow (EOF) was found to be 19- to 76-fold lower than that of with bare fused-silica capillary. Optimal performance was observed using the chlorodimethyloctylsilane (OCT)- and poly(vinylpyrrolidone) (PVP)-coated capillary and hydroxyethylcellulose (HEC) as the polymer network. More recently, Weber et al. [53] proposed a novel method for the detection of unknown mutations called enhanced mismatch mutation analysis, which is also based on electrophoretic heteroduplex analysis. Their experimental results showed that the combination of high-resolution block-copolymer sieving matrix poly(acrylamide- $\gamma$ -polydimethylacrylamide), and nucleosides as additives in the electrophoretic medium increased the resolution significantly between the homoduplex and heteroduplex peaks. The enhanced mismatch mutation analysis method was compared to denaturing HPLC in a large-scale mutation study of the breast cancer-associated gene *BRCA2* and the success rate of detection of both methods was comparable (94%).

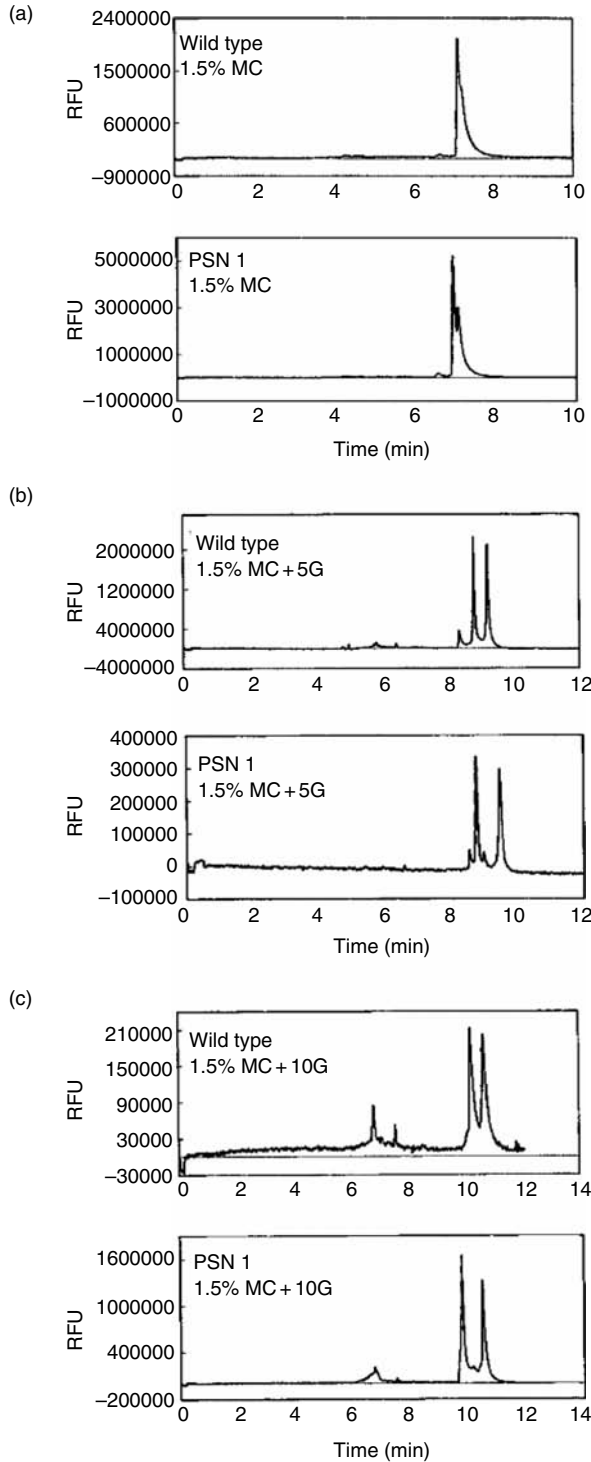

Single-strand conformation polymorphism (SSCP) is a simple and versatile method combining PCR amplification, denaturation of DNA molecules, and the analysis of denatured fragments by electrophoresis. This technique, originally developed by Orita et al. [54], is based on subtle sequence differences (often just a single base pair) that can result in a different three-dimensional conformation and concomitantly measurable differences in their electrophoresis mobility. Hofman-Bang et al. [55] developed a multiplex CE-based SSCP screening protocol on an automated genotyping platform for mutation detection in the *SCN5A* gene coding for the alpha-subunit of the cardiac Na<sup>+</sup> ion channel. The separation was carried out by using a commercial polymer at 18°C and 30°C. Disease-causing mutations were scattered over the DNA sequence, making it difficult to screen for specific mutations that could cause several diseases, such as long QT syndrome, Brugada syndrome, idiopathic ventricular fibrillation, sick sinus node syndrome, progressive conduction disease, dilated cardiomyopathy, and atrial standstill. These diseases exhibited variable expressivity and identification of gene carriers was clinically important, particularly in sudden infant and adult death syndromes. The method was highly efficient with a false positive rate of 0.5% of the analyzed amplicons. Holmila and Husgafvel-Pursiainen [56] compared CE-SSCP, denaturant gradient gel electrophoresis (DGGE), and direct sequencing to investigate the benefits and sensitivity of each of the methods for the detection of unknown TP53 mutations in human lung cancer. Their study revealed that direct sequencing performed less well in finding mutations than the other two methods, and CE-SSCP was found to be a fast and highly reproducible method, also considerably less laborious compared to DGGE, for screening of unknown TP53 mutations. The CE-SSCP analysis was performed using ABI PRISM

**FIGURE 6.2** Effect of different coatings on CE-based heteroduplex analysis. The PCR products were amplified from a heterozygous individual containing 1294del40 mutation in the *BRCA1* gene and analyzed under the following conditions: Injection: 20 s at 370 V/cm. Separation: 370 V/cm (current 27.0–27.6  $\mu\text{A}$ ), using reversed polarity. EOF of the bare fused-silica capillary was  $3.7 \times 10^{-4} \text{ cm}^2/\text{V}\cdot\text{s}$  under the conditions used. The different silanizing reagents and polymers used for modifying the surface of the capillary were as follows: (a)  $\text{CH}_2 = \text{C}(\text{CH}_3)\text{COO}(\text{CH}_2)_3\text{Si}(\text{OCH}_3)_3$  (MET), PVP, EOF is  $8.5 \times 10^{-6} \text{ cm}^2/\text{V}\cdot\text{s}$ ; 24.8  $\mu\text{A}$ . (b)  $\text{CH}_2 = \text{C}(\text{CH}_2)\text{Si}(\text{CH}_3)_2(\text{Cl})$  (ALLYL), PVP, EOF is  $8.9 \times 10^{-6} \text{ cm}^2/\text{V}\cdot\text{s}$ ; 25.0  $\mu\text{A}$ . (c)  $\text{Cl}(\text{CH}_2)_4\text{Si}(\text{CH}_3)_2(\text{Cl})$  (BUTYL), PVP, EOF is  $19.7 \times 10^{-6} \text{ cm}^2/\text{V}\cdot\text{s}$ ; 25.5  $\mu\text{A}$ . 310 capillary sequencer at 30°C, and with ABI PRISM 3100 Avant capillary sequencer at five different analysis temperatures (18°C, 25°C, 30°C, 35°C, and 40°C). Electrophoresis time was 30 min with the applied voltage of 13 kV. The separation media were 5% GeneScan Polymer in 1 $\times$  Tris-borate-EDTA (TBE) buffer containing 10% glycerol. Endo et al. [57] studied SSCP parameters that might affect the mutation analysis in the *K-ras* gene—such as electric field strength, separation temperature, polymer, and additive in the sieving matrix (high concentration methyl cellulose)—by CE and microchip electrophoresis. Figure 6.3 shows the effect of glycerol concentration in the buffer

**FIGURE 6.3** Effects of glycerol concentration in the buffer on CE-SSCP analysis of PSN1 and the wild-type of *K-ras* gene. Experimental conditions: 1.5% MC in 50 mM Trisborate buffer; (a) without glycerol; (b) with 5% glycerol; (c) with 10% glycerol; electric field: 300 V/cm; samples were labeled with FAM. RFU represents relative fluorescence unit. (From Endo, Y., et al., *Electrophoresis*, 26, 3380, 2005. With permission.)

on CE-SSCP analysis of PSN1 and the wild-type *K-ras* gene. Better resolution of single-stranded DNAs was obtained with the addition of 5% glycerol to the buffer system. However, as it can be seen in Figure 6.3c, the separation time was increased with increasing glycerol concentration. Analysis of seven mutants of the *K-ras* gene was accomplished in 10 min by CE and in 1 min by microchip electrophoresis under optimized separation conditions. Culiati et al. [58] identified point mutations in the mouse genome induced by *N*-ethyl-*N*-nitrosourea using a new high-throughput mutation-scanning technique: temperature-gradient CE (TGCE). TGCE detects the presence of partially denatured heteroduplex molecules that are resolved from homoduplexes through their differential mobilities during CE conducted with a closely controlled temperature gradient. All TGCE analyses were conducted using the SCE9610 Genetic Analysis System (Spectrumedix). The default running condition was a broad 60–68°C temperature ramp with 5 kV injection voltage and 60 s injection time.

#### 6.4.1.2 Forensic Application/Identity Testing

Individual DNA fingerprints can be provided by microsatellite- or SNP analysis and can be used in forensic testing, paternity testing, and identification of suitable recipients for organ transplantation, just to mention a few. A recent review summarizes the most relevant examples of analytical applications of CE techniques in the forensic field from 2001 till 2004 [25]. In an earlier review, Butler et al. [24] detailed the characteristics of DNA typing with short tandem repeat (STR) markers widely used for a variety of applications including human identification. Y-chromosome STRs (Y-STRs) provided valuable information in cases of rape and questioned paternity. This test also allowed genetic identification of male lineages. In a study of Johnson et al. [59], a Y-STR 10-plex on a commercially available automated genetic analyzer was validated for use in forensic and paternity laboratories. In a comparison study, Dixon et al. [60] used artificially degraded samples and demonstrably obtained a profile using SNPs instead of STRs for certain sample types with greater likelihood. A method for simultaneous analysis of SNPs has been developed and validated to analyze highly degraded and low copy number DNA templates (i.e., <100 pg) for scenarios including mass disaster identification. The multiplex assay interrogated 20 autosomal noncoding loci—not in linkage disequilibrium—and Amelogenin for sex determination. The samples were amplified in a single-tube PCR and analyzed by an automated CE-based sequencer. Inagaki et al. [61] developed a novel 39-plex typing system for SNP study. Thirty-seven genomic DNA fragments containing a total of 38 SNPs and one sex-discriminating site were amplified in a multiplex PCR. Following the reaction, single nucleotide primer extension reaction was performed by dividing these SNP loci into five groups. The SNP type of each of the 39 loci was determined in the same run by an ABI PRISM™ 310 Genetic Analyzer using POP-4 polymer in 47 cm × 0.050 mm ID capillaries applying a newly designed multi-injection method. In this novel technique, the collection time was set to 1 or 2 min for the first four groups and 20 min for the last group. The method was applied in forensic cases of paternity testing and personal identification.

An additional interesting forensic application of CE is the identification of differences to determine the species of botanical evidence found at a crime site or to associate a sample with a source. Amplified fragment length polymorphism (AFLP) analysis of botanical forensic evidence provided a means of obtaining a reproducible DNA profile in a relatively short period of time for species with no available sequence information. Bless et al. [62] obtained AFLP profiles of 40 *Acer rubrum* trees using an automated DNA fragment analyzer. This information could be used to link a piece of evidence with a particular location or a suspect. Another important application for investigating an accident or a crime is dog DNA profiling, as dogs are intensely integrated in human social life. Several STR markers were analyzed for the individualization of dogs using an ABI PRISM 3100 Genetic Analyzer with POP-4 gel in 36-cm capillary arrays using default instrument settings [63].

Graft rejection is one of the most severe complications after allogenic transplants in leukemia. Detection of increasing quantities of lymphoid and myeloid host cells might be predictive of graft

rejection and leukemia relapse, respectively. A sensitive and automatic method of quantifying the degree of mixed chimerism after allogenic stem cell transplantation was based on PCR assays of polymorphic STRs. CE allowed quantification of the recipient's cells relative to the donor's cells by calculating ratios between STR alleles [64].

#### 6.4.1.3 Diagnosis of Infectious Diseases

Identification of bacteria, viruses, and fungi is crucial for diagnostic and therapeutic purposes; however, microbiologists often have problems with microorganisms that are difficult to culture. Molecular methods on the other hand enable detection of these infectious agents without requiring the presence of viable organisms to allow appropriate identification. PCR can be used to target conserved stretches of DNA, similar to the region encoding 16S ribosomal RNA. These conserved sequences enable robust applications for the identification of unknown or known infectious agents. Several groups reported case histories in instances where infectious agents were identified based on the sequence analysis of *16S rRNA* gene (*rDNA*). Sequencing was carried out using the ABI Big Dye cycle sequencing reaction kit with AmpliTaq FS DNA polymerase and the electrophoresis was performed on an ABI 310 capillary analyzer. Analysis of the sequences and clustering was performed by GeneCompar, version 2.0 (Applied Maths, Kortrijk, Belgium) [65,66]. In some cases, 16S rDNA sequence determination does not seem to be sufficient for species identification just like in the case of some *Helicobacter* species commonly found in dogs and cats. Phylogenetically, these species are highly related to each other, thus their *16S rRNA* gene sequences show >99% similarity. A multiplex PCR method was described based on the tRNA intergenic spacers and in the urease gene, combined with CE in the study. The PCR products were separated using an automated genetic analyzer and the tRNA intergenic spacers amplified in tDNA-PCR were sequenced by using the BigDye Terminator cycle sequencing kit (Applied Biosystems). The sequencing products were electrophoretically separated by a commercially available multicapillary genetic analyzer. Their procedure was shown to be very useful in determining the species identity of "*Helicobacter heilmannii*"-like organisms observed in human stomachs and would facilitate research concerning their possible zoonotic importance [67]. CE also offers great versatility in studying viral systems. Krylova et al. [68] demonstrated the utility of a P/ACE MDQ instrument for monitoring DNA release from virus particles in a running buffer of 25 mM sodium tetraborate containing 10 mM SDS. Drug development targeting viral propagation requires fast and sensitive methods for *in vitro* monitoring of viral DNA release. A T5 bacteriophage/*Escherichia coli* K-12 model was reported to study molecular mechanisms of viral infections and to evaluate antiviral drug candidates. The identification of clinically significant fungi species was demonstrated by the amplification of noncoding internal transcribed spacer regions of the *rRNA* gene and sequencing. All PCR/sequencing identifications from positive broths were in agreement with the final species identification of the isolates grown from subculture. Early identification of fungi by PCR/sequencing method may facilitate prompt and more appropriate antifungal therapy [69].

An earlier review by Righetti and Gelfi [70] describes a number of applications using capillary zone electrophoresis with sieving liquid polymers (mostly linear polyacrylamides and celluloses) for the analysis of PCR products of clinically relevant, diagnostic DNA samples. The fields of microbiology and virology were also covered, just like human genetics, quantitative gene dosage, forensic medicine, and therapeutic DNA.

It has to be taken into account that microorganisms can also be separated, identified, and characterized by CE without the necessity of using PCR. A comprehensive review of Desai and Armstrong [71] gives details about these possibilities, such as the recent paper of Gao et al. [72] who detected *Staphylococcus aureus* by a combination of monoclonal antibody-coated latex and CE. CZE separations were performed on a Beckman P/ACE MDQ System equipped with a photodiode array detector. A 27-cm-long capillary column was used for the separation (20 cm to the detection window) applying 215 kV at a constant temperature of 25°C.

**FIGURE 6.4** CE trace showing the deletion of the 3p telomere. The peak area of the 3p telomere is reduced in the patient sample when compared to the control sample. (From Rooms, L., et al., *Hum Mutat*, 23, 17, 2004. With permission.)

#### 6.4.1.4 Molecular Karyotyping

Conventional karyotyping (chromosome banding) is one of the most widely used techniques in routine cytogenetics and has been invaluable in the search for chromosomal aberrations causally related to, for example, congenital mental retardation and malformation syndromes. It requires culturing of cells from viable tissues but many clinical specimens may fail to provide adequate cellularity for karyotyping and it also has a rather limited resolution (5–10 million bp). To solve these problems, molecular karyotyping assays have been developed that allow sensitive and specific detection of single copy number changes of submicroscopic chromosomal regions throughout the entire human genome. Among such methods are array-based comparative genomic hybridization (array CGH), fluorescent *in situ* hybridization (FISH), and multiplex ligation-dependent probe amplification (MLPA). MLPA is a recently developed technique, which is based on PCR amplification of ligated probes hybridized to chromosome regions in question using unique primers attached to the probes, making multiplexing easier. Only probes hybridized to a target sequence will be ligated and subsequently amplified in the PCR. After separation by CGE, the peak area of each amplification product reflects the relative copy number of that target sequence. Sequences that are deleted or duplicated can also be easily identified, such as the deletion of the 3p telomere in Figure 6.4 [73,74]. However, it should be noted that balanced translocations could not be detected by CE methods at this time.

#### 6.4.1.5 Quantification of Cellular mRNA/Expression Analysis

Quantitative transcript analysis is usually carried out by microarray techniques, real-time PCR, or even with serial analysis of gene expression (SAGE) [75–78]. An alternative of these techniques is competitive template reverse transcriptase method described by Gilliland et al. [79] in which the PCR mix contains a known amount of competitor DNA that differs from the cDNA of interest only by having, for example, a mutated internal restriction enzyme site. Therefore, the competitor and the unknown amount of target DNA compete for the same primers. The ratio of products remains constant through the coamplification and can be readily quantified by CE and LIF [80,81]. In the paper of Warner et al. [82] bronchogenic carcinoma was diagnosed with the help of standardized reverse transcriptase PCR (StART-PCR)—which is a

modification of competitive template reverse transcriptase method—since morphological analysis of cytologic samples obtained by fine-needle aspirate or bronchoscopy was not sensitive enough (65–80%). They measured the *c-myc* × *E2F-1/p21* index in cDNA samples and found that the index may augment cytomorphologic diagnosis of bronchogenic carcinoma biopsy samples, particularly those considered nondiagnostic by cytomorphologic criteria. After amplification, each PCR product was analyzed by microchip electrophoresis on an Agilent 2100 Bioanalyzer instrument [82]. Relative quantification of mutated and normal mRNAs was carried out by amplification refractory mutation sequencing PCR assay using 5-carboxyfluorescein dye-labeled mutation-specific primers and a commercial DNA analyzer with standard protocols [83]. A method was designed and validated to detect a point mutation in the *Janus tyrosine kinase 2* gene in patients with chronic myeloproliferative disorders. The proposed method might complement current technologies based on genomic DNA analysis. Spyres et al. [84] described a semiautomated PCR-based technology, called quantitative rapid analysis of gene expression (Q-RAGE), which provided fast measurements of mRNA abundance with extremely high sensitivity using fluorescent detection of the specific products. An array of sixteen 36-cm-long fused-silica capillaries were used in an ABI 3100 instrument employing POP-4 separation polymer. They claimed that their method was more sensitive compared to SAGE and its throughput was higher than that of real-time PCR or StaRT-PCR. The flexibility of Q-RAGE makes it eminently well suited for large-scale validation of microarray results and for more directed quantitative studies of medium-sized sets of related genes, especially when low-abundance transcripts are of interest.

#### 6.4.2 DNA SEQUENCING

DNA sequencing enables to yield the greatest amount of information by identifying the order of each deoxynucleotide base in a particular DNA molecule. With this knowledge, for example, one can locate regulatory elements and gene sequences, make comparisons between homologous genes across species, and identify mutations. In the 1970s, two DNA-sequencing methods were independently developed. Maxam and Gilbert [85] used a “chemical cleavage protocol,” while Sanger [86] designed a procedure similar to the natural process of DNA replication. Even though both teams shared the 1980 Nobel Prize, the Sanger method became the industry standard because of its practicality. Sanger’s method is based on dideoxy chain termination using ddNTPs in addition to the normal nucleotides (dNTPs) in appropriate concentrations. When these ddNTPs are integrated into the newly built-up nucleotide chain, they prohibit the addition of further nucleotides due to the lack of their phosphodiester bond forming OH group, thus the DNA chain is terminated. When different fluorescent labels are attached to each of the four reaction products (primer or terminator), DNA sequencing can be carried out in one test tube as multispectral imaging can readily determine which fragment ends with what base by simple fluorescent signal based differentiation. In the beginning of the various Genome Projects (Human, Mice, Rice, etc.), most laboratories did DNA sequencing by means of very labor-intensive and time-consuming slab gel electrophoresis, also facing difficulties with automation. The first paper on high-resolution single base separation of DNA fragments using CGE was published in 1988 with the promise that the method was applicable for automated DNA sequencing [87]. In this early work, cross-linked polyacrylamide gels were utilized within the capillary, in analogy to slab gel electrophoresis [38]. Later, it was found that the cross-linked matrix could not withstand osmotic shock occurring when salt plugs migrated through the gel-filled capillary. Therefore, it became clear that non-cross-linked (so-called physical gels) had much better characteristics in this respect. Initially, covalent coatings were utilized to minimize EOF [88]; more recently, dynamic (i.e., adsorbed) coatings prevailed [89]. It was clear that if CE were to be selected as the technology to sequence the Human Genome, researchers had to find the means for automatic replenishment of the polymer matrix, as no one was interested in reusing a polymer matrix due to fear of cross-contamination. Changing columns after each run

**FIGURE 6.5** Separation of single-color DNA sequencing of larger than 590 bases by using (a) POP-6, (b) MegaBACE matrix, and (c) quasi-IPN. Temperature: 60°C. Capillary, 40 cm effective length, 75  $\mu$ m ID. DNA injection, 41 V/cm and 30 s for POP-6, 50 V/cm and 40 s for MegaBACE matrix, 75 V/cm and 8 s for quasi-IPN; running electric field strength, 200 V/cm for POP-6, 150 V/cm for MegaBACE matrix and quasi-IPN. (From Wang, Y., et al., *Electrophoresis*, 26, 126, 2005. With permission.)

was also not a workable strategy. In 1990, Guttman [3] demonstrated that, through the use of solutions of linear polyacrylamide and high pressure, it was possible to automatically replace the polymer after each run and still maintain the high separation efficiency. This was a key step forward, because it proved the potential of CE to become the basis of an automated DNA-sequencing instrument. The technology was further developed for long read-length sequencing by Karger and coworkers [90] in the late 1990s. It was also recognized that with longer DNA chains, reptation-like migration became more significant and this stretching phenomenon reduced chain length-based electrophoretic mobility differences to the point where separation was unsuccessful. After numerous optimization and improvement steps by increasing the molecular weight of the sieving polymer, 1000 base read lengths were achieved in 1996 at high column temperatures (50°C) [91]. Today, high-molecular-weight linear polymers are used routinely for DNA sequencing and further developments on DNA separation media are carried out by the use of copolymers, possessing high sieving ability, low viscosity, and dynamic coating ability [92]. As it was difficult for homopolymers to possess all the properties that can meet the different challenges, copolymers were used to combine the desirable properties of the different monomers. On the basis of this principle, a range of DNA separation matrices were developed featuring dynamic coating ability, low viscosity, and/or adjustable viscosity covering a wide range of read length. The latest results are summarized in the paper of Wang et al. [93] and Figure 6.5 compares the separation efficiency of two polymers and a copolymer.

Another significant improvement in capillary-based DNA sequencing was multiplexing (i.e., using arrays of capillaries) [10]. This topic has been extensively reviewed by a number of groups, just to list a few [5,94–97]; however, it is important to highlight the work of Kheterpal and Mathies [98], Li and Yeung [99], Dovichi and Zhang [100], and Kamahori and Kambara [101] for their contributions on automated multicapillary instrumentation.

### 6.4.3 PURITY CONTROL OF SYNTHETIC NUCLEOTIDES

#### 6.4.4 OLIGONUCLEOTIDES

Oligonucleotides are commonly used for DNA amplification in PCR mixtures as primers, for *in situ* hybridization techniques as probes for detecting PCR products, and for antiviral and anticancer treatment as antisense oligonucleotide therapeutic agents, just to list the most important applications. In all of these instances, the oligonucleotides have to be of high purity, so their quality control after synthesis is very important. All synthetic oligonucleotides should be tested for a defect in length or sequence. The study of Willems et al. [102] showed that the combination of capillary zone electrophoresis and electrospray ionization quadrupole-time of flight mass spectrometry allowed the identification of oligonucleotides differing in length by only one nucleotide, and also any misincorporated nucleotide by measuring tiny mass differences. Another approach for such tests was published by Olson et al. [103] who modified an automated multicapillary DNA sequencer and applied noncovalent fluorescent labeling.

##### 6.4.4.1 Antisense DNA

Antisense therapeutics are synthetic oligonucleotides that have a complementary base sequence to a target messenger RNA which encodes for disease-causing proteins or to the double-stranded DNA which the mRNA is transcribed from. These molecules inactivate the genetic message, thus inhibiting gene expression. Since oligonucleotides with a phosphodiester backbone are very susceptible to nuclease degradation, DNA analogs with phosphorus-modified backbone (e.g., phosphorothioates and methylphosphonates) are of high interest as they exhibit increased resistance against degradation. Another type of antisense DNA is called as peptide nucleic acid. In these molecules, the deoxyribose-phosphate backbone is substituted by a pseudopeptide backbone. Synthetic peptide nucleic acid oligomers have been used in recent years in molecular biology procedures, diagnostic assays and therapies. Some of these applications typically require stringent purity criteria for the antisense DNA agents.

A paper by Chen and Gallo [104] on the instrumental and technological aspects of analyzing antisense DNA in biological samples recommends the use of CGE to reveal the pharmacokinetics of these molecules. An earlier review by DeDionisio and Lloyd [105] described a CGE-based method for the purity analysis of antisense oligonucleotides after their chemical synthesis and for a range of applications in the field of antisense-based technology. In addition, a CGE-based analysis method using eCAP™ ssDNA 100-R gel in a Beckman PACE 5510 instrument was presented by the same group for the analysis of a N3' → P5' phosphoramidate/phosphorothioate chimera, a second generation antisense oligonucleotide, prior and after purification [106]. More recently, Malek and Khaledi [107] used CE with LIF (CE-LIF) detection to evaluate the effectiveness of delivery and fate of a model 25mer DNA-based phosphorothioate antisense drug in HeLa cells. Belenky et al. [108] described a CE method for sequence determination of antisense DNA analogs of unknown base composition, while Froim et al. [109] developed a method of phosphorothioate antisense DNA-sequencing analysis using UV detection (i.e., with no fluorescent or other labeling requirement). Vilenchik et al. [110] applied high-performance CE for low level and rapid monitoring of phosphorothioate DNA that modulated *in vitro* gene expression of human immunodeficiency virus (HIV). The method was based on Watson-Crick hybridization between phosphodiester and the target DNA. Various techniques of staining or labeling were investigated to improve detection limits (0.1 ng/mL).

#### 6.4.5 SEPARATION OF LARGE DNA MOLECULES (> 2 kb)

Initial efforts in large DNA fragment analysis tended to apply constant electric fields. The size limit of high resolution was demonstrably about 20,000 bp [111,112], while in case of low-resolution

requirement it was as high as 48.5 kb using linear polyacrylamide in CE [113]. DNA fragments (72 bp to 23.1 kb) were separated in ultradilute HEC polymer solutions (<0.002% w/w) using high voltage. On the basis of their results, Barron et al. [114] developed a transient entanglement coupling mechanism theory for DNA separation, which suggested that there was no a priori upper size limit of DNA separation by CE at a constant electric field. More recently, Chiu and Chang [115] demonstrated that HEC solution at concentrations higher than its entanglement threshold provided good separation for large DNA fragments in the presence of EOF at high pH. Separation of DNA fragments ranging in size from 5 to 40 kb was completed in 6 min using 1.5% HEC, prepared in 20 mM methylamine-borate (pH 12.0). A novel separation mechanism was demonstrated by Zheng and Yeung [116], which was based on radial migration in CE with additionally applied hydrodynamic flow. Without the need for gel/polymer or complex instrumentation, this separation technique—while also applicable for proteins, cells, and so on—was complementary to CGE and field-flow fractionation techniques.

Plasmid analysis is often used in recombinant DNA technology. A new separation matrix, consisting of poly(*N*-isopropylacrylamide) (PNIPAM) polymer and mannitol as small molecule additive, was used for CE-based plasmid DNA separation. Supercoiled, linear, and nicked conformers of lambda plasmid were separated in 1% PNIPAM + 6% mannitol. The effect of the applied mannitol concentration on the separation quality is shown in Figure 6.6 [117].

Application of pulsed electric fields in conjunction with dilute polymer solutions are one way to extend the size limit of DNA fragment analysis in CE. In the early 1990s, Heiger et al. [40] demonstrated the use of pulsed-field electrophoresis to enhance the separation of large DNA molecules using linear polyacrylamide matrix. Later, Kim and Morris [118] separated long-chain double-stranded DNA (<10 kb and >1.5 Mb) in less than 4 min in buffers containing ultradilute polymer solutions. They concluded that field inversion with higher peak amplitude in the forward direction than in the reverse, but with equal pulse durations, provided the best resolution if running time was an issue. Kabatek et al. [119] examined the behavior of large DNA fragments in pulsed-field CE under various temperatures in short capillaries. Tseng et al. [120] reported the analysis of long DNA molecules by nanoparticle-filled CE under the influences of hydrodynamic and electrokinetic forces. The polymer composite prepared from gold nanoparticles and poly(ethyleneoxide) was filled into the capillary column as separation matrix. Separations of lambda-DNA (0.12–23.1 kb) and high-molecular-weight DNA markers (8.27–48.5 kb) by nanoparticle-filled CE, under the electric field strength of 140 V/cm with the additional hydrodynamic flow velocity of 554  $\mu\text{m/s}$ , were accomplished within 5 min. Electrophoresis of very long DNA molecules (T4 DNA: 166 kb; *S. pombe* chromosomal DNA: 3–6 Mb) in linear polyacrylamide solutions was investigated by fluorescence microscopy and CE [121]. It was found that at higher polymer concentrations, the shape of the migrating DNA changed from U shape to linear shape, and it was possible to separate the DNA molecules under this linear shape motion. Actually, Mb-sized DNAs were well separated within 5 min in the region of the linear shape motion by means of CE with a d.c. field. Considering that it usually takes 20 h to separate Mb-sized DNAs by standard pulsed-field gel electrophoresis, this result proved extremely useful for the separation of giant DNA molecules.

#### 6.4.6 ANALYSIS OF MONONUCLEOTIDES AND NUCLEOSIDES

Deoxyribonucleic acid and ribonucleic acid, as well as their nucleotides, nucleosides, and base constituents play an important role in many vital biochemical processes of medical interest. To better understand these processes, fundamental investigations into the structure, occurrence, search for modifications, and biochemical impact of structural variation are required. Thus, reliable high-resolution analytical methods for the separation and identification of the nucleic acid constituents (often at extremely low concentration levels) had to be developed. Chromatography (including reversed-phase liquid chromatography), ion exchange chromatography, dHPLC, and electrophoresis

**FIGURE 6.6** Separation of *\_X174/HaeIII* DNA by CE with: (a) 1.5% + PNIPAM + 2% mannitol; (b) 1.5% PNIPAM + 4% mannitol; (c) 1.5% PNIPAM + 6% mannitol; (d) 1.5% PNIPAM + 8% mannitol; (e) 1.5% PNIPAM + 10% mannitol. Capillary, 75/365  $\mu\text{m}$  i.d./o.d., and 32/40 cm efficient/total length; inject, 5 s at  $-8$  kV; separation electric field strength 220 V/cm. (From Zhou, P., et al., *J Chromatogr A*, 1083, 173, 2005. With permission.)

(slab gel and other modes) were the major techniques that have been attempted for the analysis of nucleic acids, nucleotides, nucleosides, and bases.

#### 6.4.6.1 Nucleotides

Nucleotides are among the most important metabolites in a cell. Besides being the monomeric units of the major nucleic acids of RNA and DNA, nucleotides are also required for numerous other important functions within cells. These functions include (1) acting as energy carriers in phosphate transfer reactions [adenosine 5'-triphosphate (ATP), guanosine 5'-triphosphate (GTP)]; (2) supplying the basic structures for important compounds, such as cofactors ( $\text{NAD}^+$ ,  $\text{NADP}^+$ , FAD, and coenzyme A); (3) serving as mediators of several important cellular processes such as secondary messengers in signal transduction events [cyclic adenosine 5'-monophosphate (cAMP), cyclic guanosine

5'-monophosphate (cGMP)]; (4) controlling many enzymatic reactions through allosteric effects on enzyme activity; and (5) acting as activated intermediates in numerous biosynthetic reactions (*S*-adenosylmethionine, also referred to as *S*-AdoMet). Nucleotide analyses by CE were reportedly carried out in biochemical, biomedical, and pharmacological studies, as well as in the food industry [122–128]. A new method based on pressure-assisted CE coupled to electrospray ionization mass spectrometry was recently developed by Harada et al. [124] for anionic metabolome analysis, including nucleotides. The key step of the method was that CE polarity was inverted from conventional CE analysis for anions with the use of uncoated fused-silica capillary.

#### 6.4.6.2 Nucleoside Analogs

Several nucleoside analogs are chemically synthesized and used as therapeutics, for example, to inhibit specific enzymatic activities. Such analogs can be cytostatics (e.g., 6-mercaptopurine, 5-fluorouracil, 5-iodo-2'-deoxyuridine, and 6-thioguanine), because they interfere with DNA synthesis, thus preferentially kill rapidly dividing cells like tumor cells. Another family of nucleoside analogs has been used as therapeutics for viral infection treatment, such as for HIV. Azidothymidine (AZT) was the first of such analogs, but followed by many others: ddI (dideoxyinosine), ddC (dideoxycytidine), d4T (didehydro-deoxythymidine), and so forth. Nucleoside analogs are also used to suppress the immune system after organ transplantation and to reduce the likelihood of transplant rejection by the host. CZE has proved to be a suitable and useful method for the determination of acid–base dissociation constants ( $pK_a$ ) of new synthetic compounds of amino- and (amino)guanidinopurine nucleoside analogs, such as acyclic nucleoside phosphonate, acyclic nucleoside phosphonate diesters, and other related compounds [129]. Determination of this characteristic seemed to be very important in the optimization stage of new drug development projects to understand their passage and metabolism.

In an earlier study, Balayiannis et al. [130] developed a capillary zone electrophoresis method for the analysis of a series of novel synthetic dideoxynucleoside analogs with potential anti-HIV activity. The method was readily applied for purity testing as well as to resolve *cis* and *trans* diastereomers. The purity and separation of diastereomers of such analogs are of great importance for further testing of their biological and pharmacological activity.

#### 6.4.6.3 DNA Adducts

The initial step in chemical carcinogenesis is believed to be the covalent attachment of a chemical to DNA to form DNA adducts, like the extensively studied 8-hydroxyguanine. DNA adducts are most often used as molecular dosimeters of exposure. If not repaired correctly, these modifications may lead to mutations and eventually to cancer, in particular if the adduct is located in an oncogene or in a tumor suppressor gene. Therefore, significant efforts are being made to understand how the diversity in DNA adduct conformations can affect cellular responses to DNA damage. Analysis of DNA adducts can be carried out on the nucleotide or nucleoside level after enzymatic digestion. Analytical methods used for the detection of DNA adducts must have excellent sensitivity, since only 1 in  $10^6$  to 1 in  $10^{12}$  bases are usually modified that represents a great challenge. Next to immunoassays and fluorescence-based assays, the most common method is  $^{32}\text{P}$ -postlabeling, but CE-MS holds the potential to replace it in the near future. Markushin et al. [131] recently reported that catechol estrogen quinines-derived DNA adducts are present in urine samples from subjects with prostate cancer. Their finding suggests that if it can be repeated in larger sample sizes, the presence of depurinating adducts in human urine samples may be used as prostate cancer biomarker.

### 6.5 FUTURE PROSPECTIVE

Recent technological developments in nucleic acid analysis by electric field mediated separation techniques are tending toward miniaturization with the goal to provide high-speed and low-cost

clinical analysis tools. CE, and more recently microchip electrophoresis, features the use of small sample volumes, low reagent consumption, and equally important in a high-throughput clinical environment, almost negligible waste. Another essential impact of miniaturization in capillary and microchip-based techniques is the potential for system integration of several processing steps, such as sample preparation, desalting, PCR amplification, restriction digestion, separation, fraction collection, and so forth. The speed of CE and microchip electrophoresis is significantly higher than that of any other conventional electrophoresis methods, and its cost is also favorable, especially in a disposable plastic chip format. Multicapillary and microchip-based bioanalytical methods will probably play a significant role in the future of biomedical and clinical applications [4].

## 7.1 INTRODUCTION

Carbohydrates are widely distributed in nature. Generally speaking, they represent a class of polyhydroxylated compounds, which contain a carbonyl functional group, aldehyde or ketone, often as semiacetal or hemiketal. The abundance of hydroxyl groups and a carbonyl functionality result in the formation of diverse oligomers and macromolecules. Carbohydrate biopolymers, oligo- and polysaccharides, are often very structurally complex comprising monosaccharides linked by glycosidic bonds. The most common examples are  $\alpha$ - and  $\beta$ -1,4-linked polyglucans, for example, cellulose, the main constituent of plant cell walls, or starch, which is present in large quantities in plant seeds and roots. Many fruits contain high concentration of oligosaccharides based on glucose, fructose, and raffinose building blocks. On the other hand, bacterial cell walls are built of complex glycans containing glucosamine, muramic acid, and oligosaccharide derivatives of various monosaccharides. Various kinds of carbohydrates play important roles in animal and human tissues supporting their living activities. For example, glucose is a major constituent of blood that generates energy via TCA metabolic cycle (tricarboxylic acid cycle, also known as citric acid cycle, or the Krebs cycle). Glycogen, a highly branched glucose polymer, is the principal energy storage in animal and human

cells. Abnormal increase of glucose in blood is a symptom of diabetes; therefore, rapid estimation of its level is an important task in clinical applications. Polymerized glucosamine constructs hard shell animal and insect substances. Besides, carbohydrates exist in living organisms in various forms of glycoconjugates. Glycan moieties in glycoconjugates, where oligosaccharide chains are covalently linked to an aglycon (e.g., protein or lipid), are very structurally and functionally diverse. They are responsible for key functions in protein folding and stability, biological recognition, and cell–cell interaction processes [1–3]. Glycoconjugates act as receptors on the cell surface. Structures of glyco-moieties range from relatively simple, as in glycosphingolipids (GSLs) and some glycoproteins, to extraordinary complex mucins and proteoglycans (PGs). Saccharides have an enormous potential to carry information, far exceeding that of proteins and nucleic acids [4], due to diversity of monomer building blocks and linkages between them, as well as substitute groups. Recent advances in the research of biological roles of glycans in glycoconjugates call for the development of more sensitive and reproducible analytical methods to determine their compositions and structures.

In spite of the apparent significance, carbohydrate separation and analysis technology has not been as universal in life sciences and biotechnology as nucleic acid and protein analysis. Heterogeneity of oligo- and polysaccharides in molecular weight, primary sequence and branching, linkage, variety of sugar structural isoforms, and lack of chromophore/fluorophore or active functional groups have presented a challenge. A number of analytical methods have been applied to carbohydrate analysis, including paper and thin-layer chromatography [5,6], gas chromatography [8], high-performance liquid chromatography (HPLC) [7], high-pH anion-exchange chromatography (HPAEC) [9–12], supercritical fluid chromatography [13], affinity chromatography [14], polyacrylamide slab gel electrophoresis and capillary electrophoresis (CE) as separation, and mass spectrometry and nuclear magnetic resonance spectroscopy as structural characterization techniques [15]. CE features the highest separation efficiency in carbohydrate analysis compared with the other reported methods. A number of excellent reviews on carbohydrate analysis by CE have been published in the past [16–21], which described the method in detail.

This chapter is intended to summarize most significant advances in carbohydrate analysis by CE-based techniques during the past decade. Clearly, it is no longer possible to write a comprehensive review of the massive literature published recently, which includes a variety of different aspects and applications involving carbohydrate analysis. Therefore, the focus has been made on the most significant and interesting, in the author's opinion, developments in high separation efficiency of CE, hyphenated techniques, in particular, CE-mass spectrometry (CE-MS) and analysis of complex polysaccharides and glycoconjugates. In addition, special attention has been paid to specific applications, recently emerging in pharmaceutical and bioindustrial arenas. These include analysis of polysaccharides and glycoconjugates in drugs, analysis of traditional Chinese medicines, and approaches to high-throughput carbohydrate profiling at the large industrial scale, particularly, problems associated with the processes of biomass conversion to fermentable sugars. Recent trends toward miniaturization of CE carbohydrate analysis have also been reviewed.

## 7.2 BACKGROUND: HIGH-PERFORMANCE CE SEPARATIONS OF CARBOHYDRATES

Numerous research papers and reviews on carbohydrate separations by CE have been written for the past several years. Researches have successfully addressed problems, such as tremendous diversity and complexity of this class of compounds, polar and neutral nature of most carbohydrates, their low ultraviolet (UV) extinction coefficients, and lack of functional groups. In the previous edition of this book, Olechno and Nolan [16] published a comprehensive overview of the CE separation techniques, attempted and developed for intact and derivatized carbohydrates, charged and neutral, as well as detection approaches by UV, indirect fluorescence, electrochemical (e.g., amperometric) detection, refractive index, and laser-induced fluorescence (LIF). A variety of buffer systems were

introduced, depending on the nature of mono- and oligosaccharides of interest: acidic and basic, using normal or reversed polarity, either with electroosmotic flow (EOF) present or suppressed. For more details and specific examples, the reader is directed to Reference 16. In brief, the most popular buffers utilized have been phosphates (pH 3 and 9), borates (pH 8–9), mixed phosphate-borate systems, acetates, and so forth [16]. Addition of surfactants, such as sodium dodecyl sulfate (SDS) or cetyltrimethylammonium bromide (CTAB), has often improved the peak efficiency due to micellar electrokinetic chromatography (MEKC) effect. Other additives have been exploited as well, for example, triethylamine to improve run-to-run reproducibility, or polyethyleneoxide (PEO) to enhance resolution, most likely, by imposing additional sugar–polymer interactions based on hydrogen bonding. Owing to weak acidic properties, neutral sugars become ionized at very high-pH values (pH 12–13) and can be separated according to their  $pK_a$  differences under strongly alkaline conditions (analogous to HPAEC). Borate-assisted CE has been widely used for the analysis of both native and derivatized sugars. Borate ions are known to form anionic complexes with polyols (e.g., sugars) and more stable adducts are typically formed with *cis*-oriented hydroxyl groups. Therefore, in the presence of borate anions the resolving power of CE can be significantly enhanced, and very structurally similar carbohydrate molecules can be separated.

In most cases, carbohydrate molecules must be derivatized to render charge, prior to or during electrophoretic separation, as majority of carbohydrates are neutral. This can be achieved by interaction with oxoacid [22] or metal ions [23], or introduction of ionic tags [24,25]. On the other hand, electrokinetic chromatography approach using hydrophilic monolithic columns, developed by Novotny and coworkers [26], extended CE applicability to neutral sugar molecules. Certain surfactants, such as SDS, for example, form negatively charged micelles in the running buffer and serve as pseudo-stationary phase that incorporates carbohydrate molecules with a hydrophobic tag [e.g., 1-phenyl-3-methyl-5-pyrazolone (PMP)] [27] to a various extent, resulting in differential migration and separation.

Absence of chromophore or fluorophore groups and very low extinction coefficients of most carbohydrate molecules called for application of alternative (to UV and fluorescence) detection methodologies. Electrochemical detection and refractometry allow direct measurements although the sensitivity is relatively low. Carbohydrates are very weak acids, and their hydroxyl groups get ionized at very high pH values (>12–13), enabling CE analysis under such strong alkaline conditions using gold or transition metal electrodes [28,29] in electrochemical detection settings.

With respect to UV or fluorescent detection, a number of methods have been developed to introduce UV absorbing and/or fluorescent tags into carbohydrate molecules. Derivatization of carbohydrates, to render chromophore/fluorophore group and/or charge, was first demonstrated in CE by Honda [22] who used 2-aminoacridone (first introduced by Hase for HPLC analysis [30]). Since then, different derivatization strategies have been explored. Most typical of these are reductive amination [e.g., 2-aminoacridone, 2-aminopyridine, 4-aminobenzoate, *p*-aminobenzonitrile, APTS, 8-amino-naphthalene-1,3,6-trisulfonic acid (ANTS), etc.]; reaction of amino sugars with 1,2-dioxo aromatic compounds to form isoindoles [e.g., *o*-phthaldehyde, 3-(4-carboxybenzoyl)-2-quinoline-carboxaldehyde]; reaction of aldoses with pyrazalones (e.g., PMP); reaction of dioxo sugars with 1,2-diaminoaromatic compounds; amidation of sugar carboxylic acids with aromatic amines through carbodiimide effect [16]. PMP tag allows quantitative labeling under mild conditions, in both pre-column mode and *in migratio* [31]. The most effective fluorescent derivatization agents have been APTS and methylglycamine-4-nitro-2,1,3-benzoxadiazole (MG-NBD) [17,32]. These methods are based on reduction amination, which results in quantitative and uniform labeling of different carbohydrates, and utilize most common Ar-ion laser for excitation (488 nm) [33–36]. The details of these and other derivatization approaches are well summarized in several articles [18–19,32].

High-performance and resolving power of CE enable distinguishing between very similar structural isomers of short oligosaccharides, which have different anomeric and positional configurations of sugar monomers. Typical separations of various APTS-labeled homooligosaccharide series are exemplified in Figure 7.1 [37]. Traces A and B correspond to oligomers, composed of glucose

**FIGURE 7.1** High-resolution CE separation of oligosaccharide structural isomers. Traces from the bottom: (A) maltooligosaccharide oligomers (DP 1–8); (B) cellooligosaccharide oligomers (DP 1–6); (C) xylooligosaccharides (DP 1–3); and (D) xylopentaose. Numbers above the peaks correspond to the DP. Conditions: fused-silica capillary, 60 cm  $\times$  50  $\mu$ m ID, effective separation length 50 cm; running buffer 25 mM lithium acetate (pH 5); dynamic coating, 1% PEO; injection 5 s at 0.5 psi (3447 Pa); applied electric field 500 V/cm; separation temperature 20°C. (Adapted from Khandurina, J. and Guttman, A. *Chromatographia*, 62, S37, 2005. With permission.)

molecules linked via  $\alpha$ -1,4 (maltooligosaccharides) and  $\beta$ -1,4(cellooligosaccharides) bonds, respectively. Numbers above the peaks denote the degree of polymerization (DP). As one can see, species with the same DP but different anomeric configuration between the monomer units ( $\alpha$  or  $\beta$ ) have different electrophoretic mobilities, and can be readily separated in CE, using 25 mM lithium acetate (pH 5) buffer in combination with a dynamically coated column and reversed polarity. The shorter cello-oligomers migrated faster than the corresponding malto-analogs (DP 2–5 peaks in traces A and B, Figure 7.1). However, the migration order was reversed above DP 5, as the cellohexasaccharide migrated slower than maltohexasaccharide. Most likely, the differences in the spatial configuration, rigidity and hydrodynamic radius of the short  $\alpha$ - and  $\beta$ -glucopyranose oligosaccharides in the solution caused this change in the migration order. Traces C and D in Figure 7.1 depict the separation of xylose series (xylose, xylobiose, xylotriose, and xylopentaose), which possess higher electrophoretic mobility compared to glucose series (traces A and B, Figure 7.1) with the same DP, due to more compact structure of pentose-based sugars versus hexose ones. Very close structural isomers of di- and trisaccharides can be resolved by CE, under suppressed EOF conditions, as demonstrated in Figure 7.2. Here, maltose and isomaltose ( $\alpha$ -1,4 and  $\alpha$ -1,6 linkages) are baseline resolved (peaks 1 and 2). On the other hand, trisaccharide analogs (maltotriose and panose, peaks 3 and 4) could be separated only with the addition of the polymer additive, PEO. The PEO additive is capable of selectively interacting with sugar hydroxyls via the formation of hydrogen bonds, thus, enhancing (or decreasing) separation selectivity. As it is illustrated in Figure 7.2, the described CE approach can provide an excellent tool for fine tuning of the separation selectivity of the carbohydrate molecules of interest. CE profile of a complex mixture of 10 mono- and oligosaccharides, constituents of plant cell walls, is presented in Figure 7.3. An excellent resolution of the three different galactobiose isoforms ( $\beta$ -1,4;  $\alpha$ -1,4; and  $\alpha$ -1,3 linkages) was achieved in capillary zone electrophoresis (CZE) format [37].

**FIGURE 7.2** CE analysis of close structural di- and trisaccharide isomers. Peaks: (1) maltose, (2) isomaltose, (3) panose, and (4) maltotriose. Conditions: 0.5% PEO (B) and 1% PEO (C) was added to the running buffer (no PEO additive in (A)). Separation temperature 15°C. Other conditions were the same as in Figure 7.1. **FIGURE 7.3** High-resolution analysis of a combined mono- and oligosaccharide mixture representing fragments of major cell wall components of bioindustrial interest. (1) Galacturonic acid, (2) digalacturonic acid, (3) trigalacturonic acid, (4) rhamnose, (5) galactose, (6) galactobiose  $\beta$ -1,4 linkage, (7) galactobiose  $\alpha$ -1,4 linkage, (8) galactobiose  $\alpha$ -1,3 linkage, (9) galactotriose  $\alpha$ -1,3;  $\beta$ -1,4, and (10) galactotetraose  $\alpha$ -1,3;  $\beta$ -1,4;  $\alpha$ -1,3. Conditions were the same as in Figure 7.1. (Adapted from Khandurina, J. and Guttman, A. *Chromatographia*, 62, S37, 2005. With permission.)

## 7.3 THEORETICAL AND PRACTICAL ASPECTS OF MODERN CARBOHYDRATE ANALYSIS: CE-MS

### 7.3.1 BASIC UNDERLYING PRINCIPLES

The popularity of CE-MS hyphenation has been a fast growing analytical approach, since its introduction in the late 1980s. Over the years the technique has advanced to the commercial ready-to-use

level. Still, there is a lot of development to be done toward optimization of CE-MS instrumentations, in particular, improving its robustness and efficiency. A variety of analytical applications in different fields have been investigated [38]. With respect to carbohydrate analysis, MS detection offers a way to overcome detection sensitivity problems associated with the lack of chromophore groups, as well as structural elucidation of complex carbohydrate molecules. Structural characterization of carbohydrates includes the determination of molecular weight, type, and number of saccharide components, sequence and branching, glycosidic attachment sites, anomeric configurations, conformation of glycosyl ring, and secondary structure. Electrospray ionization (ESI) and matrix-assisted laser desorption ionization (MALDI) mass spectrometry, especially in the tandem MS<sup>n</sup> mode, are the most popular approaches that offer high ionization efficiency of saccharides and possibility of their sequencing. In particular, nano-ESI-MS/MS, in both positive and negative mode, enable elaborate structural determination of carbohydrates from biological samples using only sub-pmole amounts [39–46]. Basically, three major types of ESI interfaces have been used for CE-MS coupling: coaxial sheath-flow, sheathless, and liquid junction, as schematically presented in Figure 7.4 [47]. Different modern mass analyzers e.g., ion trap (IT), quadrupole time-of-flight (QTOF), TOF-TOF, and even Fourier transform ion cyclotron resonance (FT-ICR) can provide highly informative fragmentation spectra of oligosaccharides [26,48–53]. One of the challenges in carbohydrate characterization in complex mixtures is associated with the presence of overlapping isobaric peaks that complicates spectra interpretation. In addition, modified and substituted sugar molecules are prone to in-source fragmentation due to labile nature of acetyl, phospho-, sulfo-, and other functional groups, causing loss of structural information of intact molecules. Moreover, most carbohydrates, unlike peptides and proteins, do not form multiply charged ions causing difficulties analyzing oligo- and polysaccharides of high molecular weight, which often exceeds MS detection capabilities [4].

MS analysis of complex biological mixtures of carbohydrates often follows a liquid phase separation method, such as chromatography (HPLC), CE, or capillary electrochromatography (CEC). The advantages of mass spectrometry, combined with superior resolving power of CE, have boosted glycoscreening development in biomedical research [4]. Very efficient and fast separations, automation and capabilities of miniaturization, already proven for small molecules, peptides, proteins, and nucleic acids [54–57], represent a promising analytical alternative for all types of carbohydrates. CE-MS combination can be carried out either off-line or online. The former approach was often realized by CE fraction collection followed by ESI-MS characterization of individual fractions, which contain a single carbohydrate species or mixtures of significantly reduced complexity. However, fraction dilution associated with this approach (collection of nanoliter fractions into microliter total volume) imposes additional detection sensitivity challenges, especially with limited amounts of glycoconjugate samples extracted from biological sources, and therefore, is of limited use. On the other hand, online CE-MS interface has become truly widespread during the past decade. This methodology allows minimum sample handling and consequently maximum efficiency in MS detection. A limitation though is the necessity to select ESI-MS compatible volatile buffers, which often do not possess the highest resolving power characteristics for CE. Besides, high sensitivity and high speed of data acquisition, especially for online CE-MS/MS, and certain restrictive conditions of ion formation also exist [58]. In spite of these limitations, CE-MS technique is invaluable, providing carbohydrate composition identification, quantification, and structural insights. To decipher molecular composition, MS/MS measurements are typically conducted using low-energy collision-induced dissociation (CID) in ESI applications or MALDI postsource decay (PSD). These types of fragmentation preferentially cause glycosidic bond cleavage. Sugar ring cut, on the other hand, resulting in the formation of mostly C and Y type alcoholate ions [39], provide information on the branching pattern. The latest developments in CE-MS analysis of carbohydrates are highlighted and summarized in a number of comprehensive reviews (e.g., by Zamfir and Peter-Katalinic [4], Campa et al. [59], and Kamoda and Kakehi [60]). Here, we briefly outline examples of CE-MS applications to the analysis of carbohydrates, including complex glycoconjugate mixtures, neutral and negatively

**FIGURE 7.4** Interfaces for the direct coupling of CE to ESI-MS using (A) sheathless; (B) liquid-junction; and (C) coaxial sheath-flow designs. (Adapted from Simo, C. et al. *Electrophoresis*, 26, 1306, 2005. With permission.)

charged glycopeptides and glycoproteins, glycosaminoglycans (GAGs), lipopolysaccharides (LPS), and gangliosides.

### 7.3.2 CE-MS CHARACTERIZATION OF SIMPLE SUGARS AND GLYCOCONJUGATES

CE-MS analysis of simple sugar mixtures is typically conducted using either derivatized neutral sugars or underivatized carbohydrates, containing ionizable groups (e.g., carrageenan oligosaccharides) [61]. Derivatization is typically accomplished through reductive amination coupling to negatively charged tags, such as aminobenzoic acid (ABA) [62], 8-aminonaphthalene-1,3,6-trisulfonic acid (ANTS) [59], APTS [63], and 7-amino-1,3-naphthalene-disulfonic acid (ANDSA) [64]. Positively charged tags, for example, 3-(acetylamino)6-aminoacridone [65] or rhodamine 123 [59], are sometimes used as well. Labeling results in enhanced ionization efficiency and MS response, as well as CE separation selectivity [48], for most carbohydrates regardless of their native charge. Simple sugars are often used as standard mixtures to assess performance and optimize CE-MS conditions prior to characterization of more complex samples.

Glycoproteins, a very important type of glycoconjugates, are formed during co- and posttranslational modification in eukaryotic cells. Typically, N-glycans are linked to asparagines, while O-glycan moieties to serine or threonine. Protein glycosylation is characterized by pronounced microheterogeneity of glycosylation sites, which poses challenges in controlled manufacturing of recombinant glycoprotein therapeutics [66]. CE-MS analysis has been successfully applied to characterization of sugar moieties, native or derivatized, using direct or reversed polarity CE in combination with ESI-MS or MALDI. Since typically only low concentrations of glycans are available from glycoconjugates, various derivatization approaches have been implemented to increase MS response and facilitate interpretation of MS/MS spectra of glycans. Some research groups developed new derivatizing agents with improved physicochemical properties and better suited for CE-MS applications [65,67]. Min et al. [68] reported a new interesting labeling approach based on enzymatic reaction rather than chemical derivatization. In this work a fluorescent acceptor, naphthalene-2,3-dicarboxaldehyde-asparagine-*N*-acetylglucosamine, was used. Asn-linked glycan moieties were enzymatically transferred from ovalbumin to the tag reagent. This strategy can help alleviate degradation problems sometimes observed in reductive amination, especially with unstable glycan residues (e.g., sialylated carbohydrates). A number of research groups used APTS and ANTS labeling in conjunction with CE-MS/MS analysis of N-glycans following their enzyme-assisted release from glycoproteins [69–71]. CE-UV and CE-MS electropherograms, obtained for the same oligosaccharide mixture, were compared under optimized analysis conditions in Reference 69. As expected, separation efficiency and selectivity were lower in CE-MS, primarily due to sheath liquid dilution and certain dead volume in the capillary outlet-MS interface. In addition, application of an MS-friendly buffer (6-aminocaproic acid, pH 4.1), instead of 10 mM citric acid (pH 3) used in CE-UV settings, could have contributed to the decrease of selectivity. Nevertheless, the use of powerful mass spectrometers can counterbalance the loss of separation efficiency, as it was demonstrated by successful structural characterization of a number of *N*-linked carbohydrates and other glycoconjugates [4,72,73]. The  $MS^n$  capacity of ion-trap spectrometer has been particularly useful in elucidation of fine structural details.

Analysis of high-mannose-type oligosaccharides by a combination of micro-liquid chromatography ( $\mu$ LC)-MS and CE was reported by Koller et al. [70]. The authors separated glycopeptides and high-mannose-type oligosaccharides, derived and digested from a recombinant enzyme phospholipase C expressed in *Pichia pastoris* yeast. The glycopeptides were subjected to  $\mu$ LC-ESI-MS and  $\mu$ LC-ESI-MS/MS that revealed variation in high-mannose structures in the range between  $Man_7GlcNAc_2$  and  $Man_{14}GlcNAc_2$ . Then, high-performance CE was applied to identify possible positional isomers of the high-mannose structures. One  $Man_9GlcNAc_2$ , two  $Man_{10}GlcNAc_2$ , three  $Man_{11}GlcNAc_2$ ,  $Man_{12}GlcNAc_2$ , and  $Man_{13}GlcNAc_2$ , and two  $Man_{14}GlcNAc_2$  were identified, while no  $Man_7GlcNAc_2$  and  $Man_8GlcNAc_2$  were observed (Figure 7.5). It was found that CE results provided complementary information to the  $\mu$ LC-ESI-MS/MS data, revealing the exact number of positional isomers in the glycan pool.

Cell surface and extracellular proteins are typically O-glycosylated, and the most abundant type of O-glycosylation is the attachment of *N*-acetylgalactosamine (GalNAc) to serine or threonine in the protein sequence by  $\alpha$ -glycosidic linkage [74]. Many eukaryotic cytoplasmic and nuclear proteins, containing such carbohydrate moiety, exhibit reciprocal glycosylation and phosphorylation during cell cycle, stimulation, and growth. In the group of O-GalNAc glycosylated proteins, musins are the most ubiquitous. They are especially interesting with respect to cancer research, understanding of cell adhesion, and metastasis processes. The distribution of O-glycans in human tissues and sera is important for diagnostic and prognostic studies [74,75]. Mucin-like O-glycans are characterized by high degree of structural variation, even at the core level, as well as in the chain elongation arising from the core extension (Figure 7.6). The carbohydrate chains often contain repeating units of *N*-acetylglucosamine, terminal sialic groups, and also noncarbohydrate substituents. Less investigated types of O-glycosylation are O-fucosylation, O-mannosylation, and O-glucosylation. These types of modifications are vital for physiological functions of proteins. O-glycans are traditionally detached

**FIGURE 7.5** High-performance CE separation of the APTS-labeled high-mannose type oligosaccharides released by PNGase F from bovine ribonuclease B (C) and PLC (D). (A) Electropherogram of the maltooligosaccharide ladder; (B) derivatization background peaks. Conditions: 48 cm neutrally coated column (58 cm total length), 50- $\mu$ m ID. LIF detection: Ar-ion laser, 488 nm excitation, 520 nm emission. Separation buffer: 25 mM acetate (pH 5); 25°C capillary cartridge temperature; pressure injection 10 s at 0.5 (A) and 2 psi (B-D). (Adapted from Koller, A. et al. *Electrophoresis*, 25, 2003, 2004. With permission.)

from the parent protein by  $\beta$ -elimination using strong bases (e.g., NaOH or hydrazine). Hydrozinolysis does not always result in the selective cleavage of O-glycans, and often is accompanied by N-glycan release, as well as modification of the reducing terminus [74] and references therein.  $\beta$ -Elimination by NaOH under reductive conditions allows chemical derivatization of the reducing end (e.g., with a fluorescent label). Nonreductive release of O-glycans by  $\beta$ -elimination is also possible [74], as well as an enzymatic release, but the latter options are limited by high substrate specificity of O-glycosidases available. Comprehensive profiling of complex glycan and glycopeptide mixtures requires sophisticated analysis methods to characterize glycosylation patterns and structures of individual components, and the coupling of CE separation devices to ESI-MS or MALDI-MS is a powerful approach. Off-line CE-MALDI analysis has been used for the characterization of musin carbohydrate chains, comprising up to six GalNAc moieties [75]. CE-MS/MS interface enabled deducting molecular structure of individual glycopeptide components based on specific fragmentation, especially when micro- and nano-ESI sources are used. O-glycopeptides in urine of patients, suffering from a hereditary *N*-acetylhexosaminidase deficiency, were profiled by this approach, using high-pH and MS-compatible buffer for CE separation, sheathless CE-ESI-MS interface, and QTOF-MS equipped with automated high-speed MS-MS/MS switching [75]. The MS/MS fragmentation of glycans results mainly in the formation of Y and C types of ions, which are indicative of the specific structures of the parent ions. The sheathless CE-ESI/QTOF design proved to be one of the most suited designs for glycomics, providing high coverage of detection and identification of CE-MS data, MS-MS/MS switching, electrospray stability, and acquisition rate [74,75].

The glycan MS fragmentation nomenclature introduced by Costello, Domon, and Vath [76–79] is a widely accepted system used by most of the MS and glycoconjugate community. The simplest fragmentation of the carbohydrate moiety of glycoconjugates and glycosides results from the cleavage of the glycosidic bond and therefore provides information on the sugar sequence. More complex processes involving the fragmentation of the sugar ring can occur, particularly, in CID-MS/MS spectra. These ions are more difficult to assign, although they contain important structural information. Figure 7.7 schematically illustrates the nomenclature. Fragments are designated  $A_i$ ,  $B_i$ , and  $C_i$ , where  $i$  represents the number of the glycosidic bond cleaved, counted from nonreducing end. Ions containing aglycone, or the reducing sugar unit in case of oligosaccharides, are labeled as  $X_j$ ,  $Y_j$ , and  $Z_j$ , where  $j$  is the number of interglycosidic bond counted from aglycone, or reducing end. The glycosidic bond linking to aglycone is 0. More complex fragmentations involve cleavage of C–C bonds of the sugar ring. The product ions are designated as  $A_i$  and  $X_j$ . Since several ring cleavage pathways are possible, two additional superscripts are used (e.g.,  $^{k,l}A_j$ ) to indicate the sugar ring bonds that have been broken [78]. This system, described in more detail elsewhere [78,80], comprises types of cleavages, observed in collision-induced decomposition MS/MS spectra of carbohydrate moiety of glycoconjugates, and is applicable to both positive and negative ionization modes.

Glycolipids are carbohydrate-attached lipids (e.g., phospholipids) found on the outer exoplasmic surface of all eukaryotic cell membranes. Their biological role is to provide energy and serve as markers for cellular recognition. One subtype is LPSs, which are major components of the cell membrane of Gram-negative bacteria, contributing greatly to the structural integrity, and protecting the membrane from certain kinds of chemical attacks. LPS are endotoxins and induce a strong response from normal animal immune systems. It comprises three parts: polysaccharide (O) side chains, core polysaccharides, and lipid A. A lipid A contains certain fatty acids (e.g., hydroxymyristic acid), and is inserted into the outer membrane while the rest of an LPS projects from the surface. A core polysaccharide contains unusual sugars, such as keto-deoxyoctulonate and heptulose. It also contains two glucosamine sugar derivatives, each having three fatty acids with phosphate or pyrophosphate attached. The core polysaccharide is attached to lipid A, which is also in part responsible for the toxicity of Gram-negative bacteria. The polysaccharide side chain is referred as the O-antigen of the bacteria. O side chain (O-antigen) is also a polysaccharide chain that extends from the core polysaccharide. The composition of the O side chain varies between different Gram-negative bacterial strains. O side chains are easily recognized by the host antibodies, however, the nature of

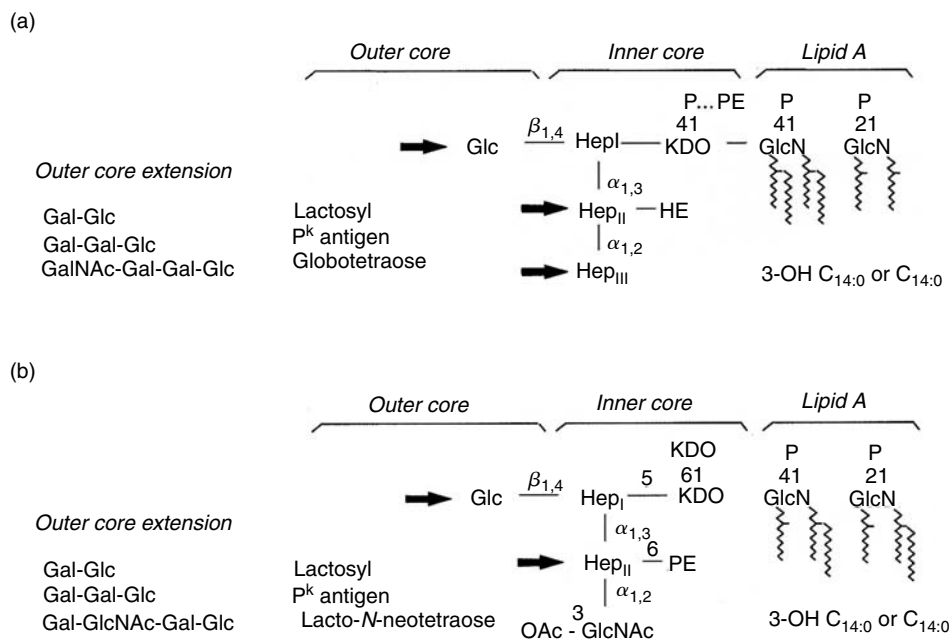

**FIGURE 7.7** Types of carbohydrate fragmentation. (Adapted from Domon, B. and Costello, C. E. *Glycoconjugate J*, 5, 397, 1988. With permission.)

the chain can easily be modified by the bacteria to avoid detection. LPS also increases the negative charge of the cell wall and helps stabilize the overall membrane structure [81,82].

A comprehensive discussion on the application of CE-MS to the analysis of complex LPS can be found in Reference 83 and references therein. Various research groups developed electrophoretic conditions to conduct trace-level enrichment and separation of closely related glycoforms and isoforms. Sensitive detection of glycolipids from as little as five bacterial colonies has been demonstrated. Mixed MS scanning functions can assist in the identification of specific LPS functionalities [e.g., pyrophosphoethanolamine, phosphocholine, and *N*-acetylneuraminic acid (Neu5Ac)]. High resolving power of CE combined with sensitivity of tandem MS provides a unique analytical tool to probe subtle structural differences and location of oligosaccharide isoforms of LPS. Correlation of structural changes in bacterial strains and isogenic mutants allow establishing functional gene relationships, using CE-MS screening capabilities and wide dynamic range.

Figure 7.8 shows structure of the oligosaccharide region of LPS from *Neisseria meningitidis* and *Haemophilus influenzae*. LPS of *H. influenzae* contains a common L-glycero-D-manno-heptose inner-core trisaccharide unit attached to the lipid A via a phosphorylated 2-keto-3-deoxyoctulosonic acid (KDO) residue (Figure 7.8A). Similarly, *N. meningitidis* (Figure 7.8B) has a conserved inner core structure with two KDOs, two heptoses (Hep), and one *N*-acetylglucosamine (GlcNAc). Further carbohydrate extension can occur at each heptose. In addition, various noncarbohydrate substituents can be incorporated, for example, acetyl (Ac), phosphate (P), phosphoethanolamine (PE), pyrophosphoethanolamine (PPE), phosphocholine (PC), as well as different aminoacids (Ala, Ser, Thr, Lys). Details on typical LPS extraction and preparation methods are well described in Reference 83. Hydrozinolysis can be utilized to release *O*-linked fatty acids, and, if necessary, enzyme sialidase to remove Neu5Ac residues. Li et al. [83] described interfacing of a CE instrument with a triple quad

**FIGURE 7.8** Structure of the conserved inner core oligosaccharide regions of LPS from *N. meningitidis* and *H. influenzae*. (A) *Haemophilus influenzae* capsular and noncapsular strains. or QTOF mass spectrometers via a microionspray assembly, using isopropanol–methanol sheath liquid, a bare fused-silica capillary, and morpholine–formic acid (or ammonium acetate) buffer (pH 9) with 5% methanol. To maintain high separation efficiency of CE ( $N > 150,000$  plates/m), the injection volume should be kept below 2% of the total column volume (e.g., 40 nL for 1 m  $\times$  50  $\mu$ m ID capillary) [84]. MS identification of bacterial glycolipids can be achieved using 100–300 pg on column loadings, which typically translates into low  $\mu$ g/mL detection limit when using ESI. Different techniques to improve LPS sample loading have been explored, including preconcentration via transient isotachopheresis, hydrophobic adsorption membrane at the sample inlet, and field amplification stacking using a microdialysis interface junction and polarity switching ([83] and references therein).

CE-MS has been employed for the structural elucidation of an O-chain polysaccharide (LPS component exposed on bacteria cell surface and mediating host–cell invasion and other cell–cell interaction processes) from *Aeromonas salmonicida* strains [85,86]. The authors used in-source fragmentation approach for the analysis of these complex macromolecules. As mentioned above, saccharides typically form singly charged ions during the ESI process. Therefore, the masses of these oligosaccharides often exceed the mass limit of common mass spectrometers (e.g., quadrupole or ion-trap types). The in-source fragmentation technique produces fragments that can be readily detected by these instruments.

LPS are often presented by a complex distribution of closely related glycoforms varying by length and site of attachment. Structural characterization of these diverse populations is important for the development of protein therapeutics—antibodies specifically targeted toward these immunodeterminate structures. Glycoforms in the different families of glycolipids are identified based on the progressive extension of Hex residues on the core structure, and concurrent increase in molecular weight and decrease in electrophoretic mobility. This approach is described in great detail by Li et al.

**FIGURE 7.9** Analysis of sialylated O-deacylated LPS from *H. influenzae* 375. (A) Results for *H. influenzae* 375 wild type strain. (B) Strain grown in presence of CMP Neu5Ac. (C) Strain following incubation with  $\alpha$ -2,3 sialidase. The total ion electropherogram (solid line) is shown together with the fragment anion  $m/z$  290 characteristic of Neu5Ac. The arrows indicate the migration of the glycolipid shown as an inset on the right in B and C. (Adapted from Li, J. et al. *Methods Enzymol*, 405, 369, 2005. With permission.)

[83]. In addition to isoform analysis, monitoring of trace-level glycolipids present as a small subset in a bacterial extract, is often required. To probe characteristic functional groups and residues, such as P, PE, PPE, PC, and Neu5Ac, CE-ESI-MS has been successfully applied [83] using in-source fragmentation and selected ion monitoring (SIM) mode. The ability to probe specific functionalities can also be an important analytical tool in monitoring incorporation of monosaccharides by glycosyltransferases or their removal by glycosidases [83], as illustrated in Figure 7.9 for Neu5Ac residue in *H. influenzae* 375 strain. The precise location of a modification or the assignment of branching site on the glycolipid structure typically requires using tandem MS/MS. Higher order MS ( $MS^n$  with FT-ICR, for example) helps rationalize the observation of characteristic fragment ions or assess fragmentation pathways.

Glycosphingolipids (GSLs) are a subtype of glycolipids, containing aminoalcohol sphingosine, which include cerebrosides, gangliosides, and globosides. GSLs are ubiquitously distributed among all eukaryotic species and some bacteria. Since GSLs are secondary metabolites, their direct and comprehensive analyses must be considered an essential complement to genomic and proteomic approaches and establishing the structural repertoire and functional roles of these compounds within an organism. Gangliosides, for example, are composed of a GSL (ceramide and oligosaccharide) with one or more sialic acids linked on the sugar chain. It is a component in the cell plasma membrane, which modulates cell signal transduction events. They have recently been found to be of great importance in immunology. Natural and semisynthetic gangliosides are considered possible therapeutics for neurodegenerative disorders. A detailed review on GSLs and their structural analysis, mostly by various MS techniques, can be found in Reference 80. Several research groups [87–89] applied CE-MS technique to ganglioside analysis. Online glycoscreening of gangliosides by CE-nano-ESI-QTOF-MS [87] is feasible, provided suitable buffer systems, compatible with MS and ensuring acceptable CE resolution, are developed. Ju et al. [90] demonstrated good sensitivity

and electrophoretic resolution of a number of gangliosides. MEKC has been coupled with ESI-MS by Tseng et al. [91] who used nonvolatile buffer systems.

Bindila et al. [72] reported a method for the analysis of underivatized glycoconjugates by CE-TOF-MS. The method was first optimized using simple monosaccharides followed by the application to the studies of urine samples from patients with *N*-acetylglucosaminidase deficiency syndrome. Identification of nearly 50 major and minor species, O-glycosylated sialylated amino acids and peptides in patient's urine, using a CE buffer of 6.4% formic acid in 60% methanol at pH 2.8 (adjusted with  $\text{NH}_3$ ), was demonstrated. Another research group applied CE-MS approach to the analysis of APTS-labeled structural isomers of glucooligosaccharides [63]. The known properties of borate ions to form complexes with sugars, changing their hydrodynamic characteristics and therefore improving the resolving power of CE, were also exploited in the CE-MS format. Isomeric LPS and their isomeric glycoforms from *N. meningitidis* were distinguished and characterized by Li et al. [91], employing CE-MS interface in either positive or negative mode.

More examples on CE-MS analysis of various glycoconjugates, including PGs, LPSs, gangliosides, highly glycosylated peptides, and so forth, can be found in References 4, 59,60, and 83.

## 7.4 APPLICATIONS

### 7.4.1 COMPLEX POLYSACCHARIDES

Complex polysaccharides, glucosaminoglycans (GAGs), are a class of ubiquitous macromolecules exhibiting a wide range of biological functions. They exist as side chains of PGs in the cells and extracellular matrix. The recent development of analytical tools for their study has spurred a virtual explosion in the field of glycomics. A number of electrophoretic separation techniques, including agarose gel, CE, and fluorophore-assisted carbohydrate electrophoresis (FACE), have been employed for the structural analysis and quantification of hyaluronic acid (HA), chondroitin sulfate (CS), dermatan sulfate (DS), keratan sulfate (KS), heparan sulfate (HS), heparin (Hep), and acidic bacterial polysaccharides [93]. Moreover, certain diagnostic analytical applications have been developed to detect fine structural and compositional changes of GAGs at various pathological conditions. These have been accomplished by analyzing oligosaccharides derived from GAGs by enzymatic or chemical degradation. The major analytical advances in this field in the past decade have been reviewed in Reference 93.

GAGs are linear, complex, and polydisperse polysaccharides [94–99]. Most of them, except for KS, consist of alternating copolymers of uronic acids and amino sugars, and their structures are commonly represented by disaccharide sequences. KS, CS, DS, HS, and Hep are sulfated heteropolysaccharides with different degrees of density and positional distribution of sulfate groups. These compounds are very heterogeneous not only by structure but also in biological and pharmacological activities. With the exception of HA, GAG chains are covalently attached at their reducing end through an *O*-glycosidic linkage to a serine residue or *N*-linked to asparagine (e.g., KS) in a core protein [100–103]. Some glycobiology studies suggest that PGs are not only structural components but also regulate many cellular and physiological processes (e.g., cell proliferation and differentiation) [101,104–106]. Most GAGs are obtained from animal sources by extraction and purification processes [99]. Recently, these natural substances have also been chemically modified to get synthetic analogues and GAGs-based drugs [107,108].

Figure 7.10 shows structures of some typical GAGs. For example, HA is a linear polysaccharide composed of alternating residues of the monosaccharides D-glucuronic acid and *N*-acetyl-D-glucosamine linked by  $\beta$ -1,3 bonds in repeating units; and these disaccharides are connected via  $\beta$ -1,4 linkages [109,110]. On the other hand, the repeatable blocks in KS molecules are *N*-acetyl-lactosamine fragments of  $-\beta$ -1,3-[D-galactose- $\beta$ -1,4-*N*-acetyl-D-glucosamine]- $\beta$ -1,3-, which are typically sulfated at C6 position of acetylglucosamine and sometimes at C6 of galactose [111]. Structures of some other typical GAGs are schematically shown in Figure 7.10 and described in more detail in Reference 93 and references therein.

**FIGURE 7.10** Structures of disaccharides forming GAGs. Major modifications for each structure are illustrated (R = H or SO<sub>3</sub><sup>-</sup>) but minor variations are possible. (Adapted from Volpi, N. and Maccari, F. *J Chromatogr B Analyt Technol Biomed Life Sci*, 834, 1, 2006. With permission.)

Separation and quantification of GAGs compounds in mixed samples have been conducted by one- and two-dimensional electrophoresis on cellulose acetate strips, nitrocellulose membranes, agarose gels, and polyacrylamide gels (PAGE), using staining dyes for detection (alcian blue, toluidine blue, azure A, methylene blue, combined azure blue, and silver staining) [93]. CZE in uncoated fused-silica capillaries, as well as MEKC, have been successfully exploited for GAGs analysis. In the latter case, SDS or CTAB was used in the basic borate buffers [112–114]. In addition, microemulsion electrokinetic capillary chromatography mode was demonstrated, where GAGs species can be separated based on partitioning into oil droplets moving in the running buffer [93]. Different modes of CE were realized with either normal or reversed polarity, under basic or acidic (suppressed EOF) conditions, respectively. Proven benefits of CE, such as ease of use, fast analysis, very small sample amount requirements, high resolution and sensitivity, and reproducible quantification, worked very

**FIGURE 7.11** HPCE electropherograms of unsaturated disaccharide  $\Delta$ HexAFrc-GalNAc, forming polysaccharide K4 (K4), and  $\Delta$ HexA-GalNAc of defructosylated K4 product (K4d). (Adapted from Volpi, N. *Electrophoresis*, 24, 1063, 2003. With permission.)

well especially for nonsulfated GAGs, that is, HA and bacterial polysaccharides, oligosaccharides, and disaccharides generated by enzymatic digestion reactions [112–114]. The possibility to label GAGs polysaccharides or their depolymerized short fragments with chromophores or fluorophores, to significantly boost sensitivity, is another attractive feature of CE analysis. FACE, based on 2-aminoacridone (2-AMAC) derivatization, has been applied to the analysis of plant cell wall polysaccharides [115], and HA and GAGs disaccharides [116]. As an example, Figure 7.11 presents CE separation of two disaccharides, products of chondroitinase digestion of polysaccharides from uropathogenic *Escherichia coli* K4 bacteria and its defructosylated product [117]. SDS MEKC mode in uncoated fused-silica capillary under normal polarity and UV detection (230 nm) was used in this work. However, this approach required enzymatic treatment of bacterial polysaccharides with lyases. In the other study of the same group [118], direct CE analysis of native K4 and defructosylated K4 has been developed. The two polyanions were separated and detected within 30 min, as depicted in Figure 7.12. Linear region of quantification was observed in the 30–210 ng range. Other bacteria polysaccharides and membrane LPS have been analyzed by high-performance CE [119,120] and the results were invaluable for characterization and quantification of these complex polymers in biological and medical research.

A method for the determination of HA oligomers by CE-MS was reported by Kuhn et al. [121]. Oligosaccharides of 4–16 DP were generated by enzymatic digestion of HA with bacterial hyaluronidase, followed by CE-MS analysis. Structural information was obtained in  $MS^n$  experiments using an ion-trap instrument (IT-MS). Another research group [122] described a homemade sheathless ESI interface for the highly sensitive analysis of GAGs by CE-MS: CS and dermatan oligosaccharides of extended chain length and increased degree of sulfonation from decorin transfected human embryonic kidney cells were detected. More examples of CE-MS characterization of complex polysaccharides are presented in Sections 7.3.2 and 7.4.2, as well reviewed in References 4, 59, and 93.

**FIGURE 7.12** HPCE electropherograms of the polysaccharide K4 (K4) and defructosylated K4 polysaccharide (K4d). (Adapted from Volpi, N. *Electrophoresis*, 25, 692, 2004. With permission.)

## 7.4.2 CARBOHYDRATES IN PHARMACEUTICALS

In drug development and clinical and forensic applications, the popularity of CE and CE-MS technologies have grown due to high discrimination power of CE and possibility to directly analyze complex biological matrices, such as serum, urine, or other fluids [123,124]. This section overviews most typical examples related to carbohydrate analysis in biopharmaceutical research. More details and references on the topic can be found in recent comprehensive reviews [38,59,60,123,125]. Overall, implementation of CE in pharmaceutical bioanalysis has tremendous potential by providing additional detailed information on the structure of oligosaccharide fragments in glycoconjugates of pharmaceutical interest and ultimately contributing to the development of more effective and safe medicines.

### 7.4.2.1 Glycoproteins

Glycosylation is one of the most common co- and post-translational modifications of the proteins. Carbohydrate moieties in glycoproteins have direct effect on their biological activity and cellular functions, such as protein folding, recognition, signaling, immune response, differentiation, and so forth [126–128]. Modern recombinant technologies enable production of protein pharmaceuticals in living cells. However, inherent structural heterogeneity in glycosylation patterns affect their efficacy, pharmacokinetic and pharmacodynamic properties [129,130], and therefore should be carefully controlled. The structure and composition of carbohydrate chains depend on the expression conditions in the host cells and purification steps involved in the production processes. Characterization of complex heterogeneous carbohydrate chains is a challenging, yet important, task in production optimization, regulatory submissions, and quality control. Glycosylation patterns and heterogeneity are not directly controlled by genes, therefore cannot be fully predicted by protein expression studies. Stand-alone CE and CE-MS<sup>n</sup> have become methods of choice in analysis of glycoforms of protein and antibody therapeutics in biopharmaceutical research and development. High sensitivity and resolution of CE permit detection of fmol and amol amounts of oligosaccharides, when using an appropriate fluorescent-labeling method and LIF detection. Remarkably, oligosaccharide analysis at a single cell level has been reported [131].

Recombinant human erythropoietin (rhuEPO), one of the most successful recombinant protein therapeutics on the market, has three *N*-linked and one *O*-linked glycosylation sites, and each glycan can have variable number of sialic acid residues [132]. Isoelectrofocusing (IEF) in capillary format has been successfully demonstrated to resolve rhuEPO glycoforms, replacing time- and labor-consuming slab gels IEF [58,133–135]. Noticeably, this methodology is now included in *European Pharmacopoeia* [136]. The separation was performed in a bare fused-silica capillary using a buffer containing putresine and urea. To overcome irreproducibility issues [58,135,136], capillary surface modification through covalent and/or dynamic coating, was utilized [137]. Monitoring changes in glycoprotein heterogeneity by CE separation of glycoforms is now in use in many quality control labs for release and stability testing.

Structural analysis of *N*-linked oligosaccharides is typically conducted by their enzymatic release from the protein, derivatization with a suitable fluorescent tag, and CE separation. A variety of oligosaccharide standards have been developed to facilitate identification of unknown species based on migration time comparison [60,138]. For further structural characterization, glycans can be fractionated and subjected to LC-ESI-MS or MALDI-TOF-MS analysis [139–141]. Alternatively, online CE-MS analysis is feasible as described in Section 7.3.1.

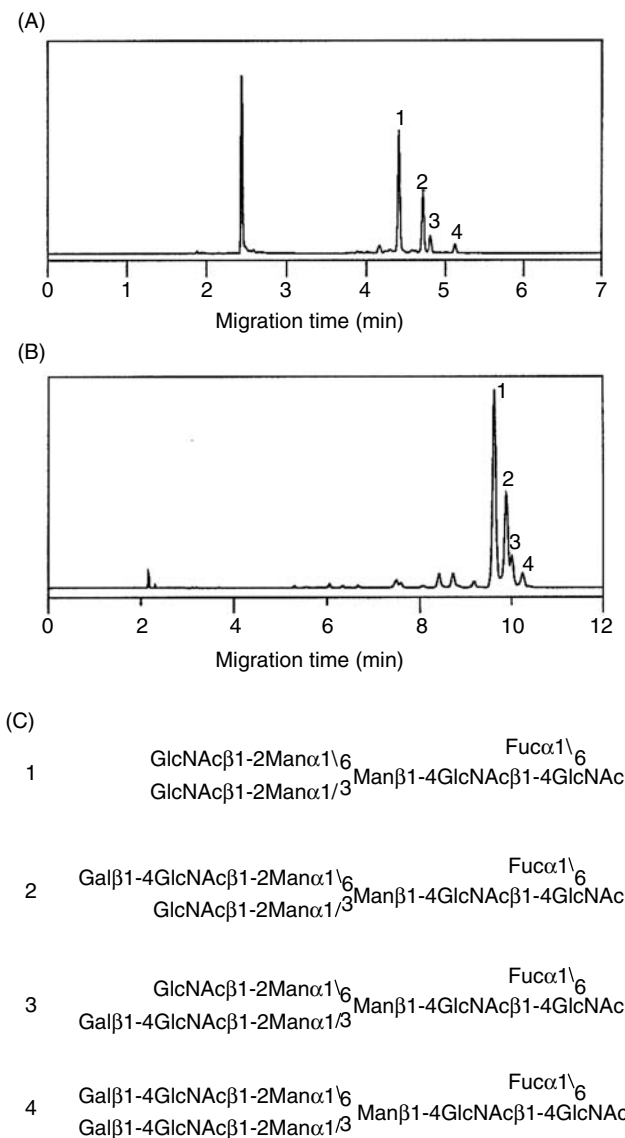

Sequencing of oligosaccharides can be accomplished by their digestion with various exoglycosidase enzymes, followed by CE analysis and peak shift monitoring [60,142]. Specific glycosidase cleavage is useful to distinguish positional isomers and glycosidic linkages. For example, Gal $\beta$ -1,4GlcNAc and Gal $\beta$ -1,3GlcNAc at nonreducing end can be discriminated using  $\beta$ -1,4 galactosidase or  $\beta$ -1,3 galactosidase. In glycan profiling of therapeutic antibody rituximab, two positional isomers of biantennary *N*-linked oligosaccharides (with one galactose at nonreducing terminal of different arms) were separated in CE, as shown in Figure 7.13 (peaks 2 and 3) [143]. The oligosaccharides can be identified using  $\alpha$ -1,2 and  $\alpha$ -1,3 mannosidase digestion following *N*-acetylhexosaminidase treatment [144]. Such subtle structural differences could not be resolved by MS or MS/MS methods.

Capillary affinity electrophoresis (CAE) based on specific carbohydrate–protein interaction, is a valuable method in carbohydrate characterization. A variety of carbohydrate-binding proteins (e.g., lectins) specific to certain oligosaccharide structures are available and have been exploited by different research groups to characterize glycoprotein pharmaceuticals [145,146].

In recombinant antibodies [147], oligosaccharide moieties are attached to the Fc region of antibodies and often control their biological activity and stability. CE-LIF analysis of oligosaccharides derived from recombinant monoclonal IgGs has been used by different researchers and exhibited high degree of reproducibility and accuracy in the determination of composition of the released glycan isoforms. A number of examples of application of CE-based technology to glycan profiling of therapeutic antibodies can be found in References 59, 60, 144, and 142.

#### 7.4.2.2 Analysis of Complex Polysaccharides in Drugs

Certain GAGs and other sulfated polysaccharides are known to possess anti-inflammatory properties. Some of them are also used as anticlotting and anti-arthritis agents. Recent studies by Liang et al. [148–150], using CZE, demonstrated that heparin, carrageenan, and dextran sulfate interact with a hematopoietic growth factor, granulocyte colony-stimulating factor (G-CSF), and have potential therapeutic effect on cancers through inhibition of the growth and induction of the differentiation of the leukemia cells. Such phenomenon might be of great importance for the treatment of patients under radio- and chemotherapy, since heparin, for instance, appears to protect G-CSF from degradation, therefore, increase its circulation half-life. It was found that these interactions are dependent on the polysaccharide chain length and sulfate content. For example, separation, identification, and interaction of heparin with G-CSF were accomplished by CE, following enzymatic digestion of heparin with heparinase to render smaller oligosaccharides [150]. The oligosaccharides were well separated in CE using 50 mM phosphate buffer (pH 9). The smaller di- and trisaccharides were also identified by CE-ESI-MS.

**FIGURE 7.13** Oligosaccharide maps of trastuzumab by CE. (A) Oligosaccharides derivatized with APTS, (B) oligosaccharides derivatized with 3-AA. Analytical conditions: (a) capillary DB-1 (50  $\mu$ m ID, 20 cm effective length, 30 cm total length); running buffer 50 mM Tris–acetate buffer (pH 7.0) containing 0.5% PEG70000; injection 0.5 psi for 5 s; applied voltage, 18 kV at 25°C. (b) Capillary DB-1 (100  $\mu$ m ID, 20 cm effective length, 30 cm total length); running buffer 100 mM Tris–borate buffer (pH 8.3) containing 10% PEG70000; injection 1.0 psi for 10 s; applied voltage 25 kV at 25°C. LIF detection 405 nm emission/325 nm ex (He–Cd laser). (C) Structures of major oligosaccharides in rituximab, peaks 1–4. (Adapted from Kamoda, S. et al. *J Chromatogr A*, 1050, 211, 2004. With permission.)

The presence of native ionizable groups in GAGs and some other polysaccharides make them particularly suited for both CE and MS, without need for derivatization. A number of examples of the CE separation and CE-MS characterization of GAGs oligosaccharides can be found in literature [59,87–89,121,151,152]. Both positive and negative ionization modes, as well as normal and reversed CE polarities, were tested for analysis of heparin oligomers [151], although negative ionization was

particularly useful for complex mixtures. In many cases, use of low pressure in conjunction with CE voltage, especially in the reversed separation mode, helped boost electromigration, and electro-spray stability [121,151]. MS/MS fragmentation enabled qualitative and quantitative identification of coeluting species, for example, disaccharides IIS-IIIS and  $\Delta$ UAS(1 $\rightarrow$ 4) $\alpha$ -d-GlcNAc6s (IIA)- $\Delta$ UA2S(1 $\rightarrow$ 4) $\alpha$ -d-GlcNAc(IIIA) [152]. MS/MS fragmentation results in loss of sulfate groups in di- and trisulfated disaccharides, and loss of water and ring cleavage in mono- and nonsulfated ones. It was shown that limits of detection (LODs) were comparable (low- $\mu$ M range) for CE-UV and CE-MS [152]. A coated capillary was used to enhance and stabilize EOF and characterize oligosaccharides of HA, up to 16mer, under positive CE polarity and negative ESI [152].

Degree of sulfation of GAGs, in particular oversulfation, affect their biological activity [87–89]; therefore, structural studies are important in the analysis of these compounds. Zamfir et al. [87–89] have extensively studied DS and CS using CE-ESI-MS, both off-line and online. Mild MS/MS fragmentation conditions allowed preventing sulfate cleavage and more effectively detecting multiply charge ions, while higher collision energy produced smaller fragments and was more useful for structure elucidation. Introduction of sheathless CE-MS interface with nano-ESI probe resulted in improved overall performance of the analysis and LOD in pmol range [89]. Structural characterization of CS/DS derived from skin fibroblast secretion lit more light toward understanding of binding activity to fibroblast growth factor-2 (FGF2) [88], which is related to epithelial cell proliferation and growth of new blood vessels (i.e., angiogenesis). Overall, CE-MS/MS approach seems to represent a powerful tool for structural characterization of sulfated GAGs.

#### 7.4.2.3 Glucuronidation of Drugs

Glucuronidation and *N*-glucuronidation are major inactivating pathways for a vast variety of endogenous and exogenous molecules, such as drugs. Therefore, analysis of glucuronidated drug metabolites is of importance for drug development and clinical and forensic applications. Owing to ionic nature of glucuronidated compounds, CE and MS are often the methods of choice for their identification and characterization.

For example, detection of opioids in body fluids is needed in clinical and forensic toxicology because of their widespread use for both therapeutic and illicit purposes. CE-MS analysis of urine proved to be a very efficient approach in the detection of opioids' metabolites [153–155]. Urinary samples of codeine, dihydrocodein, morphine and their glucuronides, and oxycodone and its metabolites were successfully analyzed by Wey et al. [153–155], utilizing CZE-based immunoassay, as well as CE-UV and CE-ion trap MS. These researchers investigated effects of different pretreatments and found that solid-phase extraction (SPE) and liquid–liquid extraction improved detection limits [154]. CE separation before MS detection versus direct MS has been beneficial, since it enabled resolution of the compounds with identical fragmentation patterns (e.g., morphine-2-glucuronide and morphine-6-glucuronide). Besides, direct MS analysis required significantly larger amount of samples.

CE-ESI-MS<sup>n</sup> has been used for the analysis of entacapone and tolcapone and their metabolites [156]. These drugs are administered in combination with anti-Parkinson's levodopa. The main metabolites found were 3-*O*-glucuronide conjugates, and the analytical approach proved to be reproducible and very sensitive. The latter should facilitate direct metabolite identification in complex biological matrices.

CE and CE-ESI-MS were exploited for the analysis of lorazepam (3-hydroxy-1,4-benzodiazepine) and its metabolites in urine [157]. This drug is commonly used for the treatment of anxiety and as a sedative and hypnotic agent. The authors found that 75% of administered lorazepam is excreted in urine as its 3-*O*-glucuronide. Interestingly, since glucuronidation occurs at the chiral center of the molecule, two diastereoisomers can be formed, which was confirmed by MEKC analysis of urine extracts and also *in vitro*, via incubation of the drug with human liver microsomes and 5'-diphospho-glucuronic acid as coenzyme. The evidence of stereoselectivity of lorazepam

glucuronidation, with one diastereoisomer being formed preferentially than the other, was found as well. Achiral analysis was performed with a running buffer composed of 6 mM Na<sub>2</sub>B<sub>4</sub>O<sub>7</sub>, 10 mM Na<sub>2</sub>PO<sub>4</sub> (pH 9.1), and 75 mM SDS. For enantioselective analysis, the same buffer was diluted with isopropanol (2.5%), and 2-hydroxypropyl-cyclodextrin stereoselector was added. CE-MS experiments were performed in negative ESI mode with ammonium acetate as a separation buffer (pH 9 adjusted with concentrated ammonia) and a sheath liquid containing 50% methanol with 0.1% concentrated ammonia to ensure the formation of negatively charged ions. CE-MS<sup>2</sup> and CE-MS<sup>3</sup> experiments were conducted to confirm the presence of lorazepam and its 3-*O*-glucuronide, respectively.

#### 7.4.2.4 Characterization of Oligosaccharides in Pathogenic Bacteria

Pathogenic bacteria contain LPS and capsular polysaccharides (CPS) in their outer membranes. These compounds play important role in virulent properties of bacterial species, that is, invasion into human immune system through molecular mimicry mechanisms [158]. LPS functions have been under experimental research for several years due to their role in activating many transcriptional factors, which become active after stimulation with LPS. LPS also produces many types of mediators involved in septic shock. Structural characterization of the core oligosaccharide domain and O-chain polysaccharide components help identify the infecting pathogens and classify new strains, and therefore, contributes to the development of antibacterial drugs. For example, *Pseudomonas aeruginosa* is a Gram-negative bacterium affecting individuals suffering from cystic fibrosis, certain cancers, and immunodeficiency. The wild type of this pathogen expresses a heterogeneous population of O-PSs, and LPSs obtained from cystic fibrosis patients have been found to be deficient of O-chain extension [159].

To facilitate analysis of LPS/CPS, a partial hydrolysis is typically employed, either chemical or enzymatic, which is specific for each type of polysaccharide. Hydrolysis is usually followed by purification by a chromatographic means. Taking into consideration these time-consuming sample preparation steps, online coupling of separation and structural characterization methods represent advantage of potential minimization of sample pretreatment efforts. CE-MS have been exploited in this type of applications by several research groups. Li et al. [86] used ESI-MS in-source fragmentation technique, following CE separation, to break down CPSs and O-PS obtained from *Aeromonas pleuropneumoniae*, instead of conventional chemical degradation pretreatment. This approach helped to avoid extra sample preparation steps while keeping O-PS structure intact [85,86]. The latter also allowed acquiring information on O-acetylation of the molecules. In addition, online preconcentration methods coupled with CE-MS have been attempted [159].

CE-MS was used for the characterization of LPSs at different structural levels, gaining more understanding of mechanisms of action of the pathogens and, consequently, effecting drug design. *Moraxella catarrhalis* is a pathogen affecting the respiratory tract and middle ear causing otitis. CE-MS/MS analysis of oligosaccharides derived from this bacterium revealed both basic (glucosamine) and acidic groups (deoxy-manno-octulosonic acid) [158]. Mycobacteria contain lipoarabinomannans (LAMs) as their capsular components, which comprise arabinomannan core and a hydrophobic anchor, (e.g., phosphatidyl-*myo*-inositol). The immunological activity of LAMs depends on both cap and anchor structure: arabinofuranosyl side chains can be substituted with either mannose (ManLAMs) or phosphatidyl-*myo*-inositol (PI-LAMs) [59,160]. Nonvirulent mycobacteria have been shown to have preferentially PI-LAMs, while ManLAMs were found in pathogenic *Mycobacterium tuberculosis*, *Mycobacterium bovis*, and *Mycobacterium leprae*. Manno oligosaccharides can be hydrolytically released, derivatized by reductive amination with APTS, and undergo CE, coupled online or off-line with MS, using either nano-ESI source or MALDI-TOF [160]. More examples on characterization of oligosaccharides derived from bacterial sources can be found in Reference 59.

### 7.4.2.5 Sugar Analysis in Traditional Chinese Drugs

There has been growing attention to traditional Chinese drugs (TCD) in the world, due to their effectiveness in a number of disease therapies. Various sugars, including mono-, oligo-, and polysaccharides, are significant constituents of traditional Chinese herbs, reaching in some cases up to 80–90% of the whole plant dry weight [125]. There are over 300 kinds of polysaccharides extracted from natural plants. Among those, water-soluble polysaccharides typically possess most valuable pharmaceutical properties. The mechanisms of pharmaceutical effects of bioactive sugars have been extensively studied, and the number of their therapeutic applications have been increasing [161,162].

Most promising areas are anticancer activity [163–165], immune system stimulation [166–168] through the production of interleukins and T and B cell regeneration, anti-HIV effects (polysaccharides inhibiting binding of HIV to T cells) [169], blood sugar reduction (enhancing secretion of insulin and carbohydrate metabolism) [125,170], and anti-inflammatory [171,172].

The analysis of pharmaceutical polysaccharides and other sugars in TCD typically involves extraction, purification, and characterization steps. Water and weak basic solutions, as well as some organic solvents, at different temperatures, are typically used to extract sugars [125]. Purification can be accomplished by serial precipitation and chromatography steps (e.g., size exclusion, gel permeation, ion exchange, etc.) [125]. Electromigration separation methods for the analysis of sugar constituents of TCD have been gaining popularity in the past decade, due to their high separation efficiency and compatibility with UV, LIF, refraction index (RI), and electrochemical detection techniques, as well as hyphenation with MS and NMR. CE occupies a special niche in carbohydrate analysis, and TCD are not exception. In addition to high performance of CE, emphasized throughout this chapter, simplicity of instrumentation and low sample and all the reagents consumption are the main reasons for that. TCD sugars are usually separated and identified by CE as mono- and oligosaccharides, from which the composition of polysaccharides can be derived. Thus, complex polysaccharides are typically hydrolyzed to render simpler oligomers and monomers. Electrochemical detection and LIF of underivatized and fluorescently labeled saccharides, respectively, are highly sensitive. For example, when using amperometric detection approach  $\mu\text{M}$  sensitivity level for monosaccharides can be achieved with copper or gold electrodes [173–175]. Different aqueous separation buffers have been utilized, including highly basic ones ( $\text{pH} > 11\text{--}12$ ), when most neutral sugars become negatively charged due to their weak acidic properties. Sodium hydroxide based running buffers, borate ( $\text{pH} 10$ ), phosphate–borate buffers, used in combination with uncoated fused-silica capillaries, have most often been mentioned. Certain buffer additives, for example, surfactants (SDS, CTAB), THF, tryptophan, can often improve separation efficiency. Examples and references to analysis of carbohydrates in traditional Chinese medicines can be found in the recent review article by Wang and Fang [125].

One promising approach to be exploited more in the future with respect to TCD analysis is microchip-based CE. It is expected to enable ultimate integrated and highly sensitive systems to be built [176–178]. CE-MS coupling represents another area of fast development in carbohydrate analysis of TCD, as it has advanced in other applications in research, biopharmaceutical, and bioindustrial fields.

### 7.4.3 CARBOHYDRATES IN FOODS

Carbohydrate composition of foods and feeds allow characterization of the quality, ripeness, possible adulterations, and so forth. CE-MS approach has been widely used in analysis of foods. With a few exceptions [179], food carbohydrates are analyzed without any derivatization. Arabinose, ribose, xylose, inositol, galactose, fructose, and mannitol were monitored by CE-ESI-MS, using highly alkaline CE running buffer and negative ionization mode [180], reaching LOD 0.5–30  $\mu\text{g}/\text{mL}$ . Figure 7.14 exemplifies different carbohydrate patterns in red and white wines. The higher contents for most sugars were found in white wines. CEC-ESI-MS approach was exploited for the analysis of

**FIGURE 7.14** CE-MS total ion current (TIC) and SIM electropherograms for (A) a red wine and (B) white wine sample. CE conditions: fused-silica capillary (70 cm length to detection, 50 mm ID); running buffer 300 mM diethylamine (DEA); running voltage 20 kV; injection at 50 mbar for 9 s. ESI-quadrupole MS conditions: negative ion mode; capillary voltage 5 kV; sheath liquid 2-propanol:water (80:20 v/v) with 0.25% DEA at a flow rate of 4 mL/min; drying gas  $N_2$  at a flow rate of 1.4 L/min and a temperature of  $1507^\circ C$ ; nebulizer pressure 0 psi. Peaks: 1: deoxyribose; 2: arabinose; 3: ribose; 4: xylose; 5: galactose; 6: glucose; 7: fructose; 8: inositol; 9: mannitol. (Adapted from Klampfl, C. W. and Buchberger, W. *Electrophoresis*, 22, 2737, 2001. With permission.)

enzymatically digested GAGs [151] and other derivatized and underivatized glycans [69], complex oligosaccharide mixtures using hydrophilic monolithic columns [26], and FT-MS to achieve high mass resolution [53]. MEKC-ESI-MS was attempted to the analysis of iridoid glycosides in plant samples from different species [181]; in this case, the partial filling technique was used to prevent surfactants from entering the MS interface. Gellan gum, a complex sugar polymer food additive, was detected based on the occurrence of a characteristic tetrasaccharide released in the process of enzymatic digestion by a specific gellan degrading enzyme [182]. Low molecular weight sugar-based acids (gluconic and isosaccharinic) present in ale were unambiguously identified by CE-MS, which

helped overcome the problem associated with comigration of the two acids by SIM application during acquisition of MS spectra [183]. Glycoalkaloids of vegetable origin are also compounds of interest due to their toxic properties and occasional presence in food products. CE-MS was used to separate some typical glycoalkaloids, as well as related aglycones, in potatoes ( $\alpha$ -chaconine,  $\alpha$ -solanine, solanidine) and tomatoes ( $\alpha$ -tomatine, tomatidine) [184]. In this case, nonaqueous CE coupled with SIM or SRM (selected reaction monitoring) MS mode resulted in excellent separation and identification of all the investigated compounds. Moreover, nonaqueous buffer was found to significantly improve ionization efficiency. Another interesting application of CE-MS was reported by Bringmann et al. [185] who characterized glucosinolates from seeds, the compounds of anticarcinogenic effects. The authors employed IT analyzer for structural elucidation, while TOF MS was used for information on elemental and isotopic composition. Higher analysis efficiency was achieved compared to chromatographic methods, resulting in not only identification of known compounds but also discovery of some new ones.

#### 7.4.4 BIOINDUSTRIAL APPLICATIONS

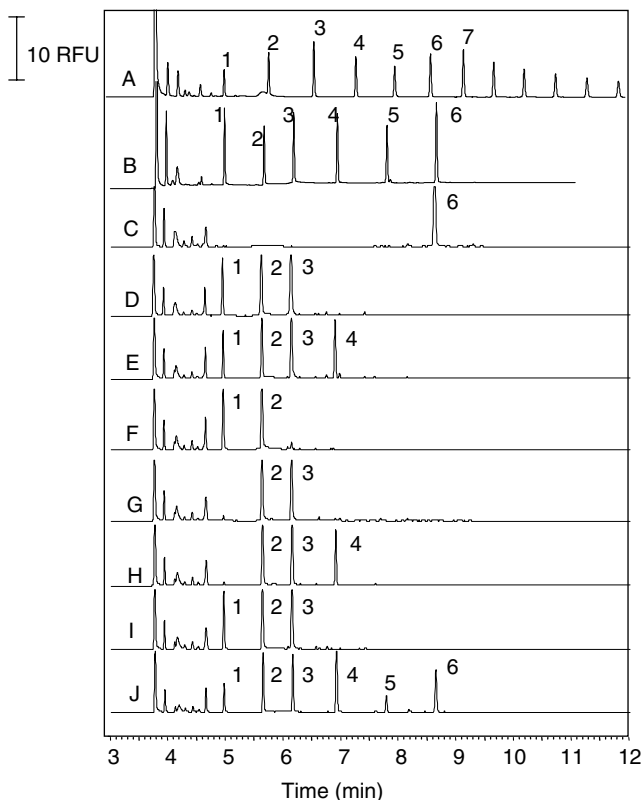

Enzymatic saccharification of lignocellulosic biomass to fermentable sugars is of great importance for a number of agroindustrial processes. These include conversion of cellulose and hemicelluloses to fuels and other important chemicals, delignification of paper pulp, digestibility enhancement of animal feed stock, clarification of juices, to name just a few. Chemical pretreatment methods in conjunction with proper cost-effective enzyme combinations (e.g., hemicellulases or cellulases) tailored to each specific biomass will enable production of fuel additives, such as ethanol, and other valuable chemicals by fermentation from this vast renewable resource [186–190]. Various agricultural residues, such as corn fiber and stover, wheat and rice straw, and so forth, contain up to 40% hemicellulose, the second most abundant polysaccharide in nature after cellulose. Cost-effective conversion of these materials to valuable chemicals is a current issue for the industry [188]. Lignocellulosic biomass structure is very complex [186,187]. Industrial corn fiber contains cellulose chains, assembled into highly crystalline and aggregated structures, microfibrils and fibers. The cellulose fibers are imbedded in a matrix of hemicellulose (highly branched heteropolysaccharides) and lignin. Cellulose and hemicellulose degrading enzymes are found in nature either as enzyme complexes or free in solution [191]. Different enzyme classes are involved in the biological depolymerization of cellulose and hemicellulose components: cellulases (endoglucanases, cellobiohydrolases, and  $\beta$ -glucosidases); xylanases to degrade the hemicellulose backbone, as well as accessory enzymes, for example, arabinofuranosidases, mannanases, galactosidases, glucuronidases, ferulic acid esterases and acetyl-xylan esterases. It is desirable to find high-specific activity enzymes that effectively hydrolyze biomass fiber in synergistic fashion [189]. Evaluation of different enzymes and their combinations, optimization of the reaction conditions (temperature, pH, reagent concentration, reaction time, etc.) are critical. Therefore, hundreds and thousands of samples are to be analyzed to screen the various enzyme combinations, tune reaction parameters, and characterize novel expressed recombinant enzymes and microorganisms.

Implementation of efficient and robust industrial scale bioconversion processes requires high-throughput analysis of mono- and oligosaccharide products, released by enzymatic digestion of various biomasses, to evaluate activity of enzymes and microorganisms. CE with LIF detection offers excellent resolving power and high sensitivity, superior to many other analytical approaches [192]. High-resolution separations of complex carbohydrate mixtures, simple sugars, glycoforms of glycoproteins, and glycolipid oligosaccharides by CE have been demonstrated for the past decade [19,48,193]. Using suitable fluorescent-labeling procedures, charged derivatives of various carbohydrates can be formed enabling attomole detection level in CE [193]. The majority of carbohydrate derivatization methods utilize tagging of the reducing termini with a fluorophore via reductive amination [34]. APTS is one of the most popular of such derivatization agents, providing very bright fluorescence and good spectral characteristics suitable for the commonly used Ar-ion laser [195].

There is a great demand for large, industrial-scale carbohydrate profiling methods to meet the current growing needs to screen enzymatic activity of recombinant enzyme and microorganism libraries. A few advances have been made to date to establish reliable high-throughput methodology for automated oligosaccharide analysis. Morell et al. [196] adapted a polyacrylamide slab gel based DNA-sequencing device to parallel multilane analysis of oligosaccharide products of enzymatic digests of starches. Although, good resolution up to DP 75 and sensitivity (1 fmol per oligosaccharide) were achieved, the technique had limitations with respect to reproducibility, precise tracking of gel lanes, resolution of subtle differences in profiles, and labor consumption. Another research group [197] utilized a similar DNA-sequencing instrument using 32 parallel lanes, in combination with sample preparation, derivatization and cleanup steps, to accomplish ultrasensitive profiling and sequencing of *N*-linked glycans. On the other hand, CE demonstrated superior performance enabling fast and reproducible separation in the range of DP 1–100, providing at the same time flexibility of separation formats for the development of various assays [48]. A multicapillary CE-based DNA analyzer combined with 96-well-plate-based sample preparation method and a thermocycler were used to perform high-throughput clinical analysis of *N*-linked oligosaccharides from serum protein of liver disease patients [141].

Khandurina et al. [198] demonstrated the capabilities of a single CE instrument to provide automated high resolution and quantitative analysis of mono- and oligosaccharide products of enzymatic digestion of cellohexaose, as a model substrate, and corn fiber biomass in bioindustrial settings. The authors developed various protocols to accommodate different assays needs. Unattended batch sample processing from 96-well plates after the one-step derivatization reaction enabled reliable industrial-scale carbohydrate profiling. A single CE system (P/ACE MDQ; Beckman Coulter) was employed, with the cathode on the inlet side and anode on the outlet side (reversed polarity), since the negatively charged APTS-labeled oligosaccharides migrate toward the anode under applied electric field. For the CE analysis, either bare fused-silica (Polymicro Technologies, Phoenix, AZ) or coated capillary columns (eCAP™ N-CHO Capillary; Beckman Coulter) of 50 μm ID were used, with the effective separation length either 48 cm to achieve high resolution or 10 cm in fast screening experiments. 25 mM lithium acetate (pH 5) buffer was used as running buffer. Samples were injected by vacuum for 5–10 s at 0.5 psi (3447 Pa) and separated at 500 V/cm electric field strength. In case of uncoated capillaries, a dynamic coating by 1% polyethylene oxide (MW 600,000 Da) was utilized to suppress EOF. Figure 7.15 shows high-resolution oligosaccharide profiling by CE using 48 cm effective separation length. Traces A and B depict the electropherograms of a maltooligosaccharide ladder and cello-oligomer standards, respectively. There are well-observable differences in migration times of the oligosaccharides with the same DP but different linkages between glucose monomer units (e.g., maltose vs. cellobiose, maltotriose vs. cellotriose, etc.). These differences result from the changes in structure and, therefore, hydrodynamic radius of the molecules, having either  $\alpha$ -1,4 or  $\beta$ -1,4 glycosidic bonds. Profiles C–J in Figure 7.15 show CE analyses of the reaction products of cellohexaose digestion (trace C) using different cellulases. Precise monitoring of the differences in cellulase enzymatic activity, revealing a variety of combinations of glucose, cellobiose, cellotriose, cellotetraose, and cellopentaose, was readily achieved by CE. The excellent migration time reproducibility allowed easy identification of the cello-oligomer products of the cellohexaose enzymatic hydrolysis.

Separation of monosaccharides is a challenging task, particularly due to very minor differences between most common sugar molecules, representing the building blocks of lignocellulosic biomasses. Monosaccharide analysis by CE has been previously demonstrated using borate-based buffer systems at high pH (>9), taking advantage of the resolution enhancement due to anionic complex formation between the polyhydroxy compounds (sugars) and borate [199,200]. Good separation performance was demonstrated using CZE [200] or MEKC [27] in bare fused-silica capillaries under EOF conditions. However, in most cases an internal standard was required to account for possible migration time shifts. The authors [198] have found that comparable separation performance of some monosaccharides (major building blocks of hemicellulose) can be achieved using the same CE

**FIGURE 7.15** High-resolution oligosaccharide profiling by CE. Traces: (A) Maltooligosaccharide ladder; (B) cellobiosaccharide ladder; (C) model substrate cellohexaose; (D–J) products of enzymatic digestion of cellohexaose by seven different enzymes with cellulase activity. Numbers above peaks correspond to DP of oligosaccharides. Conditions: eCAP neutral coated capillary (50  $\mu\text{m}$  ID); effective separation length 48 cm; electric field strength 500 V/cm; running buffer 25 mM lithium acetate (pH 5); injection 5 s at 0.5 psi (3447 Pa). (Adapted from Khandurina, J. et al. *Electrophoresis*, 25, 2326, 2004. With permission.)

conditions, as described above for oligosaccharide profiling. Moreover, the absence of EOF typically renders more reproducible performance and elimination of additional rinsing steps, otherwise required.

Trace A in Figure 7.16 shows a well-resolved separation of a mixture of the five monosaccharides of interest in just 5 min, using 25 mM lithium acetate (pH 5) running buffer under apparently zero EOF conditions. Glucuronic acid (1) is the fastest migrating sugar, due to its additional charge, followed by the pentoses of xylose (2) and arabinose (3), and the hexoses of glucose (4) and galactose (5), respectively. By this means, monosaccharide reaction products of corn fiber hydrolysis, either chemical or enzymatic, can be easily identified, assuming very similar labeling efficiency for all the released monosaccharides [34,196]. Traces B and C in Figure 7.3 depict separations of sugars released from equal amounts of corn fiber by acidic hydrolysis, for 2 h at 100°C, with 1 M sulfuric acid and 2 M tetrafluoroacetic acid (TFA), respectively. The glucose (4), most likely, comes from the cellulose domains of corn fiber. To identify the peaks precisely, in ambiguous cases, the samples were spiked with proper amounts of standards. Trace D in Figure 7.16 delineates decomposition products of corn fiber under harsh hydrolysis conditions, started with 72%  $\text{H}_2\text{SO}_4$  for 1 h followed by dilution to 4%, autoclaving at 120°C for 1 h, and storing for 4 months after the treatment. This procedure apparently resulted in the release of significantly more monosaccharides, as one can observe from the increased peak areas of this particular trace. In addition, the relative glucose concentration was

**FIGURE 7.16** Monosaccharide analysis by CE under zero EOF condition. Traces: (A) five standard sugar mix (1: glucuronic acid, 2: xylose, 3: arabinose, 4: glucose, and 5: galactose); (B) corn fiber acid hydrolysates—1 M sulfuric acid; (C) 2 M TFA; (D) 72% sulfuric acid; (E) corn fiber enzymatic digestion. Conditions: same as in previous figure, except a bare fused-silica capillary (50 $\mu$ m ID, 48 cm effective separation length) was used with dynamic PEO coating. (Adapted from Khandurina, J. et al. *Electrophoresis*, 25, 2326, 2004. With permission.)

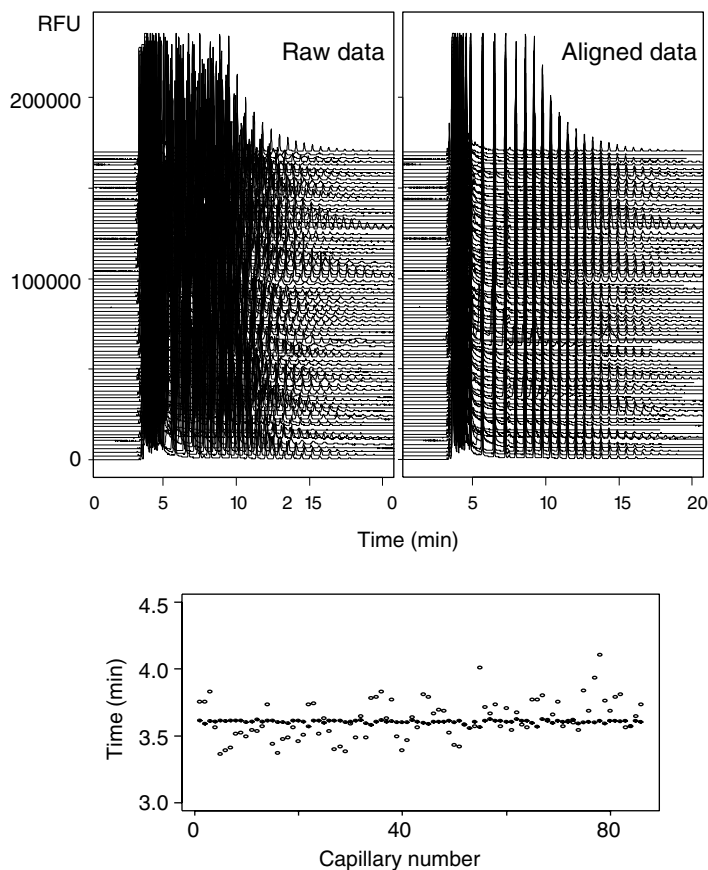

substantially elevated (peak 4) compared with milder hydrolysis conditions. An illustrative example of the enzymatic digestion of corn fiber by a fungal culture medium is shown in Trace E (Figure 7.16). The lower relative content of the released xylose, compared with the acidic hydrolysates, was caused by lack of xylanase activity in the enzyme system used in the experiment. Most of the other earlier migrating peaks in the electropherogram are probably associated with background and matrix effects originating from the labeling reaction and constituents of the enzyme medium.

The same research group introduced a 96-capillary array electrophoresis (CAE) approach for large-scale mono- and oligosaccharide analysis and characterization [201,202]. In this work, a DNA sequencer, MegaBACE1000 (Amersham Biosciences) was adapted for carbohydrate screening by developing and optimizing operational protocols and data processing tools. This approach brings high-performance carbohydrate analysis within reach of life sciences laboratories without the need for additional costly equipment, and helps expedite the pace of discovery and development of biomass conversion processes, as well as glycobiology studies. Carbohydrate samples (1  $\mu$ L) were labeled in 96-well plate format, through reductive amination by the addition of 2  $\mu$ L of 0.2 M APTS in 15% acetic acid and 2  $\mu$ L of 1 M NaBH<sub>3</sub>CN in tetrahydrofuran [19,34,48,193,194]. The plates were incubated for 1 h at 75°C, followed by the addition of 100  $\mu$ L water to stop the reaction. Before CE analysis, the APTS-labeled samples were further diluted in water (up to three orders of magnitude depending on the initial concentration of carbohydrates), resulting in low nM concentration range of each derivatized carbohydrate species. The authors found that uncoated fused-silica capillary arrays (The Gel Company, San Francisco, CA) in combination with dynamic PEO coating render more consistent performance and significantly longer lifetime compared to original covalently

coated capillary arrays, designed for DNA-sequencing applications. The dynamic coating is easily regenerated before each run by sequential washing with hydrochloric acid, water, PEO solution in the running buffer, and finally lithium acetate running buffer. It is important to emphasize that carbohydrate analysis was performed in CZE (open tube) mode and, therefore, more sensitive to capillary surface quality and any residual EOF, unlike in DNA sequencing and genotyping, where viscous sieving media can compensate for some coating nonuniformity and deterioration. To further speed up the process, the dynamic coating polymer can be directly added to the running buffer. One important problem to avoid in carbohydrate CAE is a possible siphoning effect caused by uneven liquid levels in inlet and outlet buffer reservoirs [202]. Capillary-to-capillary and run-to-run variation in migration time and signal intensity necessitated the development of data normalization tools. Internal bracketing fluorescent standards were incorporated into the analysis enabling CAE trace alignment. A four-color detection system allowed a choice of different fluorophores to spectrally separate the sample peaks and internal standards in the corresponding detection channels. An excess of unreacted APTS, remaining in the samples after derivatization and migrating faster than the labeled sugars, was used as leading bracketing standard. A fluorescent dye sulforhodamine B (SRB), emitting in the red spectral region ( $\lambda_{\text{max}} = 586 \text{ nm}$ ) and migrating with similar mobility as the maltooligosaccharide of DP 16, served as a terminating bracketing standard. A set of programming tools were developed to process the data and properly normalize migration time for each electropherograms based on internal bracketing standards. The procedure is described in detail in Reference 201. Figure 7.17 presents a set of raw (left) and aligned (right) electropherograms, utilizing the developed algorithm. APTS-derivatized maltooligosaccharide ladder mixed with the terminating bracketing standard (SRB) was used in this experiment. As one can see, all corresponding oligosaccharide peaks match very well in the aligned data set in the right panel. The lower panel in Figure 7.17 delineates the migration time of APTS peak across the entire 96-CAE before and after the normalization procedure. A mixture of four monosaccharides, xylose, arabinose, glucose, and galactose were also successfully separated by CAE under low-pH conditions (Figure 7.18). The data were normalized, similar to the maltooligosaccharide ladder, enabling an accurate peak identification of closely migrating monosaccharides. Figure 7.18 shows five representative traces of such analysis before (upper panel) and after (lower panel) the data normalization. Albeit, the efficiency of APTS-labeling reaction is very similar for most monosaccharide product and short oligosaccharide product, precise quantification requires correction for possible small differences [201]. This can be accomplished by introduction of another internal standard into the sample derivatization mix, for example, oligosaccharide migrating with no overlapping with the sugars of interest. Relative labeling efficiency coefficients can be derived this way and used for accurate quantification of the sugars of interest in the unknown samples [201]. The described large-scale qualitative and quantitative carbohydrate profiling method based on 96-CAE can accommodate high-throughput demands of the biotechnology industry. The areas of application for the developed methodology include biomass conversion processes, which require massive screening of enzymatic reaction products to evaluate large libraries of recombinant enzymes and microorganisms, as well as protein glycosylation studies.

#### 7.4.5 MINIATURIZATION IN CARBOHYDRATE ANALYSIS

The recent fast developing trend for miniaturization of analytical systems has influenced carbohydrate analysis as well. Advances in microfabrication technologies, microfluidics-based devices, and microchip electrophoresis in particular, in combination with available high-sensitivity detection methods, stimulated a series of attempts to implement carbohydrate analysis on-chip. However, advancement of on-chip glycomics has been somewhat limited compared to fast growth of microscale genomic and proteomic applications. A number of limitations, such as lack of charge and functional groups and detection issues, present a challenge. Suzuki and Honda [17] have briefly summarized the latest

**FIGURE 7.17** Migration time normalization and CAE data alignment. Left and right panels represent raw and aligned traces, respectively, for maltooligosaccharide ladder samples containing SRB as internal bracketing standard. The lower panel shows migration time standard deviation for APTS peak before and after normalization procedure. See details of data processing in the text. Conditions: injection 10 s at 5 kV, separation 15 kV (240 V/cm), temperature 30°C, 25 mM lithium acetate (pH 5) separation buffer, uncoated fused-silica capillary arrays dynamically coated with PEO (see details in the text). Arrows and numbers indicate DP of oligosaccharides, for reference. (Adapted from Khandurina, J. et al. *Electrophoresis*, 25, 3122, 2004. With permission.)

developments in this area. Mechref and Novotny [32] described chip approaches in glycomics, both CE and chromatography based, in their latest review.

Miniaturization of sample handling and processing steps should significantly reduce losses associated with adsorption at the surfaces, sample transfers, as well as potential contamination. Integration and concomitant minimization of the analysis steps on-chip, including purification, concentration, separation, and detection, will ultimately enhance sensitivity and efficiency of the carbohydrate analysis, and glycan screening in particular.

Several research groups implemented carbohydrate analysis on-chip with direct detection of underivatized sugar molecules. Electrochemical detection is the most attractive approach, as it offers reasonable sensitivity and selectivity, and it is ideally suited for microchip format. Schwarz et al. [203] developed amperometric detection of sugars using microfabricated copper electrode. They separated fructose, sucrose, and galactose in 70 s on a glass chip with 50- $\mu\text{m}$  wide and 20- $\mu\text{m}$  deep microchannel and double tee injection geometry. The detection was based on Teflon-coated platinum wire plated with copper and inserted in the end of the separation channel etched in a conical shape. The detection limit down to 1  $\mu\text{M}$  was achieved. Hebert and coworkers [204] reported an

**FIGURE 7.18** CAE analysis and data alignment for monosaccharides. Only five traces representing wells # 60–65 of a sample plate are shown to better visualize the separation and data processing performance. Raw and normalized data are in the upper and lower panels, respectively. The first migrating peak in each trace is unreacted APTS followed by xylose, arabinose, glucose, and galactose, in order of migration. Electrophoretic conditions (except for injection at 1 kV for 5 s) and internal bracketing standards are the same as in previous figure. (Adapted from Khandurina, J. et al. *Electrophoresis*, 25, 3122, 2004. With permission.)

interesting detection system based on sinusoidal voltammetry, where Fourier transformation was used to convert current data, associated with carbohydrate molecules, into the frequency domain, thus, effectively isolating the analyte signal from background current. A polydimethylsiloxane chip with a planar copper electrode was fabricated, enabling detection limit of 200 amol and efficiency of  $10^5$  theoretical plates per meter. The signal-to-noise ratio was enhanced by utilizing a digital lock-in method, which allowed selective picking and masking of carbohydrate signals. An on-chip-pulsed amperometric detection system, described by Fanguy and Henry [205], accomplished analysis of glucose, xylose, and maltose in 4 cm separation channel with a platinum electrode built in the end part of the channel. The authors demonstrated a linear response in 20–500  $\mu\text{M}$  concentration range, with 20  $\mu\text{M}$  detection limit. A unique system, combining flow injection and short CE, was constructed by Fu and Fang [206]. Some carbohydrates were monitored by amperometric detection on a horizontal channel connected to a vertical plastic tubing. A solution of glucose and sucrose was continuously introduced by droplets from the tubing into the junction with the channel followed by electrophoretic separation. Sugars were separated in 60 s on a 5- $\mu\text{m}$  ID and 5-cm-long capillary, with a dynamic range of 10–1000  $\mu\text{M}$ .

Refractometry is another approach for direct detection of carbohydrates. An interesting holography-based refractive index detector was implemented by Burggraf et al. [207]. A cyclic channel of 80 mm in circumference and 10- $\mu\text{m}$  deep was fabricated. The detection scheme was constructed having a diode laser beam (670 nm) split into two beams, one passing through the separation

channel and the second through the adjacent reference channel. A photodiode array detected changes in holographic optical image. Separation time (17 s) of raffinose, sucrose, and *N*-acetylglucosamine was achieved, with the detection optimum at 10 mM level (600–900 fmol of injected material). Although the analysis sensitivity was quite limited, the described coupling of electrophoresis microchip and refractive index detector can be used for certain application when sensitivity is not required (e.g., measurements of simple sugars in foods).

The most successful microchip separations were achieved with derivatized carbohydrates when a UV absorbing or, better, fluorescent tag is introduced. On-chip UV detection suffered from low sensitivity and allowed only mM detection level using PMP label and free zone electrophoresis in borate buffer [208]. To alleviate poor detection limit, microchip Shimadzu instrument is equipped with the special whole-channel detection system, where the signal is enhanced by simultaneous accumulation and averaging of the absorption data from multiple points. Baba and coworkers [209] analyzed APTS-labeled oligosaccharides on a Hitachi SV1100 microchip system using a blue light emitting diode (LED) source and confocal fluorescent detection configuration. In this work, a plastic polymethylmethacrylate (PMMA) chip was employed, and the detrimental adsorption of APTS to PMMA material was alleviated by dynamic coating with methylcellulose to the running buffer. The maltooligosaccharides were resolved up to DP 10 (maltodecaose) in 2 min. In another work from the same group [210] protein glycosylation structures were analyzed: high-mannose-type glycans were enzymatically released from bovine spleen ribonuclease B and separated on-chip, using asymmetric pinched injection with field-amplified stacking resulting in 20-fold improved sensitivity. Derivatization of sugar reducing ends by reductive amination has been undoubtedly one of the most successful and universal approaches; however, some classes of carbohydrates contain functional groups that are suitable for alternative chemical couplings. For example, hexosamines and their derivatives possess an amino group at the C2 position, and therefore can be readily fluorescently labeled via reactions developed for aminoacids. Suzuki et al. [211] implemented a condensation reaction of hexosamines with 4-nitro-2,1,3-benzoxadiazole 7-fluoride (NBD-F), followed by a microchip electrophoresis on a quartz chip using 33 mm separation distance and Ar-ion LIF detection. The authors separated glucosamine, galactosamine, and their corresponding reduced forms, glucosaminitol and galactosaminitol, in 1 min under free buffer conditions (phenylborate sugar complexes), reaching detection limit of 2.5  $\mu$ M (0.5 fmol injected amount). The same labeling methodology was successfully applied to *O*-linked glycans enzymatically stripped from glycoproteins (e.g., bovine submaxillary mucin).

Another interesting example of miniaturized carbohydrate analysis is on-chip integration of enzymatic reactions, conventionally used for sugar determination, with electrophoretic separation of the reaction products. Wang and coworkers [174] demonstrated a simultaneous assay of glucose, ascorbic acid, and acetaminophen on a microchip with cross-channels and a gold electrode assembly in the separation channel. The sample containing glucose was mixed with glucose oxidase (GOx) in the channel intersection, followed by the oxidation reaction and separation of the generated hydrogen peroxide from ascorbic acid and acetaminophen. The latter two species migrated more slowly due to their anionic nature. The gold-coated thick-film amperometric detector was positioned downstream in the separation channel, and the glucose level was assessed based on comparison of response with and without GOx (Figure 7.19) [174]. The same group reported an oxidase/dehydrogenase assay, implemented on-chip, for the measurements of glucose and ethanol [175]. The developed assay was applied to the analysis of wine samples.

Integration of microchip CE and MS is a new emerging technology, which is expected to enhance high-throughput glycan mapping and sequencing. The combination of microfluidics, automation/robotization, and software for assignment of MS data has already been implemented by introducing Advion Nanomate dispenser and chip to glycoscreening by coupling it to QTOF and FT-ICR mass analyzers [73]. The fully automated chip-based MS approach for complex carbohydrate system analysis was applied to urine analysis of patient suffering from hereditary diseases. Addition of sample CE prepreparation to the ESI-QTOF via Nanomate system has been demonstrated

**FIGURE 7.19** Layout of the separation/reaction microchip for bioassays of glucose, ascorbic acid, uric acid, and acetaminophen (upper panel). Enzymatic and separation processes along the reaction/separation channel of the CE biochip (lower panel). (Adapted from Wang, J. et al. *Anal Chem*, 72, 2514, 2000. With permission.)

to provide advantages compared to more conventional CE-MS interface, that is, higher ionization yield, decreased in-source fragmentation, and stable spray [212].

Recently, a total serum protein N-glycosylation profiling was attempted on a CE chip by Ehrlich and coworkers [213]. The authors employed a glass chip with a double-tee injector and a 4% linear polyacrylamide sieving medium (analogous to nucleic acid separations). Profiling of serum samples from chronic hepatitis patients identified the differences in N-glycan composition in cirrhotic and noncirrhotic cases, and demonstrated the potential of microchip approach for these types of clinical studies.

Integrated microchips, packed with reversed-chromatographic phase and interfaced with TOF [214] or IT [215] MS, for the analysis of oligosaccharides, *O*- and *N*-glycans of different sources have also been reported.

Although only relatively simple carbohydrate systems have been transferred on-chip so far, primarily due to resolution limitation in short separation distances and sensitivity challenges in microchannels, rapid progress in this area is expected in the nearest future. Column efficiencies observed in microchannels were similar or higher (the latter was due to shorter injection plugs realized in microchip settings) compared to conventional CE format. Shorter separation paths utilized in miniaturized analysis settings limit complexity of analytes, which can be successfully resolved. On the other hand, microfabricated devices offer a number of other attractive analytical advantages. One of them is possibility of integration, that is, combining sample prep and derivatization, separation, and detection steps on a single integrated device [216,217]. Second, disposable microchips can be inexpensively mass produced and utilized in testing analytical kits or point-of-care diagnostic tools in food, environmental, and medical applications.

## 7.5 METHOD DEVELOPMENT GUIDELINES

As it has been emphasized throughout this chapter, CE in its various modes of separation and detection is suitable for the analysis of a wide variety of carbohydrate molecules, that is, mono-, oligo-, and polysaccharides, glycopeptides, glycoproteins, and glycolipids. This can be credited to the progress made in the capillary column technology, introduction of novel electrolyte systems, as well as the development of various detection approaches, such as indirect UV and LIF detection, electrochemical detection, CE-MS interface, and precolumn labeling with suitable chromophores and fluorophores. Precolumn derivatization proved to be one of the most elegant approaches for the separation and detection of carbohydrates. Among the different reaction schemes, introduced for the labeling of carbohydrates, multiply charged tags (ANDSA, ANTS, and APTS) have become the most popular, not only because of their high detection sensitivity by either UV or LIF, but also because they yield derivatives that are readily separated by CE.

Majority of CE separations are typically accomplished utilizing borate complexation, for both derivatized and underivatized carbohydrates. However, noncomplexing electrolyte systems (phosphate, acetate based buffers, for example) are often successfully used as well. As it has been described in Section 7.2, borate complexation enhances small structural differences of structurally similar molecules, resulting into highly selective separations of multicomponent sugar mixtures. Under a given set of conditions, various sugars, whether charged or neutral, undergo varying degrees of complexation with borate leading to differences in the electrophoretic mobilities of the complexed solutes and hence separation.

Highly alkaline electrolyte solutions, for example, lithium, potassium, or sodium hydroxide at  $\text{pH} > 12$  have been proved to be useful in the separation of underivatized saccharides by CZE. The resolution of various saccharides is typically improved with pH increase (up to pH 13) due to increasing ionization of the separated analytes. In addition, the nature of the alkali-metal influences the resolution of the sugar analytes.

The separations at extremely high pH can only be performed in bare fused-silica capillaries, since most coatings undergo hydrolytic degradation under the highly basic conditions. The use of electrolyte systems containing alkaline-earth metals for the separation of neutral carbohydrates by CZE is mainly based on differences in the extent of complexation of the divalent metals with the carbohydrate solutes, as well as the size and shape of the molecule. These systems provided a different selectivity from that of borate buffers, although the resolution is often inferior.

The electrolyte systems in CE can be easily modified and tailored to a specific separation task. For example, most glycolipids are not compatible with aqueous electrolyte solutions but they can be readily separated in their monomeric forms in hydroorganic buffers. Buffer additives, such as

surfactants and polymers, often enhance separation efficiency. Examples of various separation buffer systems, suitable for different classes of carbohydrates, and approaches to their development can be found in the above sections, dedicated to specific types of carbohydrate species and their sources, and references therein.

Characterization of glycoconjugates are typically carried out by first cleaving the carbohydrate moieties from glycoproteins, glycolipids, GAGs, or other complex molecules, often followed by further reduction of the structure complexity through enzymatic digestion and/or depolymerization.

Owing to enormous diversity and complexity of carbohydrates and their conjugates with other classes of biomolecules, it is impossible to briefly outline any definitive guidelines for analysis method development. Each type of carbohydrate molecules should be approached separately, based on its specific properties, such as molecular weight, linearity or branching, presence/absence of the reducing end, charge, additional functional groups present, matrix complexity, and so forth. Therefore, the reader is directed to the above sections to find basic modern strategies, as well as specific protocols in the corresponding references, for sample preparation, derivatization, separation, and detection in the analysis and structural characterization of simple and complex saccharides and glycoconjugates in pharmaceuticals, foods, plants, bacteria, animal tissues, and other sources.

## 7.6 CONCLUSIONS AND OUTLOOK

Progress in carbohydrate research and concomitant advances of analytical methodologies during the past decade have been undoubtedly remarkable. In particular, the expansion of CE and its various implementations supported the increasing demand for new level of information output, such as integrated systems biology approach.

The future developments in CE-based analysis of carbohydrates are envisioned to bring forward automation and miniaturization to ensure high-throughput and large-scale carbohydrate profiling to keep up with the industrial needs. On the other hand, capabilities of elaborate structural insights into complex carbohydrate molecules should be further developed as well. Hyphenated techniques, such as CE-MS, offer possibility to identify composition of complex polysaccharides and glycoconjugates, as well as their sequence and fine structural details, that is, isomeric configurations, branching, substitutions, linkages between monomer units, and so forth. Glycomics and glycoproteomics deserve special attention, as part of system biology efforts toward complete understanding of the complexity of living organisms. Just like the developments in genomics, transcriptomics, proteomics, and metabolomics, functional glycomics is strongly dependent on the current and future advances in analytical methodologies and instrumentation. Quantitative measurements are essential to better understanding of cellular and molecular interactions associated with different physiological and pathological processes in living systems. CE-based methodologies directly combined with MS are particularly useful in this respect. Electromigration techniques, for example, CZE, MEKC, and CEC, exhibit most superior resolving power enabling separation and identification of close oligosaccharide isomers. LIF is most preferred detection approach for high-sensitivity profiling of glycan mixtures by CE. Coupling these techniques to MS is still a challenging task, although significant progress has been made. Increasing number of manufacturers, offering ready-to-use CE-MS instruments and a variety of available interfaces (especially nanospray sheathless approach), represent a step forward toward a more routine use of carbohydrate analysis by CE-MS. Growing sophistication of MS instrumentation fuels development of new CE-MS applications, involving IT, TOF, TOF-TOF, and FT-ICR. CE-MS<sup>n</sup> offers powerful capabilities. However, optimization of this technology, including instrumental solutions, sample preparation, and separation aspects, is still in progress, and robust standardized systems and protocols are to be refined yet. Careful choice of separation buffers is the key, as many salts and other buffer components adversely affect sensitivity of most MS detectors.

It is reasonable to expect that microfluidic and chip-based technology will become widely applicable to glycomics, as it has already become in many aspects of genomics and proteomics. Miniaturized CE-MS technology should develop into reliable task-oriented commercial instrumentation, applicable to investigation of different biological systems under well-designed conditions.

## 8.1 INTRODUCTION

Modern science is firmly entrenched in the “omics” era. Spurred by the human genome project, omics-thinking quickly spread to ribonucleic acid (RNA), proteins, and now metabolites. Although different technologies are required for each specific omic endeavor, they all have similar goals of attempting to garner as much information about a specific class of biomolecules as possible. Another thing that each has in common that often goes overlooked is the need for separation. While very complex mixtures of deoxyribonucleic acid (DNA), RNA, protein, or metabolites are introduced to the appropriate analytical instrumentation, the technology still measures each basic unit (whether it be a base, transcript, or peptide) individually. For example, even though entire transcriptomes are introduced to array platform, the RNA transcripts must be separated via annealing to their complementary strand for a quantitative signal to be deciphered for each. While proteomics, one of the foci of this chapter, is arguably driven by the development of mass spectrometry (MS) technology, separation technologies have been just as instrumental in its development. If proteomics was limited to direct infusion techniques, we would still be floundering in the detection of only the highest abundant proteins present within biological samples.

When integrating a separation technique into a MS-based proteomics study many different aspects need to be considered. The first consideration is if an online or an off-line separation of the proteome sample will be integrated into the research plan. There are a large number of separation techniques available to do off-line.<sup>1</sup> These include many different chromatography [e.g., strong/weak cation exchange (S/WCX), strong/weak anion exchange (S/WAX), reversed-phase (RP), size exclusion, etc.] and electrophoretic gel and capillary electrophoresis (CE) [e.g., capillary zone electrophoresis (CZE), isoelectric focusing (IEF), isotachopheresis (ITC), etc.] methods. Off-line separations are simpler, easier to perform, and require no instrument modification. In addition, a simple solvent exchange step can be administered to each fraction to introduce the correct conditions for downstream MS analysis. RP columns packed with C18 particles are most commonly used to

remove salts and other MS incompatible materials from fractions collected via off-line separations. The next consideration is the amount of material available for fractionation. This consideration is where chromatographic methods have a decided advantage over gel-based electrophoretic techniques. Proteins in a proteomic sample are fractionated off-line mainly to simplify the mixture prior to high-performance liquid chromatography/mass spectrometry (HPLC/MS) analysis and are normally done when a significant amount (50–200  $\mu\text{g}$ ) of protein is available. Although chromatography columns have the capacity to handle such samples sizes, typical gel electrophoretic methods are unsuitable for these amounts of materials.<sup>2</sup> This aspect is the primary reason that SCX has become the most popular choice of off-line liquid-based separations for MS-based proteomic studies. The final design aspect that needs to be considered is the choice of online separation that will be used with direct MS analysis. The most important consideration for this part of the study is making the solvent conditions compatible with electrospray ionization (ESI).<sup>3</sup> ESI requires the solvent to be volatile, acidic, and contain only low levels of salts and buffers. ESI is almost intolerable to detergents.

The most popular type of separation technique to which MS has been directly coupled is reversed-phase liquid chromatography (RPLC). This chromatography has all the necessary attributes that make it an excellent choice for online MS analysis. What is not optimal, however, is its speed and resolution. RP columns require re-equilibration between analyses when gradient mobile phases are used, leading to an almost 25% downtime when using this type of separation. While many laboratories have implemented column-switching so that one column is being used for online MS analysis while the other is re-equilibrating, this technology is not widely used and has issues related to repositioning of the column within the ESI source. While the resolution of RPLC is quite good, the duty cycles of tandem MS instruments is so short that even higher resolution separations could provide a greater solution for maximizing proteome coverage. It is in these two areas that CE has distinct advantages.

Capillary electrophoresis is an excellent microseparation technique that has been used for the separation of a wide diversity of different molecules.<sup>4</sup> Its separation capabilities extend to ions, small molecules (such as amino acids), and large biomolecules (such as peptides, proteins, and nucleic acids). Indeed the human genome project owes its success, in part, to the use of CE for the separation of DNA bases. In the past, CE has been combined with detection devices such as ultraviolet (UV) and laser-induced fluorescence (LIF) spectrophotometers. The detection of the separated analytes is carried out on column by etching the capillary. Unfortunately, UV detection lacks sensitivity and not every compound of interest will absorb in the UV region of the spectrum. Detection using LIF is sensitive, however, the analytes of interest may require derivatization with a fluorescent tag or have an aromatic amino acid in their structure (e.g., proteins and peptides). An advantage of MS detection that neither UV nor LIF detection provides is the information necessary to directly determine the structure of the detected analyte(s).

Mass spectrometry, however, has high sensitivity for the detection of a wide variety of analytes. When operated in a multistage, MS mode can provide information to assist in the determination of the structural formula of the molecules of interest. A marriage of CE and MS would potentially result in an extremely powerful tool for the separation, identification, and characterization of a wide range of molecules. Unfortunately, the online interfacing of CE with MS is not trivial and presents several technological challenges not present with CE-UV or CE-LIF. Some major issues are the requirements of both the CE continuous electrical circuit for electrophoretic separation and the mass spectrometer electrical contact for efficient ESI. Running buffers normally used in CE, such as sodium phosphate or borate that have low volatility, are not compatible with ESI-MS. These buffers need to be replaced with volatile buffers such as ammonium formate or acetate. This substitution, however, may have a detrimental impact on the quality of the separation.

The resolution afforded with CE is a good match for the duty cycle times of present day tandem MS instruments, particularly in the area of proteomics. In the past, the speed at which mass spectrometers selected, isolated, fragmented, and detected peptide ions did not warrant extremely high resolution

separations because some analytes would not be present long enough in the MS source to be surveyed by the instrument. Nowadays, with the speed of mass spectrometers such as the linear-ion traps, peptides that are present for only a few seconds (i.e., <10) still have a high probability of being selected for tandem MS analysis. The biggest drawback in using CE online with MS is the amount of material that can be loaded onto the capillary. Although MS is a sensitive detection technique, it still has its limits. Sample sizes in the range of 1–10  $\mu\text{g}$  are typically loaded onto a capillary RP column for subsequent MS analysis. Unfortunately, CE capillaries have a very limited volume and can only accommodate sample amount in the nanogram (ng) range. Fortunately, the use of on-column preconcentration devices has enabled the loading of greater amounts of material onto CE capillaries.<sup>5</sup>

## 8.2 ONLINE CE–ESI/MS SYSTEM REQUIREMENTS

An online CE–ESI/MS system is made up of a CE instrument, a mass spectrometer, an interface that will allow the transfer of analytes from the CE column outlet to the MS source, a closed CE electrical circuit for electrophoretic separation of the analyte mixture, and a closed electrical circuit for the generation of continuous, stable and uniform fine spray stream that affords sensitive MS detection. The challenge in coupling CE directly online with ESI-MS is achieving electrical continuity that allows uninterrupted operation of both systems, without affecting the quality of the CE separation or the ESI efficiency (which is directly related to the detection sensitivity). The coupling of CE to MS has been a challenging problem because an ideal interface is one that is constructed in such a way that the CE separation column and the spray tip form a single continuous unit in order to eliminate any dead volume that may lead to diffusion and affect the quality of separation. In addition, the design should preserve the electric circuits of both the CE system and the spray tip. Also, it would be advantageous if no external solvent is added to the system (sheath liquid) that dilutes the analyte concentration and affects the detection sensitivity.

The most popular choice for coupling CE with ESI/MS is the coaxial sheath flow interface. Coaxial sheath flow was introduced as the first CE-MS interface in 1987.<sup>6</sup> This coupling device uses three concentric capillaries in which the CE capillary (used for the actual analyte separation) is innermost and protrudes into the ESI source region. A stainless steel capillary (the ESI needle) is placed around the CE capillary and delivers a sheath liquid. The sheath liquid is required to complete the electrical circuit necessary for both CE separation and ESI. The sheath liquid comes into contact with both the CE buffer and ESI needle. The sheath liquid is usually a mixture of a volatile acid,  $\text{H}_2\text{O}$ , and an organic modifier, such as methanol ( $\text{CH}_3\text{OH}$ ) or acetonitrile (ACN). The sheath liquid may also contain an electrolyte since it also acts as the outlet buffer for the CE separation process. The electrolyte concentration must be carefully selected, as both separation and ionization efficiency must be considered. A high electrolyte concentration will provide good separation efficiency but will negatively impact ESI efficiency. The sheath liquid is mixed with the CE buffer at the very tip of the capillary within the ESI source region. It is critical to keep the mixing volume as small as possible to maximize ES stability and sensitivity. Therefore, the distance that the CE capillary extends past the sheath liquid capillary is very important. While the correct distance may need to be determined through experimentation, it is generally in the range of 0.1–0.5 mm. Both of these capillaries are placed within a third concentric stainless steel tube that delivers a gas flow, which is necessary for effective desorption of the electrosprayed ions as well as providing the necessary cooling of the CE capillary.

## 8.3 SHEATH VERSUS SHEATHLESS INTERFACES

There are many advantages of sheathless interfaces compared to those that require a sheath flow.<sup>7,8</sup> The main difference between sheath and sheathless interface designs is that sheathless interface does not require the external flow of a coaxial sheath liquid to establish electrical contact with the CE

effluent to facilitate the ESI process. Introduction of a sheath liquid dilutes the analytes and results in poorer detection limits. Indeed, a comparable sheathless interface can give an order of magnitude greater sensitivity than its counterpart that requires a sheath liquid. One of the major weaknesses of CE is that although the mass detection levels are quite high the amount of sample that may be injected onto the capillary is low. Dilution of the analytes by sheath liquid only serves to compound this deficiency. The construction of an interface with sheath flow is also more complicated, requiring coupling of different capillaries on connectors. In principle, the sheathless interface is the best design for coupling CE online with ESI-MS, since the flow rates required for each technique are compatible and no dilution of the analytes occurs during separation and elution, thereby maximizing the signal recorded by the mass spectrometer.

## 8.4 SHEATHLESS DESIGN STRATEGIES

Several different types of sheathless designs have been introduced that satisfy the requirement of closing the CE separation capillary circuit while simultaneously providing an electrical potential to the spray tip for ESI. These include the use of a single capillary, two capillaries, and three capillaries.<sup>5</sup>

Many methods for interfacing CE with MS using a single-capillary format whereby uninterrupted electrical contact required for CE and ESI was established by different means have been introduced. An example of such is shown in Figure 8.1a. The first single capillary-sheathless interface was introduced by Wahl et al.<sup>9</sup> who coated the capillary outlet with a conductive metal (i.e., silver deposition) at the cathode end. This coating served to define the CE field strength along the capillary column and provide the necessary ESI potential. One of the best features of this design is that it did not interfere with the CE separation process. Since this work, a number of studies reported using similar strategies for coating the capillary's cathodic end with metal, polymer, or carbon.<sup>10,11</sup> The biggest drawback to these coating methods was their lack of mechanical stability. The coatings would slowly disintegrate and each CE capillary was only useful for a few hours to days. The stability of the metal coating by precoating the capillary with materials such as silanes, silicon oxide, or chromium improved the length of the capillary's lifetime.

**FIGURE 8.1** (a) Schematic diagram of a single capillary design for CE-MS. (From Cao, P. and Moini, M., *J. Am. Soc. Mass Spectrom.*, 8, 561, 1997.) In this design, a small hole is drilled into the capillary through which a platinum wire is inserted. (b) Schematic of a two capillary design for CE-MS in which two pieces of fused-silica capillaries are connected via a section of dialysis tubing. (From Severs, J. C. and Smith, R. D., *Anal. Chem.*, 69, 2154, 1997.) This junction is immersed into the CE buffer and into which a copper electrode is inserted.

Other groups have taken different approaches that require directly inserting a metal wire into the CE capillary. For example, Cao and Moini<sup>10</sup> constructed a sheathless interface by inserting a platinum wire (25  $\mu\text{m}$  diameter by 0.2–0.3 cm in length), through a pinhole that was drilled into a 150- $\mu\text{m}$  o.d. fused-silica capillary. The pinhole was positioned approximately 2 cm from the outlet of the capillary. Epoxy was used to maintain the position of the wire as well as seal the capillary. The platinum wire electrode serves as both the low voltage electrode of the CE electric circuit and as a connection for the ESI voltage. This design proved to be stable over the maximum time studied (i.e., 50 min), however, such capillaries are difficult to construct (requiring a dental drill to create a small opening) and the presence of the wire may generate turbulent flow that affects the resolution of the CE separation. The laboratories of Wahl and Smith<sup>12</sup> developed a similar “micro-hole” method, however, in this case an interface whereby the electrical connection was made was constructed by drilling a small hole 2 cm from the end of the separation capillary. The micro-hole was then sealed with conductive gold epoxy. While this method allows for the necessary electrical conductance, the design is cumbersome and the proper capillaries are not easy to construct.

Our laboratory developed a simple sheathless interface for CE-MS in which the separation column, an electrical porous junction, and the spray tip are integrated within a single piece of a fused-silica capillary, as illustrated in Figure 8.2.<sup>13</sup> The electrical potential to induce ESI is introduced through a porous junction across a 3–4 mm length of fused silica. A 3–4 mm section of the polyimide coating was removed from the capillary approximately 5 cm from end of the spray tip. Electrical conductance between the solute within the capillary and the anode buffer was achieved by etching the exposed section using hydrofluoric acid (HF). This etching reduced the outside diameter of the capillary at this point without affecting the inner diameter. The HF etching requires approximately 6 h and reduces the capillary wall to about 15–20  $\mu\text{m}$ . Since the porous junction created by HF etching is fragile, the capillary must be secured inside the reservoir protecting it from breaking. The reservoir contains the buffer for closing the CE circuit and providing the voltage necessary for ESI. This design proved to be quite rugged as this group reported continuous operation of the same column for over a 2-week period with no evidence of deterioration in separation or ESI performance.

**FIGURE 8.2** Schematic diagram of a CE-MS design that incorporates etching of the capillary wall to enable electrical conductance and a solid-phase extraction disk for pre-concentration of the sample prior to CE-MS analysis. (From Janini, G. M., et al., *Anal. Chem.*, 76, 1615, 2003. With permission.)

The same group followed up on this initial design by adding the capability for on-column sample enrichment into the sheathless interface.<sup>4</sup> A small solid-phase extraction cartridge, made of RP material, was attached to the CE capillary near the point of injection. Optimization of the proper capillary diameters showed that they could achieve a mass limit of detection of 500 amol for CE-MS/MS analysis of a standard peptide using a 20- $\mu\text{m}$  i.d. capillary. This design brings to reality a true zero dead-volume sheathless CE—MS interface with the ability to preconcentrate the sample within the same capillary.

Another strategy for coupling CE with MS is a sheathless interface in which two pieces of capillary are used. In this method the CE separation capillary is connected to a short spray tip (which functions as the ESI needle) via a sleeve. The sleeve can be prepared from microdialysis tubing, stainless steel tubing, or a micro-tee junction. Severs and Smith<sup>14</sup> developed a separation capillary that is connected to a 2-cm-long ESI emitter capillary via a 1.5 cm length of dialysis tubing. Epoxy is then applied to maintain the connection between the tubing and capillary pieces, as illustrated in Figure 8.1b. The manufactured capillary is then inserted through a 250  $\mu\text{L}$  Eppendorf pipet tip containing an electrolyte identical to that employed for the CE separation. Connection of the pipet tip to an *x-y-z* stage allows the position of the spray tip relative to the MS orifice for maximum detection sensitivity. A copper wire is inserted in the electrolyte reservoir and connected to a high-voltage power supply to provide the necessary voltage for the CE separation and ESI.

The group of Tong et al.<sup>15</sup> developed a sheathless liquid–metal junction interface for CE-MS by removing approximately 2–3 mm length of polyimide coating from a coated capillary (5–10 cm long), and exposing the fused-silica tip to 48–51% HF. This resulted in etching of the exposed fused silica and the polyimide coating was further burned to expose approximately 3 mm of the tapered tip. The butt ends of the tip and CE capillary were then carefully polished flat. A liquid–metal junction was then created with a polyether ether ketone (PEEK) micro-tee. The side channel of the tee was enlarged to accommodate a 2.5 cm length of 0.06 cm diameter gold wire. The electrospray tip and the separation capillary were carefully butted together along the channel of the micro-tee and connected via microfittings. The gold wire was inserted into the side channel of the micro-tee to supply the electrical connection to supply the required voltage for ESI.

Other researchers have also reported on the design of three-piece capillary/spray tips in which the electrical contact is established through a porous glass joint that is connected to the CE capillary using polytetrafluoroethylene (PTFE) sleeves on one side and the spray tip on the other. A different three-piece designed based on the one previously described, used a porous glass joint. In this design, the polyimide layer was burned off a 2–3 mm piece of a 3-cm-long fused-silica capillary.<sup>16</sup> This exposed portion was etched with HF to reduce the thickness of the capillary wall to  $<20 \mu\text{m}$ . This porous glass joint was inserted into a piece of PTFE, in which a small notch was cut through its center. The diameter of this notch matched that of the outer diameter of the capillary. The porous glass joint was coupled to the CE column with the aid of a PTFE sleeve, and the ESI emitter was connected to the other side of the porous glass joint. To conduct online CE separations the porous fused silica was immersed in 1% acetic acid and voltage was applied to the acidic solution to drive both the CE separation and ESI.

## 8.5 PROTEOMIC ANALYSIS USING CE-MS

Currently there is no greater focus within proteomics than the discovery of biomarkers of various disease states. The number of proteomic techniques and strategies that are being utilized in an attempt to find novel biomarkers is a veritable “who’s who” list of available methods. The number of different methods being attempted is related to a number of different factors including the enormity of the experimental question, complexity of human biofluids, and the lack of success achieved using one single design. While the primary separation technologies that have been combined with MS for the discovery of biomarkers are two-dimensional polyacrylamide gel electrophoresis (2D-PAGE)

two-dimensional polyacrylamide gel electrophoresis, and RPLC, CE has also played a role in this research area. In a study attempting to find indicators of graft vs. host disease (GvHD) in patients that had received allogeneic hematopoietic stem cell transplants (HSCT), investigators examined the CE-MS profiles of urine obtained from 40 HSCT patients and 5 patients with sepsis.<sup>17</sup> They were able to find 16 differentially urine-excreted peptides that indicated the presence of GvHD. In a cross validation study using the pattern generated by these markers, they correctly diagnose GvHD with a sensitivity and specificity of 82% and 100%, respectively.

While the above study utilized urine, probably no biofluid has attracted the attention of the proteomic biomarker discovery field as serum and plasma. Although the analysis of serum by RPLC-MS has almost become routine, such is not the case for CE-MS. In a proof of principle study to show the efficacy of using CE-MS to find differentially abundant proteins in serum, the group of Sassi et al.<sup>18</sup> analyzed groups of sera that were spiked with different concentrations of known standard peptides. The groups of sera were analyzed by CE-MS and the standard peptides were successfully identified as being differentially abundant with a success rate of 95%.

These first promising data using CE-MS to detect biomarkers in serum/plasma was a prospective, randomized, open-label trial to assess the effect of vitamin C deficiency on oxidative stress and analyze inflammatory markers in hemodialysis patients.<sup>19</sup> The CE-MS analysis of plasma obtained from dialysis patients and those with normal renal functions showed more than 30 polypeptides that were significantly different in abundance between the two groups. This study showed that oral vitamin C supplementation did indeed have an effect on the plasma proteome of dialysis patients.

Another important biofluid that has been utilized in CE-MS biomarker discovery studies is cerebrospinal fluid (CSF). Because of the blood–brain barrier, blood has limited diagnostic potential for nervous system related diseases, such as Alzheimer’s disease (AD). CSF is a clear, colorless liquid that provides mechanical protection for the brain. The proteomic content of CSF is similar to that of blood, in that 70% of CSF’s protein content consists of isoforms of albumin, transferrin, and immunoglobulins. A study conducted by Wetterhall et al.<sup>20</sup> described a method for analyzing CSF, by first digesting the proteome into tryptic peptides and then analyzing these using CE coupled directly online with FT-ICR MS. In the first step, CSF was analyzed by CE-MS to establish the ability to identify peptides/proteins within this biofluid. Using the mass measurement accuracy capabilities of FTICR-MS, 30 proteins were identified with mass measurement errors of less than 5 parts per million (ppm). In an alternative approach, Wittke et al.<sup>21</sup> obviated the tryptic digestion step, however, they depleted the high abundance proteins from CSF prior to its analysis by CE-MS. They were able to detect 450 different proteins in the molecular mass range of 800–15,000 Da. They proceeded to use this experimental setup to analyze protein patterns within CSF from 4 healthy donors, 8 patients with AD and 7 with schizophrenia. They were able to find peaks that were capable of differentiating AD and schizophrenic patients, but were unable to differentiate these two groups from the controls. While the number of samples analyzed in this study was low, it did show the potential of direct CE-MS as a diagnostic tool for brain-related disorders.

Current literature suggests CE-MS is potentially a powerful tool for the detection of biomarkers in a variety of biofluids. It has the ability to reliably detect peptides within biological samples at a rate far greater than conventional RPLC-MS. There are, however, several challenges that remain. While the ability of CE-MS to provide information on hundreds of peptides in a single sample has been established, and the diagnostic ability of many of patterns of these peptides has been shown, the link to potential physiological function of these markers is still lacking. This deficiency is primarily due to the inability to routinely identify the sequence and therefore the identity of these peptide peaks. At this point, the diagnostic features are simply; just features and not known proteins. To identify these putative biomarkers is extremely difficult when one considers that they must be isolated from an extremely complex mixture (e.g., serum, plasma, etc.) and significant sequencing is required to establish their identity. While CE has been established with MS/MS capable instrumentation, the broad identification of proteins in complex biofluids is still not at the level of RPLC-MS/MS.

## 9.1 INTRODUCTION

The small sample volumes used in capillary electrophoresis (CE) make the technique suitable for myriad small-scale biochemical and materials science applications. These small volumes also require detection methods that exhibit high sensitivity and suitable selectivity. Such rigorous demands on detector performance can have important consequences with respect to other aspects of the CE system. For example, it is well known that higher efficiency and faster separations are achieved using smaller inner diameter (ID) capillaries. And yet 50- $\mu\text{m}$  ID capillaries are more common than 5- $\mu\text{m}$  ID capillaries in systems using light-based detection, primarily because the longer optical path length of the larger capillary aids in detection. In this way, the performance of the detection system can dictate the overall performance of a given CE system. Thus, knowledge of the various detection modes available, as well as their respective figures of merit, aids in designing CE-based methods of analysis (see Table 9.1).<sup>1</sup>

In addition to a working knowledge of the various detection schemes available for CE, the sensitivity, selectivity, and detectability requirements of the particular analyte(s) and application should be considered when choosing a suitable detector. In a setting where the CE system will be devoted to a single application, the detector's parameters can be tuned to optimize the detection of the analyte(s) of interest for that application. If, however, the instrument is to be used for a wide variety of applications, then versatility is of primary importance, which may come at the expense of optimal performance for any individual analyte. If none of the available detection methods allows for adequate detection of the analyte(s) of interest, it may be possible to chemically modify the analyte by derivatization in order to render it detectable.<sup>2</sup>

This chapter describes detection methods for CE that involve probing a sample with electromagnetic radiation. While the discussion will emphasize the two most common forms of light-based

**TABLE 9.1**  
**Light-Based Detection Modes for CE, and Corresponding Limits of Detection**

Detection Principle	Minimum Detectable Concentration (M)	Minimum Detectable Quantity (mol)	Representative Detectable Molecules
Direct absorbance	$10^{-5}$ to $10^{-7}$	$10^{-13}$ to $10^{-16}$	Most
Indirect absorbance	$10^{-4}$ to $10^{-6}$	$10^{-12}$ to $10^{-15}$	Small ions, amino acids, fatty acids, polymers
Laser-induced fluorescence	$10^{-9}$ to $10^{-12}$	$10^{-18}$ to $10^{-21}$	Dyes, amino acids, peptides, proteins, carbohydrates, nucleotides, vitamins, pharmaceuticals
Indirect fluorescence	$10^{-6}$ to $10^{-8}$	$10^{-14}$ to $10^{-16}$	Small ions, pollutants, amino acids, peptides
Chemiluminescence	$10^{-7}$ to $10^{-9}$	$10^{-14}$ to $10^{-16}$	Dyes, amino acids, peptides, proteins, nucleotides
Thermo-optical absorbance	$10^{-5}$ to $10^{-7}$	$10^{-15}$ to $10^{-18}$	Dyes, amino acids, proteins, nucleotides, vitamins
Radioactivity	$10^{-6}$ to $10^{-10}$	$10^{-14}$ to $10^{-18}$	Small ions, amino acids, peptides, proteins, nucleotides, pharmaceuticals
Raman	$10^{-3}$ to $10^{-5}$	$10^{-12}$ to $10^{-15}$	Dyes, small ions, amino acids, nucleotides

Source: Adapted from Khaledi, M. G., in *Chemical Analysis: A Series of Monographs on Analytical Chemistry and Its Applications*, 1st ed., Winefordner, J. D. (ed.), Wiley-Interscience, Raleigh, 1998, pp. 308–9.

detection—ultraviolet-visible (UV-Vis) absorbance and fluorescence detection—other less common methods, such as thermo-optical detection, are discussed as well. Prior to discussion of the individual detection schemes, the basic considerations and requirements of optical detectors for CE are presented.

There have been a number of important developments in light-based detection for CE since the previous edition of this work was published. For example, multichannel detection has become more common for absorbance as well as fluorescence, and Fourier transform infrared (FTIR) and nuclear magnetic resonance spectroscopies are now viable detection modes. Thus, while the purpose of this chapter is to describe the instrumentation and performance of more common optical detectors, newer methods are presented throughout.

Finally, it is worth noting that limits of detection of a system mentioned throughout the chapter depend on the separation performance, preconcentration steps, and mode of operation (i.e., zone electrophoresis, electrochromatography, isotachopheresis, etc.) of the separation system. Thus, one can often optimize a CE method to improve the overall system performance, given the sample stacking and other approaches that may be appropriate for a particular sample type or application.<sup>3–6</sup>

## 9.2 GENERAL CONSIDERATIONS FOR DETECTORS

### 9.2.1 THE DETECTOR CELL

The capillaries typically used in CE are made up of fused silica, with IDs of 10–100  $\mu\text{m}$ , outer diameters (ODs) of 100–375  $\mu\text{m}$ , and coated with a 10–30  $\mu\text{m}$  protective layer of polyimide (PI). There are several locations relative to this capillary where detection can take place. These detection locations include on-column, end-column, whole-column, and post-column detection.

For on-column detection, a portion of the protective PI coating is removed, either by acid application (hot  $\text{HNO}_3$ ) or by burning. This results in a cylindrical length of bare fused silica, which is used as the detection window. The window is generally placed as close as practicable to the outlet of the capillary in order to maximize the fraction of the capillary used for the separation.

End-column detection is done by coupling the outlet of the capillary to an external detection cell. The properties of this detection cell (path length, material, etc.) can be tailored to allow for high sensitivity and low analyte limits of detection. The careful selection of coupling and transfer fluidics, such as zero dead-volume unions, ensures that the high resolution afforded by CE is maintained within the end-column detector.

In the post-column detection configuration, detection is carried out at a location remote to the outlet of the capillary. For example, in radionuclide detection, the capillary eluent is spotted onto a membrane or collected as fractions, and subsequently exposed to a scintillator for detection.<sup>7,8</sup> Post-column detection allows for the separation and detection to be independently optimized. In the case of radionuclide detection, the detector integration time can be maximized without a corresponding loss in resolution (see Section 9.2.2).

Whole-column imaging can be used to view the entire separation process as it occurs. As an example, this type of detection is often used in capillary isoelectric focusing in order to determine when substances have become sufficiently concentrated for collection and further characterization. To do this, the capillary can be held stationary while mobile scanning systems scan the length of the capillary,<sup>9</sup> or detectors with high spatial resolution such as charge-coupled devices (CCDs) can image the entire capillary at once.<sup>10</sup> These imaging detectors typically measure UV-Vis absorbance or fluorescence.

### 9.2.2 RESOLUTION AND RESPONSE TIME

In general, the signal-to-noise ratio (SNR) of a detected peak increases with longer detector integration times. With the exception of post-column detectors, the integration time is limited by the velocity

of the migrating analyte bands. Typical flow rates are on the order of 10–100 nL/min, resulting in analyte bands that migrate through the detector cell on the order of a second. In peak profile analysis, six or more data points are desired over the width of the peak band in order to describe it adequately. This means that the length of the detection cell should be restricted to one-sixth of the width of the narrowest band; common cell lengths are 100–200  $\mu\text{m}$ . There are several strategies that can be used to increase detector response within these general spatial and temporal restrictions, including reducing the operating voltage of the separation, as well as transient stopped- or reduced-flow detection.<sup>11</sup>

### 9.2.3 MAXIMIZING SEPARATION EFFICIENCY

The magnitude of detector response for a given amount of analyte is maximized when the analyte is confined within narrow bands. As described in Chapter 1, there are several important considerations for maintaining high efficiency in CE. These include voltage, temperature, and sample introduction. In general, the use of the highest practicable voltages maximizes efficiency. Also, since temperature gradients decrease efficiency, narrow bore capillaries allow for more effective heat dissipation. Peak dispersion can be minimized by ensuring that the concentration of any given analyte is more than two orders of magnitude lower than the concentration of the background electrolyte.<sup>12</sup>

### 9.2.4 FIGURES OF MERIT

Selection of an appropriate detection method for CE is facilitated by a comparison of each method's respective figures of merit. The relevant figures of merit include the limit of detection (LOD), sensitivity, and linear dynamic range.

The LOD is a measure of the smallest amount of analyte that can be detected. Typically, LODs are defined as the concentration or absolute amount (mass or moles) of analyte that yields a signal that is equal to three times the standard deviation of the baseline signal.

Sensitivity describes the ability of a detector to differentiate between different amounts of analyte. When a plot of signal versus amount of analyte generally yields a straight line, the term "sensitivity" refers to the slope of this line.

It is observed that the relationship between signal and concentration is linear over a finite range of concentrations. At higher concentrations, various phenomena (scattering, nonlinear optical processes, "inner filter" effect, etc.) lead to deviations from linearity. The range of concentrations where a linear relationship between signal and concentration holds is known as the linear dynamic range of the detector.

As mentioned in Section 9.1, these figures of merit depend not only on the detection system, but also on other factors as well, including the nature of the analyte, the composition of the separation medium, and the mode of operation of the separation system.

### 9.2.5 QUALITATIVE VERSUS QUANTITATIVE INFORMATION

The linear relationship between analyte concentration and detector response can be exploited to gain quantitative information about an "unknown" sample. To do this, solutions of known concentrations are used to generate a standard plot of intensity versus concentration, which is then used to determine the concentration of the unknown.

In addition to this quantitative information, it is also possible to obtain qualitative information about an analyte, such as the presence or absence of specific functional groups and their relative locations or orientations. A subset of the available optical detection methods are capable of providing this information, such as multiwavelength UV-Vis absorbance or fluorescence, nuclear magnetic resonance, and Raman spectroscopies; these techniques will be discussed in more detail in this chapter.

## 9.2.6 INDIRECT DETECTION

Detection methods are typically chosen based on the characteristics of the analyte of interest, for example, absorbance detectors for highly absorbing species, or fluorescence detectors for intrinsic fluorophores with sufficient quantum yields. There are, however, cases where the analyte lacks the properties that enable it to be analyzed by any of the conventional detection methods. If this is the case, and suitable derivatization chemistry is unavailable, it may be possible to detect the analyte indirectly.<sup>13–17</sup> To do this, a signal-generating substance is incorporated into the separation medium, and the presence of the analyte is detected as a decrease in the measured signal. The observed decrease is due to the displacement of the signal-generating species by the analyte; charge-density conservation and solubility changes are mechanisms by which this displacement can occur. Indirect detection has been used in conjunction with absorbance, electrochemical, and fluorescence detection systems.

## 9.3 ABSORBANCE DETECTION

### 9.3.1 THEORY

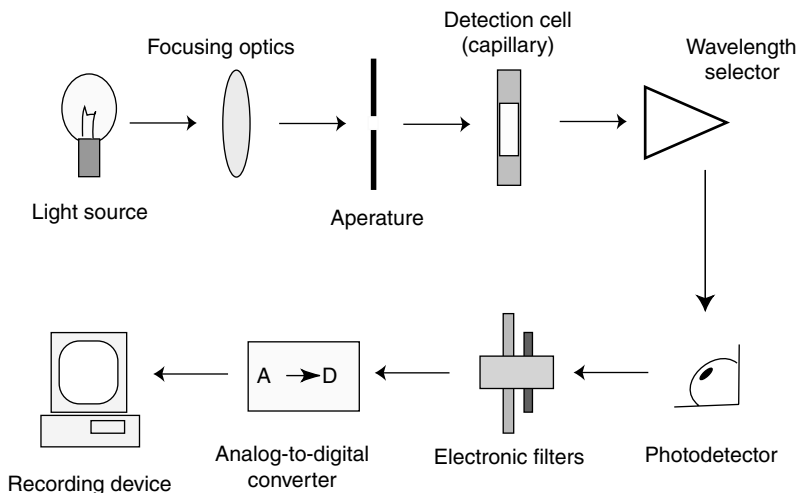

The term absorbance refers to a phenomenon whereby a molecule is promoted to an excited state by a photon. Absorbance is normally determined by measuring the transmission of light through a sample. Transmittance,  $T$ , is the ratio of intensity of a light beam before and after it passes through a solution, that is,  $T \equiv I/I_0$ , where  $I$  is the intensity after passing through the sample and  $I_0$  is the initial intensity. Absorbance,  $A$ , is related to the transmission by  $A = -\log(T)$ .

A solution's absorbance can be related to its constituent molecular components by the Beer–Lambert law:  $A = \varepsilon lc$ , where  $\varepsilon$  is the molar absorptivity (in units of inverse length per M),  $l$  is the path length through which the light passes, and  $c$  is the concentration of the absorbing species. The molar absorptivity of a substance is dependent on various parameters, including the solution pH, solvent polarity, and the wavelength of light. It can be seen from the Beer–Lambert law that, for a fixed path length and molar absorptivity, the absorbance of a solution is linearly dependent on the concentration of the absorbing species in solution. This relationship allows for the quantification of an absorbing species, if the measured value is within the dynamic range of the instrument (see Section 9.2.4).

There are several considerations with respect to measuring absorbance in CE. First, the decrease in measured light intensity after passing through a solution is due to both stray light/scattering processes and absorbance. Thus, it is important that the stray light/scattering be accounted for when relating absorbance to analyte concentration. This is typically accomplished by making appropriate “blank” measurements of a solution containing all of the pertinent buffers and solvents, but without the analyte of interest. Second, the magnitude of the measured signal scales with the path length. In CE, capillary IDs are kept small in order to minimize the deleterious effects of temperature gradients on resolution. This trade-off between detector performance and separation resolution is characteristic of light-based detection methods for CE and underscores the importance of a working knowledge of both the principles of CE and of the various methods of detection.

### 9.3.2 INSTRUMENTATION

Figure 9.1 shows the layout of a typical absorbance detector for CE. The light generated by the source is collected and focused into a beam by the focusing optics. The spatial profile of this beam can be defined by an aperture, which also serves to reduce background light. The beam passes through the detection cell, where the analyte absorbs a portion of the incident light. The emerging beam is then spectrally filtered by a prism or spectrograph to select the desired wavelength(s) and detected by an appropriate signal transducer, such as a photodiode array or photomultiplier tube. The resulting

**FIGURE 9.1** Flow-diagram of an absorbance detection system for CE.

signal is either displayed using an analogue device or it is converted to a digital signal and sent to a PC for analysis. The following subsections describe some of these essential components in greater detail.

### 9.3.2.1 Light Source

The primary considerations with respect to light sources for absorbance-based detectors are output stability and spectral characteristics. Because analyte quantification is dependent on the measured intensity of light after it emerges from the detection cell, it is important that the amount of light that enters the cell does not fluctuate in time. Thus, light sources that produce a stable output of light are integral to the satisfactory performance of an absorbance-based detector. In addition to output stability, the spectral characteristics of the output are of importance. Not only must the wavelengths provided match the absorbance bands of the analyte(s) of interest, but also the spectral profile must be suitable as well. Some detectors monitor a single wavelength, so that narrow emission lines are preferred, while wavelength-resolved instruments require a source with a broad spectral output.

Light sources that are suitable for use in absorbance-based detectors include atomic emission lamps, deuterium arc lamps, lasers, and light-emitting diodes (LEDs). In atomic emission lamps, photons are generated when electronically excited atoms relax to their ground states. Atomic emission lamps are available that use transition metals such as mercury, cadmium, and zinc, which generate strong emission lines at 254, 229, and 214 nm, respectively. These line source lamps are a reasonable choice for systems that require only a single (or relatively few) output wavelength(s). In addition, there are a number of blackbody lamps available that emit broadband radiation, such as a tungsten filament, which produces a range of wavelengths from 350 to 2500 nm. Another broadband source is the deuterium arc lamp. In contrast to atomic emission lamps, the UV light provided by the deuterium arc lamp is due to the radiant decay of molecular deuterium. The lamp produces a relatively stable output in the range of 160–400 nm, and is the most commonly used light source for absorbance detectors.

In addition to the various lamps, lasers can be used as light sources for absorbance detectors. The highly directional, spatially coherent emission from lasers can be efficiently collected and focused to a small spot within a capillary. These characteristics make lasers a viable choice for sources in absorbance detection systems (especially for smaller-diameter capillaries), although their use is less

common than the various incoherent lamps. More recently, LEDs have been used as light sources for optical detectors for CE, including absorbance detectors.<sup>18–20</sup> The low cost and compact size of LEDs make them well suited for field-deployable sensors and lab-on-a-chip applications.

As mentioned above, output stability is important. All sources exhibit some degree of output fluctuation, and so many instruments include a means by which these fluctuations can be monitored. The most common approach is to use a beam-splitter or displacer to generate a reference beam that can be monitored by an auxiliary detector.<sup>21</sup> The reference channel can serve to minimize the effects of instability on detection limits, although various factors (including shot noise) place restrictions on this ability.

### 9.3.2.2 Focusing Optics

The performance of an absorbance detector is dependent on the ability to effectively couple the excitation source to the detection cell. This involves collecting and focusing as much source light as practical into the detection zone, as well as minimizing the stray source light that reaches the detector without interacting with the analyte.<sup>22</sup>

Various lenses and lens arrangements are available to collect and focus a large fraction of the incident source light. Commonly used lenses include the plano-convex singlet, as well as the quartz ball lens. The specific lens arrangement that best suits a given detector is dependent on the source used. As an alternative to the use of lenses, fiber optics can be effective in coupling the source light to the detection cell (as well as coupling the detection zone to the detector).<sup>23–25</sup> The use of fiber optics allows for flexibility in the placement of the source and detector and enables the illumination of multiple capillaries or multiple locations on the same capillary, although fiber optics are more difficult to interface for the smallest diameter capillaries.

The amount of stray light that reaches the detector can be minimized by the appropriate use of apertures placed before/after the detection cell.<sup>22</sup> A pre-cell aperture can be used to block extraneous light and allow only a well-defined cross section to pass through the capillary. For applications where high spatial resolution is critical, the lateral dimension of this area (along the capillary) can be decreased. In addition, a second aperture, placed after the detection cell but in front of the detector, can be used to prevent light that is scattered off the capillary walls from reaching the detector.

### 9.3.2.3 The Detection Cell

The most common illumination geometry used in absorbance detection cells is the transcolumn configuration (Figure 9.2a), in which the light passes through the detection cell along a path that is perpendicular to the length of the capillary. For on-column detection, this sets the maximum optical path length at the ID of the capillary. As mentioned previously, the performance of a light-based detector is directly proportional to this path length. Thus, it is not surprising that numerous approaches to extending the effective path length of optical detectors have been reported in the literature.

Axial-capillary illumination (Figure 9.2b) is an approach to increasing optical path length that involves focusing the source light into the capillary bore and directing it along the capillary axis.<sup>26</sup> In this set-up, the tightly focused lamp light or laser beam is directed into the capillary inlet, and the light exiting the outlet end of the capillary is detected by an appropriate signal transducer. Axial illumination relies on partial internal reflection within the capillary, which, in turn, requires that the refractive index of the separation buffer be greater than that of the capillary walls. The light exiting the capillary contains both the wall-propagated and internally propagated light rays, and so spatial filtering or increasing the refractive index of the separation medium is used to selectively measure the internally propagated rays.

A Z-cell can be constructed by heating the capillary in several places, and bending it into the shape of a Z, as shown in Figure 9.2c. The source light enters the cell at the first of the two bends, propagates axially through the capillary, and exits the cell at the other bend. The use of a Z-shaped cell

**FIGURE 9.2** Different detector cell types used to increase the path length for optical detection. (a) Trans-capillary illumination, (b) axial-capillary illumination, (c) Z-cell capillary, (d) bubble cell capillary, and (e) rectangular capillary trans-illumination.

has been reported to yield up to a 10-fold improvement in detection limits relative to conventional transcolumn illumination.<sup>22</sup>

The bubble cell increases the optical path length by expanding the ID of a small length of capillary that makes up the detection zone relative to the ID of the rest of the capillary, as shown in Figure 9.2d. Path length increases of up to fivefold have been reported using the bubble cell, for example, a 125- $\mu\text{m}$  ID bubble cell formed on a 25- $\mu\text{m}$  ID capillary.<sup>27</sup>

While the most common cross section for fused-silica capillaries is circular, square cross section capillaries have been employed in CE (Figure 9.2e). Square capillaries minimize the scattering caused by curved capillary surfaces, and increase the probed volume relative to a circular capillary of the same width. Originally, these rectangular capillaries were made up of borosilicate glass, which is opaque in the UV.<sup>28</sup> More recently, square fused-silica capillaries have become commercially available and are a viable option for increasing the path length in UV absorbance detectors.<sup>29,30</sup>

### 9.3.3 WAVELENGTH SELECTION

Measuring absorbance at 200–325 nm is often satisfactory for general-use absorbance detectors, as most analytes (including many biomolecules) have some absorbance at these wavelengths.<sup>31</sup> There are, however, cases where the analyte(s) of interest do not absorb appreciably in this range.<sup>32</sup> Thus, it may be beneficial to determine a more suitable wavelength for a particular analyte, for example, when dealing with low-abundance analytes or buffers that strongly absorb at these wavelengths. The optimum wavelength is the one that gives the maximum SNR for the analyte. Often, this wavelength is the one where the analyte exhibits maximum absorbance ( $\lambda_{\text{max}}$ ). A spectrophotometer can be used to generate background-subtracted absorbance spectra, which can in turn be used to identify  $\lambda_{\text{max}}$ .

As an alternative to selecting and monitoring absorbance at a single wavelength, it is possible to use a multiwavelength absorbance detection system. These systems involve either rapid scanning gratings<sup>33</sup> used in conjunction with a single channel detector or, more commonly, a fixed spectrograph used with a photodiode array.<sup>34–36</sup> Indeed, a majority of the available commercial CE instruments use wavelength-resolved diode-array absorbance detection. There are a number of reasons for the popularity of these instruments, which have been discussed in detail elsewhere.<sup>37,38</sup> With these instruments, it is not necessary to select an appropriate wavelength for detection and quantification before analysis; the optimal wavelength for each analyte can be determined and used for subsequent data analysis after running the samples of interest. The spectral information provided by these detectors can also be useful for analyte identification or characterization, by comparing the spectral features of a peak of interest to those of standard solutions. Not only is this beneficial for analyzing

“unknown” samples, but also it facilitates method development, since differences in separation conditions can alter migration times and even elution order. Moreover, completely unresolved peaks can be identified as such, because the observed spectral characteristics will differ from those of any pure analyte (i.e., peak purity confirmation).<sup>39</sup> For partially resolved components, the multichannel data can be used in conjunction with various computational approaches to enable quantification of the constituent components, without having to change separation conditions and reanalyze samples.<sup>39,40</sup>

## 9.4 FLUORESCENCE DETECTION

### 9.4.1 THEORY

Fluorescence is a process in which a photon is emitted by an electronically excited molecule as it relaxes to its ground electronic state. Each of the relevant electronic states contains numerous vibrational sublevels, and so fluorescence excitation and emission spectra are relatively broad. The manifold of various vibronic states of a fluorophore results in unique and complex emission spectra, which may enable differentiation between two closely related molecules. In addition, the observed emission spectra are dependent on the local chemical environment of the fluorophore, and can differ depending on factors such as solvent polarity and solution pH. Indeed, this exquisite dependence of emission spectra on surroundings can be used to deduce the relative location of tryptophan residues within a protein. An excellent overview of the qualitative aspects of fluorescence can be found in Lacowicz’s text on the subject.<sup>41</sup>

The observed magnitude of fluorescence emission is given by  $I_f = cdkI_lQ_f$ , where  $I_f$  is the intensity of fluorescence (photons  $\text{cm}^{-2} \text{s}^{-1}$ ),  $c$  is the concentration of the fluorophore (M),  $d$  is the path length of excitation (cm),  $k$  is the base-ten logarithm of the molar absorptivity ( $\epsilon$ , see Section 9.3),  $I_l$  is the intensity of the laser, and  $Q_f$  is the fluorescence quantum yield (unitless).<sup>42</sup> The dependence of the fluorescence signal on the intensity of the excitation source suggests that high-power light sources can be used. In practice, however, the optimal laser power is also a function of other factors such as analyte photostability, and so should be determined empirically.<sup>43,44</sup>

Fluorescence detection affords the lowest reported detection limits of the various detector types for CE (Table 9.1). The high performance of fluorescence-based detection systems results from a number of characteristics. First, a single fluorophore molecule can cycle repeatedly between excitation and emission, thus generating up to thousands of photons before exiting the detection zone or undergoing photodestruction. Second, the observed emission spectrum is shifted relative to the excitation wavelength(s), so that filters can be used to minimize the amount of scattered excitation radiation that reaches the detector. As a result, single molecule detection is possible using LIF, and LIF-based detection systems for CE are capable of providing LODs in the yoctomole range.<sup>45,46</sup>

### 9.4.2 INSTRUMENTATION

The basic fluorescence detection system in CE consists of several components, including an excitation source, a detection cell, collection optics, and a detector. Within these requirements, there are a wide variety of possible optical configurations, and vastly differing performance specifications between systems. The design constraints and general considerations relevant to the development of a fluorescence detection system have been detailed in the literature.<sup>47–50</sup> The following sections will discuss the major components of a fluorescence detection system and recent innovations.

#### 9.4.2.1 Light Source

There are a number of criteria relevant to the selection of an appropriate light source for a CE fluorescence detection system. As with sources for absorbance detectors, the output wavelength and

spectral characteristics are important, as is the stability of the source output. In addition, the intensity of a light source is important for fluorescence detectors, as the observed signal scales with the excitation irradiance. The sources for fluorescence detection can be differentiated into two types, coherent (lasers) and incoherent (lamps). Jorgenson and Lukacs<sup>51–53</sup> built the first fluorescence detector for CE in 1981, and it used a high-pressure mercury lamp for excitation. Such types of incoherent lamps, combined with predetection cell monochromators to filter out unwanted wavelengths from the emission source, provide flexibility in wavelength selection to match the wavelength of maximum absorbance for an analyte. Stabilized arc lamps are becoming increasingly available that, along with spatial filters and carefully constructed optical setups, allow for sensitive detection for chromophore-labeled analytes, such as detection limits of 10 pM for fluorescein-labeled amino acids.<sup>54,55</sup>

The use of LEDs as sources for fluorescence is becoming more commonplace.<sup>56–59</sup> As mentioned previously (in Section 9.3), the small footprint and low cost of these sources make them a good choice for microchip (e.g.,  $\mu$ TAS or lab-on-a-chip) devices. It is likely that these sources will become more commonplace as the output power generated by these sources increases.

Lasers are another source of excitation radiation used in fluorescence detection systems. The high-directional output of a laser maximizes the fraction of total output that can be easily focused down to a spot size compatible with the dimensions of CE detection cells. The output of a laser is also typically monochromatic, or a discrete set of spectrally narrow lines. This type of output makes it relatively easy to filter out low-level incoherent plasma radiation and undesired emission lines without greatly diminishing the overall output power. In addition, many lasers provide flexibility in terms of pulse width and repetition rate, which allows one to optimize excitation with respect to analyte photostability.

The original reported use of lasers in CE with fluorescence detection was described by Gassmann et al.<sup>60</sup> in which laser-induced fluorescence (LIF) was used to distinguish and measure the chiral enantiomers in mixtures of dansylated amino acids. Since that time, lasers have become commonplace in CE systems with fluorescence detection. The most common types of lasers used have been the He–Cd, Ar-ion, and He–Ne lasers, as they are relatively inexpensive and have emission lines that match commonly used fluorescent reagents, such as *o*-phthalaldehyde (OPA) (325 nm) and fluorescamine (354 nm).

The majority of LIF instruments use excitation wavelengths in the visible portion of the spectrum.<sup>61</sup> There is, however, interest in the development of LIF instruments that use near-infrared (NIR) excitation.<sup>62</sup> There are several reasons for this, including the availability of inexpensive NIR diode lasers, as well as the decreased likelihood of photobleaching or significant Raman background at longer wavelengths. The further development of suitable derivatization strategies will increase the number of applications that can be addressed by NIR-LIF.<sup>63,64</sup>

At the opposite end of the spectrum, UV sources for CE-LIF are becoming increasingly popular. UV radiation is capable of inducing fluorescence in many intrinsic fluorophores, including a number of biologically relevant molecules. The frequency-doubled Ar-ion laser (257 nm) was one of the first examples reported of UV-excitation for CE-LIF, and yielded improvements in LODs for a number of substances, such as conalbumin ( $1.4 \times 10^{-8}$  M).<sup>65</sup> As another example, a frequency-doubled Kr laser operating at 284 nm has been used for the analysis of neuropeptides and small biomolecules, and exhibited LODs for tryptophan of  $\sim 800$  zmol.<sup>66</sup> In addition to frequency-doubled ion lasers, a number of relatively inexpensive pulsed lasers such as frequency quadrupled YAG (266 nm),<sup>67</sup> KrF (248 nm),<sup>68</sup> and hollow-cathode metal vapor lasers have appeared, which provide deep-UV excitation (e.g., 224 and 248 nm).<sup>69–73</sup>

Multiphoton excitation is another strategy for exciting the same transitions that UV sources excite, while using NIR or visible lasers and associated optical elements.<sup>74,75</sup> In multiphoton excitation, two or three photons are absorbed by a fluorophore, which is then promoted to a vibronic state with an associated energy that is equal to the sum of the energies of the individual absorbed photons. Because the photons must be absorbed simultaneously (e.g., within  $\sim 1$  fs), this technique requires high peak

power. More specifically, the observed fluorescence emission is proportional to  $I_{\text{peak}}^n$ , where  $I_{\text{peak}}$  is the peak intensity of the excitation radiation and  $n$  is the number of photons involved in the transition. The small probe volumes dictated by this nonlinear intensity dependence are compatible with the small ID capillaries used in CE; this technique has been used to detect a variety of substances after CE separation, including the aromatic amino acids, nucleotides, and monoamine neurotransmitters such as serotonin.<sup>76,77</sup>

#### 9.4.2.2 The Detection Cell

On-column capillary detection is the most widely employed configuration in CE with fluorescence detection, as shown in Figure 9.3a. A small window is made on the capillary by burning off a section

**FIGURE 9.3** Schematic diagrams of two CE-LIF detection systems. (a) On-column CE-LIF and (b) end-column sheath-flow CE-LIF.

of the polyimide coating. In most cases, the source light is focused through this window, although axial illumination (directed up the bore of the capillary) has been used as well.<sup>26</sup> In either case, the fluorescence emission is collected through the window. Collection can take place orthogonal to the light source, or coaxial with it, as in the epi-illumination configuration.<sup>49,78</sup> Immersion of the cylindrical detection window in an index-matching solution can be helpful in maximizing excitation and collection efficiency.<sup>79</sup>

End-column detection is another frequently used configuration for fluorescence-based CE detection systems. One example is the sheath-flow cuvette, originally used for flow cytometry adapted to CE by Dovichi and coworkers (Figure 9.3b).<sup>80–82</sup> In sheath-flow post-column detection, the end of the capillary is inserted into a cuvette into which buffer is flowing. The linear flow rate of the sheath buffer is set to match or slightly exceed the electroosmotic flow of the capillary, thus minimizing turbulence and maintaining a narrow sample stream. The laser is focused to a spot immediately below the outlet of the capillary; the use of a cuvette with a square cross section maximizes the amount of excitation light that is transmitted into the probe volume. This type of detection cell is especially useful for CE-LIF systems using UV-excitation, as metal ions present in fused-silica capillary walls give rise to a broadband luminescent background. Impressive limits of detection have been obtained using the sheath-flow cuvette.<sup>83,84</sup> For example, detection limits of  $10^{-13}$  M have been reported for numerous rhodamine-based fluorophores.<sup>85,86</sup>

The post-column configuration has also been used in conjunction with fluorescence. Typically, this involves depositing the eluent on a membrane, or collecting fractions, as is commonly done in HPLC.<sup>87–89</sup> The resulting spots or fractions can then be imaged with an appropriate fluorimeter, fluorescence microscope, or other suitable fluorescence detector.

### 9.4.2.3 Collection Optics

The ideal collection optic would collect fluorescence from a  $4\pi sr$  solid angle around the detection zone with 100% efficiency, while being completely inefficient at collecting scattered laser light. Obviously, there exists no such optic, but there are various approaches reported in the literature taken to emulate this ideal. In most cases, either a high numerical aperture microscope objective or a fiber-optic system is used to collect the fluorescence and transmit it to the signal transducer.

Microscope objectives used as collection optics have yielded the lowest reported LODs in CE with fluorescence detection. They can be used alone or as part of a complete microscope setup. A high-numerical-aperture objective collects a large quantity of light from a very small region and focuses it onto the detector.

A number of fiber optic-based systems have been described for CE-LIF systems.<sup>90–92</sup> These systems boast a small footprint, and the terminal of the fiber optic can be placed exceedingly close to the detection window, thus enabling high collection efficiency. Hence, fiber optics are an excellent choice for systems where the overall footprint must be kept to a minimum, such as field-deployable sensors or lab-on-a-chip applications.

Fluorescence-based CE detection systems generally also include a spatial filter and wavelength filter located between the collection optics and the detector, in order to minimize the amount of Rayleigh and Raman scatter that reaches the detector. Careful selection of the filter wavelength range and rejection characteristics, based on the desired detected wavelength range and the spectral output of the source, is important to achieving optimal detector performance. The use of line sources such as lasers is advantageous in this respect, as a narrow pass filter can be used to block excitation radiation while minimizing the amount of fluorescence that is blocked.

## 9.4.3 MULTIDIMENSIONAL FLUORESCENCE

### 9.4.3.1 Wavelength-Resolved Fluorescence

In wavelength-resolved fluorescence detection, a complete emission spectrum is generated for each time point. The resulting data are plotted as a three-dimensional electropherogram, with axes

**FIGURE 9.4** (a) Schematic diagram of a CCD-based wavelength-resolved CE-LIF instrument. (b) Wavelength-resolved electropherogram of a mixture of seven peptides containing tryptophan and tyrosine residues. (Adapted from Timperman, A. T., et al., *Anal. Chem.*, 67, 3421, 1995. With permission.)

corresponding to time, wavelength, and fluorescence intensity. The first report of wavelength-resolved fluorescence detection for microscale separations was by Swaile and Sepaniak in 1989,<sup>35</sup> in which a spectrograph was used to disperse the fluorescence onto a photodiode array with 4-nm spectral resolution. The advent of higher-sensitivity array detectors, such as CCDs,<sup>93</sup> made this type of detection feasible for low-abundance analytes (see Figure 9.4), as demonstrated by 100 molecule detection limits for sulforhodamine<sup>94</sup> and 3 nM LODs for the neurotransmitter serotonin.<sup>95</sup>

Multichannel fluorescence detection can also be carried out using a series of dichroic beamsplitters and photomultiplier tubes (PMTs) in place of a spectrograph and CCD.<sup>96</sup> Rather than generating a high-resolution emission spectrum, this type of detector divides the collected emission into several channels, each of which corresponds to a relatively broad range of wavelengths. Peaks are identified based on a ratiometric “fingerprint” calculated from the relative intensities of the channels. This “fingerprint” is capable of differentiating two closely related substances, such as various catecholamine neurotransmitters.

Spectrally resolved fluorescence detection for CE has found a variety of applications and is often used for the detection and identification of various biologically relevant intrinsic fluorophores, including amino acids, proteins, neuropeptides, and small molecule neurotransmitters.<sup>66,95</sup> For example, wavelength-resolved fluorescence was used to elucidate various aspects of serotonin catabolism.<sup>97–99</sup> In addition, multichannel fluorescence detection was used to differentiate each of four fluorescently labeled dideoxy bases that terminate replication in a polymerase chain reaction.<sup>48,100</sup> This technique was instrumental in sequencing the human genome, as well as those of other organisms such as *Drosophila melanogaster* and *Caenorhabditis elegans*.

### 9.4.3.2 Time-Resolved Fluorescence

While wavelength-resolved fluorescence is the most common form of multidimensional fluorescence detection in CE, other forms of multidimensional fluorescence have also been reported. Time-resolved fluorescence involves measuring the temporal evolution of the fluorescence signal, and using this information to differentiate various analytes.<sup>101</sup> For example, high-resolution time-domain data can be used to calculate fluorescence lifetime of an analyte, which in turn can assist in peak identification by discriminating between short-lived and long-lived fluorophores.<sup>102</sup> Moreover, typical fluorescence lifetimes are orders of magnitude longer than scattering lifetimes (both Rayleigh and Raman). As a result, the signals resulting from scattering and fluorescence can be effectively deconvolved.

### 9.4.3.3 Polarization Fluorescence

In addition to wavelength and time-resolved fluorescence techniques, polarization fluorescence can yield important information about an analyte.<sup>41</sup> This is especially true when differentiating between chiral compounds. Combining, for example, a fluorescently tagged antibody immunoassay with polarization detection allows for very sensitive detection limits of chiral enantiomers. Laser-induced fluorescence polarization (LIFP) has been used to detect concentrations as low as 0.9 nM of an antibody-bound cyclosporine A (an immunosuppressive drug) in human blood.<sup>103</sup> A conventional single channel fluorescence detector can be easily modified to perform such measurements, simply by adding the appropriate polarization filters.

## 9.4.4 DETECTING BIOMOLECULES

### 9.4.4.1 Derivatization

As mentioned previously, fluorescence-based detection exhibits the lowest reported detection limits of any detection mode for CE. And while this is true, the effective use of fluorescence detection is contingent upon the ability to induce fluorescence in the analyte of interest with reasonable quantum efficiency. While native fluorescence is appropriate for a number of analytes, many others (including many of biological relevance) are either not intrinsically fluorescent or exhibit low fluorescence quantum yields. As a result, a significant amount of research has been devoted to appropriate labeling methods, whereby a fluorescent moiety is covalently bound to the analyte of interest in order to enable its detection.<sup>104</sup> While attaching fluorescent probes to molecules is not unique to CE, the small sample volumes involved make the development of suitable derivatization reactions and procedures critically important.

Derivatization can be carried out end-column, on-column, or precolumn, with the latter being the most common. With precolumn derivatization, large starting sample volumes and a large molar excess of derivatizing reagents can be used, and the reaction can be allowed to proceed indefinitely. These steps minimize losses due to dilution or sample handling, and help to ensure that the derivatization reaction proceeds to completion. Precolumn derivatization of lysine-containing neuropeptides with fluorescamine has shown pmol detection limits,<sup>105</sup> and 3-(*p*-carboxybenzoyl)quinoline-2-carboxaldehyde was used to gain a detection limit of 9 zmol ( $10^{-21}$ ) for arginine.<sup>106</sup> While using large volumes of the sample solution helps to minimize the effects of dilution by the derivatizing reagents, there are times when this is not possible. This is the case in many biological applications, such as single-cell analysis. For example, Oates and coworkers<sup>107,108</sup> demonstrated derivatization of proteins and peptides from a single cell in a 25 nL volume using naphthalene-2,3-dicarboxaldehyde (NDA) as the derivatant. Derivatization of intracellular signaling compounds can be done by using the cell itself as a reaction chamber. Selective derivatization with monobromobimane of thiol-containing compounds within a single red blood cell,<sup>15</sup> as well as selective

derivatization of glutathiones by NDA in single neuroblastoma cells were some of the first reports published showing successful derivatization within a single cell.<sup>109</sup>

On-column analyte derivatization is another approach often used. For on-column labeling, it is beneficial to use a reagent that is nonfluorescent in its unreacted form, such as NDA. Gilman and Ewing<sup>110</sup> were able to use on-column labeling with NDA to analyze a whole PC12 cell. To do this, they injected the intact cell followed by a plug of derivatization mixture, and left the voltage off for a brief time interval to facilitate cell lysis and derivatization prior to CE analysis. On-column derivatization can also be carried out using low-volume connectors attached near the outlet of the capillary to introduce derivatization reagent. Carefully constructed transfer fluidics maintain separation efficiency upon introduction of the derivatant. This type of apparatus can be constructed by laser-drilling holes into the separation capillary and introducing the reagent by gravity through a T-connector. The introduction of OPA into the capillary using this arrangement allows for femtomole amounts of amino acids to be detected.<sup>111</sup>

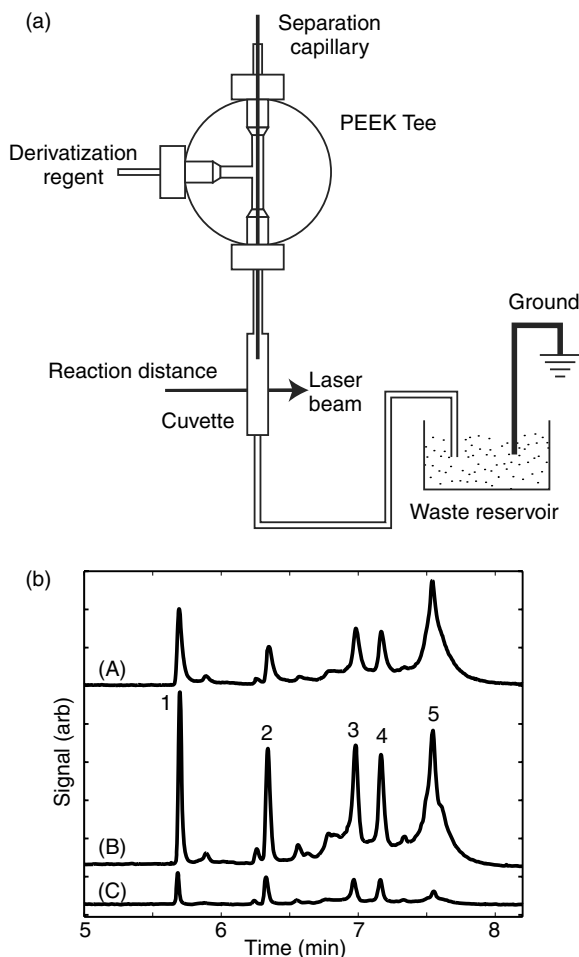

There are cases when it is desirable to carry out derivatization after the separation has taken place. For example, small molecules can be difficult to separate after derivatization, because the size of the label is often large relative to the analyte. In addition, some analytes have multiple reactive sites (such as amino groups) where derivatization can occur. This can result in a distribution of fluorescence products from a single analyte, each giving rise to a peak on the electropherogram. To address these and other complications, a number of methods have been developed to perform end-column derivatization. Most end-column systems employ a similar set of components, including a micropump to add derivatization reagent to the CE effluent and a secondary column where the labeling reactions occur before the tagged analytes reach the detector. The simplest approach is to use a sheath-flow system to introduce the reactants, such as the coaxial capillary reactor system originally described by Rose and Jorgenson.<sup>112</sup> In this setup, OPA was introduced at the outlet of the capillary tip, allowing for attomole detection limits. Another approach is to use the sheath-flow cuvette (discussed earlier) as a derivatization reactor; the fluorogenic reagent is simply added to the sheath-flow buffer (Figure 9.5).<sup>113,114</sup>

Another end-column derivatization system involves a gap junction reactor, as described by Albin et al.<sup>115</sup> In the gap junction reactor, two capillaries are separated by a small gap in which the fluorophore is introduced. Careful alignment of the two capillaries ensures that high separation efficiency is maintained at the junction. The gap junction interface is an excellent choice when using high-cost derivates, as smaller volumes can be used for reagent introduction.

For all of the various end-column derivatization schemes, it is important that labeling reactions be chosen that exhibit fast kinetics. This ensures that derivatization is complete before the analytes enter the detection zone, which in turn ensures maximum analyte detectability. Common derivates with suitable kinetics for end-column detection include fluorescamine, OPA, and NDA.<sup>2,116,117</sup> In addition to kinetics, the selection of an appropriate derivatization reaction can be influenced by other factors, including the potential side reactions for a given set of reagents and analytes, equilibrium and concentration considerations, and the pH at which the derivatization is carried out.

#### 9.4.4.2 Native Fluorescence

When possible, it can be advantageous to take advantage of an analyte's intrinsic fluorescence. Ideally, native fluorescence would exhibit a high quantum yield and could be excited with readily available excitation sources. Unfortunately, few compounds exhibit fluorescence in the spectral range of the most common lasers, that is, the visible portion of the spectrum. Nonetheless, there are some compounds that fluoresce upon excitation with visible light. Examples include many pharmaceutical compounds,<sup>118–120</sup> porphyrins,<sup>121,122</sup> and vitamin B6 metabolites.<sup>123</sup> In contrast, excitation below 300 nm excites quite a number of biomolecules, including proteins and peptides containing Tyr, Trp, or Phe residues, polycyclic aromatic hydrocarbons, as well as nucleosides and DNA.<sup>95,124–126</sup> For

**FIGURE 9.5** (a) Schematic diagram of the sheath-flow post-column reactor. (b) Separation of protein standards derivatized with NDA/ $\beta$ -mercaptoethanol at a height difference of (A) 0.5 cm, (B) 3 cm, and (C) 6 cm between the derivatization solution reservoir and waste reservoir. (Adapted from Ye, M. L., *J. Chromatogr. A*, 1022, 201, 2004. With permission.)

example, laser-induced native fluorescence can be used to detect epinephrine and norepinephrine content of single bovine adrenal medullary cells (Figure 9.6).<sup>127</sup>

Most applications of native fluorescence detection involve the direct detection of a fluorescent analyte of interest. However, native fluorescence can also be used indirectly to detect the presence of nonfluorescent species. For example, the presence of a nonfluorescent enzyme can be detected based on its conversion of substrate into natively fluorescent products. This is often used in conjunction with electrophoretically mediated microanalysis, in which differences in buffer mobilities enable on-column mixing and reaction of enzymes with substrates.<sup>128</sup> One such study exploited the intrinsic fluorescence of nicotinamide adenine dinucleotide (NADH) to investigate differences in the reactivity of individual molecules of lactate dehydrogenase.<sup>129</sup>

The quantum efficiencies and photostabilities of most intrinsically fluorescent biomolecules are modest relative to those of the available fluorescent labels. There are, however, several factors that can affect these quantum yields. The ionic strength and pH of the separation conditions, as well as the presence or absence of organic additives, can have a significant effect on the fluorescent properties (i.e., quantum yields and Stokes' shift) of these analytes.<sup>41,130</sup> Thus, if sensitivity is of

**FIGURE 9.6** Electrophoretic separation of intracellular components of a single bovine adrenal medullary cell detected by laser-induced native fluorescence. utmost importance for a particular application, the separation buffer can be optimized in terms of analyte fluorescence and separation efficiency.

## 9.5 THERMOOPTICAL DETECTION

Thermo-optical detection exploits the deflection of light that occurs as a result of changes in the refractive index of a light-absorbing solution. Although it is a transmittance-based detection method, it is distinct from absorbance detection in that the measured decrease in transmittance is related to changes in the index of refraction of the absorbing solution. This detection mode involves the use of two laser beams that intersect in the detection zone of the capillary. One of the beams, the “probe” beam, passes through the detection cell, and is detected by a photodiode or other appropriate signal transducer. The second beam, the “pump” beam, is selected to match the absorbance profile of the separation medium. This beam is temporally chopped, so that it passes through the detection window only transiently. The index of refraction of the separation medium changes in time as a result of heat-induced density changes in the solution, depending on whether or not the pump beam is passing through the detection cell. As a consequence, the transmittance of the probe beam changes in time, which can be measured by the photodetector. Furthermore, the change in refractive index that occurs is dependent on the absorbing species in the separation medium. Hence, as different substances migrate through the detection zone, the magnitude of the detected signal changes. The electropherogram is generated by plotting the difference in transmittance between “pump on” and “pump off” as a function of time.

Thermo-optical detection has been combined with CE and used for protein and peptide Edman degradation sequencing detection, native protein detection, as well as the analysis of derivatized amino acid mixtures.<sup>131–134</sup> Frequency-doubled argon-ion lasers have been employed to supply an UV (257 nm) pump beam for the analysis of dansylated amino acids as well as the analysis of etoposide and etoposide phosphate in human blood plasma.<sup>135,136</sup> In addition, two-color thermo-optical absorbance detectors have been constructed, where each laser serves a dual role of “pump” and “probe”; this system can be used to detect analytes that absorb in differing regions of the electromagnetic spectrum.

The use of a near-field thermal lens system to increase pump beam absorption has recently been reported by Pyell and coworkers.<sup>137</sup> This innovation has resulted in a nearly 30-fold improvement in detection limits for a multitude of nitroaromatic compounds, including a 0.15 mg/L detection limit (compared to a previously reported LOD of 3.4 mg/L) for 2-nitrotoluene.

## 9.6 CHEMILUMINESCENCE

Chemiluminescence (CL) is a phenomenon whereby the electronically excited state product of a chemical reaction generates optical radiation during relaxation to its ground state. There are two general mechanisms of CL that are employed in the context of detection for CE.<sup>138</sup> In direct CL, the photon(s) are emitted by the excited state reaction product as it relaxes to the ground state. In the second, the relaxation of the excited state takes place via energy transfer to a fluorophore, which subsequently fluoresces; this is referred to as sensitized CL, because a fluorophore with a high quantum yield can be used.

CL is an attractive detection method for CE in part due to its simple instrumentation. An external radiation source is not required, reduces instrument cost, complexity, as well as the overall footprint of the instrument. In addition, since there is no background from an excitation source, there is no need to filter the collected radiation, which increases detection efficiency. In its simplest form, a CE-CL instrument can consist of only a capillary, power supply, and a detector, such as a PMT or photodiode detector. The small footprint of such instrumentation is particularly attractive for microscale total analysis systems ( $\mu$ TAS) or lab-on-a-chip applications.<sup>139,140</sup>

CL detection can be used to probe intrinsic luminescence, such as that found in numerous biological systems (bioluminescence), or analytes of interest can be derivatized by reaction with an isothiocyanate or succinimidyl ester-linked chemiluminescent moiety. The first reported use of CL for CE detection was by Hara et al.<sup>141–143</sup> who used peroxyoxolate as the luminophore to detect a protein–dye complex. Since then, CL has been used successfully to detect a variety of substances after CE separation including metal ions,<sup>144</sup> amino acids,<sup>145</sup> peptides<sup>146</sup> and proteins,<sup>147</sup> and even DNA.<sup>148</sup>

CL involves a chemical reaction between two or more species, and so the magnitude of the detected signal is a function of each of these substances. To facilitate quantification of one of these, the concentrations of the others must be held constant, or otherwise known. Several distinct strategies have emerged to enable this, including coaxial flow on-column detection, off-column detection, and end-column detection.<sup>149,150</sup> One method that has gained considerable attention recently is to generate the luminophore *in situ* by an electron transfer reaction facilitated by an electrode; this specific type of CL is referred to as electrogenerated chemiluminescence (ECL). For example, ruthenium (II) tris(2,2'-bipyridine) can be oxidized to  $\text{Ru}(\text{bpy})_3^{2+}$ , which undergoes a chemiluminescent reaction with various analytes.<sup>151–156</sup> Not only can this luminophore be used with biologically relevant analytes such as amino acids and NADH without their prior derivatization, but the reactive state of the luminophore can be regenerated by oxidation at an electrode in the detection zone.

Many developments in CL detection have taken place since the last edition of this book. There are a number of reviews that highlight current research in the field.<sup>149,150</sup> Given the relative low cost, simplicity, and small footprint of CL detectors, as well as the persistent drive toward miniaturization of analytical instruments, it is likely that research in CL detection for CE will continue to progress at a rapid pace.

## 9.7 RADIONUCLIDE DETECTION

In radionuclide detection, the presence of a radiolabeled analyte is detected by the response of a secondary substance to the radioactive decay of the radiolabel. The secondary substance is referred to as a scintillator, and it responds to collision with a radioactive particle by the emission of photons. Since it is this emission of photons that is actually measured in radionuclide detection, it is appropriate that this method of detection be included in a chapter covering light-based detection methods. Radionuclide detection is both highly sensitive and selective. The high sensitivity of this technique is due to the ease of detection of the energetic decay events, in conjunction with a very low natural background. The high selectivity of this technique results from the fact that only the radiolabeled sample yields a detectable response. As a consequence, it is possible, for example, to inject a

living system with a radiolabeled sample and investigate various metabolic pathways or biochemical changes by following the movement of the radiolabeled nuclei, without interference from unlabeled compounds.

The sensitivity and detection limits for radionuclide detection depend in large part on the particular radioactive nuclei being used. More specifically, the isotope's rate of decay and particle energy determine the lowest attainable detection limit. In addition, the sensitivity is dependent on the observation time of the isotope and the fraction of events detected, which can be expressed as follows:

$$\text{counts} = (\text{DPS}) (\text{time observed}) (\text{efficiency of detector})$$

where "counts" represents the number of detector counts recorded over an observed peak, "DPS" (measured in Becquerels, or Bq) represents the number of radioactive decompositions per second from the sample, "time observed" is the amount of time (in seconds) a radioactive molecule spends in the detection volume, and "efficiency of detector" is the average fractional number of events sensed by the detector per total number of events. DPS is directly proportional to the concentration of a particular isotope in a given sample, which is determined by the isotope's rate of decay. The rate of decay for an isotope is described as the amount of time for half the nuclei in a sample to decay, commonly expressed in days or years, also known as the half-life ( $t_{1/2}$ ). These rates can vary widely, from more than  $10^{22}$  years for very stable radionuclides, to  $10^{-6}$  s for highly unstable ones. More reasonable ranges for isotopes used in CE analysis are those of  $^{32}\text{P}$  with a half-life of 14.2 days, and  $^{14}\text{C}$  with a half-life of  $5.73 \times 10^3$  years. Because peak times in CE are normally limited to a few seconds, the "time observed" term in the preceding equation limits the counts observed, and hence the overall detection sensitivity when measurements are performed online. In addition, it is evident from the "DPS" term that the shorter the half-life of the isotope, the more likely the detector will see enough events in a given amount of time to obtain a clear signal. Another consideration worth noting is that high-energy decay events are more easily detected than low-energy events. This is due to the decreased probability that an intervening atom will absorb a higher-energy particle before it reaches the scintillator. Common particle energies for isotopes used in online radionuclide detection in CE range from 1.71 MeV for  $^{32}\text{P}$  to 0.156 MeV for  $^{14}\text{C}$ . The higher-energy particles are generally able to travel a longer distance before being absorbed. Besides the differing particle energies, there are also different forms of decay for radioparticles, the most common in CE detection being the emission of negative ( $\beta^-$ ) particles, positive ( $\beta^+$ ) particles, and neutral gamma rays ( $\gamma$ ).

Both on-column and post-column detection schemes have been developed for radionuclide detection for CE. The most common type used is an on-column configuration, which yields detection limits in the  $10^{-9}$  M range for isotopes such as  $^{32}\text{P}$ . Isotachophoretic separations of  $^{14}\text{C}$  were among the first examples of online capillary radionuclide detection, performed by Kaniansky et al.<sup>157–159</sup> The associated instrument uses 300- $\mu\text{m}$  ID fluorinated ethylene-propylene copolymer capillary tubing, and the separation eluent flows directly into a plastic scintillator cell between two PMTs. The scintillation events are detected coincidentally between the two PMTs, such that only if both PMTs receive an input within a short time will they register the count as signal. This kind of coincidence detection ensures that nonscintillation photons that come from outside the detection cell and only hit one PMT are not counted. This system exhibits a detection limit of 16 Bq for  $^{14}\text{C}$  analytes, with a detector efficiency of 13–15%.

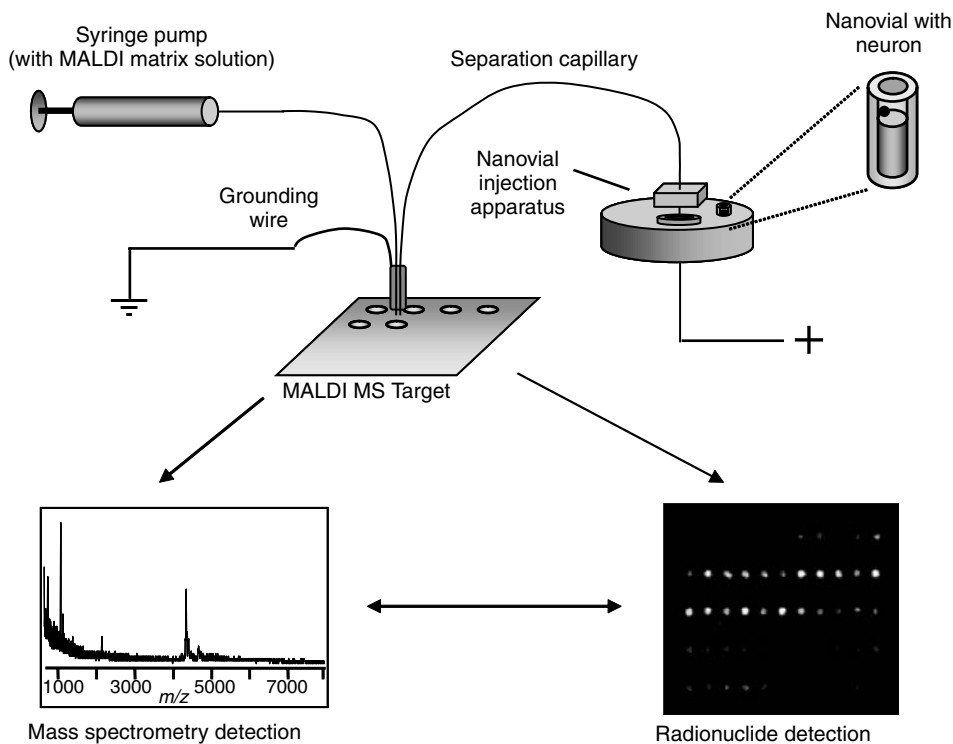

Gamma-emitting radioparticles are typically much higher in energy than beta particles, and so their detection requires a more dense scintillator material. The CE separation and detection of radiopharmaceuticals containing  $^{99}\text{Tc}$  was first reported by Altria et al.<sup>160</sup> who constructed an instrument in which the capillary passes through a block of solid scintillator; the solid scintillator emits photons in response to impinging  $\gamma$ -rays.

A similar design was employed by Pentoney et al.<sup>161</sup> in the pursuit of detecting  $^{32}\text{P}$  particles, using a  $\gamma^-$  and  $\beta^-$  sensitive Cd-Te detector. The sensitivity of this instrument was augmented by the

use of flow-programming—reducing the voltage while an analyte is in the detection window in order to increase residence (and hence integration) time. Similar systems were developed by Klunder et al.<sup>162</sup> to detect fissionable materials, in which the radioactivity detector consists of conical plastic scintillating material, with the capillary passing through the center to provide a near  $4\pi sr$  detection geometry. This type of system provides an 80% detection efficiency and detects the decay of  $^{152}\text{Eu}$  and  $^{137}\text{Cs}$  at the nCi level.

In biological studies, two important radionuclides are  $^3\text{H}$  and  $^{35}\text{S}$ , due to their common presence in small molecules and proteins, respectively. Unfortunately,  $^3\text{H}$  and  $^{35}\text{S}$  lack sufficiently energetic decay products to penetrate the capillary wall and so must be sampled outside the capillary tubing if they are to be detected. Tracht et al.<sup>7,8</sup> developed a post-column method to detect these low-energy  $\beta^-$  particle emitters. In this setup, the end of the capillary is painted with a conductive paint to maintain an electrical circuit, and the capillary eluent is deposited directly onto a binding membrane with the aid of a multiaxis translation stage. Scintillation compounds deposited onto the membrane will luminesce from any radioactive decay present in the sample (Figure 9.7). The intensity can be measured with a photodetector, or the plate can be read by a phosphorimager. This post-column CE collection and exposure system has since been used for a number of nanoscale biological analyses, from analysis of a single neuron<sup>163</sup> to observation of synthase activity within a ganglion.<sup>164</sup>

A major advantage unique to the coupling CE with radionuclide experiments is the significant reduction in the volume of hazardous waste generated as compared to what would be generated using other separation methods such as high-pressure liquid chromatography (HPLC). Furthermore, the abundance of potential applications in the biological sciences and environmental monitoring will ensure the continued development of this method of analysis in years to come.

**FIGURE 9.7** Post-column radionuclide detection system for CE. The spots can be analyzed by other detection modes, such as mass spectrometry, to gain additional information. (Reprinted from Page, J. S., et al., *Anal. Chem.*, 74, 497, 2002. With permission.)

## 9.8 OTHER LIGHT-BASED DETECTION METHODS

The set of optical detection techniques presented thus far in this chapter is not comprehensive; emphasis has been placed on those that are most common in CE, the most influential to the field, or both. There are other optical detection modes in various stages of development, each one with its own unique characteristics. Many of these alternative detection modes aim to provide structural information about the analyte being detected. One such method uses FTIR detection. FTIR detection is of interest because it is potentially a nearly universal detection method and provides a wealth of structural information. The nearly universal nature of IR activity also presents challenges, as the capillary itself as well as the separation buffer are often IR-absorbing. Thus, most attempts at FTIR detection for CE have been off-line; the eluting bands are sprayed onto an IR-transparent (e.g., CaF<sub>2</sub>) disk using a glass or metal nebulizer for subsequent (off-line) FTIR analysis.<sup>165,166</sup> The instrumentation for online FTIR detection was developed for HPLC before its implementation in CE.<sup>167</sup> The first report of online CE-FTIR appeared some 4 years later, in which adenosine, guanosine, and adenosine-5'-monophosphate were separated, and the online-generated IR spectra were compared with standard IR spectra.<sup>168</sup> The most recent report of CE-FTIR uses mid-IR detection to distinguish between different sugars in fruit juices; this is the first report of using CE-FTIR to differentiate compounds in “real” samples.<sup>169</sup> In these reports, LODs were in the sub- to low-millimolar (>0.2 mM) range; this technique holds great promise for elucidating structural information from samples, and future work in this field will likely enhance the performance of this technique for commercial application.

Raman spectroscopy (RS) is another detection method for CE that is potentially useful for providing structural information about an eluting analyte. The use of special Raman modes, such as resonance Raman spectroscopy (RRS) and surface-enhanced Raman spectroscopy (SERS), offer substantial signal enhancements ( $10^2$ – $10^{15}$ ) compared to other Raman processes. RRS and SERS have been coupled with CE both online and off-line (so-called at-line); an excellent review has been published recently covering considerations for at-line and online coupling of Raman spectroscopies to liquid separations, including CE.<sup>170</sup> For “at-line” SERS, the CE eluent can be spotted on an appropriate substrate, such as a thin film of gold, before being subjected to Raman spectroscopic analysis.<sup>171,172</sup> Online CE-SERS analysis has also been reported using a silver colloid solution (with appropriate electrolytes) as a separation medium.<sup>173</sup> RRS was coupled online to CE as early as 1991. More recently, online UV CE-RRS was used to obtain spectral information from the separated components of standard mixtures of aromatic sulfonic acids and nucleotides. Through the enhancement factors of RRS and SERS, and recent work toward the adaptation of deep-UV and tunable wavelength lasers to CE-RRS, RS has become an intriguing and useful detection method for obtaining structural information from small-volume separations.

Radio frequency (RF) electromagnetic radiation can be used to induce nuclear spin transitions in the presence of an external magnetic field, thus enabling detection via NMR. NMR can be used to both detect and obtain structural information about analytes that are not electroactive and do not possess a chromophore. Hence, research is ongoing with the aim of improving the online coupling of NMR to microscale separations. The use of NMR on nanoliter volume samples was first enabled by the development of the microcoil probe, which consists of a thin copper wire (rf coil) wrapped around a small diameter (e.g., 50  $\mu\text{m}$ ) capillary.<sup>174–176</sup> A variety of approaches have been used in conjunction with the microcoil probe in order to enhance the detected signal. Sample concentration techniques, such as capillary isotachopheresis, have been used to improve analyte detectability and enable trace analysis.<sup>177</sup> The generation of high-resolution NMR spectra can be accomplished using periodic stopped-flow CE to increase the spectral acquisition time.<sup>11,178</sup> Several methods have been developed to enable continuous-flow separations and high resolution, including the dual microcoil split-flow method<sup>179</sup> and a “splitless” method.<sup>180</sup> For example, in the dual microcoil method, multiple capillaries are interconnected such that a separated band can be directed to a secondary capillary and microcoiled, parked, and analyzed, while the separation continues in the primary capillary.<sup>179</sup>

Several relatively recent reviews have been published that discuss the application of NMR detection for microscale separations (including CE) in more detail.<sup>181,182</sup>

Future research will determine whether the potential of these techniques for structure-based analyte identification can be realized in the form of practicable and profitable detection methods for CE.

## 9.9 CONCLUSIONS

As CE continues to evolve, it is not surprising to see a concomitant development of optical detection methods. Detector innovations have been required to keep up with smaller diameter capillaries, faster separations, parallel capillary systems, and microfluidic-based electrophoretic formats. In parallel to these changes, more flexible and higher performance imaging detectors, UV light sources, and clever applications of these advances continue to push the envelope in terms of light-based detection for CE.

While this chapter summarizes the state-of-the-art in optical detection, it is perhaps worthwhile to speculate as to the potential fruits of this continued development, that is, the future of light-based detection for CE. While photodiode array-based absorbance detection will continue to dominate CE detection, fluorescence detection will be used for an ever-increasing set of CE-applications. For example, the widespread use of fluorescence microscopy in biological and biomedical research ensures that new derivatization chemistries will be developed, allowing a wider range of analytes to be characterized using fluorescence. Further development of low-cost deep-UV sources is likely to lead to the proliferation of native fluorescence detection. This, in turn, will be accompanied by a dramatic increase in the use of multichannel systems to provide information about the identity of eluting analytes. And of course, solid-state light sources will replace lasers in many applications.

Outside of absorbance and fluorescence, microchip CL systems will become more common, likely using ECL with *in situ* regenerated lumophores. Will the next decades finally witness the commercial development of a capillary-scale Raman probe? Of course, the continued hyphenation of UV-absorbance, mass spectrometry, and other detection schemes will push the envelope of information-rich detection systems for small-volume separations.

## 10.1 INTRODUCTION

The first miniaturized analytical device reported was a gas chromatographic analyzer fabricated from silicon in 1979.<sup>1</sup> The work showed the separation of a simple mixture of compounds in only a few seconds. While unperfected, this was an example unlike anything else reported in the literature at that time, and while the scientific community did not immediately grasp the achievements of Terry and coworkers, they did see a glimpse of the future provided in this work with respect to the value of miniaturizing analytical methods. Multiple papers followed this initial work in miniaturization over the next 12 years<sup>2–11</sup>; however, it was not until the concept of a total analysis system (TAS) was first proposed by Manz et al.<sup>12</sup> in 1990 that the concept of miniaturization began to have a significant impact.

The TAS concept was originally motivated by a lack of adequate sensors for the detection of specific species from a complex mixture. It was hypothesized in this seminal paper<sup>12</sup> that, by improving the sample treatment steps, an ultrasensitive sensor would not be required if interfering chemical compounds were removed. A TAS, as proposed, entailed initial sampling, transport of the sample, sample pretreatment steps, and the final detection of the analyte. Miniaturization of all

**FIGURE 10.1** An increase in microfluidics publications. A search was performed using the term “microfluidics” and the number of publications was graphed as a function of publication year. The data shown represent the total number of journal articles (---), patents (· · ·), and the sum of both (—).

of the processes required for total analysis, a micrototal analysis system ( $\mu$ TAS), would allow the development of a TAS that performs these functions at the site of measurement. Additional benefits are also derived in decreasing the size of a TAS, that include decreased volumes of required sample, decreased reagent consumption and the potential for dramatically reduced analysis times.

From its inception, the driving force behind the miniaturization of electrophoretic separation techniques was related to an enhancement in its analytical performance, rather than a reduction in size.<sup>12</sup> Because separation efficiency is a function of the applied voltage, microfluidic devices utilize shorter separation lengths along with the application of high voltages typically used in capillary-based analysis, resulting in fast, efficient separations. In addition, and perhaps most importantly, microchips also offer the opportunity to integrate sample-processing steps onto the same device used for separations, producing the  $\mu$ TAS initially described by Manz and coworkers. Process integration results in a decrease in total analysis time as well as a reduction in potential contamination because sample handling between processes is eliminated.

Microfluidic devices are becoming increasingly more prevalent in the scientific arena, not only revealed by a rise in the number of reports in the literature but also by the release of commercial products. A graph plotting publications versus time, as shown in Figure 10.1, highlights the increased number of reports using these miniaturized devices since the inception of the original TAS concept. The goal of this chapter is to educate the novice microchip user on fabrication methods and “tricks of the trade” regarding glass and polymer [specifically poly(dimethylsiloxane) or PDMS] microdevices with a view to application of these devices.

## 10.2 BACKGROUND

The initial experiments transitioning the capillary electrophoretic separation method to a microdevice were performed by Manz et al.<sup>13</sup> This paper, which provides details about the process of fabricating the devices, describes the four different processes necessary for standard one-mask microfabrication; these processes included film deposition, photolithography, etching, and bonding. These processes were used to fabricate a fluidic layer in silicon, which was sealed with a glass cover plate, and then the device was used for the electrophoretic separation of amino acids. The techniques outlined in this original paper for microfabrication in glass and silicon are still used today (and detailed below), along with additional advances required to generate the significantly more complex devices now being reported in the literature. The goal of this background section is to cover the basic definitions and concepts, all of which are addressed in more detail in subsequent sections.

Film deposition refers to the deposition of materials, such as photoresist and metals, onto the wafer. These materials can serve as protective layers during etching, or can act as a master for polymeric devices fabricated using molding. Metal layers are usually deposited using sputtering or vacuum deposition, with chrome being used most frequently because of its avid bonding to both glass and silicon. Photoresists are photoactive materials normally coated on wafers using spin coating to deposit a material onto the surface at a desired thickness. An alternative to conventional spin coating of photoresist has been developed using a constant-volume injection method,<sup>14</sup> which provides an increased pattern definition of the photoresist structures under the conditions investigated. All of these methods require cleanroom conditions and extensive instrumentation to provide either the protective surface that can be patterned for etching or for the development of a master used for PDMS molding.

Once the photoresist has been deposited, the channel geometry required for the final device is “imprinted” onto the photoresist. This is normally performed using a photomask containing the microchip design, through which a ultraviolet (UV) light is passed, exposing the photoresist in the appropriate areas, to transfer the pattern from the mask onto the photoresist. Photolithography, a well-established method from the microelectronics industry, is widely utilized but requires initial production of the photomask. Recent reports describe methods for patterning photoresist without a mask, the most promising of which is laser direct-write systems in which the design is transferred to the photoresist using a laser that travels along the desired pattern on the chip surface creating features based on a schematic contained within the software file used to create the design.<sup>15,16</sup>

With the traditional etching method for fabricating glass or silicon devices, the desired pattern is transferred to the photoresist by exposure of the photoresist to UV light in the pattern designated by the design. This UV-induced damage to the photoresist makes it susceptible to removal with a developer, which is essentially a buffered alkaline solution, exposing the underlying metal layers that cover the wafer. Once these are removed, exposure to hydrofluoric acid (HF) etches the glass or silicon at a rate that can be predetermined based on the substrate used and the concentration of HF used in the etch solution. It is noteworthy to mention that HF is a hazardous acid that must be handled with extreme caution, and appropriate countermeasures must be taken upon exposure. In another work, a combination of photoresist and sacrificial metal layers were used that have an increased resistance to HF and, therefore, allowed even deeper glass etching ( $>300\ \mu\text{m}$ ).<sup>17</sup> Wet chemical etching with HF has also been performed without a mask, using patterned PDMS sealed to the glass with HF flowed through the PDMS channels to etch corresponding channels in the glass substrate.<sup>18</sup> The same concept was also applied to a plastic substrate where an etchant, in place of HF, was pumped through the PDMS channels.<sup>19</sup>

Because of the hazards of HF, alternatives to wet chemical etching have also been reported; Belloy et al.<sup>20</sup> used powder blasting to fabricate high-aspect ratio structures in glass. Their technology uses a beam of powder particles that erodes the protective layers patterned on a substrate; this technique allowed for fabrication of free-standing monolithic glass microstructures. A similar method called deep reactive ion etching (DRIE) was used by Ceriotti et al.<sup>21</sup> to fabricate rectangular channels for UV-detection in fused-silica wafers. DRIE, as well as regular reactive ion etching, involves bombarding the material to be etched with highly energetic chemically reactive ions, typically fluoride, to collide with the material's surface and remove surface atoms in the process. All of these etching processes are used to generate channels with depths in the 1–500  $\mu\text{m}$  range. Pushing the limits of structure size, Hibara et al.<sup>22</sup> fabricated channels with only nanometer dimensions in fused silica by fast atom beam etching; this method uses accelerated neutral particles to bombard the surface. An additional method for the generation of nanometer channels was reported by Ionescu et al.,<sup>23</sup> who used enzymes to create nanometer-sized depressions in a protein surface for nanofluidic photolithography. Proteases were delivered with scanning probe microscopy and were able to precisely control the dimensions of the resulting features.<sup>24</sup>

Once channels/chambers have been etched in to the substrate, it is bonded to a flat cover plate to enclose the channels and complete the fluidic architecture of the microchip. With glass microdevices, thermal bonding is used most frequently, with heating to a temperature that approaches their glass transition temperature while under pressure, allowing the glass plates to fuse. For silicon/silicon, and for glass/silicon bonding, anodic bonding is often employed in which a high voltage is applied between the top and bottom layers, causing the two to fuse. Both of these bonding procedures utilize high temperatures, which may not be desirable if metals or other components are an integral part of the device. Other microchip bonding methods have been reported including techniques utilizing silicate solutions,<sup>25–27</sup> UV-curable adhesive,<sup>28,29</sup> and low-temperature methods,<sup>30–33</sup> many of which are carried out at low temperatures (<150°C), and, therefore, are ideal for surfaces that require modification (i.e., metallization) prior to bonding.

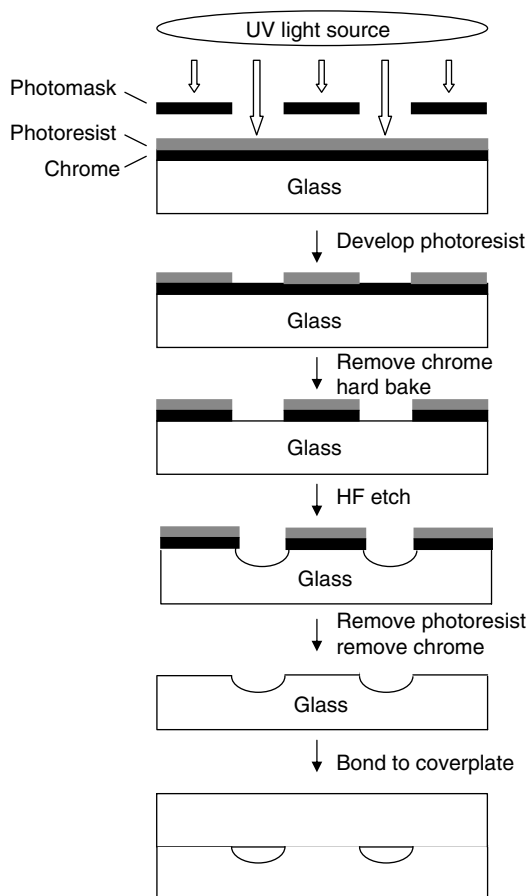

### 10.3 GLASS MICROCHIP FABRICATION

Glass offers some distinct advantages over other substrates that are used to fabricate microdevices. It is optically-transparent through much of the visible and UV spectrum, its surface chemistry is reasonably well-characterized, it is compatible with most solvents, and it can withstand high temperature applications due to its high glass transition temperature. One of the most significant drawbacks associated with using glass as a substrate is the apparent requirement for a cleanroom-based fabrication facility. However, while cleanroom environments are useful if available, they are not a necessity as glass devices can be fabricated outside a cleanroom. In line with this, the need to sputter metals and spin-coat photoresist can be avoided with commercially available silicon and glass wafers that are pre-coated with the necessary layers in a variety of sizes and material, in many ways eliminating the need for sophisticated facilities. For the photolithography step, a laminar flow hood can be used to protect the surface and mask from dust during the exposure, ensuring exact replication of the mask image in the photoresist. Yellow lighting is also required to prevent unwanted exposure of the photoresist, and all the postexposure steps can be performed in an acid-resistant hood (e.g., polypropylene). More detailed methods for the fabrication steps, beginning with pre-coated wafers, are presented in the following sections.

#### 10.3.1 PHOTOLITHOGRAPHY AND WET ETCHING OF GLASS MICROCHIPS

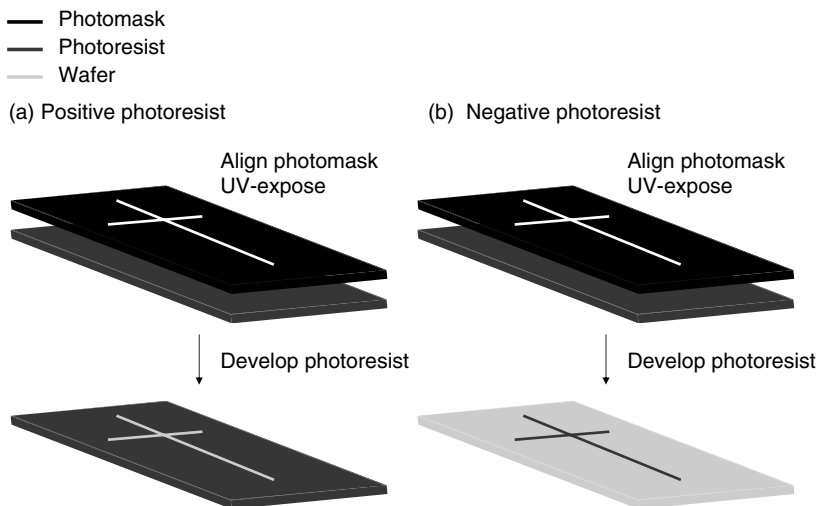

Glass microchips are traditionally fabricated using standard photolithography techniques exploiting either a film or metal masks (Photosciences, San Jose, CA) for design transfer, and wet chemical etching for structure creation (Figure 10.2). For both types of masks, the chip image is created using software (e.g., AutoCAD or Adobe Illustrator) that contains the design for the channels, chambers, and reservoirs desired in the microfluidic chip. The computer image can be transferred lithographically onto a film by most commercial printing companies using a high-resolution printer (~2500 dpi)—this makes the mask generation inexpensive (a few tens of dollars), allowing the user to quickly and easily modify the design with successive iteration. While the resolution of the printer restricts designs to features greater than about 20  $\mu\text{m}$  (width), in most cases, microfluidic channels range from 40 to 200  $\mu\text{m}$  deep and, thus, film masks prove adequate for most applications. Creating a metal mask is a more costly endeavor (hundreds of dollars per mask) and is typically done when either higher resolution structures are required or the user has defined a final design that is tried and true. This is created through the fabrication of the microfluidic architecture into a glass substrate, followed by a metallization step to increase the robustness of the mask. While these metal-on-glass masks are more expensive, they can be used repeatedly without degradation (unless dropped), and allow for higher resolution structures (<20  $\mu\text{m}$  initial channel width) to be fabricated.

Borosilicate glass has traditionally been used as substrate for glass microchips (e.g., Schott 1.1-mm-thick BOROFLOAT), but quartz<sup>34</sup> and soda lime<sup>35</sup> glass have also been used. Borosilicate

**FIGURE 10.2** A diagram illustrating the processes involved in microchip fabrication using standard photolithography and wet chemical etching methods.

glass plates can be obtained commercially, precoated with sacrificial chromium ( $<1 \mu\text{m}$  thickness) layered underneath a coating of photoresist. To transfer the image from the photomask to the photoresist, a high power (e.g., 350 W) UV exposure system is normally used, with the exposure time being dependent on the thickness and type of photoresist; a 5 second exposure works well with the commercially coated plates described above. The UV exposure system can be used with a mask aligner, but is only essential if exact alignment is required, or if multiple exposures are to be used; extended low power UV sources can also be sufficient, but could require exposure times. For exposure, the photomask is placed over the coated wafer and the photoresist irradiated with UV light through the mask. If a film mask is used (flimsy in nature), a clean bare glass plate is placed over it to obtain intimate contact with the surface of the photoresist (i.e., to hold it flat) and ensure accurate transfer of the image. The exposed glass is placed in a developer solution and, in the case of a positive photoresist, the photoresist that was exposed to the UV radiation is removed, revealing the underlying chromium layer (see Figure 10.3). In contrast, negative photoresist becomes insoluble where the UV radiation was incident,<sup>36</sup> therefore, the photoresist not exposed to the UV would be removed. In general, either a positive or a negative photoresist can be used as long as the photomask is designed accordingly. For most photoresists, a “hard bake” is required after the photoresist has been developed—this stabilizes it for further processing and eliminates additional light sensitivity. The time and temperature for hard baking varies based on the choice of photoresist, but normally these range around  $110^\circ\text{C}$  for 30 min and this can be carried out on a standard laboratory hot plate.

**FIGURE 10.3** Positive and negative photoresists. An illustration demonstrating the difference between (a) positive and (b) negative photoresists when used in photolithography.

25	3
10	0.6

The chromium layer exposed by removal of the photoresist is dissolved using a chromium etchant solution to reveal the underlying glass; all of the solutions used in the photolithography process (developer, chromium etchant, stripper) are commercially-available from a number of sources. Once the chrome is removed, the glass plate is immersed in an HF solution, which will etch away the exposed glass. The etching rate is dependent on the HF concentration of the solution and the type of glass. Borosilicate glass etches very slowly, and higher concentrations of HF are normally used with this glass; soda lime glass etches rapidly due to the high concentration of ions in the glass, and buffered etch solutions utilizing ammonium fluoride are often used to control the etch rate. The etch rate is also dependent on the final depth required for the features in the device, as long exposures to HF solution begin to consume the photoresist and chrome protective surfaces, causing pitting in the areas where etching was not desired. At the same time, etching at excessively rapid each rates can cause irregular surfaces to be formed on the bottom and walls of the channel, and other components are often included in the etch solution to ameliorate this effect. An exemplary etch solution for borosilicate glass is 10% HF/10%  $\text{HNO}_3$  in water and provides an etch rate of approximately  $0.6 \mu\text{m}/\text{min}$ , which will decrease as the solution is used. Table 10.1 provides a general guide for achieving different etch rates by varying the concentration of HF. Gentle rocking during the process also provides a cleaner etched surface, as precipitate forms during etching which can build up in the channel structures unless removed. For carrying out the etching, costly acid-resistant containers are often specified (e.g., Nalgene), but better, lower-cost alternatives can be

reusable polypropylene food storage containers; the polypropylene is completely HF resistant, and these containers have tight-fitting, spill-proof lids that make it easy to store the HF solutions when not in use. Once the etching is complete, the protective layer of baked photoresist is removed using a photoresist stripper, and the underlying chrome layer is removed using the chromium etchant.

One important aspect to bear in mind with this process is that glass is isotropically-etched by HF meaning that the glass structure is etched laterally at the same time it is etched deep—this results in hemispherical or U-shaped channels. As a result of this phenomenon, side etching of the glass quickly undercuts the protective chrome layer that has been deposited on top of the substrate, resulting in a top channel width that is slightly larger than what would be expected. This widening at the top occurs in concert with depth etching and must be taken into account when determining the depth of the etch and used accordingly to define the width of the channel designed into the mask. While this places limitations on the possible dimensions of structures that can be attained, and does not allow for high aspect ratio structures in finished glass devices, this can be advantageous in two important ways. The first is that isotropic etching provides a simple and inexpensive method for determining the depth of the etched structures. A microscope containing an eyepiece reticule can be used to measure the channel width at the top of the structure (the distance between the chrome flanking the sides of the structure). The etch depth can be calculated by

$$\text{Depth} = (\text{top width of channel} - \text{original width})/2,$$

where the top width of the channel is measured using the microscope and the original width is known from the mask design, or it can be measured prior to etching. This method provides an approximate depth of the channel, and can be used for most applications. Exact measurements of the etch depth can be obtained using a profilometer in cases where knowing the depth is critical. A traditional profilometer uses a stylus tip which is mobilized across the surface; its vertical deflection, as it “profiles” the surface, provides measurements of surface features in the nano- to micrometer range. More recently, optical profilometers have been developed that provide similar information without the need for the stylus. In our hands, fabrication involves estimating an etch rate based on the chemical ratio of the etch solution or etch rates reported in the literature for the use of etch solutions of a particular composition. After a specific etch time, the glass plate is removed from the etch solution, immersed into a large volume of water to terminate the etching, then rinsed thoroughly with water, and the depth of the structure measured by profilometry. These measurements are used to empirically determine the etch rate for better control of timing to achieve a specific channel depth.

The second advantage of the isotropic etching is the ability to easily form weirs—an abrupt narrowing of the channel—for retaining beads of the appropriate size. Within the channel design itself, a line across the channel is left unexposed. As the exposed part of the channel etches, the chrome line across it is undercut from both sides by the side etching of the HF. As long as the line is less than twice the final depth, it will be completely undercut and removed during the etching process. Careful predetermination of the width of the line allows the final height of the weir to be controlled (i.e., when the etching from the two sides connect). A less reproducible method for generating weirs, but useful for etching different depths on a device with a single exposure, is to cover parts of the exposed glass with an HF resistant tape during the initial part of the etching process. The deeper desired features can be etched part way and the tape removed for the remaining etch time.

### 10.3.2 DRILLING AND DICING GLASS MICROCHIPS

Once the etched layer containing the desired microchannel structures is completed, access holes at the entrance and exit location of each channel must be fabricated in either the etched plate or a cover plate. The simplest and most popular method involves drilling holes through the glass with a 1.1 mm diamond-tipped drill bit using a simple Dremel tool and miniature drill press, both of

which are available at a local hardware store.<sup>37</sup> Slight submersion of the glass plate in water while drilling prevents heating of the drill bit, eliminating wear of the cutting surface and allowing the bits to be reused multiple times (however appropriate precautions must be taken, as this is a power tool connected to a high-voltage power source). Silicon carbide drill bits can also be used for drilling glass and are also readily available in a variety of diameters. More complicated drilling can be achieved using a computer numerical controlled (CNC) mill, which is a more expensive option for drilling holes, but may be a good choice if accurate placement of the hole location is required or if a large number of holes are required in a device.<sup>38</sup> A simple program guides the CNC mill to each of multiple locations on a glass substrate in the  $X$ - $Y$  plane, with an accuracy in a simple system down to  $\sim 5$   $\mu\text{m}$ , as well as controlling the speed and drilled depth (the  $Z$ -axis). While less efficient on simple chip designs, or initial prototypes because of the setup time involved (alignment in particular), it is extremely useful for device designs that contain multiple access holes or designs that will be utilized multiple times. We have utilized this system to drill holes in a wafer containing 8 chips each with 20 holes.<sup>39</sup> Alternative methods for generating holes in glass substrates are also available, such as laser ablation,<sup>40</sup> but these are mainly used with substrates that are not amenable to standard drilling or in situations where very small holes are required.

In addition to drilling, cutting the glass plates is often required. Glass substrates used to fabricate microchips are commonly 4"–6" in diameter—those etched in our laboratory are normally 5"  $\times$  5" in size—but the final dimensions of the devices are significantly smaller. Consequently, each mask will contain multiple devices to be fabricated in a single glass plate during the etching process. Each of the individual devices, along with the corresponding cover plates, needs to be diced prior to the bonding step. Scoring and snapping is the traditional method for cutting glass, which utilizes a diamond-tipped scoring tool for scoring the glass on one side, followed by application of pressure to the other side so as to snap it. While this method is simple and easy to employ, it is not foolproof as the glass does not always break along the scored line, and requires both practice and confidence to master. A more accurate and reliable way to dice the microchips utilizes a glass-cutting saw with a thin diamond-edged blade. While wafer saws created for the microelectronics industry are available for this purpose, a simple and inexpensive option is to use a commercial ceramic tile saw (available at hardware stores). The blade on a tile saw is normally designed for grinding away the tile during cutting, but this blade is easily replaced with a thin diamond-edged blade designed for the more expensive wafer saws. This provides a simple method for cutting the glass wafers into individual devices without worrying about cracking or breaking the etched plate at unwanted locations.

### 10.3.3 GLASS MICROCHIP BONDING TECHNIQUES

The most common glass bonding technique is thermal bonding, where the etched glass chip and cover plate are properly aligned, brought into intimate contact and placed into a programmable, high temperature oven where heating to 640–690°C for roughly 6–8 hours is required for annealing the glass. While thermal bonding is simple in principle, it is the slowest and, arguably, the most unpredictable step in microchip fabrication procedure. There are two main aspects that play a role in achieving successful thermal bonding, cleanliness and contact. Any organic residue on the glass plates will prevent them from annealing, thus the surfaces of the etched and cover plates are often cleaned using piranha wash (3:1 mixture of concentrated  $\text{H}_2\text{SO}_4$ : $\text{H}_2\text{O}_2$ ) before assembly. An easier method involves simply wiping the plates with an ammonia-based window cleaner to thoroughly clean the glass surface; however, use of this method may result in partially unbonded devices that will never bond completely. Wiping the glass with lint-free wipes prior to assembly is advantageous as any glass particles that might have adhered to the surface during the glass cutting or drilling procedures will be removed. Care must be taken in wiping the glass plates in this manner as the edges can be sharp. Once cleaned, the top and bottom must be aligned and pressed together to achieve intimate contact between the two plates. This is easily detected by the formation

and disappearance of “Newton rings” (rainbow circles) that form when the distance between the two plates approaches the wavelengths of visible light. Although the float glass is manufactured to be optically flat, the processing alters the surface enough that significant pressure (under heat) is required to achieve this intimate contact. This can be achieved with small individual weights or a press, all the while, careful not to stress the glass to the point that it breaks. Simply squeezing the glass plates between ones thumbs can often achieve some areas of intimate contact, and a drop of water to wet the surface and keep the plates aligned during oven loading will also increase the chances of success. Dust or glass particles between the plates are easily detected after assembly (Newton rings), at which point, the plates must be disassembled and cleaned. Putting the plates together in a cleanroom or laminar flow hood assists in avoiding some of these problems, but equal success can be achieved directly in the laboratory environment. The assembled device (etched and cover plates) are placed between two polished graphite sheets or ceramic plates in a high temperature furnace, with or without a weight ( $\sim 5$  kg) placed on top to apply additional pressure during the heating process. The bonding cycle is normally performed in four steps, a rapid heating up to about  $550^{\circ}\text{C}$ , a slow heating up to the annealing temperature ( $640$ – $690^{\circ}\text{C}$ ), a hold at the annealing temperature ( $3$ – $10$  h), and an unforced cool-down step that allows the glass to cool slowly back to room temperature.

Multiple bonding cycles are often used to generate devices that are completely bonded. The annealing temperature in the step program is normally raised  $5^{\circ}\text{C}$  with each subsequent bonding step, as long as the melting temperature of the glass is not exceeded. Two issues to be aware of in the high temperature bonding procedure are that the graphite or ceramic used to sandwich the fabricated devices must be polished, otherwise imperfections or roughness in these may be transferred to the outer surface of the glass devices, giving them a frosted appearance or creating unwanted features in the surface that can interfere with optical detection and visualization of the channels inside. In addition, above certain temperatures (e.g.,  $\sim 670^{\circ}\text{C}$  with borofloat glass), the glass will fuse to the ceramic plates during the annealing process. To prevent this, a liquid graphite coating is applied to the ceramic plates, allowed to dry, then polished flat before the glass chips are placed between them.

In addition to high temperature bonding, a number of other bonding procedures have been reported (described in the Section 10.2). These procedures are most often used when additional functionality is to be incorporated into the chip. Most often this is metal sputtered onto the microchip architecture for electrodes or electrochemical detection, but could also include modification to the channel surface or incorporation of materials that cannot withstand the high bonding temperatures. In these cases, alternative cleaning methods may also need to be employed and the protocol for microchip bonding altered.<sup>41</sup>

#### 10.3.4 POSTBONDING CLEANING OF GLASS MICRODEVICES

Owing to the high temperatures and long dwell times associated with the thermal bonding steps, the surface of the glass within the channel becomes dehydrated, which will ultimately affect not only the electroosmotic flow (EOF) in the channel, but also reactions on the glass surface important for permanently or dynamically coating the channels. Rehydrating the glass surface involves increasing the ability to wet the glass usually through the formation of hydroxyl groups in an isolated or geminal formation; this results in an increase in reproducible electrophoretic separations and allows for consistent coating of the channels. While many techniques have been suggested as effective for cleaning glass microchannels, adequate rehydration is required after the devices are bonded, and a simple rinse with NaOH is not sufficient for this purpose. Cras et al.<sup>42</sup> evaluated nine different popular techniques for glass cleaning and preparing the glass for silanization. We have had success adapting to borofloat, a technique described by Cras et al. for soda lime glass: a 30-min rinse with a 1:1 mixture of methanol:concentrated HCl, a thorough rinse with water, a 30-min rinse with concentrated  $\text{H}_2\text{SO}_4$ , followed by a second rinse with water.

**TABLE 10.2**  
**Comparison of Polymers and Glass Properties**

	Glass	PDMS	PMMA	PI
Polymer type	NA	Elastomeric	Thermoplastic	Thermoplastic
Glass temperature (°C)	525	−120	106	285
Useful temperature range (°C)	≤500	−40 to 50	−70 to 100	−73 to 240
Thermal conductivity (W/mK)	1.2	0.17 to 0.3	0.186	0.2
Visible transmittance (%)	>90	91	92	87
Surface charge (native)	Yes	Weak	Yes	No
Chemical resistance				
Acid	Excellent	Fair–good	Good	Fair–good
Solvent	Excellent	Poor	Poor	Fair
Alkalis	Excellent	Poor–fair	Excellent	Fair–good

The information for the polymer properties was adapted from Sun and Kwok<sup>43</sup> and Becker and Gartner.<sup>81</sup> The polymers listed include poly(dimethylsiloxane) (PDMS), polymethyl methacrylate (PMMA) and polyimide (PI). The information for the glass properties was obtained from the Schott website, specifically BOROFLOAT<sup>®</sup> 33.

## 10.4 FABRICATION OF POLYMERIC MICRODEVICES

The glass fabrication technique detailed above is used extensively, but for many first time microdevice researchers, the rapid prototyping technique first described by Whitesides and coworkers<sup>49</sup> using PDMS provides an easy starting point. Moreover, glass is not the ideal substrate for many applications, and for this reason, a variety of polymers have been utilized for fabrication of microchips. In general, polymers can be classified into three categories based on their properties: thermoplastics, thermoset, and elastomers.<sup>43</sup> Thermoplastics are a class of polymers that consist of unlinked or weakly cross-linked chains, which soften and flow when heated above their glass transition temperature ( $T_g$ ). Examples of these polymers include polymethyl methacrylate (PMMA), polycarbonate (PC), and polyimide (PI). Thermoset polymers<sup>44</sup> contrast thermoplastics in that they are heavily cross-linked and do not melt or flow upon heating; examples include phenol formaldehyde and vinyl esters. The last category, elastomeric polymers, consists of weakly cross-linked polymer chains that form structures, which remain flexible and elastic after polymerization; an increasingly popular example for microfluidic device fabrication is PDMS. A described list of polymers from each class that have been used as having utility for microfluidic devices and their associated properties, can be seen in Table 10.2. The choice of substrate is dictated by a range of variables, such as the application of interest, the available materials and fabrication, and the solvents/reagents to be used, to name a few. For example, PI does not have an inherent surface charge and channels in PI would require surface treatment in order to perform separations requiring a substantial EOF. This section will focus on PDMS because of its ease of use; chapters in this volume written by DeVoe and Lee (Chapter 33), Carrilho (Chapter 41), Woolley (Chapter 51) and Henry (Chapter 52) provide details on the fabrication of microdevices from other polymeric substrates.

Microdevices fabricated in PDMS have been used for electrophoresis<sup>45</sup> as well as a variety of other applications ranging from cell sorting<sup>46</sup> to combinatorial screening.<sup>47</sup> PDMS is a heterogeneous polymer exhibiting methyl on the surface, which imparts significant hydrophobicity; its surface structure is illustrated in Figure 10.4. It is flexible, inexpensive, and optically transparent (down to 280 nm) making it compatible with many optical detection methods.<sup>48</sup> Owing to the flexibility of PDMS, it easily forms reversible bonds with another flat surface through van der Waals interactions. The seal can easily be broken by peeling the PDMS from the surface intact, thus yielding a single piece reusable in this manner; irreversible bonds can also be formed between PDMS and a number of other materials including glass and PDMS itself (discussed in detail below).<sup>48,49</sup> Owing to the

**FIGURE 10.4** Chemical structure of PDMS at the surface. (Adapted from <http://mrsec.wisc.edu/Edetc/background/PDMS/index.html>)

popularity of PDMS for microfluidic devices, a number of reviews have been written<sup>43,48,50</sup> detailing the procedures for making and using these devices. However, one must be cognizant of the drawbacks associated with the hydrophobic nature of the polymer.<sup>51</sup>

Numerous methods for device fabrication, based on the particular polymer selected, have been reported.<sup>43</sup> For fabrication of PDMS microdevices, rapid prototyping<sup>49</sup> and replica molding are two processes that are readily used. These methods allow for fabrication of microdevices in a matter of hours, with the only drawback being the inability to make channels smaller than 20  $\mu\text{m}$ . For rapid prototyping, a photoresist is spin coated onto a wafer in the same way it is for as with the glass fabrication; however, the photoresist for this application must be as thick as the desired depth of the channels and a photoresist created from SU-8 is used most often for this purpose. Photolithography is used to transfer the fluidic design from the mask to the photoresist, but in this case, the SU-8 remains on the wafer where the channels and chambers are desired in the PDMS surface. With this approach the SU-8 forms a master that can be used repeatedly for replica molding to fabricate devices. This involves simply casting the polymer over the master to make the fluidic layer that can be sealed to another piece of PDMS or a glass cover plate.

### 10.4.1 FABRICATION OF THE MASTER

A common method for fabricating PDMS microfluidic devices is to use a silicon wafer and SU-8 photoresist. To assist in adhesion of the photoresist to the Si wafer, a cleaning step and/or a surface treatment with hexamethyldisilazane (HMDS) is performed prior to spinning on the photoresist. Placing the wafer into a 10% (v/v) HF bath for roughly 1–2 min will remove surface silanols, rendering the surface hydrophobic; piranha wash has also been used for this purpose.<sup>52</sup> Treatment of Si wafers with HMDS can be performed simply by rinsing the wafer with methanol, spinning a small amount of HMDS onto the surface and baking at 105°C for 5 min before spinning on the photoresist. Either method should provide a surface adequate for adhesion between the Si wafer and SU-8. When spinning the photoresist onto a blank Si wafer, the viscosity of the SU-8 as well as the speed and duration of the spin will dictate the thickness of the SU-8 layer (and therefore the depth of the channels in the PDMS). SU-8 is available in a number of formulations designed specifically for achieving particular photoresist thickness upon spin coating. A soft bake is then performed to evaporate the solvent from the SU-8 layer and improve the adhesion of the resist to the Si wafer—this step can be accomplished on a hot plate and is best performed at 95°C (the heating time is dependent on the thickness of the photoresist). Standard photolithography methods are used to transfer the image from the mask to the photoresist, where the exposed SU-8 is cross-linked by the UV light to make it insoluble in the developer (propyleneglycolmethylether acetate-PGMEA). The master is then placed into the developer to remove the uncrosslinked photoresist, leaving the design that is

desired in the PDMS as a raised structure on the surface. The final step involves a hard bake of the master (done at 105°C for at least 15 minutes depending on the thickness of the photoresist) which stabilizes the photoresist. To assist in removal of cured PDMS from the master, the SU-8 master can be silanized through using vapor deposition by simply placing it into a chamber with a tridecafluoro-1,1,2,2-tetrahydrooctyl-1-trichlorosilane solution, essentially making the surface a nonstick-type coating.

For all steps that involve heating, there are several noteworthy details. Attention must be paid to the flatness of the surface used for the soft and hard baking steps, particularly if a hot plate is used. If the surface is not heated evenly, there could be an uneven distribution of the SU-8 layer, causing unwanted variation in structure depth in the PDMS microchips fabricated from the master. The transition rates associated with the heating and cooling are also important and should not occur rapidly. The coefficients of thermal expansion for SU-8 and the Si wafer are very different, and if the heating/cooling step is expedited, the SU-8 layer could delaminate from the wafer. In our experience with using a hot plate for heating, it may be best to use a separate hot plate set to 65°C for an intermediate heating step prior to bringing the master to 95°C on a second hot plate.<sup>52</sup> The master need only be exposed to 65°C for about 1–2 min before transfer to the higher temperature.

This method for fabrication of a master is the traditional method, but does require access to a cleanroom and instrumentation for spin coating the photoresist to the desired thickness as well as exposing the photoresist to UV light. A master for PDMS molding can be fabricated out of any material; however, be aware that there are predefined limitations on the size of the features that are set by the method used to generate the master. Micromachining capabilities can be used to generate a master from metal substrates or other polymers (such as PMMA) that work just as well as the traditional method, but removal of PDMS from the master after the casting process can be an issue. We have found micromachined Teflon to be an excellent substrate for fabrication of masters, particularly when it comes to ease of removal of the PDMS. A distinct advantages of this approach is that the mold can be heated to more rapidly cure the PDMS without destroying or altering the master in the process.

#### 10.4.2 PDMS DEVICE FABRICATION

Assuming a master of sufficient quality has been created, fabrication of the PDMS microdevice can be attempted. PDMS is purchased as a two-component system consisting of the elastomeric base and a curing agent, both in liquid form at room temperature. Sylgard 184 (Dow Corning) is the most widely-used PDMS formulation, which uses a base:curing agent ratio of 10:1 (by weight as recommended by the manufacturer). Harder or stickier polymers can be created by varying the ratio of the two as needed for a particular application. Once the two components are mixed thoroughly, the mixture should be degassed to remove any air bubbles; this can be accomplished by placing the PDMS into a vacuum chamber and applying adequate vacuum to gently degas the PDMS. The master should be placed in a container to hold the liquid PDMS, which is then slowly poured over the master (taking care to avoid introducing bubbles) and allowed to cure. At room temperature, at least 18 hours is required for the PDMS to completely crosslink, but this time can be reduced by increasing the temperature. For example, at 40°C the PDMS will cure in less than 4 h, and the process will only consume 2 hours at 70°C. A PDMS cover plate for the device can be fabricated simultaneously, by pouring additional PDMS over a blank Si wafer and allowing it to cure at the same time. Once the PDMS has cured, the device can be easily cut to size with a razor blade, and access holes introduced into the device using a simple hole punch.

#### 10.4.3 PDMS BONDING

Bonding of PDMS devices, in general, is much simpler than the thermal bonding required for glass devices. To obtain a reversible bond between PDMS and any number of complimentary substrates

(glass, silicon, or another piece of PDMS), a cleaning step must be performed to ensure that the seal between the fluidic layer and the cover plate is water tight, at least to the extent that it can withstand the pressures associated with flow through the device. Cleaning the surfaces to assure no dust or particles are present on either surface is a must, followed by rinsing the PDMS thoroughly with ethanol and allowing to dry. The layers are then gently pressed together manually, starting at one corner and making sure no air bubbles are trapped between the two surfaces. Because the bonding is reversible, if air bubbles do appear, or if particles remain on the surface, the layers can be separated (by simply peeling them apart), recleaned, and rebonded. A more permanent seal can also be obtained, both by activation of the PDMS surface using either a plasma oxidizer (plasma cleaner)<sup>48,49</sup> or a UV source that generates ozone near the surfaces to be activated. This activation of the surface is immediately followed by manually pressing the layers together, allowing the two surfaces to react and form a permanent bond; curing the devices at 80°C for 2.5 hours aids in improving the avid nature of the bonding.

A clever alternative bonding procedure for sealing PDMS to itself was reported by Quake and coworkers and involves altering the elastomer:base ratio in the two layers.<sup>53</sup> They utilized a ratio of 20:1 for the fluidic layer and 5:1 for the cover layer, so that when the device was oven-bonded, the two layers fused together as a result of the excess curing agent in one layer and excess base in the other. This method of bonding completely eliminates the seam between the two layers, negating the opportunity for fluid leakage between the layers.

#### 10.4.4 PDMS SURFACE

After the PDMS device has been fabricated, the separation channel (or other structures) may require surface modification to suit the needs of the chemistry desired. Unmodified PDMS is hydrophobic with no charge,<sup>51</sup> therefore yielding a very weak EOF. One approach to decreasing the hydrophobicity in PDMS surface is to invoke the use of the plasma cleaning method prior to bonding. Through the introduction of ionizable silanols created by the plasma, this method temporarily renders the surface hydrophilic, allowing for direct use in this state or providing the option of further surface modification. However, the user should be aware that this effect is only temporary, lasting several tens of minutes to a few hours (depending on the system and the oxidation process)—consequently, expediency in cleaning and assembling is advised.<sup>54</sup> For more information about altering the surface of PDMS, please refer to Chapter 52 by Henry and coworkers.

### 10.5 PERFORMING MICROCHIP ELECTROPHORESIS

From the earliest inception of the microchip as an analytical platform,<sup>1,55</sup> rapid separations were demonstrated. The major components required for microchip-based electrophoresis (ME) include a detection system, a power supply, and a computer with programmable software for data collection and control of the applied voltages and data collection/manipulation; a schematic diagram illustrating these components can be seen in Figure 10.5. While there are a number of different detection systems that can be utilized with microchips (see Chapter 45 by Karlinsey and coworkers), a fluorescence detection system (a homemade fluorescence microscope at its core), is the most widely utilized. There are several parameters to consider when choosing a power supply, including the number of voltage outputs required and the range of electric fields that are desired. For a standard “cross-t” chip design, a minimum of four voltage outputs are required to control the sample injection and separation. As the complexity of the chip design increases, more outputs may be necessary. One of the benefits of glass devices is the inherent ability to dissipate heat; consequently, reasonably large voltages can be applied and dual-polarity, high-voltage supplies are typically used. In addition, the holes drilled into the microfluidic device may not be large enough to accommodate a sufficient volume of buffer to allow for electrical contact with the platinum electrodes during the separation. The simplest solution

**FIGURE 10.5** A schematic diagram of an LIF system. The laser beam is reflected up by a dichroic filter and focused into the separation channel by a microscope objective. The resultant excitation passes back down through the dichroic and bandpass filters, and is directed onto the PMT. The computer is used to collect a voltage output from the PMT proportional to the fluorescence detected. A power supply is used to apply the appropriate voltages to the microchip reservoirs, to perform electrophoresis.

for obtaining expanded volume reservoirs involves cutting the large ends off of pipette tips and gluing them onto the chip to act as reservoirs—more recently, commercially-developed reservoirs for microchips have become available.

A detection system is required to track the progress of the separation, and with the increasing popularity of microchips for separations, a variety of different detection options are now available. By far, the most prevalent detection system described in the literature is laser-induced fluorescence (LIF). Chapter 45 by Karlinsey and coworkers not only provides a guide to selection of the components for LIF, but also easy-to-follow strategies for alignment of the optics in the LIF system (as well as reviewing other detection modes used in microfluidics). The components used in an LIF system are a light detection module, such as a photomultiplier tube or charge-coupled device (CCD) camera, a laser source, optics for alignment (to guide excitation light in and collect emitted light out) for efficient detection, a computer with reasonable processing speed for data collection, and a user-friendly software for interfacing with the hardware. LabVIEW software (National Instruments) is commonly used as the interface, and allows for easy application-specific computer programming to provide software interfaces that provide exquisite control over data collection and control of the detection system.

### 10.5.1 ELECTROPHORETIC SEPARATIONS

When performing electrophoretic separations, the cross-t design originally proposed by Verheggen et al.<sup>5</sup> for electrokinetic (EK) injection of sample is the most popular; Figure 10.6a shows a typical cross-t design. Using the appropriate buffer for the separation of interest, the channel surface must be conditioned in a manner not too dissimilar to those processes used with capillary systems. If the separation to be performed requires EOF, the rigorous cleaning method suggested in Section 10.3.4 is recommended. All channels of the device are filled with buffer along with the reservoirs to ensure electrical contact between the platinum electrodes and the solution. A larger volume of buffer in the reservoirs minimizes problems with buffer depletion which can have adverse effects on the separation (see Chapter 1 by Landers). Consistent with the scheme in Figure 10.6a, the sample is placed in the reservoir SI and a voltage applied between SI and SO to allow for mobilization of sample from reservoir SI to reservoir SO. After the voltage has been applied for a predetermined amount of time, voltage is applied to the BO and BI reservoirs to electrophorese the sample (down) into the separation channel, thus, completing the injection process. The detection system, in this case, the incoming laser light and the photomultiplier tube (PMT), are positioned at a point in the separation channel

**FIGURE 10.6** Schematic representation of microchip electrophoresis device designs (a) shows a traditional cross-t design while (b) shows an offset cross-t. The reservoirs are labeled as follows: SI is the sample inlet, SO is sample outlet, BI is buffer inlet, and BO is buffer outlet. A closer view of the cross-t can be seen in the dotted boxes during sample injection and separation; the sample is in gray and the + and – represent the position and what type of voltage is being applied.

commensurate with providing the necessary effective length for the separation—the sample analytes passing that detection point are excited and the resultant fluorescence collected.

For sample injection on a microdevice, a few different modes of EK injection have been reported. Ramsey and coworkers described a floating injection, in which the BI and BO reservoirs are both floating during the sample injection; this can lead to a variable volume plug due to diffusion.<sup>56</sup> A “pinched” injection allows for a constant-volume injection by also pumping buffer from the separation channel along the sample channel, minimizing the length of the plug.<sup>56</sup> Another injection mode involves slightly modifying the device design to incorporate an offset cross-t.<sup>57</sup> With this design, the incoming and outgoing channels are offset relative to the separation channel, thus elongating the sample plug length to be injected (Figure 10.6b). As with EK injections in capillary systems, there is a bias toward higher mobility analytes when performing EK injections in a microdevice. For example, when performing microdevice-based DNA separations with a sieving matrix, EOF is predominantly suppressed and the applied voltage is used to attract the (anionic) DNA across the sample arm to the sample outlet. However, long injection times (upwards of 60 seconds) are generally needed to obtain a representative sample in the cross-t because the mobility of smaller DNA fragments dominates during the initial phase of the injection process.

## 10.5.2 EXEMPLARY SEPARATIONS

In 1992, the first microchip-based electrophoretic separation was performed: two fluorescent dyes, fluorescein and calcein, were separated in a glass/silicon device utilizing LIF as the detection method.<sup>13,58</sup> While the analysis time was not significantly shorter than separations that could be accomplished using capillary electrophoresis (CE), there was a drastic reduction in the consumption of sample and reagents (i.e., electrophoresis buffer). Shortly thereafter, faster chip-based separations began to emerge in the literature. Seiler et al.<sup>59</sup> were able to separate three fluorescein 5-isothiocyanate (FITC)-labeled amino acids—arginine, phenylalanine, and glutamine—in less than 120 seconds using a separation distance of 9.6 cm; the electropherogram and conditions are shown in Figure 10.7. Ramsey and coworkers<sup>60</sup> decreased the separation length to 0.9 mm and were able to baseline resolve fluorescein and rhodamine B in a fraction of a second (150 milliseconds).

The early success of zone electrophoresis in a microchip gave way to DNA separations in microdevices. Mathies and coworkers were among the pioneers in this section of the microfluidics field, successfully resolving the restriction fragments of  $\Phi$ X174 *Hae*III in 120 seconds, which ranged from 70 to 1000 base-pairs in length.<sup>61</sup> This technology has since been advanced tremendously, with

**FIGURE 10.7** Microchip electropherogram of three 10  $\mu$ M FITC-labeled amino acids (Arg, Phe, and Gln in a pH 9.2 carbonate buffer). Electrokinetic injection was performed by applying a voltage of 250 V for 60 s ( $\sim$ 1-mm plug length). For the separation, a voltage of 10 kV was applied (6.3 kV between injector and detector). The separation distance from injection to detection was 9.6 cm. (Reprinted from Seiler, K., et al., *Analytical Chemistry*, 65, 1481, 1993. With permission.)

multiple groups having accomplished high-resolution separations (including DNA sequencing) and contributed advancements to this arena.<sup>62,63</sup> High-throughput DNA electrophoresis microchips have also been demonstrated to be functional (shown in Figure 10.8), with Paegel et al.<sup>38</sup> having multiplexed 96 channels on a radial capillary electrophoresis microchannel plate using a four-color rotary confocal fluorescence scanner for detection. Tapered turns have been included in the channel design to gain the effective separation length necessary in order to achieve the high-resolution required for DNA sequencing separations. On the detection front, Karlinsey and Landers<sup>64</sup> have shown the value of multicolor detection using an acoustooptical tunable filter (AOTF), an approach easily capable of detecting tens of different colors without any moving parts—they illustrate this with the detection of biowarfare agents. The electropherogram shown in Figure 10.9 provides an exemplary separation of a PCR-generated fragment amplified from *Bacillus anthracis* labeled with a TET dye and co-injected with a ROX-labeled sizing standard. They also show the utility of the AOTF for rapid channel alignment, sample scanning to collect spectral information from the desired analytes, and displayed the wide range of wavelength detection by performing simultaneous 19 wavelength detection. DNA separations on microdevices have also been successful for decreasing the analysis time associated with many post-amplification separations for molecular diagnostics, such as single-stranded conformation polymorphism (SSCP) for the detection of breast cancer,<sup>65</sup> tandem SSCP/heteroduplex analysis for detecting p53 mutations,<sup>66</sup> and the detection of biowarfare agents using an AOTF to detect multiple fluorescent signals.<sup>64</sup> These topics are covered in more detail in individual chapters in this book.

Electrophoretic separations involving proteins have also been successfully adapted to microfluidic devices utilizing electrophoretic techniques that go beyond capillary zone electrophoresis. Giordano et al.<sup>68</sup> separated partially purified human plasma using a microchip-based capillary electrophoresis-SDS analysis. Figure 10.10 shows a comparison between the glass microchip separation with an 11% acrylamide SDS-PAGE gel separation. Traditionally, this separation had been performed using capillary electrophoresis and UV-detection and suffered from poor detection limits. Through the use of a dynamic labeling dye, they were able to achieve improved sensitivity without a loss of resolution. Liu et al.<sup>69</sup> modified the separation channels in PMMA microchips using an atom-transfer radical polymerization to graft polyethylene glycol to the surface. This passivation

**FIGURE 10.8** Overall layout of the (a) 96-lane DNA sequencing microchannel plate. (b) expanded view of the injector. Each doublet features two sample reservoirs and common cathod and waste reservoirs. The arm from the sample to the separation channel is  $85\text{-}\mu\text{m}$  wide, and the arm from the waste to the separation channel is  $300\text{-}\mu\text{m}$  wide. The separation channel connecting the central anode and cathode is  $200\text{-}\mu\text{m}$  wide (c) expanded view of the hyperturn region. The turns are symmetrically tapered with a tapering length of  $100\text{ }\mu\text{m}$ , a turn channel width of  $65\text{ }\mu\text{m}$ , and a radius of curvature of  $250\text{ }\mu\text{m}$ . Channel widths and lengths are not drawn to scale. (Reprinted from Paegel, B. M. et al., *Proceedings of the National Academy of Science USA* 99, 575, 2002. With permission.)

**FIGURE 10.9** Amplified TET-anthrax fragment coinjected electrokinetically with a ROX sizing standard and separated under denaturing conditions. Data were obtained by the AOTF between emission wavelengths at 18 Hz, and the electropherograms are offset for clarity. Inset: sizing plot with ladder (diamond) and anthrax (square) peaks. (Reprinted from Karlinsey J. M. and Landers, J. P., *Analytical Chemistry* 78, 5593, 2006. With permission.)

step allowed for a separation with increased resolution of the components of bovine serum albumin (BSA) when compared to an uncoated PMMA micro device; the resultant electropherogram can be seen in Figure 10.11. Roman et al.<sup>70</sup> used micellar-EK chromatography in a PDMS device to provide high-resolution separations of standard proteins and hydrophobic molecules by adding SDS as a dynamic channel coating.<sup>71</sup> Isoelectric focusing has also been utilized successfully in the microformat for the separation of proteins with multiple detection techniques including LIF,<sup>72–75</sup> UV detection<sup>76</sup> and whole-column detection.<sup>76,77</sup> While most microchip IEF methods have used either

**FIGURE 10.10** Comparison of 11% acrylamide SDS-PAGE gel separation of partially purified human plasma with microchip-based CE-SDS analysis. Separation conditions include 25 mM Tris-CHES, 1 mM DTT, 0.1% SDS, 370 V/cm field strength, electrokinetic injection and 0.2% (v/v) NanoOrange (excitation 488 nm and emission 590 nm). (Reprinted from Giordano, B. C. et al., *Analytical Chemistry* 76, 4711, 2004. With permission.)

**FIGURE 10.11** Microchip CE of FITC-BSA. (a) Polyethylene glycol (PEG)-grafted and (b) untreated chip. Peaks 1a, 1b, and 1c are the three main components of the BSA sample. The PEG was grafted onto the PMMA surface using an atom-transfer radical polymerization. (Reprinted from Liu, J. et al., *Analytical Chemistry* 76, 6953, 2004. With permission.)

EOF- or chemically-induced mobilization of the focused zones past the detector, Guillo et al.<sup>75</sup> illustrated the use of on-chip pumping, generated by elastomeric diaphragm pumps in a three-layer device (one PDMS layer sandwiched by two glass layers), to mobilize the zones. The authors explored the effect of mobilization flow rates on the separation of two amino acids, L-lysine and L-histidine; the electropherograms can be seen in Figure 10.12.

Other biologically-relevant analytes, in addition to DNA and proteins, have been successfully separated on microchip. Figure 10.13 shows the successful electrophoretic separation of 8-aminopyrene-1,3,6-trisulfonate (APTES)-labeled N-linked oligosaccharides from ribonuclease B,

**FIGURE 10.12** Effect of mobilization flow rates on the overall separation performance of L-lysine and L-histidine. The glass fluidic layer was coated using a modified Hjerten coating. The samples were labeled with FQ. The focusing step was performed at 7.6 kV for 6 min, and then the mobilization step was initiated. Valve actuation conditions for mobilization: actuation vacuum: 60 kPa; actuation pressure ranging from 3 to 20 kPa. (Reprinted from Guillo, C., et al., *Lab on a Chip* 7, 117, 2007. With permission.)

**FIGURE 10.13** Microchip electropherograms of 8-aminopyrene-1,3,6-trisulfonate (APTS)-labeled N-linked oligosaccharides from ribonuclease B (A) and APTS-labeled oligosaccharide ladder (B). Experimental conditions:  $E_{sep} = 300$  V/cm, 0.5% methyl cellulose in 20 mM phosphate buffer (pH 6.66). (Reprinted from Dang, F., et al., *Journal of Chromatography A* 1109, 141, 2006. With permission.)

using microchips fabricated in PMMA.<sup>78</sup> The authors achieved separation in a channel that had a 30-mm effective separation length and have also extended this work to include fast profiling of N-linked complex oligosaccharides released from three other glycoproteins. The separation of lipids, an area of growing interest, has also been accomplished on microchips. Lin et al.<sup>79</sup> reported on the separation of anionic phosphoinositides on a single-sipper microdevice (Figure 10.14). Once a method for successful electrophoretic separations was established, the authors used their technology to monitor the activity of lipid-modifying enzymes. They were able to show the applicability of the method to high-throughput screening applications by demonstrating phospholipase A<sub>2</sub> in a 384-well format; this technology offers an attractive alternative to current methods that involve radioactive substrates. In an elegant report, Vrouwe et al.<sup>80</sup> showed the ability to detect lithium in blood samples down

**FIGURE 10.14** Separation of anionic phosphoinositides on a single-sipper microchip. Separation conditions: sample injection time, 0.5 s; buffer time, 800 s; field strength: 530 V/cm; pressure,  $-1.65$  psi (vacuum); lipid concentration:  $1.3 \mu\text{M}$  each and labeled with BODIPY FL on the acyl chain. (Reprinted from Lin, S., et al., *Analytical Biochemistry* 314, 101, 2003. With permission.)

**FIGURE 10.15** Electropherogram of an (a) aqueous calibration mixture containing 140 mmol/L sodium and 2 mmol/L lithium, (b) citrated whole blood enriched with 2 mmol/L lithium, (c) whole blood without anticoagulant, and (d) heparinized plasma from a patient on lithium therapy containing 0.62 mmol/L lithium. (Reprinted from Vrouwe, E. X., et al., *Clinical Chemistry* 53, 121, 2007. With permission.)

to levels of 0.15 mmol/L. Figure 10.15 shows an exemplary separation from samples that included whole blood, citrated whole blood, and heparinized whole blood while detecting sodium, calcium, magnesium, and lithium. Through the incorporation of a plexiglass sample collector, the authors have created a functional device capable of point-of-care analysis. To further challenge their device, the plexiglass sample collector was tested with a blinded study where they tested five-patient serum samples on the microchip, and were able to detect lithium concentrations similar to that determined using ion-selective electrodes.

## 10.6 CONCLUDING REMARKS

The purpose of this chapter has been two-fold. First, to highlight some of the basic methods and substrates that have been successfully utilized to create microfluidic devices. We have attempted to describe these methods, albeit at a rudimentary level, in a manner that allows for someone skilled in CE to fabricate, functionalize and execute microchip-based electrophoresis. In addition to the basic

methodologies provided here, the second aim was to provide a few ‘tricks of the trade’ from our own experience, ones that should enable a novice to create devices of standard cross-t design, or even more complex and innovative designs tuned to their specific applications. It is noteworthy that, this is not a comprehensive methods treatise on chip fabrication, and that every microchip fabricator, regardless of the substrate used, has their own ‘tricks of the trade’—methodology preferences that enhance their fabrication success with the substrate and design of choice. It is our goal that the methods given here (and in other chapters in this book) enable the reader to enter into the microchip fabrication arena where they can demonstrate the application of microfluidics in ways that, to-date, have not been revealed. But perhaps more important than enhancing the availability of microfluidics to researchers looking to adapt this analytical platform into their lab, we have enabled the novices of today to become the microfluidics leaders of tomorrow.

## 11.1 INTRODUCTION AND BACKGROUND OF AFFINITY METHODS

Affinity methods play a crucial role in modern life sciences. In addition to affinity purification, their applications include quantitative analyses of biomolecules, studies of biomolecular interactions, and selection of affinity probes and drug candidates from complex mixtures, such as combinatorial libraries. Conceptually, all affinity methods are based on noncovalent binding of a ligand (L) and a target (T) with the formation of a ligand–target complex (C):

where  $k_{\text{on}}$  and  $k_{\text{off}}$  are rate constants of complex formation and dissociation, respectively. The stability of the complex is typically described in terms of the equilibrium dissociation constant:

$$K_d = \frac{k_{\text{off}}}{k_{\text{on}}} \quad (11.2)$$

Methods for the measurement of equilibrium and rate constants can be classified into two categories: mixture-based and separation-based (Figure 11.1). The first category includes light

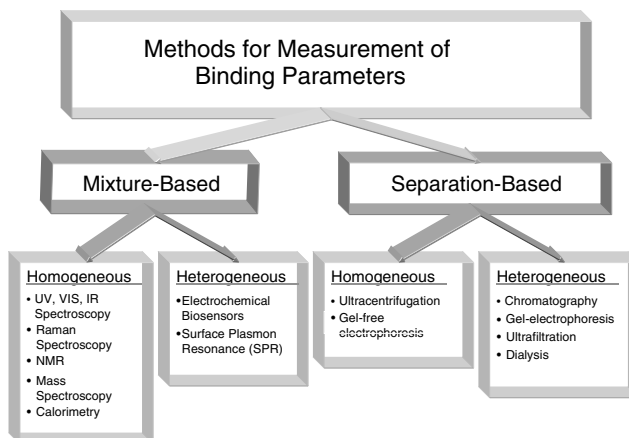

FIGURE 11.1 Classification of affinity methods.

absorption, fluorescence spectroscopy, nuclear magnetic resonance (NMR), Fourier transform infrared spectroscopy (FTIR), mass spectrometry (MS), Raman spectroscopy, potentiometry, and calorimetry. The separation-based methods include dialysis, ultrafiltration, ultracentrifugation, chromatography (liquid chromatography and thin-layer chromatography), and electrophoresis (planar and capillary electrophoresis). Separation-based methods can detect individual interacting components and/or complexes, thus avoiding the interference of other components.

Mixture-based and separation-based methods can be subdivided into two broad categories: heterogeneous and homogeneous binding assays. In heterogeneous assays, T is affixed to a solid substrate, while L is dissolved in a solution and can bind T affixed to the surface. In an advanced heterogeneous mixture-based technique such as SPR, T is affixed to a sensor that can change its optical or electrical signal upon L binding to T.<sup>1,2</sup> In SPR,  $K_d$  can be found in a series of equilibrium experiments. The concentration of L in the solution is varied and L and T are allowed to reach equilibrium. The signal from the sensor versus the concentration of L has a characteristic sigmoidal shape and  $K_d$  can be found from the curve by identifying the concentration of L at which the signal is equal to half of its maximum amplitude. The  $k_{off}$  value can be determined by SPR in a single nonequilibrium experiment in which the equilibrium is disturbed by fast replacing the solution of L with a buffer devoid of L. The complex on the surface dissociates in the absence of L in the solution, and the complex dissociation generates an exponential signal on the sensor.

Heterogeneous binding assays have certain advantages and drawbacks. The most serious drawback is that affixing T to the surface changes the structure of T. The extent of such change depends on the method of immobilization. The change in the structure can potentially affect binding of L to T. This problem is especially severe for L that binds to T through interaction with a large part of T. In addition, the immobilization of T on the surface may be time consuming and expensive. Moreover, nonspecific interactions with the surface are always a concern.

In homogeneous binding assays, T and L are mixed and allowed to form a complex in solution; neither of the molecules affixed to the surface. Complex formation is followed by either monitoring the changing physical–chemical properties of L or T upon binding. Such properties can be optical (absorption, fluorescence, polarization) or separation-related (chromatographic or electrophoretic mobility). Equilibrium experiments with varying concentrations of L can be used similarly to heterogeneous analyses to find  $K_d$ . Nonequilibrium stopped-flow experiments, in which L and T are mixed in a fast fashion and the change in spectral properties is monitored, can be used to find  $k_{on}$ .

Separation-based affinity methods can also be classified as kinetic or nonkinetic. Kinetic methods are those that do not assume equilibrium in reaction 1 and can thus be used for (1) quantitative affinity

analyses with “weak” affinity probes (high  $k_{\text{off}}$ ), (2) measuring  $k_{\text{on}}$  and  $k_{\text{off}}$ , and (3) selection of binding ligands with predefined  $k_{\text{on}}$  and  $k_{\text{off}}$ . Nonkinetic methods, in contrast, assume equilibrium and, thus, cannot serve for these tasks. The assumption of equilibrium in nonkinetic methods is not conceptually required; moreover, equilibrium cannot be maintained in separation-based affinity methods. Thus, all nonkinetic methods can be converted to kinetic methods by changing conditions and approaches for data analysis.

In general, homogeneous methods are preferable due to their simplicity and kinetic methods are preferable due to their enabling kinetic features. Until recently, the only mixture-based heterogeneous method with comprehensive kinetic capabilities was SPR. In this chapter, kinetic capillary electrophoresis (KCE) is described as a conceptual platform for separation-based homogeneous methods with comprehensive kinetic capabilities, which will find multiple applications in chemistry, biology, medicine, and drug discovery.

## 11.2 THEORY OF KINETIC CAPILLARY ELECTROPHORESIS

Kinetic capillary electrophoresis is defined as capillary electrophoretic separation of species that interact during electrophoresis.<sup>3–5</sup> Thus, KCE involves two major processes: affinity interaction of L and T, described by Equation 11.1, and separation of L, T, and C based on differences in their electrophoretic velocities,  $v_L$ ,  $v_T$ , and  $v_C$ , respectively. These two processes are described by the following general system of partial differential equations:

$$\begin{aligned} \frac{\partial L(t,x)}{\partial t} + v_L \frac{\partial L(t,x)}{\partial x} &= -k_{\text{on}}L(t,x)T(t,x) + k_{\text{off}}C(t,x) \\ \frac{\partial T(t,x)}{\partial t} + v_T \frac{\partial T(t,x)}{\partial x} &= -k_{\text{on}}L(t,x)T(t,x) + k_{\text{off}}C(t,x) \\ \frac{\partial C(t,x)}{\partial t} + v_C \frac{\partial C(t,x)}{\partial x} &= -k_{\text{off}}C(t,x) + k_{\text{on}}L(t,x)T(t,x) \end{aligned} \quad (11.3)$$

where  $L$ ,  $T$ , and  $C$  are concentrations of L, T, and C, respectively;  $t$  is time passed since the beginning of separation; and  $x$  is the distance from the injection end of the capillary. System 11.3 describes two basic processes, which are always present in KCE. Depending on species studied and a specific analytical setup, other processes, such as binding with complex stoichiometry, diffusion, adsorption to capillary walls, and so forth, can play significant roles in KCE. In such cases, mathematical terms, describing additional processes, must be added to system 11.3. The solution of system 11.3 depends on the initial and boundary conditions: initial distribution of L, T, and C along the capillary and the way L, T, and C are introduced into the capillary and removed from the capillary during separation. This solution can be found nonnumerically for specific sets of initial and boundary conditions and specific assumptions.<sup>6–9</sup> For KCE to be a generic approach, it is required that system 11.3 be solved for any set of conditions; such solutions can be found only numerically.

## 11.3 KINETIC CAPILLARY ELECTROPHORESIS METHODS

Every set of qualitatively unique initial and boundary conditions for system 11.3 defines a unique KCE method. Here we will describe six KCE methods: nonequilibrium capillary electrophoresis of the equilibrium mixtures (NECEEM), sweeping CE (SweepCE), continuous NECEEM (cNECEEM), short SweepCE (sSweepCE), plug-plug KCE (ppKCE), and short SweepCE of Equilibrium Mixture (sSweepCEEM). Table 11.1 contains drawings that schematically illustrate initial and boundary conditions and show the mathematical representation of initial and boundary conditions. It also contains representative functions  $L(t)$ ,  $T(t)$ , and  $C(t)$  for a fixed  $x$  for each method. The notion of equilibrium mixture (EM) refers to the mixture of L, T, and C at equilibrium, typically prepared

outside the capillary. The concentrations of the three components ( $\tilde{T}$ ,  $\tilde{L}$ , and  $\tilde{C}$ ) in the EM are interconnected through the equilibrium dissociation constant,  $K_d$ , as  $K_d = (\tilde{T}\tilde{L})/\tilde{C}$ .

### 11.3.1 NECEEM

Nonequilibrium capillary electrophoresis of the equilibrium mixtures (NECEEM) is a unique KCE method that facilitates finding both  $K_d$  and  $k_{off}$  from a single electropherogram.<sup>6</sup> Mechanistically, it is similar to previously introduced affinity probe capillary electrophoresis (APCE)<sup>10-12</sup> and falls

into a broad category of capillary zone electrophoresis (CZE).<sup>13–18</sup> APCE was introduced as being applicable to systems having suitably stable complexes where the dissociation rate constants are small in the scale of characteristic separation times. In other words, the characteristic time of dissociation is much longer than the characteristic separation time. That is why, APCE has been applied only to measuring equilibrium constants but not rate constants.

So far, NECEEM was used to study the interaction between several proteins and DNA such as an *Escherichia coli* single-stranded DNA-binding protein (SSB) and a fluorescently labeled oligonucleotide (ssDNA),<sup>6,7,19</sup> *Taq* DNA polymerase and its aptamer,<sup>19</sup> thrombin and its aptamer,<sup>20</sup> Tau protein and single-stranded and double-stranded DNA,<sup>21</sup> protein farnesyltransferase (PFTase) and its aptamer,<sup>22</sup> MutS protein and its aptamer,<sup>23</sup> h-Ras protein and its aptamer,<sup>24,25</sup> and Mef2c protein and double-stranded DNA it naturally binds.<sup>26</sup> It has also been used to study protein–peptide interactions.<sup>12</sup>

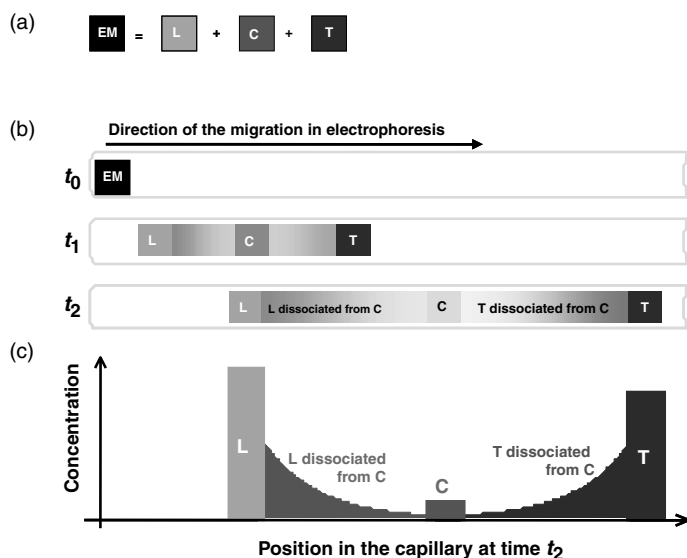

In NECEEM, a short plug of the EM is injected into the inlet of the capillary, which is prefilled with the run buffer. Separation is carried out with both inlet and outlet reservoirs containing the run buffer only. C continuously dissociates during electrophoresis. If separation is efficient, re-association of T and L can be neglected. The resulting NECEEM electropherograms contain three peaks of T, C, and L and two exponential “smears” of L and T, which occur from the dissociation of C whose migration times and areas are used to calculate  $k_{\text{off}}$  and  $K_{\text{d}}$  (Figure 11.2). The important feature of NECEEM is that a single electropherogram contains data sufficient for finding both  $K_{\text{d}}$  and  $k_{\text{off}}$ . NECEEM starts with the EM; therefore, it has a memory of the equilibrium necessary for finding  $K_{\text{d}}$ . Although a single electropherogram is sufficient to find both  $K_{\text{d}}$  and  $k_{\text{off}}$ , for accurate measurements of the constants and their experimental errors several experiments have to be performed. The essential feature of NECEEM electropherograms is that the areas of peaks and smears in them are proportional to the amounts of corresponding species. A single NECEEM electropherogram can be used for finding four measurable parameters required for the determination of  $K_{\text{d}}$  and  $k_{\text{off}}$  (Figure 11.3).  $A_1$  is the area of the peak corresponding to L, which was free in the EM.  $A_3$  is the area of the exponential smear left by L dissociated from C during the separation.  $A_2$  is the area of the peak corresponding to C, which remained intact by the time of passing the detector. Finally,  $t_{\text{C}}$  is the migration time of the complex.

The values of  $K_{\text{d}}$  and  $k_{\text{off}}$  can be calculated using the following algebraic formulas<sup>8</sup>:

$$K_{\text{d}} = \frac{[T]_0 (1 + A_1/(A_2 + A_3)) - [L]_0}{1 + (A_2 + A_3)/A_1}, \quad (11.4)$$

$$k_{\text{off}} = \frac{\ln((A_2 + A_3)/A_2)}{t_{\text{C}}}, \quad (11.5)$$

where  $[T]_0$  and  $[L]_0$  are total concentrations of T and L in the EM, which include free components and complexes. Advantageously, areas and migration time associated with a single species only (L in our example) are required. This simplifies the use of fluorescence detection because finding a strategy for labeling a single species is relatively easy. A major step in the method development for NECEEM involves finding conditions for good quality separation of L from C. Figure 11.3 shows an experimental NECEEM electropherogram. In this example, interaction between ssDNA and ssDNA-binding protein was studied. In the experimental electropherogram, the peaks have Gaussian-type shapes rather than rectangular ones presented in a schematic electropherogram in Figure 11.2. While measuring the areas, it is important to accurately define the boundary between them. The boundary between  $A_1$  and  $A_3$  can be found by comparing the peak of free L in the presence and absence of T. It was shown that the uncertainty in defining the boundaries between the areas leads to experimental errors in the range of 10%. This is an acceptable level of experimental errors for most applications. Alternatively, mathematical modeling of a NECEEM electropherogram can be used to find both  $K_{\text{d}}$  and  $k_{\text{off}}$  from the nonlinear regression analysis without the need to define the areas. Typically, the area method is used as a simple, fast, and acceptably accurate approach.<sup>8</sup>

**FIGURE 11.2** Conceptual representation of nonequilibrium capillary electrophoresis of equilibrium mixtures (NECEEM). (a) Components of the equilibrium mixture (EM): free ligand (L), free target (T), and the ligand-target complex (C). (b) NECEEM-based separation of L, T, and C. A short plug of the equilibrium mixture is injected into a capillary at time  $t_0$ . High voltage is then applied. It is assumed that T migrates faster than L; C typically has an intermediate mobility. Equilibrium fractions of free L and T migrate as individual zones, which do not change in time. The equilibrium fraction of C continuously dissociates during separation (time  $t_1$  and  $t_2$ ), leaving smears of L and T. By time  $t_2$ , only a fraction of C remains intact. (c) The graph shows concentrations of the separated components as functions of the position in the capillary at time  $t_2$ .

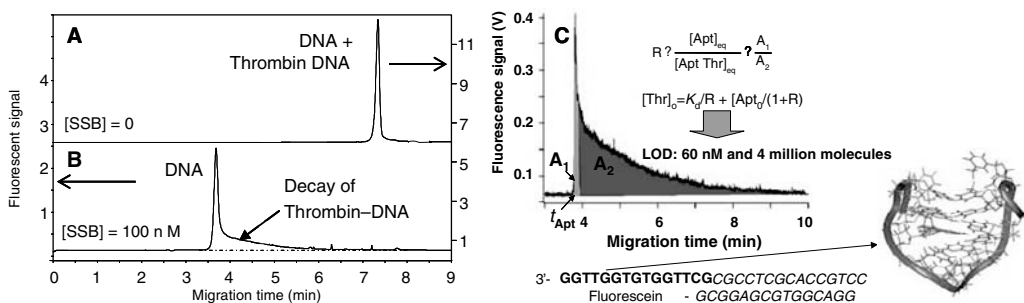

**FIGURE 11.3** Example of a NECEEM electropherogram for the interaction between fluorescently labeled ssDNA (ligand) and single-stranded binding (SSB) protein (target).  $t_C$  and  $t_L$  are the migration time of the complex and the ligand, respectively.

NECEEM-based determination of  $K_d$  and  $k_{off}$  is fast and accurate, and it has a wide and adjustable dynamic range. The upper limit of  $K_d$  values depends on the highest concentration of T available and can be as high as millimolar. This allows for the measurement of  $K_d$  values for very low-bulk affinities of naive combinatorial libraries.<sup>24</sup> The lower limit of  $K_d$  depends on the concentration limit

of detection; for fluorescence detection, it can be as low as picomolar. The dynamic range of  $k_{\text{off}}$  values is defined by the migration time of the complex, which can be easily regulated by the length of the capillary, electric field, or electro-osmotic velocity. The practically proven dynamic range of  $k_{\text{off}}$  spans from  $10^{-4}$  to  $1 \text{ s}^{-1}$ .<sup>6,8,12,19–21,27–29</sup> Although only one electropherogram is required for finding both  $K_d$  and  $k_{\text{off}}$ , the concentration of T (if L is used as a detectable species) should be within an order of magnitude from the  $K_d$  value. Titration of T with 10-time increments in concentration is recommended as the fastest way of finding suitable T. Furthermore, conducting several experiments may be required to find the experimental deviation of the  $K_d$  value. The equilibrium is typically established in the incubation buffer, whereas dissociation occurs in the electrophoresis run buffer. The values of  $K_d$  and  $k_{\text{off}}$  are, thus, measured for the incubation buffer and run buffer, respectively. If the incubation buffer and the electrophoresis run buffer are identical, then  $K_d$  and  $k_{\text{off}}$  are determined under the same conditions, and  $k_{\text{on}}$  can be calculated as  $k_{\text{on}} = k_{\text{off}}/K_d$ . It is typically possible to make the incubation and run buffers identical. An example of when such matching is difficult is when T is the protein, which requires a high salt concentration. CE cannot tolerate high salt concentrations in the run buffer because of the high Joule heating, which can deteriorate the quality of separation.

### 11.3.1.1 Affinity-Mediated NECEEM

To explain the rationale for affinity-mediated NECEEM, it needs to be emphasized that NECEEM requires good separation of free ligand from the target–ligand complex. If the separation is poor, the accuracy of the method with respect to the determination of rate constants and equilibrium constants decreases. Affinity-mediated NECEEM is based on the insight that adding to the run buffer a background affinity agent, which can bind free ligand but not the target–ligand complex, can improve the separation by changing the mobility of free ligand while not affecting that of the complex. Affinity-mediated NECEEM was demonstrated for interaction between thrombin and its DNA aptamer by using the single-stranded binding (SSB) protein from *E. coli* as a background affinity agent in the run buffer (Figure 11.4).<sup>20,30</sup> Hypothetically, affinity-mediated NECEEM can be also realized with a target-binding affinity agent, such as an antibody, instead of a ligand-binding agent, provided that the agent binds the target but does not bind the target–ligand complex. A serious assumption used in affinity-mediated NECEEM is that the affinity agent does not affect the interaction between the target and a ligand.

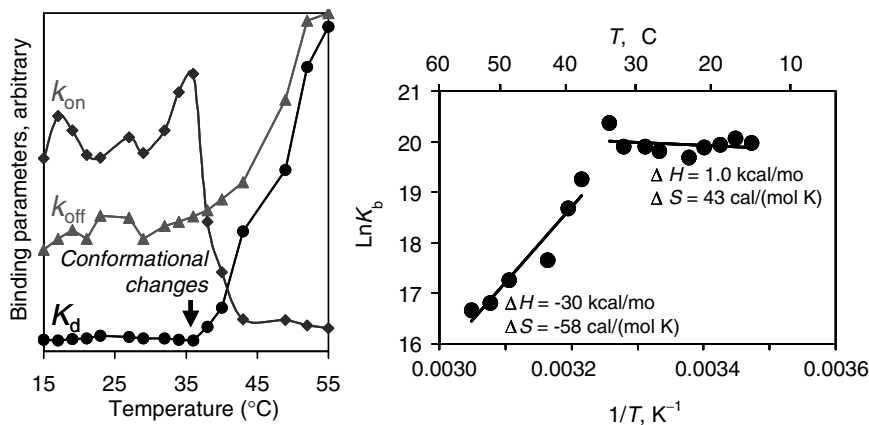

**FIGURE 11.4** Affinity-mediated NECEEM. (a) Separation of thrombin and its aptamer (DNA) in the absence of SSB in the run buffer. (b) Separation of thrombin and DNA in the presence of SSB. (c) Quantitative detection of thrombin without observing the peak of the complex and just uses a decay of the complex. The structure of the aptamer (bottom of c) for human thrombin (boldface) with an additional 16-nucleotide sequence and a fluorescein-labeled probe that is complementary to the additional 16mer sequence. Complementary strands are given in italics.

### 11.3.1.2 Temperature-Controlled NECEEM

Temperature-controlled NECEEM was developed to study thermochemistry of target–ligand interactions (protein–DNA interaction as one of the examples).<sup>19</sup> Knowing how temperature influences kinetic and equilibrium binding parameters of noncovalent protein–DNA interactions is important for understanding fundamental biological processes, such as gene expression and DNA replication.<sup>31–35</sup> It is also essential for developing analytical applications of DNA aptamers and DNA-binding proteins in affinity and hybridization analyses and in optimizing the polymerase chain reaction (PCR).<sup>30,36–38</sup> Conventional methods for thermo-chemical studies of protein–DNA interactions have limitations. Differential scanning calorimetry (DSC) and isothermal titration calorimetry (ITC) are not applicable to finding kinetic parameters.<sup>39–41</sup> SPR can serve to determine equilibrium and kinetic parameters but it is a heterogeneous method, which requires the immobilization of either DNA or protein on the surface of a sensor.<sup>42,43</sup> Being a homogeneous kinetic method, temperature-controlled NECEEM uniquely allows finding temperature dependencies of equilibrium and kinetic parameters of complex formation without the immobilization of the interacting molecules on the surface of a solid substrate. Moreover, it requires much lower quantities of the protein than DSC, ITC, and SPR. Two protein–DNA pairs: (1) *Taq* DNA polymerase with its DNA aptamer and (2) *E. coli* single-stranded DNA-binding protein with a 20-base long ssDNA were analyzed by temperature-controlled NECEEM (Figure 11.5).<sup>19</sup> Temperature dependencies of three parameters were determined: the equilibrium binding constant ( $K_b = 1/K_d$ ), the rate constant of complex dissociation ( $k_{off}$ ), and the rate constant of complex formation ( $k_{on}$ ). The  $K_b(T)$  functions for both protein–DNA pairs had phase-transition-like points suggesting temperature-dependent conformational changes in structures of the interacting macromolecules. Temperature dependencies of  $k_{on}$  and  $k_{off}$  provided insights into how the conformational changes affected two opposite processes: binding and dissociation. Finally, thermodynamic parameters,  $\Delta H$  and  $\Delta S$ , for complex formation were found for different conformations. With its unique features and potential applicability to other macromolecular interactions, temperature-controlled NECEEM establishes a valuable addition to the arsenal of analytical methods used to study dynamic molecular complexes.

Additionally, there is a bonus application of temperature-controlled NECEEM: a nonspectroscopic approach to determining temperature in CE (Figure 11.6).<sup>44</sup> It is based on measuring a temperature-dependent rate constant of complex dissociation by NECEEM. This work was demonstrated on the dissociation of a protein–DNA complex to show that the new method allows

**FIGURE 11.5** NECEEM-measured temperature dependencies of equilibrium and kinetic binding parameters and Van't Hoff plots used for the determination of  $\Delta H$  and  $\Delta S$  for complex formation for *Taq* DNA polymerase with its DNA aptamer.

**FIGURE 11.6** Temperature dependence of NECEEM electropherograms for SSB-ssDNA interaction (left panel), and calibration curve “ $k_{\text{off}}$  versus  $T$ ” (right panel).

for temperature determination in CE with a precision of  $2^{\circ}\text{C}$ . With a number of advantages over conventional spectroscopic approaches, NECEEM-based temperature determination will find practical applications in CE method development for temperature-sensitive analyses, such as hybridization and affinity assays.

### 11.3.2 SWEEPCE

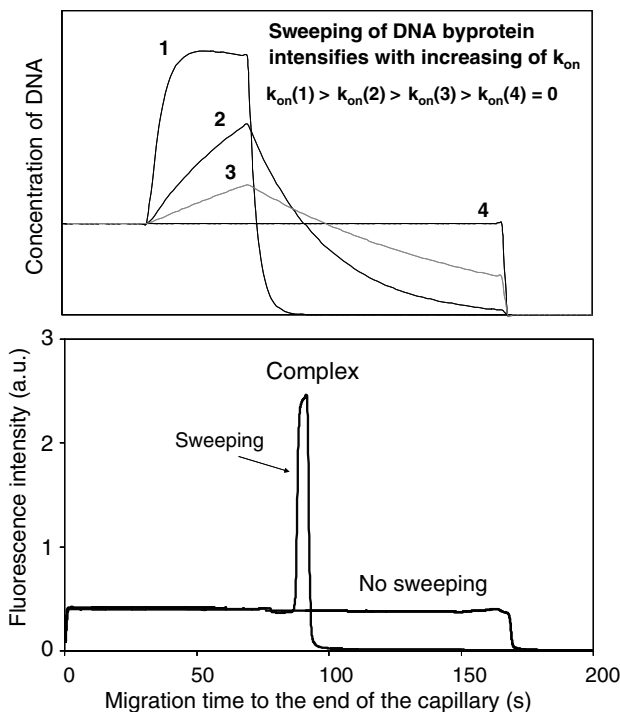

The monomolecular rate constant of complex dissociation,  $k_{\text{off}}$ , can be determined by either SPR,<sup>45,46</sup> or by NECEEM.<sup>6–8</sup> As for the bimolecular rate constant of complex formation,  $k_{\text{on}}$ , until now, the only technique available for its direct measurements was stopped-flow spectroscopy.<sup>47–49</sup> Stopped-flow spectroscopy relies on the change of spectral properties of either protein or DNA during complex formation. Such changes are often insignificant, which limits the applicability of stopped-flow methods to studies of protein–DNA interactions. SweepCE was introduced for directly measuring  $k_{\text{on}}$ , and demonstrated for studying protein–DNA interactions.<sup>50</sup> In contrast to stopped-flow spectroscopy, SweepCE does not rely on spectral changes of the protein or DNA upon complex formation. It requires only that electrophoretic mobilities of the protein and DNA be different, which is always achievable.

The concept of SweepCE is based on the sweeping of slowly migrating L by a fast migrating T during electrophoresis. The capillary is filled with L, while the inlet reservoir contains T and the outlet reservoir contains a run buffer. During electrophoresis, T continuously moves through L, causing continuous binding of T to L. Dissociation of C can also contribute to the resulting concentration profiles that contain a single peak of C and plateaus of T and L. The value of  $k_{\text{on}}$  for complex formation can be determined from the time-profile of T concentration using a simple mathematical model of the sweeping process. Mathematical analysis is an essential part of SweepCE. The method was demonstrated on the phenomenon of DNA sweeping by a DNA-binding protein in CE (Figure 11.7).

### 11.3.3 ppKCE

In ppKCE, the plugs of L and T are injected into the capillary prefilled with the run buffer. The inlet and outlet reservoirs contain the run buffer as well. During electrophoresis T moves through L causing the formation of C. When the zone of T passes L, C starts to dissociate. ppKCE can be considered as a functional hybrid of NECEEM and SweepCE. The resulting concentration profiles

**FIGURE 11.7** SweepCE is a first nonspectroscopic method for direct measuring of  $k_{on}$ . It is based on the sweeping of a slowly migrating ligand by a fast migrating target during electrophoresis. The value of  $k_{on}$  for complex formation can be determined from the time-profile of target concentration using a mathematical model of the sweeping process.

**FIGURE 11.8** ppKCE is a method for direct measurement of both rate constants,  $k_{on}$  and  $k_{off}$ . The resulting concentration profile is very similar to NECEEM with a smaller peak of a complex (area = C), a decay of the complex (area =  $L_{dis}$ ) and a free ligand (area =  $L_{free}$ ).

resemble those of NECEEM with a smaller peak of C and “smears” of T and L (Figure 11.8).<sup>3,9</sup> However, since ppKCE does not start with the EM of L and T, the resulting electropherogram does not have a “memory” of  $K_d$  but rather has a memory of  $k_{on}$  and  $k_{off}$ . Both  $k_{on}$  and  $k_{off}$  can, thus, be calculated from a single ppKCE electropherogram using areas of peaks and smears and

migration times of peaks. Calculation of rate constants of complex formation and dissociation from one experimental electropherogram is possible due to the developed simple mathematical approach without performing nonlinear regression analysis so that the method does not require expertise in mathematical modeling. So far, there has not been any method that allowed direct measurement of both rate constants. ppKCE is simple and robust. It requires only nanoliters volumes of reagents and can be readily adjusted for different ranges of both constants. This method will be useful for screening large libraries for drug candidates as well as the development of novel research and diagnostic tools.

#### 11.3.4 OTHER KCE METHODS

In cNECEEM, the inlet reservoir is filled with the EM while the capillary and the outlet reservoir contain the run buffer. During electrophoresis, C is separated from T, which moves faster, and from L, which moves slower. As a result, C continuously dissociates inside the capillary. Although dissociation is a prevalent process in cNECEEM, re-association can also contribute to the resulting concentration profiles, which are represented by smooth functions of  $T(t)$ ,  $L(t)$ , and  $C(t)$  with no pronounced peaks.

In sSweepCE, a short plug of T is injected into the capillary prefilled with L. Both inlet and outlet reservoirs contain the run buffer. T moves through L during electrophoresis causing both association of T and L and dissociation of resulting C to occur. The concentration profiles of T and C are peak-like, while that of L is a smooth function.

In sSweepCEEM, a short plug of T is injected into the capillary prefilled with the EM. Both inlet and outlet reservoirs contain the run buffer. During electrophoresis, an intricate interplay of dissociation of C and association of T and L occur resulting in sophisticated concentration profiles, which contain peaks and plateaus.

#### 11.3.5 MULTIMETHOD KCE TOOLBOX

The degree of formation and dissociation of a complex differ in different KCE methods. KCE methods, therefore, have different accuracies of determination of  $k_{\text{on}}$  and  $k_{\text{off}}$ . For example, in NECEEM, complex dissociation prevails over complex formation, thus, making it more “sensitive” to  $k_{\text{off}}$  than  $k_{\text{on}}$ . In SweepCE, in contrast, complex formation can prevail over complex dissociation, making it more sensitive to  $k_{\text{on}}$  than  $k_{\text{off}}$ . The ppKCE method can be tuned to have comparable accuracy of both  $k_{\text{on}}$  and  $k_{\text{off}}$  determination. Therefore, KCE methods, which involve EMs (e.g., NECEEM, cNECEEM, and sSweepCEEM), are expected to be more accurate for the determination of the equilibrium constant,  $K_d$ . The most accurate determination of all constants can be achieved if multiple KCE methods are combined in a single kinetic tool. The approach can be used for testing hypotheses about the mechanisms of interaction and finding kinetic parameters of the interaction. Conceptually, experimental electropherograms are obtained by multiple KCE methods first. A hypothetical model of interactions between L and T is suggested and the system of differential equations (system 11.3) is built. The experimental KCE electropherograms are fitted with simulated electropherograms simultaneously to obtain the best fits with one of the criteria used for nonlinear regression analysis (e.g., minimum chi-square). If the quality of fitting is not satisfactory, a new hypothesis is suggested for the interaction. The procedure is repeated until a satisfying hypothesis is found. The best fits for the accepted hypothesis lead to the determination of stoichiometric and kinetic parameters of the interaction. Using the general concept of KCE, other KCE methods can be defined by simply selecting new sets of initial and boundary conditions. Importantly, this approach requires no serendipity but, rather, a rational (or irrational) design of conditions, which can be performed in an intuitive way schematically depicted in Table 11.1. The multimethod KCE toolbox allowed, for example, the determination of kinetic parameters of specific and nonspecific protein–DNA interactions.<sup>3</sup>

KCE establishes a new paradigm: separation methods can be used as comprehensive kinetic tools. The majority of previous attempts to utilize chromatography and electrophoresis for studying biomolecular interactions were limited to assuming equilibrium between interacting molecules.<sup>51</sup> Not only does such an assumption limit applications to measuring equilibrium constants, but also this assumption is conceptually mistaken since separation disturbs equilibrium. Kinetics must be appreciated when separation methods are used for studies of noncovalent interactions. This appreciation can dramatically enrich analytical capabilities of the methods.

## 11.4 KCE FOR APTAMER SELECTION AND DRUG DISCOVERY

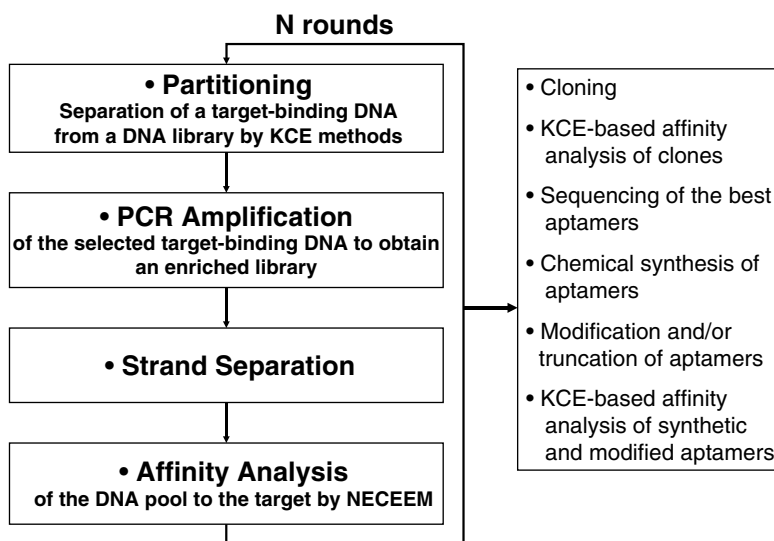

DNA or RNA aptamers are single-stranded oligonucleotides that can bind proteins, small-molecule compounds, and living cells with high affinity and specificity.<sup>52,53</sup> Aptamers are very promising affinity ligands with the potential to change the field of affinity probes and replace antibodies as diagnostic, analytical, and therapeutic reagents.<sup>54–56</sup> Aptamers have indisputable advantages over antibodies due to the simplicity and low cost of production, simplicity of chemical modifications, and simplicity of integration into different analytical schemes. The unique properties of aptamers have led to their application in multiple areas of bioanalytical and biomedical sciences. They have been successfully used in proteomics and development of bioanalytical assays,<sup>57</sup> inhibition of enzymes and receptors,<sup>7,8</sup> development of artificial enzymes (ribozymes and aptazymes),<sup>9</sup> target validation and screening for drug candidates,<sup>58–60</sup> cytometry and imaging of cellular organelles,<sup>61</sup> and development of biosensors.<sup>62</sup> Aptamers are gaining a strengthening reputation as therapeutic reagents for the treatment of different pathologies.<sup>63,64</sup> Their potential medical applications also include gene therapy and drug delivery to therapeutic targets.<sup>65</sup> Despite a great promise and a significant effort in the development of aptamers over a period of 15 years, they have only been obtained for approximately 100 protein targets.<sup>66</sup> Such a slow progress is largely due to limitations of conventional technologies used for aptamer development.

Aptamers are typically selected from large libraries of random DNA (RNA) sequences in a general approach termed Systematic Evolution of Ligands by EXponential enrichment (SELEX).<sup>67,68</sup> In essence, SELEX involves repetitive rounds of two alternating processes: (1) partitioning of aptamers from nonaptamers by separating target-bound DNA from free DNA and (2) amplification of aptamers by the PCR (Figure 11.9a).

Noninstrumental methods of partitioning, such as filtration and gel electrophoresis, were initially used for SELEX; they still dominate the area.<sup>69</sup> Because of high background (the high level of target-nonbound DNA collected along with target-bound DNA), SELEX based on conventional partitioning methods requires a large number of rounds of selection, typically greater than 10. As a result, SELEX based on conventional partitioning methods is a lengthy and resource-consuming process. It often leads to DNA structures that bind to the surfaces of the filters or chromatographic support used in partitioning rather than to the target. Counter selection is successfully employed to eliminate such “surface aptamers”; however, it introduces additional rounds of selection, thus, making the procedure even longer. Another disadvantage of too many rounds of selection is the very limited number of unique aptamer sequences obtained at the output of conventional SELEX. This disadvantage is

**FIGURE 11.9** (a and b) Schematic representation of SELEX vs. nonSELEX.

**FIGURE 11.10** Schematic representation of KCE-based selection of DNA aptamers. This figure shows a simplified flowchart of *in vitro* selection of DNA aptamers. A random DNA pool containing  $10^{11}$ – $10^{15}$  unique sequences is incubated with a target. The next steps are KCE-based measuring of bulk affinity of DNA library to the target and KCE-based partitioning of a DNA–target complex from free DNA. The collected DNA is then amplified using PCR with a fluorescein-labeled forward primer and a biotin-labeled reverse primer. DNA strands are separated using streptavidin iron particles and a fluorescently labeled strand is collected to yield the affinity-enriched DNA library. This lower diversity pool is incubated with new aliquot of the target to examine its binding affinity using NECEEM. If the affinity is not high enough, a new selection round starts. When desirable affinity is reached, pool of aptamers is cloned into bacteria, clones are screened, and the best aptamers are sequenced. Aptamer sequences can be further modified to improve binding or other specific properties.

especially critical for aptamer-based drug development, which requires as many “lead molecules” as possible. Finally, if the efficiency of partitioning is too low, SELEX can completely fail to select aptamers.

Methods of KCE,<sup>3</sup> which started with pioneering works of Heegaard and Whitesides on affinity capillary electrophoresis (ACE),<sup>15,70</sup> establish a new methodological platform for partitioning of aptamers. Two distinct KCE methods have been used for the selection of aptamers: NECEEM<sup>24,25,29</sup> and ECEEM.<sup>71,72</sup> Bowser and co-authors<sup>73,74</sup> were the first to use NECEEM in SELEX; they called the approach CE-SELEX. The partitioning efficiency of KCE methods exceeds that of conventional partitioning methods, such as filtration and column chromatography, by at least two orders of magnitude.<sup>29</sup> As a result, KCE methods decrease the number of rounds of SELEX from 10 or more (required with conventional partitioning techniques) to 1–3 (Figure 11.10). In addition, KCE methods can be equally used for the selection of aptamers and for measurements of all their binding parameters:  $K_d$ ,  $k_{on}$ ,  $k_{off}$ ,  $\Delta H$ , and  $\Delta S$ .<sup>19</sup> KCE methods have been demonstrated to facilitate selection of “smart” aptamers—ligands with predefined binding parameters.

#### 11.4.1 KCE-BASED SELECTION OF SMART APTAMERS

The designing of advanced aptamer-based diagnostics and therapeutics requires aptamers with predefined kinetic and/or thermodynamic parameters of aptamer–target interaction. Technological limitations of aptamer selection methods have so far precluded selection of such aptamers. Two KCE methods, ECEEM<sup>71,72</sup> and NECEEM,<sup>24,25,29</sup> have been successfully used for the selection of aptamers with predefined  $K_d$  and  $k_{off}$  of aptamer–target complexes. Conceptually, in ECEEM,

a mixture of a target with a DNA (RNA) library is prepared and equilibrated (Figure 11.11). A plug of the EM is injected into a capillary prefilled with a run buffer containing the target at the concentration identical to the target concentration in the EM. The components of the EM are separated by CE while quasi-equilibrium is maintained between the target and aptamers inside the capillary. The unique feature of ECEEM is that aptamers with different  $K_d$  values migrate with different and predictable mobilities. Thus, collecting fractions with different mobilities results in aptamers with different and predefined  $K_d$  values. As an example, ECEEM was used to select aptamers with predefined  $K_d$  for binding MutS protein.<sup>71</sup> Three rounds of ECEEM-based selection were sufficient to obtain aptamers with  $K_d$  values approaching theoretically predicted ones (Figure 11.11).

In the NECEEM approach, smart aptamers can be selected with predefined  $K_d$  and  $k_{\text{off}}$  as well. A combinatorial DNA library is equilibrated with a protein target and the components of the EM are separated under nonequilibrium conditions. The nonequilibrium conditions promote the dissociation of the complex during separation. Fractions collected in a time window preceding the DNA library yield pools of DNA sequences capable of binding the target and dissociating from the complex with specific rates (Figure 11.12). Being a homogeneous method with comprehensive kinetic features, NECEEM provides a means for the selection of DNA aptamers with predefined ranges of all binding parameters of complex formation ( $K_d$ ,  $k_{\text{off}}$ ,  $k_{\text{on}}$ ). First, the selection can be with respect to  $K_d$  values by varying the concentration of the protein target  $[T]$  in the EM. The ratio between protein bound and unbound ligands changes according to classical equilibrium: the ligands where  $K_d < [T]$  are preferentially bound to the protein and selected, while the ligands where  $K_d > [T]$  are preferentially unbound and not selected. Second, the selection can be implemented with respect to  $k_{\text{off}}$  values by varying time windows in which fractions are collected. Finally, selection with respect to  $k_{\text{on}}$  values can be carried out by varying the time of incubation of the library with the target. To select for a single binding constant, the parameters that control the other two binding constants should be kept unchanged.

NECEEM appears to be a more complicated method than ECEEM, because each collection window may contain ligands with totally different  $k_{\text{off}}$  values; however, ligands with  $k_{\text{off}}$  defined in Figure 11.12 are the most abundant and will be predominant after multiple rounds of selection. The concept is different in ECEEM, in which every window theoretically contains only ligands with calculated  $K_d$  values, and deviations occur only because of nonspecific interactions during separation, nonzero width of the peaks, and disturbed equilibrium. Thus, NECEEM is a more “evolutionary” method of iterative selection, which requires more than one round to select oligonucleotides with a narrow range of  $k_{\text{off}}$  values.

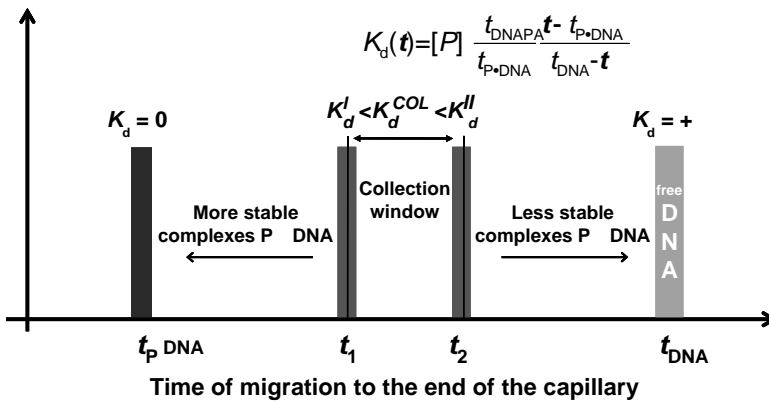

#### 11.4.2 NONSELEX SELECTION OF APTAMERS

The outstanding partitioning capabilities of KCE methods have motivated the attempt to select aptamers in a procedure that does not include intermediate amplification steps; this approach is called nonSELEX<sup>24,25</sup> (Figure 11.9b). Excluding repetitive steps of PCR amplification accelerates the procedure of aptamer selection without compromising its efficiency. Omitting repetitive steps of PCR also excludes quantitative errors associated with the exponential nature of PCR amplification, thus making nonSELEX a useful tool for studies of properties of DNA libraries with respect to their interaction with targets. For example, nonSELEX can be used to accurately back-calculate the number of aptamer molecules in the naive DNA library. Further, excluding repetitive steps of PCR allows one to avoid the bias related to differences in PCR efficiency with respect to different oligonucleotide sequences. Finally, nonSELEX can potentially provide a viable alternative to SELEX in the commercial development of aptamers. It should be noted that the implementation of nonSELEX with currently available commercial CE instrumentation has a limitation: only a fraction of the collected ligands can be sampled for the next step of nonSELEX. This limitation requires that the fraction of aptamers in the naive library be no lower than  $5 \times 10^{-10}$  for the parameters used in this protocol. Usually, the abundance of aptamers in the naive library is greater than  $5 \times 10^{-10}$ , thus making

**Separation scheme**

Equilibrium mixture **EM** = protein-DNA complex + free Protein + free DNA

$$[\text{Protein}]_{\text{EM}} = [\text{Protein}]_{\text{RunningBuffer}}$$

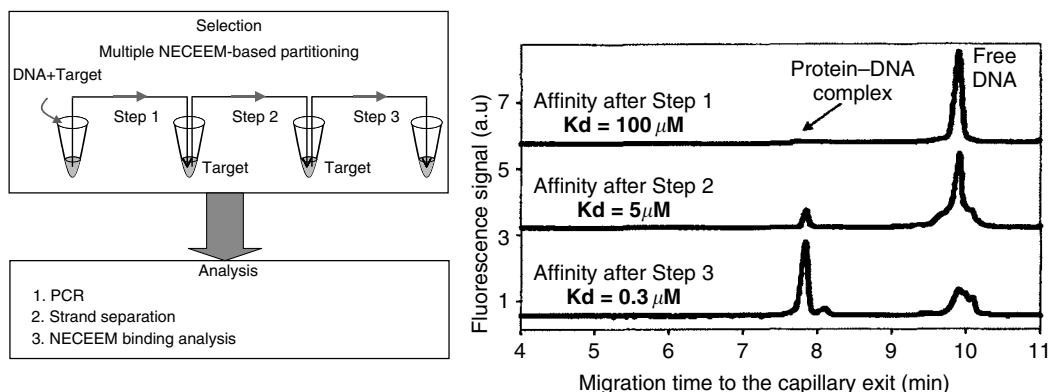

**FIGURE 11.11** ECEEM-based selection of smart aptamers with predefined  $K_d$  values.

the limitation less important. As a real example, NECEEM-based nonSELEX for the selection of DNA aptamers was shown for h-Ras protein.<sup>24</sup> Three steps of NECEEM-based partitioning in the NonSELEX approach were sufficient to improve the affinity of a DNA library to a target protein by more than four orders of magnitude (Figure 11.13). The resulting affinity was higher than that of the enriched library obtained in three rounds of NECEEM-based SELEX. Remarkably, NECEEM-based NonSELEX selection took only 1 h to complete in contrast to several days or several weeks required for a typical SELEX procedure by conventional partitioning methods. In addition, NECEEM-based NonSELEX allowed to accurately measure the abundance of aptamers in the library. Not only does

**FIGURE 11.12** NECEEM-based selection of DNA aptamers with predefined ranges of all binding parameters of complex formation ( $K_d$ ,  $k_{off}$ ,  $k_{on}$ ).

**FIGURE 11.13** NonSELEX. Partitioning of aptamers from nonaptamers in nonSELEX by multiple steps of NECEEM with no PCR amplification between the steps.

this work introduce an extremely fast and economical method for aptamer selection, but it also suggests that aptamers may be much more abundant than they are thought to be. The step-by-step protocol for nonSELEX has been published.<sup>25</sup> Even more importantly, this work opens the opportunity for the selection of drug candidates from large nonDNA libraries, which cannot be PCR-amplified and are, thus, not approachable by SELEX.

### 11.4.3 THE PROSPECTIVE OF KCE IN DRUG DISCOVERY

The nonSELEX concept provides the opportunity for the selection of affinity ligands from DNA-encoded libraries of small molecules and peptides.<sup>75,76</sup> DNA tags in such libraries encode the information, which allows one to identify structures of corresponding small molecules, when the DNA tags are PCR amplified and sequenced. Owing to the small size of the molecules with respect to that of the covalently attached DNA tag, such libraries are expected to have electrophoretic properties identical to those of DNA libraries. SELEX is not applicable to such libraries since small molecules and peptides cannot be amplified by PCR.

## 11.5 CONCLUSION

KCE is based on the major principle of separation science that a complex can be separated from a target. In this case, the kinetics of molecular interactions must be appreciated. All methods of KCE use a single instrumental platform and a single conceptual platform for solving multiple tasks associated with biomolecular screening. A variety of different KCE methods can be designed by defining different ways of interaction between molecules in CE. Because of their comprehensive analytical capabilities, KCE methods have the potential to become a workhorse of biomolecular screening. This makes KCE methods highly attractive for the pharmaceutical industry as a novel approach to the selection and characterization of drug candidates. To conclude, it is clear that KCE methods will find multiple applications in fundamental studies of biomolecular interactions, designing clinical diagnostics, and the development of affinity probes and drug candidates. New applications will emerge with further development of KCE.

## 12.1 INTRODUCTION

Most DNA sequencing today is done essentially by the same enzymatic method conceived by Frederick Sanger in the 1970s—while DNA electrophoresis instruments and molecular labels have improved (we now use fluorescent dyes, whereas Sanger used radioactive labeling), the basic

approach is the same. When we read sequence from samples produced by the Sanger method, the problem is reduced to biomolecule separation and detection. DNA molecules, each carrying a terminal fluorophore that encodes the identity of the terminal base (A, C, G, or T), must be fractionated according to chain length with single-base resolution, and for the best process efficiency, with the longest “read-length” possible. Ideally at least 600–650 bases of contiguous, high-accuracy sequence is desired per read for the *de novo* sequencing of complex genomes such as the human genome, which has a high content of repetitive DNA sequence that can be difficult to “read through” and assemble correctly if only shorter reads are available.

Accordingly, since 1990 or so, a key aspect of pushing sequencing technology forward has been perfecting the ability of electrophoresis instruments to separate DNA molecules according to size with great efficiency. A major turning point, reached in 1999, was the widespread shift of sequencing from slab gel instruments, which required genome center technicians to carry out manual steps (e.g., pouring very large, ultra-thin polyacrylamide slab gels, loading DNA samples), to automated capillary array electrophoresis (CAE) systems, which separate fluorescently labeled DNA molecules within 50- or 75- $\mu\text{m}$  inner diameter glass capillaries, in fluid, uncrosslinked polyacrylamide solutions rather than crosslinked gels. Although the basic technological approach to sequencing is still essentially “gel electrophoresis,” the greater automation provided by CAE along with intensive logistical and computational efforts in academia and private enterprise enabled a draft human genome sequence to be obtained 2 years ahead of schedule, in 2003.<sup>1,2</sup>

The sequencing of that first composite human genome, a good deal of which was done with slab gel systems, cost a total of \$3 billion.<sup>1–6</sup> Thanks to improvements to CAE and other technological developments seeded in academic research laboratories with funds granted by the National Institutes of Health (NIH)/National Human Genome Research Institute (NHGRI) as well as in industry, genome centers now analyze genomes 24 h/day by automated CAE of DNA in solutions of entangled, water-soluble polymers.<sup>7</sup> The aforementioned viscous, entangled polymer solutions are at present necessary, consumable, and expensive elements of CAE technology, as they provide the size-based separation of DNA required to read sequence by the Sanger method.

In 2004, the NIH/NHGRI initiated a race to develop new and different technologies that could decrease the cost for sequencing an individual human genome (which comprises 6 billion base pairs, considering both sets of chromosomes) from the now-current (2007) price of \$10–20 million to \$100K in the near future, and eventually to \$1K.<sup>8</sup> Changes to the separation technology could drop the cost a lot, since about 60% of the present cost of sequencing a genome is due to CAE and its required consumables (capillary arrays and polymer solutions). While CAE has transformed both science and society and remains extremely important (as the only technology suitable for the *de novo* sequencing of complex genomes, such as the human), less expensive, more efficient, and more highly parallel technologies are still greatly needed. In 2006, the National Cancer Institute (NCI) announced “The Cancer Genome Atlas” (TCGA), a new project that aims to map and analyze genetic mutations occurring in different types of human cancers; this will require full sequencing and assembly of  $\sim 15,000$  human genomes, an effort much greater in scale than the Human Genome Project (HGP).<sup>9,10</sup> A 100-fold reduction in sequencing cost to \$100K per genome will be needed if the Cancer Genome Atlas Project is to be accomplished within its presently planned budget.<sup>11</sup> The second 100-fold cost decrease, to a \$1K genome, would enable individual human genomes to be sequenced as a new aspect of general medical care. In addition, the recently announced, privately backed Archon X Prize for Genomics promises \$10 million to the first group that sequences 100 human genomes in less than 10 days,<sup>12,13</sup> which would represent a giant leap beyond the 2003 completion of the HGP. However, given current sequencing costs and the state of present technologies, old and new, it certainly seems that we have a long way to go before sequencing is cheap enough to make \$10 million an attractive prize for sequencing 100 human genomes, so that the Archon Prize can be paid out.<sup>14</sup>

Reducing sequencing costs requires both increased throughput and decreased cost per base. In practical terms, capillary electrophoresis (CE) using polymer matrices for DNA separation is

limited to a maximum read-length (the number of contiguous DNA bases that can be sequenced with high accuracy, i.e., with good single-base resolution) of about 800–900 bases, in part because of limitations imposed by the physical mechanism of DNA separation that prevails in entangled polymer solutions.<sup>14,15</sup> A phenomenon known as “biased reptation” occurs as DNA molecules move through a polymer sieving matrix in an electric field; the DNA molecules unstretch and move through the polymer “mesh” head-first in a snake-like fashion, orienting themselves in the direction of the field. The higher the electric field strength, the more DNA molecules—especially long DNA chains greater than 300 bases in length—are likely to reptate with a strong field-bias, and the weaker the dependence of DNA electrophoretic mobility on size for these reptating chains. This causes the size-dependence of DNA mobility to decrease, thereby also decreasing read-length. Therefore, capillary in a polymer matrix electrophoresis requires a balance to be struck between the increased separation speed possible under high electric fields and the decreased read-length.<sup>16</sup> DNA sequencing is also limited by the number of capillaries that can be run in parallel; CAE instruments are currently available with up to 384 capillaries, though instruments with 96 capillaries are much more typical. Polymer sieving matrix costs are a significant percentage of the cost of DNA sequencing consumables, however, and the cost of polymer increases linearly with the number of capillaries. Throughput may be increased by highly parallel separations, but the cost per base is only minimally decreased.

Miniaturized microfluidic electrophoresis devices or “chips,” which are still primarily in the research stage for the applications of DNA sequencing and genotyping [which often requires the fractionation of small, single-stranded DNA (ssDNA) molecules] are a natural next step from CE because they decrease the separation time and increase throughput, thus offering to reduce the cost per base of DNA sequencing. DNA has been separated by electrophoresis on both glass<sup>17–21</sup> and plastic<sup>22,23</sup> microchips of varying lengths. However, polymer-sieving matrices that are easily pressure-loaded into capillaries (with pressure limits > 1000 psi) are difficult to load into glass and plastic microchips (which have pressure limits in the range of 50–200 psi). If DNA could be separated by electrophoresis in free solution, that is, without a polymer sieving matrix, DNA sequencing by microchip electrophoresis would be significantly easier. Eliminating the need for polymer matrix in chip electrophoresis could decrease the cost per base even further, relative to microchip electrophoresis using separation matrices.

Woolley and Mathies<sup>24</sup> of U.C. Berkeley published the first four-color DNA sequencing results obtained on microfluidic devices back in 1995. The Mathies group then showed sequencing of 500 bases in 20 min in 1999.<sup>19</sup> Since then, the Jovanovich group at Molecular Dynamics has succeeded in sequencing 450 bases on a chip in 15 min.<sup>21</sup> While these sequencing results are certainly impressive, they are not yet fast enough, or cheap enough, to provide the “\$100,000 genome” on their own. Research groups are working to integrate several parts of the sequencing protocol (DNA extraction, purification, amplification, and detection) on a “lab-on-a-chip” microfluidic device<sup>17,25–41</sup> that includes polymer matrix-based CE as the final separation step.

In CE, polymer sieving matrices are necessary to separate DNA molecules according to size, for the reason that DNA chains behave as “free-draining” polymers during electrophoresis and also have a monotonic size-to-charge ratio, and hence elute as one peak in free-solution CE, regardless of molecular size. In free-solution electrophoresis, the electric field pulls negatively charged DNA to the cathode, as the positively charged buffer counterions that surround DNA migrate toward the anode; solvated cations move around and through the DNA coil, giving it its “free-draining” characteristic. The counterions effectively screen hydrodynamic interactions between different parts of the DNA molecule, so the molecule adopts an open conformation, causing the electrophoretic friction coefficient  $\zeta$  to scale linearly with the number of monomers in the DNA chain  $M$ . The total electrophoretic force  $F$  applied to the DNA molecule also scales linearly with the number of charges along the DNA. Each of the four deoxynucleotides (dNTPs) carries the same amount of negative charge from identical phosphate groups, causing the number of charges in a DNA molecule to scale with  $M$ . The electrophoretic velocity of DNA in free solution is calculated by dividing total force by the friction coefficient:  $v = F/\zeta \sim M/M \sim M^0$ , thus no size separation is achieved for DNA

in the absence of a gel. The sieving matrix used in capillary gel electrophoresis separates DNA molecules by size as they collide with and interact with polymers and their movement is retarded. Small DNA molecules move through the polymer matrix faster because they have fewer collisions, so that DNA molecules elute in order from smallest to largest. Interaction with polymers to effect this size separation necessarily slows down the migration of DNA.

To accomplish free-solution separations of DNA would obviously require that DNA molecules of different sizes are modified in such a way that they have size-dependent electrophoretic velocities, which could be achieved either by changing the density of charge on each monomer or by changing the dependence of the molecular friction coefficient on  $M$ . In free-solution conjugate electrophoresis (FSCE), the linear scaling of DNA's charge-to-friction ratio, described above, is abolished by attaching another molecule (which we call a "drag-tag") to each DNA chain, which perturbs the average charge density per monomer. Noolandi first suggested this general idea in 1992<sup>42</sup> and mentioned the possibility of using a natural protein as a drag-tag in 1993.<sup>43</sup> The idea is potentially very powerful, since free-solution electrophoresis would be much easier to integrate into microfluidic devices than gel electrophoresis. To try to make this concept a concrete reality, one has first to consider what the structure and properties of such a "drag-tag" molecule ought to be. Should it be charged or uncharged? If charged, should it be cationic or anionic? Experiments predict that negatively charged drag-tags might only slightly modify the electrophoretic velocity of DNA while reducing the separation efficiency, read-length, and effective drag, while a positively charged drag-tag could interact electrostatically with the negatively charged DNA and/or the microchannel walls, increasing band broadening. Thus, a neutral drag-tag seems to offer the best size-based separation of DNA; the drag-tag should act as a sort of "parachute" behind the migrating DNA molecule, slowing down the molecule. If we attach the exact same drag-tag to every DNA molecule in a mixture, the largest molecule will migrate fastest because it experiences the smallest retardation from the additional frictional drag. Hence, elution should occur in order from largest to smallest, which is the opposite order of gel electrophoresis. This chapter concerns the present state-of-the-art of this bioconjugate approach to DNA sequencing and genotyping.

Other nonelectrophoresis technologies are being developed in the search for the \$100,000 and \$1000 genomes. Several of these technologies offer promising results and are expected to play a role in the sequencing revolution currently at hand. Specifically, sequencing by synthesis (SBS) and nanopore detection methods are under development as potential nonelectrophoresis technologies.<sup>44–53</sup> SBS is currently limited to average read-lengths of about 120 bases, is not as accurate as Sanger sequencing,<sup>54</sup> and requires difficult and demanding sample preparation, amplification, and genome assembly.<sup>55</sup> CE-MS is also being investigated as a DNA sequencing method, and is likely to have relatively short read-lengths.<sup>56</sup> While these nonelectrophoretic sequencing methods are being rapidly developed, DNA sequencing by FSCE offers one potential avenue to the \$100,000 genome, especially if it is incorporated into an integrated "lab-on-a-chip"<sup>17,25–41</sup> sequencing device. The separation time for FSCE is faster than matrix-based electrophoresis, and the cost per base should be decreased by eliminating the polymer matrix. This chapter will present an overview of the free-solution electrophoresis of bioconjugates, including a brief summary of the theory, a description of the perturbing entities, recently achieved free-solution DNA separations for genotyping and sequencing, and finally, future directions for the development of this potentially powerful new technology.

## 12.2 FREE-SOLUTION CONJUGATE ELECTROPHORESIS OF DNA

Free-solution electrophoresis of DNA that has been conjugated to a friction-perturbing entity, which we call a "drag-tag," was not feasible until after the development of CE in the 1990s. Free-solution electrophoresis generates a significant amount of heat, which must be dissipated. The narrow channels used in CE have diameters in the order of 25–100  $\mu\text{m}$ , which efficiently remove this "Joule heat." Free-solution conjugate electrophoresis (FSCE) was first examined quantitatively in 1994 by Mayer

et al.<sup>57</sup> who developed the theory and named the method end-labeled free-solution electrophoresis (ELFSE). However, we prefer the name FSCE (since the drag-tag is not a “label”) and will use that name in this chapter. The original theory presented in 1994 has been further developed and was recently reviewed.<sup>14</sup> A brief summary of the general theory of FSCE will be presented here, along with several “proof-of-concept” experiments.<sup>16,58–61</sup>

### 12.2.1 THEORY OF FSCE

If DNA is electrophoresed in an aqueous buffer only (i.e., in “free-solution”), the electrophoretic mobility of an entire DNA molecule is essentially equal to the mobility of just one monomer unit of DNA. Because DNA molecules of all lengths elute at exactly the same time by free-solution electrophoresis, DNA is called a “free-draining” polymer<sup>15,58,62</sup> (as if DNA molecules are in “free fall”). The electrophoretic mobility of DNA  $\mu$  is defined as the ratio between the electrophoretic velocity  $v$  and electric field strength  $E$ . For a free-draining molecule, this ratio is equivalent to the ratio of charge  $Q$  to friction  $\zeta$ .<sup>57</sup> As each of the four dNTP monomers has an identical negatively charged phosphate group, the total charge  $Q$  of a molecule of DNA scales linearly with the number of monomers in the DNA chain  $M$ . The electrophoretic friction coefficient  $\zeta$  of a free-draining chain also scales linearly with the number of monomers in the chain; hence, the electrophoretic mobility of DNA in free-solution ( $\mu_0$ ) is given by

$$\mu_0 = \frac{v}{E} = \frac{QE/\zeta}{E} = \frac{Q}{\zeta} \propto \frac{M}{M}. \quad (12.1)$$

Because both charge and friction scale linearly with the number of DNA monomers,  $\mu(M)$  is not length-dependent. However, when an uncharged drag-tag is attached to the DNA molecule, the modified mobility is size-dependent in free-solution electrophoresis. In 1994, Mayer et al.<sup>57</sup> theorized that the mobility of this bioconjugate could be determined solely by dividing total electrical force by total friction coefficient. Assuming that an uncharged drag-tag is used, they predicted the free-solution mobility of the ssDNA conjugated to the drag-tag as

$$\mu(M) \approx \frac{\rho(M)}{\zeta(M + \alpha)} \approx \mu_0 \frac{M}{M + \alpha}, \quad (12.2)$$

where  $\mu_0 = \rho/\zeta$  is the mobility of untagged (free) ssDNA in free-solution electrophoresis and  $\alpha$  is the friction of the drag-tag in units of the friction of one base of DNA.

The original assumption made by Mayer et al.<sup>57</sup> concerning how the velocity of the ssDNA + drag-tag conjugate is calculated was found later to be true only in special cases, and to be determined by the hydrodynamic conformation of the ssDNA + drag-tag conjugate.<sup>63</sup> The theory was then further developed to determine the probability that the experimental conditions coincided with the specific hydrodynamic conformation of that special case. Luckily, that special case is actually the most common when separating these charged-uncharged conjugates in free-solution electrophoresis.<sup>14,64</sup> A brief explanation of the theory confirming this is presented below.

The ssDNA + drag-tag conjugate may adopt four basic types of hydrodynamic conformations, depending on the relative sizes of the ssDNA and the drag-tag and the intensity of the electric field  $E$  (Figure 12.1).<sup>64</sup> The electrophoretic mobility of the DNA + drag-tag depends on the hydrodynamic conformation of the conjugate when separated by free-solution electrophoresis. At equilibrium, the neutral drag-tag is integrated into the random coil of the negatively charged DNA (Figure 12.1a). When an electric field is applied during electrophoresis, the drag-tag itself does not have any intrinsic mobility because it is not charged. The ssDNA moves through the electric field according to its electrophoretic mobility and the retardation of the drag-tag. If a large enough electric field is applied ( $E_1 > E > E_0$ ), the DNA “engine” will begin to segregate itself away from the drag-tag as it is pulled

**FIGURE 12.1** Schematic representation of four potential conformations of DNA-label bioconjugates: (a) label is part of the random coil of DNA, (b) label and DNA segregate without the DNA being deformed, (c) label and DNA segregate, and DNA is stretched, (d) DNA is too small to form a coil around the label, forcing steric segregation. (Reprinted with permission from Desruisseaux, C., et al. *Macromolecules* 34, 44–52, 2001.)

by the electric field (Figure 12.1b).<sup>64</sup> When the applied electric field has a high intensity ( $E > E_1$ ), the DNA and label are segregated, and the DNA becomes fully stretched in the electric field as it is pulled through the capillary (Figure 12.1c).<sup>64</sup> In extreme cases where the drag-tag is much larger hydrodynamically than the DNA, the DNA is sterically segregated from the drag-tag because it is unable to surround the large label completely (Figure 12.1d). As bioconjugate electrophoresis aims to sequence large pieces of DNA, the theory focuses on determining the critical electric field intensity ( $E_0$ ) required to move from the random coil hydrodynamic conformation to segregation without deformation.

Before calculating the critical electric field strength  $E_0$  for the transition from the random coil to the hydrodynamic segregation regime, the mobility of labeled DNA  $\mu(M)$  in the random coil regime must be determined. The uncharged drag-tag monomers cannot be assumed to have the same hydrodynamic friction per unit as negatively charged DNA. Because each block of the DNA + drag-tag block copolymer has different friction, the so-called blob theory is used to create “supermonomers” within each block that have the same hydrodynamic properties and drag but different charge.<sup>14,65</sup> Taking into account the molecular weights of the “blobs” as determined by Kuhn lengths, the electrophoretic mobility of the DNA-label conjugate simplifies to

$$\mu = \mu_0 \frac{M_c}{M_c + \alpha_1 M_u}, \quad (12.3)$$

where  $M_c$  is the number of charged monomers of DNA,  $M_u$  is the number of neutral drag-tag monomers, and  $\alpha_1$  is the friction coefficient of each uncharged drag-tag monomer.<sup>14,64–69</sup> Using this equation, the value for  $E_0$  with typical experimental conditions was  $E_0 \approx 8$  kV/cm,<sup>14</sup> which is much larger than typical electric fields used for CE (100–300 V/cm). The possibility of segregated

and stretched DNA + drag-tag conjugates is highly unlikely under typical electrophoresis conditions; these conjugates are always in the random coil regime during electrophoresis.

The value of  $\alpha = \alpha_1 M_u$  is critically important for determining the potential separation efficiency of drag-tags for free-solution electrophoresis. Drag-tags are evaluated by their  $\alpha$ -value, and higher  $\alpha$ -values correlate to a greater amount of drag imposed on each piece of DNA, indicating that larger DNA sequencing fragments can be resolved by a particular drag-tag. The approximate elution time of a DNA + drag-tag conjugate can be determined using the equation

$$t(M) = \frac{L}{\mu_0 E} \left( 1 + \alpha_1 \frac{M_u}{M_c} \right), \quad (12.4)$$

where  $L$  is the total length of the capillary channel. This equation clearly shows that longer pieces of DNA (smaller  $M_u/M_c$  ratio) elute before shorter ones (larger  $M_u/M_c$  ratio and thus larger time), which is the opposite order of traditional CGE. This equation also offers an easy way to calculate  $\alpha = \alpha_1 M_u$ .

The first iteration of FSCE theory predicted the potential sequencing of up to 2000 bases in less than 1 h under perfect (diffusion-limited) conditions using a drag-tag with an  $\alpha$  between 100 and 200.<sup>57</sup> The initial theory, however, assumed that  $\mu(M)$  and the diffusion coefficient  $D(M)$  could be related using the Nernst–Einstein equation, which it turns out is not a valid assumption under free-solution electrophoresis conditions.<sup>70</sup> This assumption caused Mayer to overestimate the potential performance of DNA sequencing by FSCE. Further development of the theory with a correction for this error led to the following equation that estimates the maximum number of bases that can be sequenced by a drag-tag with a specified  $\alpha$ -value:

$$M_c^{1/2} (M_c + \alpha_1 M_u)^{5/4} \cong 215 \alpha_1 M_u. \quad (12.5)$$

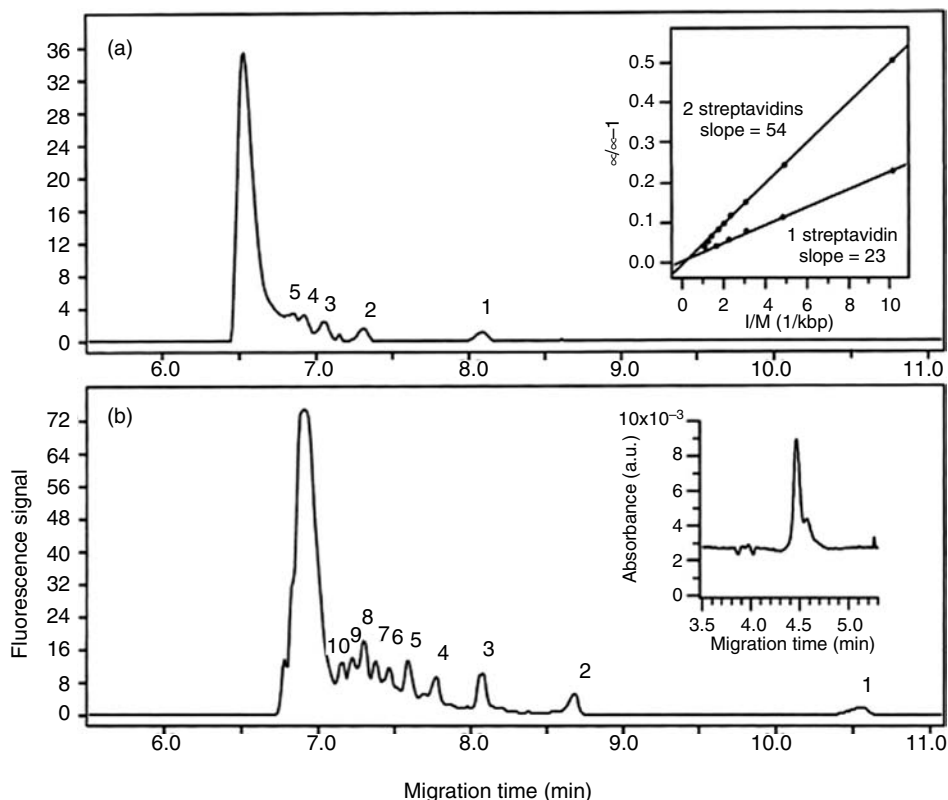

The protein streptavidin was suggested as a potential drag-tag in the early ELFSE literature.<sup>43,57,71</sup> Proteins are a natural choice for drag-tags because, in principle, they can be completely monodisperse (homogeneous in size and structure) and are large enough to provide appropriate amount of drag. Furthermore, streptavidin was chosen because it is close to electrostatically neutral under standard experimental conditions<sup>14</sup> and can be easily linked to DNA with biotin. The  $\alpha$ -value of streptavidin is approximately equivalent to the friction of 30 monomers of ssDNA.<sup>16</sup> With an  $\alpha$  of 30, the maximum read-length of DNA sequencing with a streptavidin drag-tag is predicted by theory to be 129 bases.<sup>14</sup>

## 12.2.2 PROOF-OF-CONCEPT EXPERIMENTS

### 12.2.2.1 Streptavidin

The first confirmation of the potential capabilities of ELFSE was achieved in 1998 by Heller et al.<sup>58</sup> when streptavidin was used as a drag-tag to separate double-stranded DNA (dsDNA).<sup>58</sup> Using biotinylated nucleotides and a polymerase enzyme, either one or both ends of the dsDNA were biotinylated so the dsDNA could be conjugated, end-on, with either one or two streptavidins (one on each end). Double-stranded DNA ladders (100 bp) with one or two terminal biotin moieties were generated and conjugated to streptavidin. FSCE analysis of the conjugates was run in  $1 \times$  TBE buffer (89 mM Tris, pH 8.0, 89 mM boric acid, 2 mM EDTA), and the resulting electropherograms are presented below (Figure 12.2).

Large  $\alpha$ -values are necessary to achieve good resolution of DNA, as shown by the double-labeled dsDNA ladder. When two drag-tags are attached to dsDNA, an  $\alpha$ -value of 54 imparts enough drag on the dsDNA so the 100 and 200 bp strands separate over approximately 2 min instead of less than 1 min with only one streptavidin.<sup>58</sup> This first foray into FSCE also confirmed the prediction that increased electric fields lead to higher resolution between peaks.<sup>58</sup> The electrophoretic velocity is

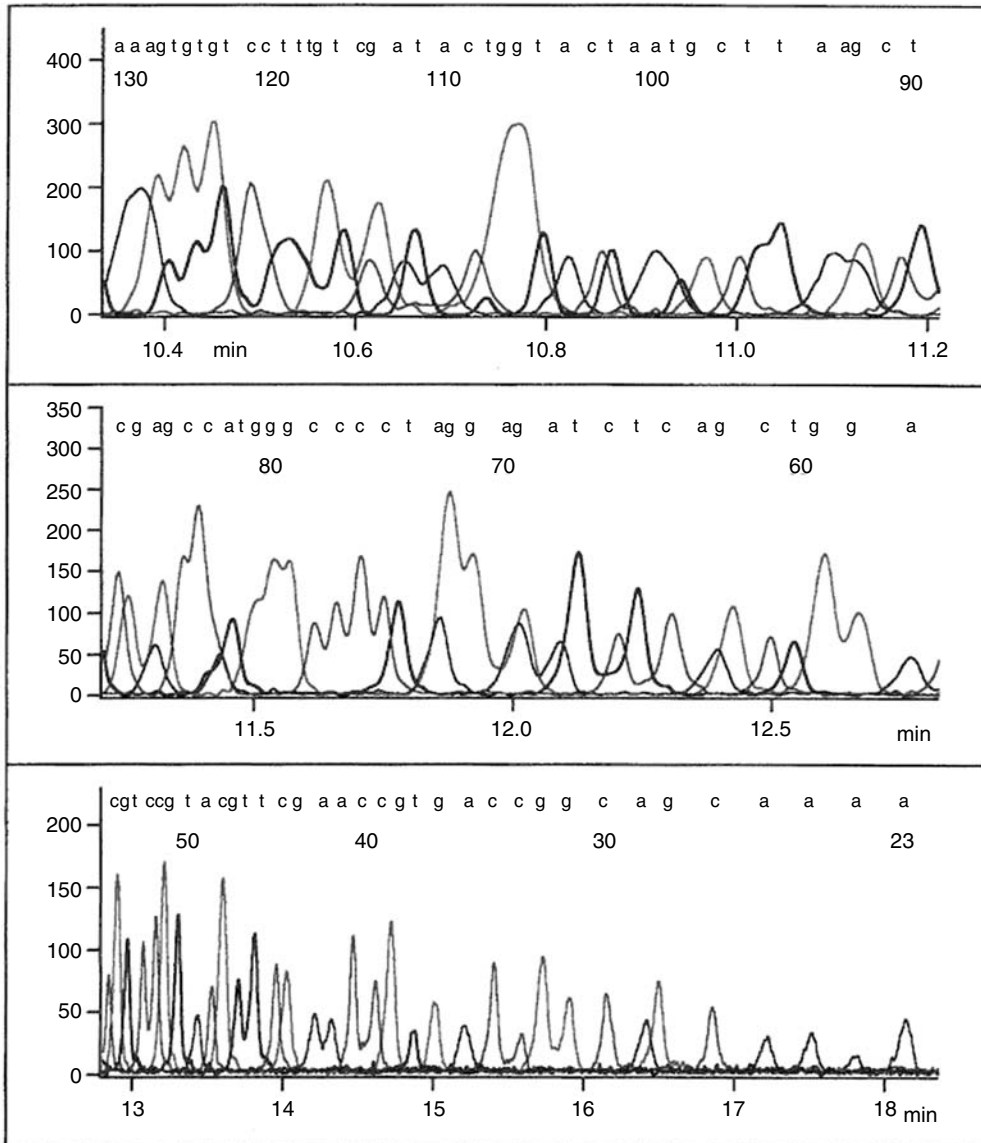

**FIGURE 12.2** Free-solution capillary electrophoresis analysis of 100 bp dsDNA ladder labeled on one (a) or both (b) ends with streptavidin. The drag of two streptavidins clearly resolves the dsDNA fragments more efficiently than one streptavidin. Inset of (a) is plot of  $\alpha/\alpha-1$  versus  $1/M$ ; the slopes of this plot are equal to the  $\alpha$  value of one or two streptavidin drag-tags. Plot inset of (b) shows the polydispersity of the streptavidin used. The large unnumbered peak at the beginning of both electropherograms is the unlabeled dsDNA. (Reprinted with permission from Heller, C., et al. *Journal of Chromatography A* 806, 113–121, 1998.)

also increased with higher electric fields without any loss of resolution, which is an advantage of FSCE over matrix-based CE systems that must balance the increased speed of separations with loss of resolution from increased electric fields.<sup>14,15</sup>

The polydispersity of the streptavidin used to separate the dsDNA (Figure 12.2b, inset) was troublesome because it potentially causes each peak of DNA to split into two or more peaks. The protein is fairly heterogeneous due to differing degrees of proteolysis and glycosylation as well as the fact that it has not one, but four active sites to react with biotin. DNA sequencing requires single-base resolution, which is clearly not possible with a polydisperse drag-tag that generates two or more peaks for each length of ssDNA. When streptavidin was purified using a homebuilt, preparative, non-denaturing polyacrylamide gel electrophoresis instrument, the polydispersity was greatly decreased.<sup>16</sup>

To fully demonstrate the potential of ELFSE, sequencing fragments were generated with a biotinylated primer. The purified streptavidin was attached to the fragments after cycle sequencing. Single-base resolution of the sequencing fragments in four colors was achieved for the first 100–110 bases in 18 min by ELFSE (Figure 12.3).<sup>16</sup> The approximately monodisperse streptavidin used here had an  $\alpha$ -value of around 24. As mentioned in Section 12.2.1, single-base resolution of 129 bases of ssDNA is predicted for a drag-tag with an  $\alpha$  of 30. Therefore, sequencing 100–110 bases with streptavidin is near the upper limit predicted by theory.

**FIGURE 12.3** DNA sequencing of M13mp18 in free-solution electrophoresis using purified streptavidin and a biotinylated sequencing primer. The bases elute in reverse order compared to traditional CGE; the base immediately after the primer elutes at 18 min. Electrophoresis conditions were 1X TAPS buffer (pH 8.5) with 7 M urea and 0.01% POP-6 as a dynamic wall coating, 34 cm effective length (45 cm total length) capillary with 20  $\mu\text{m}$  inner diameter. (Reprinted with permission from Ren, H., et al. *Electrophoresis* 20, 2501–2509, 1999.)

While reading 100–110 bases of DNA by free-solution CE is obviously not yet competitive with current matrix-based and nonelectrophoresis DNA sequencing methods, it clearly shows ELFSE's potential. Based on the streptavidin drag-tag, a drag-tag with an  $\alpha$  of 300 is predicted to resolve ssDNA sequencing fragments up to 625 bases long.<sup>16</sup> Separating sequencing fragments by microchip electrophoresis may also be able to increase the read-length by applying a higher electric field than is possible with traditional CE instruments.<sup>16,58</sup> However, several issues must be resolved before

that many bases can be separated using ELFSE. First, the mobility of the fluorescent dye labels must be determined to deconvolute the mobility shifts of the sequencing fragments induced by the four dyes. Second, an effective capillary wall coating must be developed to further decrease interactions between the walls and the bioconjugates.

Third, and most critical to long-read sequencing, is the development of a large, uncharged, monodisperse drag-tag. While streptavidin was a natural choice of drag-tag for testing the first DNA separation by FSCE, it will never be able to sequence more than 100–130 bases of DNA. Streptavidin, like almost all natural proteins, folds into a fairly compact sphere under native (nondenaturing) conditions. The frictional coefficient of spheres increases linearly with the radius; however, the radius only increases with the one-third power of the molecular weight. Therefore, streptavidin would need a molecular weight of approximately 30 million Da (a 600-fold increase in mass) to have an  $\alpha$ -value of 300.<sup>14</sup> Also, as a natural protein, streptavidin has areas of positive and negative charge on its surface that may adversely affect its ability to be an effective drag-tag. Natural, folded proteins like streptavidin are thus not the best choice of drag-tags for long-read ssDNA sequencing. A monodisperse drag-tag that is uncharged and unstructured with a large  $\alpha$ -value should theoretically provide much better sequencing results. Denaturing conditions that unfold proteins cannot be used with streptavidin without compromising the biotin-binding sites. If another method of end-on conjugation is used, proteins of either random coil or  $\alpha$ -helical secondary structure may be used. Two different approaches have been taken toward developing appropriate drag-tags, and they will be discussed in Section 12.3.

#### 12.2.2.2 Oligosaccharides

While work on FSCE has mainly focused on separating DNA molecules, the Novotny group of Indiana University has also successfully achieved free-solution separations of end-labeled, charged oligosaccharides.<sup>59–61</sup> Oligosaccharides are similar to DNA in that their charge-to-friction ratio remains constant as length changes.<sup>59</sup> Two different fluorescent labels were used as drag-tags for carbohydrates: one to increase the charge-to-friction ratio of the oligosaccharides and one to decrease it. The fluorescent label 8-aminonaphthalene-1,3,6-trisulfonic acid (ANTS) increased the charge-to-friction ratio and separated the oligosaccharides by free-solution electrophoresis with a migration order from smallest to largest. When the charge-to-friction ratio was decreased by the attachment of 6-aminoquinoline, the migration order was reversed to largest to smallest oligosaccharides, like ELFSE. Both types of labeled oligosaccharides were also run in a 1% linear polyacrylamide (LPA) matrix to determine the impact of sieving matrix on separation. The matrix increased the separation efficiency of the ANTS-labeled oligosaccharides but significantly decreased separation of the oligosaccharides with a decreased charge-to-friction ratio. The LPA slowed the larger oligosaccharides by a much larger percentage than the smaller ones, effectively cutting the separation efficiency into half.<sup>59</sup> The Novotny group has also applied FSCE to the separation of heparin oligosaccharides<sup>61</sup> and the study of how polygalacturonic acid interacts with metal ions.<sup>60</sup>

### 12.3 DRAG-TAGS FOR FSCE

Selection of an appropriate drag-tag is key to achieving successful DNA sequencing by ELFSE. The ideal drag-tag for many DNA separations of interest would have a large value of  $\alpha$ . With a large hydrodynamic drag, higher resolution and performance can be achieved for the separation of large sequencing fragments (greater than 200 bases). In addition to a high  $\alpha$ -value, several other properties are desired in the ideal drag-tag<sup>14</sup>

1. Complete monodispersity
2. Water solubility (DNA sequencing is performed under aqueous conditions)

3. Minimal to no electrostatic charge
4. Minimal adsorption to or nonspecific interaction with microchannel walls
5. Ability to be uniquely and stably attach to DNA (to ensure DNA is attached to exactly one drag-tag)

The most important property of an ideal drag-tag is complete monodispersity, where every tag is identical in charge and drag. When analyzed by free-solution CE, a monodisperse DNA + label conjugate should correspond to exactly one peak on the electropherogram. A polydisperse DNA + drag-tag conjugate, though, may show up as two or more ambiguous peaks on an electropherogram, which is not conducive to single-base resolution of ssDNA sequencing fragments. Accurate DNA sequencing would be challenging if not impossible with a polydisperse drag-tag.

Three different types of drag-tags have been examined in the search for appropriate drag-tags for sequencing and genotyping: synthetic polymers such as poly(ethylene glycol) (PEG),<sup>69</sup> poly-*N*-substituted glycines,<sup>68,72,73</sup> and genetically engineered protein polymers.<sup>68,74–76</sup> The dual requirements for complete monodispersity and sufficiently large hydrodynamic drag eliminate many commercially available synthetic polymers from consideration. Although completely monodisperse PEGs are now available, their small sizes result in low hydrodynamic drag that is insufficient for DNA separation. Larger PEG molecules with low polydispersity (PDI = 1.01) are also inadequate. When an “engine” of fluorescently labeled monodisperse ssDNA is conjugated to such PEG samples, they separate into more than 100 peaks in free-solution electrophoresis, with single-monomer resolution of the PEGs with different chain lengths.<sup>69</sup> The development of poly-*N*-substituted glycines and genetically engineered protein polymers for drag-tags will be discussed in the following sections.

To characterize a drag-tag, a completely monodisperse, fluorescently labeled ssDNA molecule is conjugated to a potentially polydisperse drag-tag. The DNA is conjugated to the drag-tag by the reaction between a maleimide-terminated drag-tag and a 5'-thiol-terminated oligomer of DNA (Figure 12.4). In electrophoresis, the monodisperse DNA acts like an “engine” that imparts the exact same amount of force on each drag-tag. Each different drag-tag is represented by a peak on the electropherogram of the free-solution separation; the polydispersity of the drag-tag can be evaluated by the resulting number of peaks. If just one product peak is present, then the drag-tag is actually

**FIGURE 12.4** Conjugation of DNA to drag-tag by reacting dye-labeled DNA terminated with a 5'-thiol group with a maleimide-terminated drag-tag. (Modified from Vreeland, W. N., et al. *Analytical Chemistry* 73, 1795–1803, 2001.)

monodisperse and can be used for DNA sequencing or genotyping. More than one product peak present indicates that the drag-tag has an underlying polydispersity that may not have been identified during a previous purification. Potential drag-tags are evaluated and their effective drag  $\alpha$  (measured in units equivalent to the drag from one base of DNA) is determined using Equation 12.3 and the identity  $\mu_0/\mu \approx t/t_0$ .<sup>14,68,69,73,75–78</sup>

### 12.3.1 SYNTHETIC POLYMERS

FSCE was first applied to the evaluation of synthetic polymers as potential drag-tags, specifically the water-soluble polymer (PEG) whose antifouling properties should keep it from interacting with the capillary walls. PEG with a polydispersity index (weight average molecular weight/number average molecular weight) of 1.01 was tested, which is considered “monodisperse” by commercial standards. The PEG-DNA bioconjugate was expected to show up on the electropherogram as essentially one peak. The necessity for absolute monodispersity of a drag-tag was quickly realized upon separating the PEG-DNA bioconjugates by free-solution CE (Figure 12.5). The polydispersity of the “monodisperse” PEG immediately ruled out its potential application as a drag-tag for DNA sequencing. Ever since this first experiment with PEG, FSCE has been the “gold standard” by which the monodispersity of a drag-tag is determined.

### 12.3.2 POLYPEPTOIDS

Polypeptoids are similar to polypeptides except the side chains are attached to the amide nitrogen of the peptide backbone instead of the  $\alpha$ -carbon<sup>79–81</sup> (Figure 12.6). Peptoids are synthesized by solid-phase synthesis on a peptide synthesizer using a “submonomer” approach<sup>79,81</sup> that proceeds by adding each “monomer” in a two-step process. With this method, many different side chain groups

**FIGURE 12.5** Electropherogram of FSCE analysis of DNA-PEG bioconjugate. A 20-base ssDNA oligomer was conjugated to a 5 kDa PEG. Separation was achieved in  $1\times$  TAPS buffer in a 100 cm (total length) capillary with 25  $\mu$ m diameter. Pressure injection was used (138 kPa-s), 300 V/cm running field strength with 5.6  $\mu$ A current. (Modified from Vreeland, W. N., et al. *Analytical Chemistry* 73, 1795–1803, 2001.)

**FIGURE 12.6** General structure of polypeptoid, with methoxyethyl as a glycine-like side chain. To attach to ssDNA, a thiol group is part of the R group at the end of the peptoid. (Modified from Haynes, R. D., et al. *Bioconjugate Chemistry* 16, 929–938, 2005; Zuckermann, R. N., et al. *Journal of the American Chemical Society* 114, 10646–10647, 1992.)

can be incorporated into the growing peptoid, including side chain analogues of amino acids. In particular, methoxyethyl has been used as a glycine-like side chain in peptoids for drag-tags because an *N*-methoxyethylglycine (NMEG) drag-tag is water-soluble, uncharged, and shows minimal or no interaction with the capillary walls.

### 12.3.2.1 Linear Polypeptoids

Peptoid drag-tags are advantageous because they can be purified to monodispersity by reversed-phase high-performance liquid chromatography (RP-HPLC). However, the solid-phase method can only synthesize linear polypeptoids up to 60 NMEG monomers before the yield drastically decreases from < 100% coupling efficiency of solid-phase synthesis.<sup>69,78</sup> The  $\alpha$ -value of peptoid drag-tags is  $\alpha \approx 0.2$ – $0.25$  per peptoid monomer.<sup>78</sup> Therefore, a linear peptoid would have to be 100–125 monomers in length to have an  $\alpha$  of 25 similar to streptavidin. Because solid-phase synthesis methods are limited to 60 monomers, achieving a large  $\alpha$  like 300 for long-read sequencing requires something other than a linear peptoid drag-tag.

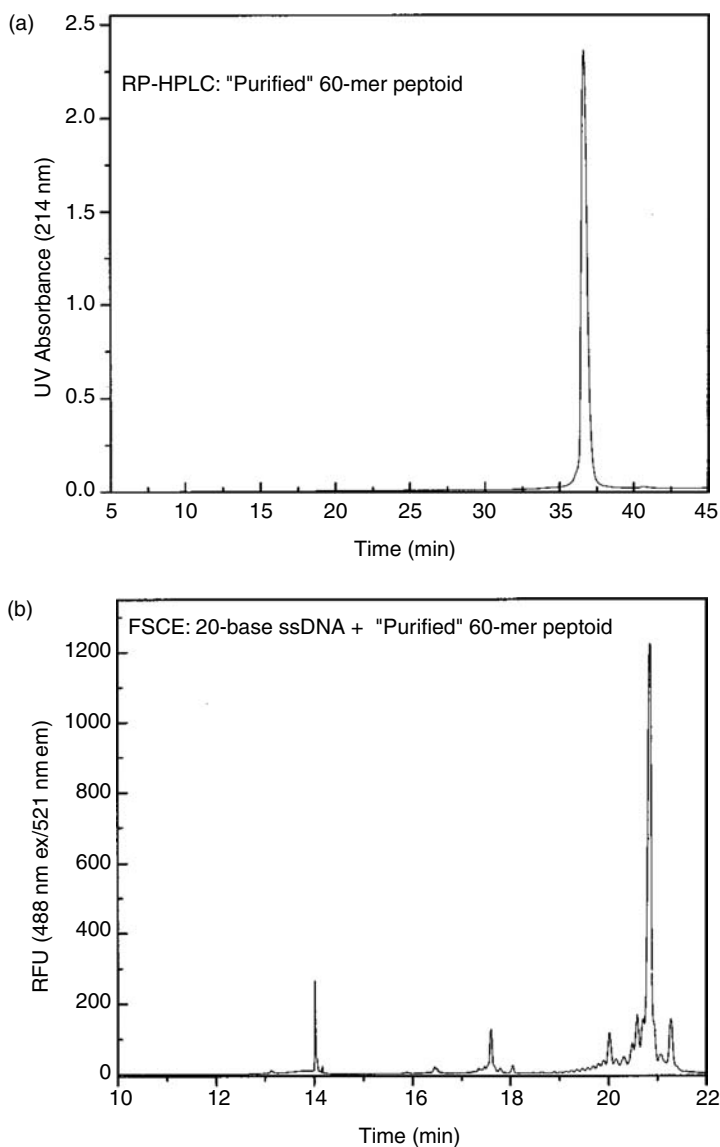

### 12.3.2.2 Branched Polypeptoids

Introducing oligopeptoid branches onto polypeptoid backbones is one approach to increase the effective drag of these synthetic drag-tags. At certain intervals in the synthesis of the peptoid backbone, side chains with a terminal  $\epsilon$ -amino group are incorporated. Branches with terminal glutamic acid residues can then be attached to the backbone via amide bonds. Using a 30mer peptoid backbone with five evenly spaced “grafting” sites, three differently sized branches were appended to the drag-tag backbone to determine the impact of branch size on the effective drag. The smallest “branch” was an acetyl group, and the other two branches were linear polypeptoid NMEGs with a length of either 4 or 8 monomers. The  $\alpha$ -value increased approximately linearly as the molar mass increased, with the effective drag of the octamer-branched drag-tag more than doubling that of the drag-tag with the acetyl groups as “branches.”<sup>77</sup> The original FSCE theory did not predict this; branched objects are more compact than if the branches were added serially to the end of a linear drag-tag and theory did not predict that the branch length would make a dramatic impact on the drag. The theory was recently re-examined, though, and now suggests several parameters to take into account when designing branches to help achieve the highest  $\alpha$ -value.<sup>14</sup> The search for the most effective drag-tag for long-read sequencing is now focused on finding the largest possible branch for a peptoid backbone.

### 12.3.2.3 Analysis of Solid-Phase Synthesis Products

FSCE can also show impurities present in solid-phase synthesis products that are not clearly evident by conventional purification methods. RP-HPLC with ultra violet (UV) detection is traditionally used to analyze solid-phase synthesis products such as peptoids and peptides as well as to separate them preparatively away from any deletion products. Since each synthetic monomer addition cycle is less than 100% efficient,<sup>73</sup> products that are one or two monomer units shorter than the desired product must be purified out to ensure monodispersity of the final polypeptide or polypeptoid. The separating power of FSCE was compared with analytical RP-HPLC traces after RP-HPLC purification (Figure 12.7). The one peak in the RP-HPLC trace actually separates into one large peak

**FIGURE 12.7** Analysis of polydispersity of a 60-unit NMEG polypeptoid drag-tag post RP-HPLC purification. RP-HPLC (a) shows one peak, but FSCE (b) shows a series of smaller peaks that may impact the drag-tag's read-length. (Reprinted from Vreeland, W. N., et al. *Bioconjugate Chemistry* 13, 663–670, 2002. With permission.)

with several smaller peaks in FSCE. While this drag-tag might have an  $\alpha$  appropriate for sequencing and is practically monodisperse by RP-HPLC, the slight polydispersity might negatively impact the read-length. Overall, FSCE is very useful for evaluating both polydispersity and the  $\alpha$ -value of a potential drag-tag and is recommended before any drag-tag is used to separate or sequence DNA.

### 12.3.3 GENETICALLY ENGINEERED PROTEIN POLYMERS

In order to meet all of the criteria for an ideal drag-tag and avoid the drawbacks of synthetic polymers or natural proteins, the approach of nonnatural “protein polymers” has been employed. Protein polymers are produced by genetic engineering and consist of a repeating amino acid sequence. In general, this repetitive sequence can be a mimic of a natural sequence motif (e.g., elastin, silk) or highly nonnatural and designed specifically for a particular structure (e.g.,  $\alpha$ -helix) or function.<sup>82–99</sup> The properties of protein polymers are determined by the selected DNA sequence that codes for the final protein and can be customized by arranging specific amino acids in a desired order. Unlike conventional, synthetic polymerization techniques, protein-based materials produced in biological systems, such as the bacterium *Escherichia coli*, offer much better control over the properties of the final product.<sup>100</sup> Protein engineering is not limited to just the 20 naturally occurring amino acids. Several researchers have successfully incorporated a wide variety of unnatural amino acid analogs into the protein production machinery of living cells.<sup>101–105</sup>

#### 12.3.3.1 Designing the Drag-Tag Sequence

The first and most important step in producing a nonnatural protein polymer is to design the actual sequence. In the genetic code, three DNA bases (a codon) code for either a particular amino acid sequence or a stop codon. The genetic code is degenerate; several different codons can correspond to the same amino acid. When designing the DNA sequence, it is important to use codons preferred by the particular host species because expressing highly repetitive protein sequences can rapidly deplete the available amino acid pool in the cell.

As mentioned previously, the ideal drag-tag characteristics are monodispersity, water solubility, lack of charged residues, unique attachment to DNA, and minimal adsorption to the microchannel walls. Based on these requirements, phenylalanine, isoleucine, tyrosine, and tryptophan were eliminated from consideration due to their strongly hydrophobic aromatic groups. Cysteine also was excluded because its thiol side-chain is highly reactive and may oxidize to form disulfide bonds. Several charged amino acids (lysine, arginine, histidine, aspartate, and glutamate) were similarly eliminated from consideration.

The first-generation of six protein polymer drag-tags that were designed for FSCE sequencing were designated PZ-1 through PZ-6. Glutamic acid was included, sparsely, in four of the sequences (even with the negative charge) to address concerns about water solubility. Valine and leucine were included in PZ-3 and PZ-4 to explore the effects of increasing hydrophobicity in drag-tags. The sequences were designed to generate random-coil structured protein polymers so each residue is exposed to the outside solvent and is not buried inside a sphere (such as in streptavidin). Unfortunately, not all of the proteins expressed well in *E. coli*, providing an important lesson to the designers and indicating the same persistence would be required. Of the proteins that could be expressed, none of these first six sequence designs was suitable as drag-tags for FSCE sequencing for the various reasons summarized in Table 12.1 and discussed in Reference 76. A key issue with the first generation drag-tags was the observed polydispersity that was later attributed to structural degradation of the drag-tag under acidic conditions, and more specifically, to deamidation of the glutamine into negatively charged glutamic acid.<sup>75</sup>

Therefore, the second generation drag-tags (PZ-7 and PZ-8) replaced glutamine with either serine or threonine, but of these only the PZ-8 sequence expressed well. Variants of this sequence containing a few serine-to-arginine mutations at different positions were also produced. The first of

**TABLE 12.1**  
**Summary of Initially Studied (Unsuitable) Drag-Tag Sequences**

Name	Repeating Sequence	Comments
PZ-1	Gly-Ser-Gly-Gln-Gly-Glu-Ser	Good expressibility and water solubility; too hydrophilic for RP-HPLC
PZ-2	Gly-Ala-Gly-Gln-Gly-Glu-Ala	purification; contains both glutamine and glutamic acid; similar electrophoretic mobility to DNA makes it poor drag-tag
PZ-3	Gly-Val-Gly-Gln-Gly-Glu-Val	Both: not well expressed by <i>E. coli</i> ; could not be purified in good yield
PZ-4	Gly-Leu-Gly-Gln-Gly-Glu-Leu	
PZ-5	Gly-Ala-Gly-Gln-Gly-Asn-Ala	Only obtained in impure preparation; both asparagine and glutamine included, which turned out to be nonideal; soluble in water only with addition of 1 M urea
PZ-6	Gly-Ala-Gly-Gln-Gly-Ser-Ala	Contains glutamine
PZ-7	Gly-Ala-Gly-Ser-Gly-Ser-Ala	Not well expressed
PZ-8	Gly-Ala-Gly-Thr-Gly-Ser-Ala	Well expressed and well behaved in aqueous solution

these variants has a mutation where one of every nine serines is replaced by a positively charged arginine. This mutant sequence and the original PZ-8 sequence have been expressed in at least three protein chain lengths (127, 253, and 505 amino acids). The average secondary structure of these proteins was profiled by circular dichroism (CD) spectroscopy, and all had spectra characteristic of random coil structures at 25°C in water. These results confirmed that the protein sequence had been successfully designed to form random coil proteins upon expression and purification.

Much effort and discussion has focused on making linear protein polymers for drag-tags but a parallel effort to create branched drag-tags is ongoing. These branched proteins have a sequence similar to the PZ proteins with the one notable exception that they include multiple lysines at varying intervals to be reactive sites for grafting on branches (either protein polymer or peptoid). A branched protein polymer is expected to generate greater hydrodynamic drag than a linear protein polymer of same length, based on the branched peptoid drag-tags.

### 12.3.3.2 Analysis of Protein Polymers as Drag-Tags

Unfortunately when these proteins are conjugated to DNA primers and analyzed in free-solution CE, all but the two 127-amino-acid proteins show multiple peaks, despite the exclusion of glutamine residues from the sequences. These additional peaks get more numerous as the protein polymer length increases, rendering these proteins useless as drag-tags. The expected effective  $\alpha$ -value can still be determined by FSCE assuming the final peak in the electropherogram is the desired protein. Figure 12.8 shows a plot of protein molecular weight versus  $\alpha$  for each protein. A clear linear trend exists for both series of proteins tested. The protein containing a few arginine mutations showed higher “effective”  $\alpha$ -values than their uncharged counterparts due to the positive charge “pulling” the molecule in the opposite direction of the DNA. No significant detrimental interaction of the positively charged drag-tags with the DNA or microchannel walls was observed. The inclusion of even more positively charged residues may increase the hydrodynamic drag and avoid the need to generate very long, uncharged, drag-tags to achieve high  $\alpha$ -values.

Meeting the requirement of a completely monodisperse drag-tag has proven more challenging than originally expected, and this work is still ongoing. Several theories have been explored and eliminated as causes of the heterogeneity, including the possibility that cell lysate proteases degrade the protein during purification. The process of histidine tag removal by formic acid with cyanogen bromide was also eliminated as a possible cause by using an enterokinase cleavage site already

**FIGURE 12.8** Chain length and charge of linear protein polymers (PZ-8 variants) versus effective  $\alpha$  as determined by FSCE.

coded into the expression vector to allow enzymatic removal of the histidine tag and by shortening the cyanogen bromide reaction time from 24 to 4 h. Also, protein obtained from cells lysed by a freeze/thaw process demonstrated the same polydispersity as those obtained from cells lysed by ultrasonication. Even though MALDI-TOF mass spectrometry appears to only show a single peak, a difference of one amino acid may be what generates additional peaks in the FSCE electropherogram.

### 12.3.4 DOUBLE-LABELED DNA

FSCE can also be used to test different labeling techniques. The dsDNA separations with streptavidin drag-tags back in 1998 revealed an anomaly: the drag from a drag-tag on both ends of the dsDNA was expected to be equivalent to double the drag of a drag-tag on only one end, but as can be seen in Figure 12.2a (inset), the effective drag from dsDNA with drag-tags on both ends is 17% more than double the drag of one drag-tag.<sup>16</sup> Accordingly, the theory of ELFSE was re-examined to determine the cause of this anomaly. The theory is thoroughly developed in Reference 68 to take these “end-effects” into account. The monomer “blobs” at the ends of the bioconjugate molecule were found to be weighted more than those in the middle of the bioconjugate in how they influence the effective drag and electrophoretic mobility of the bioconjugate.<sup>68</sup>

To determine how the theory compared to experimental data, two different lengths of linear polypeptoid NMEG drag-tags were used to test end-effects on ssDNA, and four different drag-tags (one linear polypeptoid NMEG drag-tag, one branched NMEG peptoid drag-tag, and two different protein polymer drag-tags) were used to test the effect of double-labeling dsDNA. One drag-tag on both ends of ssDNA increased the effective drag  $\alpha$  6–9% over one drag-tag that was twice as long. Double-labeling dsDNA increased the  $\alpha$  10–23% over one drag-tag twice as long.<sup>68</sup> Figure 12.9 shows

**FIGURE 12.9** Free-solution capillary electrophoresis analysis of single- and double-labeled fluorescently tagged ssDNA. (a) Is a separation with 20mer NMEG peptoid drag-tag, and (b) uses a 40mer. Peak 0 is unlabeled, “free” DNA. Peak 1 is 40mer DNA oligomer with one drag-tag; peak 2 is 20mer DNA with one drag-tag; peak 3 is 40mer DNA with two drag-tags; and peak 4 is 20mer DNA with two drag-tags. Separations were achieved in 36 cm capillaries (47 cm total length; 50  $\mu\text{m}$  inner diameter) with 22 V/cm electrokinetic injection for 15 s and current of 15  $\mu\text{A}$ . (Reprinted with permission from Meagher, R. J., et al. *Electrophoresis* 27, 1702–1712, 2006.)

the separation achieved with double-labeled ssDNA. Overall, the use of double-labeled DNA could be a way to increase the effective drag imparted by a particular drag-tag without having to synthesize another, much larger, drag-tag.

## 12.4 DNA ANALYSIS BY FSCE

### 12.4.1 DNA GENOTYPING: SINGLE-BASE EXTENSION

While DNA sequencing is often the “gold standard” in detecting disease-causing genetic mutations, it is very expensive and time- and energy intensive. A majority of the genetic mutations responsible for diseases such as sickle cell anemia, Alzheimer’s, and most cancers are single-nucleotide polymorphisms (SNPs) that are point mutations in a gene. Specifically, mutations in the *p53* gene have been implicated as the cause of many cancers; most are missense mutations that cause a change in amino acid.<sup>106–111</sup> Many different methods are currently used for detecting SNPs,<sup>112,113</sup> including single-base extension (SBE) assays. In SBE, the sample is amplified using primers that anneal one base 5′ of the known SNP location in a reaction mixture containing only fluorescently labeled

dideoxynucleotide terminators (ddNTPs) and no dNTPs. When the polymerase extends the chain from the 3' end of the primer, the ddNTP incorporated corresponds to the complement of the SNP.<sup>114</sup>

Bioconjugate electrophoresis was first applied to SBE genotyping in 2002 to separate three SNPs in the *p53* gene in approximately 9 min, testing four different mutants.<sup>72</sup> Free-solution electrophoresis is important to SBE because it eliminates the polymer matrix cost. The degree of multiplexing can also be increased much more easily with FSCE. The elution order and separation efficiency of peaks for unique loci is determined by the length of drag-tag; a longer and more expensive primer is not required. While the genotyping peaks were rather broad in these first separations, the advantages to this method are clear: multiplexed separations are possible in free-solution CE and should be easily achieved in microchip electrophoresis.

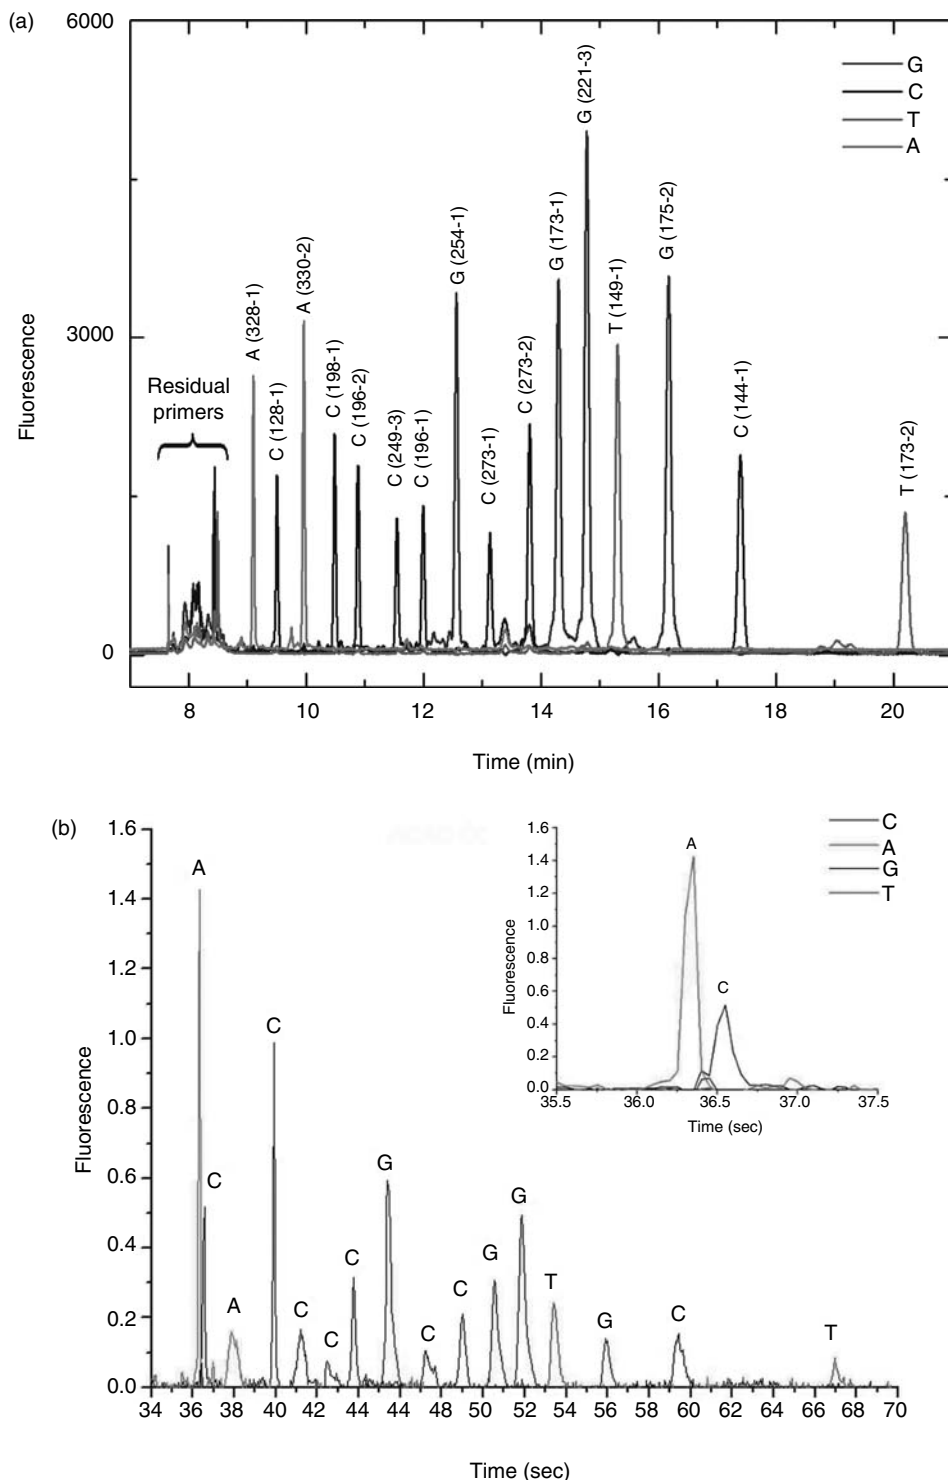

SBE-FSCE was further multiplexed in 2006 when 22 samples (21 mutants and 1 wild-type) were tested for mutations at 16 loci.<sup>115</sup> Thermal cycling times were decreased by 90%, and free-solution electrophoresis of the multiplexed SBE-FSCE reaction was performed both in capillaries (Figure 12.10a) and microfluidic devices (Figure 12.10b) with greatly improved separation resolution over the 2002 study. Separations by microchip electrophoresis decreased the separation time from 20 min in capillaries to less than 70 s in an 8-cm-long chip. The SBE-FSCE technique was 96.3% accurate in genotyping by this method; of 16 loci across 22 samples (total of 352 loci), 339 were correctly genotyped, including 5 wild-type/mutant heterozygotes that were later confirmed by direct sequencing.<sup>115</sup>

The “modular” approach of SBE-FSCE shows the promise of genotyping using free-solution bioconjugate electrophoresis. Any drag-tag can be conjugated to any primer, allowing the design of multiple different sets of primers to probe many loci. Because of the abbreviated thermal cycling protocol and rapid separation on the microchip, this assay is a promising candidate to be incorporated into an integrated microfluidic “lab-on-a-chip” device for genotyping.<sup>17,25–41,116</sup>

## 12.4.2 DNA SEQUENCING BY FSCE

Rapid, long-read DNA sequencing using capillary and/or microchannel electrophoresis is an ultimate goal of FSCE. Free-solution electrophoresis in microchips, in particular, eliminates the difficulties of loading viscous polymer matrix into the microchannels and ensures a higher run-to-run reproducibility. Because polypeptoids do not have sufficient drag capable of long-read sequencing, they have not been tried as drag-tags for sequencing. The branched peptoid drag-tag with five 8mer NMEG branches grafted to it had an  $\alpha$ -value of approximately 17,<sup>77</sup> and was used recently to sequence almost 100 bases (unpublished results R. J. Meagher, R. D. Haynes). However, the 8mer NMEG branches did not increase the effective drag of the branched polypeptoid drag-tag enough to make it as effective as the original streptavidin drag-tag.

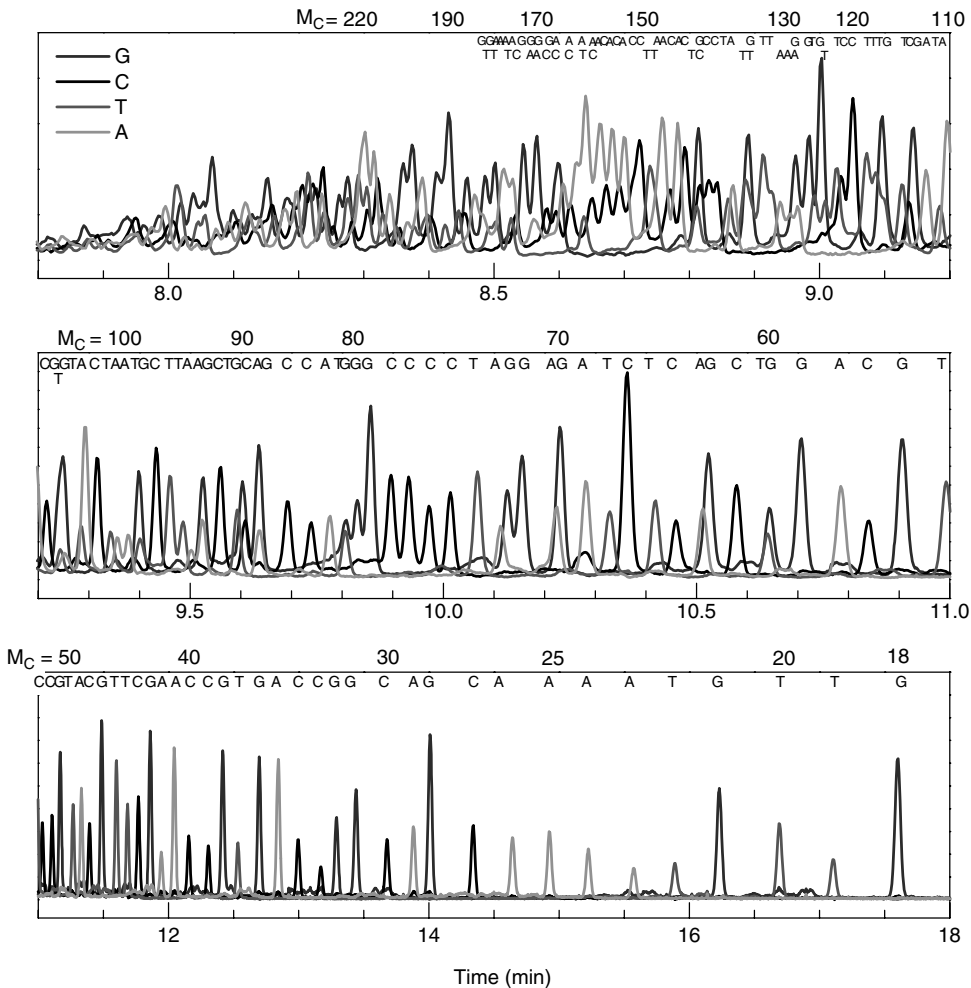

The recent successful cloning and purification of the PZ-8 protein polymer has allowed sequencing of end-labeled bioconjugates in free-solution to become a reality. The 127-amino-acid PZ-8 protein polymer has been purified almost to monodispersity, as mentioned previously. It has an  $\alpha$ -value of approximately 25, which is appropriate for ssDNA sequencing. Both PZ-8 variants have been tested as sequencing drag-tags. The PZ-8 sequence variant with two serine-to-arginine mutations has a higher effective drag than the unmutated PZ-8 (Figure 12.8) and thus was expected to have a longer read-length. To create sequencing fragments, a 5'-thiol terminated M13 primer was first conjugated to the pure, monodisperse 127-amino-acid PZ-8. A typical Sanger sequencing reaction mixture, including the drag-tag-labeled M13 primer, M13 ssDNA template, dNTPs, fluorescent dye-labeled ddNTPs, DNA polymerase, and a polymerase buffer is thermal cycled to create drag-tagged ssDNA sequencing fragments.<sup>54</sup> Notably, the sequencing reaction was carried out with the protein polymer drag-tag already conjugated to the thiolated primer, allowing for easy post-amplification cleanup and sample preparation.<sup>117</sup> The fact that the 127-amino-acid protein polymer conjugated to the 5' end of the thiolated 17mer M13 primer did not impact the DNA polymerase activity or

**FIGURE 12.10** (See color insert following page 810.) Electropherograms of multiplexed SBE-FSCE separation of 16 loci in a wild-type *p53* gene. (a) CE separation in 36 cm capillary (47 cm total length, 50  $\mu\text{m}$  inner diameter) in  $1\times$  TTE (89 mM Tris, 89 mM TAPS, 2 mM EDTA), 7 M urea and 0.5% (v/v) POP-6 for dynamic coating. (b) Separation on 8 cm microchip in  $1\times$  TTE (49 mM Tris, 49 mM TAPS, 2 mM EDTA) with 7 M urea on chip coated with poly-*N*-hydroxyethylacrylamide. Both separations were performed at 55°C. (Reprinted with permission from Meagher, R. J., et al. *Analytical Chemistry* 79, 1848–1854, 2007.)

primer–template hybridization is a positive step for the potential application of DNA sequencing by FSCE in genome centers and on integrated microfluidic devices.

The first 120 bases of sequencing of the M13 ssDNA sequencing template were very clearly resolved using the 127-amino-acid PZ-8 drag-tag with two serine-to-arginine mutations, and the next 60 bases could be distinguished with prior knowledge of the sequence (Figure 12.11), giving an effective read-length of nearly 180 bases.<sup>117</sup> Comparing Figure 12.11 with Figure 12.3, the peaks of the ssDNA sequencing analysis using the protein polymer drag-tag are significantly sharper. The 127-amino-acid protein polymer was also used to test the effect of capillary length, electrophoretic velocity, and ionic strength of the buffer on resolution of the separation of sequencing peaks. The longest capillaries allowed slightly narrower peaks with deeper valleys, at the cost of a fourfold increase in separation time, while changing electrophoretic velocity did not drastically impact the separations. Increased buffer concentrations slightly increased  $\alpha$ , but higher buffer concentrations caused more heat generation, which may degrade the quality of sequencing.<sup>117</sup>

**FIGURE 12.11** (See color insert following page 810.) DNA sequencing analysis of M13mp18 ssDNA in free-solution with genetically engineering protein polymer drag-tag in 36 cm capillary (47 cm total length, 50  $\mu\text{m}$  inner diameter) with 312 V/cm field strength and electrokinetic injection of 1 kV for 20 s. Capillaries were filled with  $1 \times$  TTE (89 mM Tris, 89 mM TAPS, 2 mM EDTA) with 7 M urea and 0.5% (v/v) POP-6 to dynamically coat the walls of the capillary. ## 12.5 METHODS DEVELOPMENT GUIDELINES

### 12.5.1 DRAG-TAG CLONING AND PRODUCTION

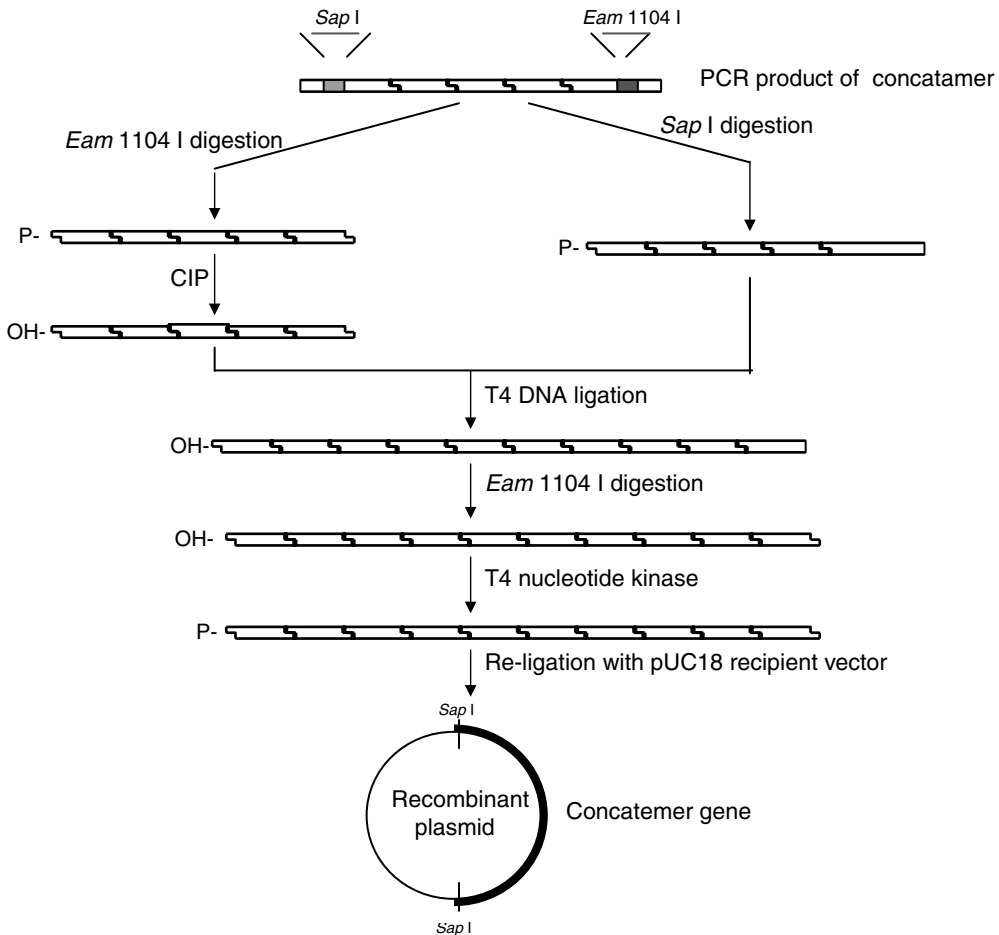

#### 12.5.1.1 Standard Protocol for Cloning and Production of Protein Polymers

Protein polymers are synthesized using biological systems (often *E. coli*) and then purified from the cell lysate by affinity chromatography. Chemical synthesis of peptides is limited to the production of short chains (<50 amino acids), and it is similarly difficult to synthesize long DNA oligonucleotides. The large repetitive gene necessary to express a protein polymer must be generated by joining several DNA “monomers” with compatible end base-pair sequences using a ligase enzyme.

Several cloning methods have been developed over the years to create repetitive genes for protein polymers.<sup>92,98,99,118–121</sup> Nonetheless, obtaining large concatemer genes was still difficult because of their limited yield after DNA ligation. Long concatemers could only be found by chance after laborious screening of hundreds of colonies. In order to consistently create the long DNA concatemers needed for expression of protein polymer drag-tags, a modified version of the seamless cloning method was developed called controlled cloning.<sup>74</sup> This method allows for the construction of large DNA concatemers without any specific sequence requirement using two Type II restriction enzymes, *Eam1104 I* and *Sap I*, which cleave downstream of their nearly identical recognition sites (Figure 12.12). Figure 12.13 illustrates the controlled cloning method for the example of doubling a multimer.

Each “monomer” of the gene is a 100 bp synthetic oligonucleotide that encodes three tandem repeats of a seven amino acid sequence. This oligomer is polymerase chain reaction (PCR)-amplified, enzymatically digested by the *Eam1104 I* enzyme to generate the 63-bp monomer DNA fragments, and then self-ligated to generate a ladder of different sized multimers. The gene is inserted into a cloning vector, pUC18, and colonies obtained after transformation of the plasmid into *E. coli* cells are screened for the desired insert sizes. Controlled cloning can then be used to combine one gene of the desired size with another, which may be the same or different in sequence and size.

After DNA sequencing confirms that the gene is correct, it is then moved into an expression plasmid, pET-19b, encoding an *N*-terminal histidine fusion tag, which is used to purify the desired protein by immobilized metal affinity chromatography (IMAC) from other cellular proteins. The protein is expressed in BLR(DE3) *E. coli* cells using either LB (Luria-Bertani) or TB (Terrific Broth) media. Cells are grown under antibiotic selection at 37°C until they reach mid-log growth phase with an OD<sub>600</sub> value between 0.6 and 0.8. The cells are then induced to begin protein expression with the addition of the lactose analog, isopropyl-β-D-thiogalactopyranoside (IPTG) at 1 mM, and grown for 3–4 h before harvesting by centrifugation. Cells are resuspended in buffer then lysed using multiple freeze/thaw cycles as well as ultrasonication. The clarified cell lysate is purified using column chromatography under denaturing conditions on either nickel or cobalt-chelated resin, which bind to the histidine tag. The protein with the affinity tag is eluted off the column with the addition of imidazole. The collected fractions are analyzed using sodium dodecyl sulfate–polyacrylamide gel electrophoresis (SDS–PAGE). Elution fractions are dialyzed against water to remove salts and small molecular weight contaminants before being lyophilized into a dry powder. Typical protein

**FIGURE 12.13** Controlled cloning method for generation of long concatemer genes. (Reprinted with permission from Won, J. I. and Barron, A. E. *Macromolecules* 35, 8281–8287, 2002.)

polymer yields range from 20 to 30 mg/L of cell culture. The purified protein is then analyzed for purity by RP-HPLC on a C4 column. Peaks are detected by UV absorbance at 220 nm. MALDI-TOF analysis yields the molecular mass of the protein sample which can then be compared to the expected mass. Removal of the affinity tag is achieved by reaction with cyanogen bromide in formic acid for 24 h.<sup>122</sup> Cleavage of the affinity tag is essential as it contains multiple positively and negatively charged amino acids that can adversely affect the drag-tag's properties in free solution.<sup>76</sup>

### 12.5.1.2 Polypeptoid Synthesis

Polypeptoid synthesis reactions are carried out on automatic peptide synthesizers (ABI 433A; Applied Biosystems, Foster City, CA). Fmoc-rink amide resin (0.25 mmol; Nova Biochem, San Diego, CA) is deprotected by treating with 20% (v/v) piperidine (ABI) in dimethylformamide (DMF; Fisher Scientific, Itasca, IL) in two 15-min treatments. To assemble the polypeptoid chain, alternating cycles of bromoacetylation and amine displacement of the bromine from the *N*-terminal alkyl halide are performed (Figure 12.14). To bromoacetylate, the resin is vortexed for 45 min with 4.3 mL of 1.2 M bromoacetic acid (Aldrich, Milwaukee, WI) in DMF and 1 mL of diisopropylcarbodiimide (DIC; Aldrich). The liquid is drained from the resin, and the resin is washed four times with 7 mL

**FIGURE 12.14** Reaction scheme for synthesis of linear NMEG polypeptoids of length 20, 40, or 60 monomer units and addition of maleimidopropionic acid. (Reprinted with permission from Vreeland, W. N., et al. *Bioconjugate Chemistry* 13, 663–670, 2002.)

of DMF. After the DMF wash, 4 mL of 1M methoxyethylamine (Aldrich) in *N*-methylpyrrolidone (NMP; Aldrich) is introduced to the reaction vessel and vortexed for 45 min to displace the amine and introduce the methoxyethyl side-chain moiety to the growing chain. The 4× DMF wash is then repeated.<sup>72,73,115</sup>

The peptoid chain is cleaved from the resin by treating it with 95% trifluoroacetic acid (TFA; Aldrich) in water for 30 min. After the peptoid is cleaved from the resin and dissolved in water, RP-HPLC is used to purify the peptoids (C18 packing, Vydac, 5 μm, 300 Å, 2.1 × 250 mm). A linear gradient of 10–60% B in A is typically run at 60°C over 50 min at a flow rate of 0.1 mL/min, where solvent A is 0.1% TFA in water and B is 0.1% TFA in acetonitrile. Polypeptoid concentrations are detected by UV absorbance at 214 nm. To fully purify the peptoids, preparative HPLC (C18 packing, Vydac, 15 μm, 300 Å, 22 × 250 mm) is run using the same solvents, gradient, time, and a flow rate of 12 mL/min.<sup>72,73,115</sup>

### 12.5.2 DNA + DRAG-TAG CONJUGATION

Conjugation of DNA to a drag-tag can be used for one of two purposes. To test the monodispersity and effective drag of a newly produced drag-tag, a fluorescently labeled DNA oligomer should be used so the bioconjugate can be tested by electrophoresis immediately postconjugation. For a sequencing or genotyping reaction, however, DNA primers should not have a fluorescent label if fluorescently labeled ddNTPs are to be used. DNA and drag-tags are conjugated through the use of a maleimide linker. For DNA to be attached to a maleimide-activated drag-tag, it must first be modified to have a thiol (-SH) functionality on its 5' terminus. Any DNA–DNA disulfide bonds present must be reduced to ensure the highest degree of conjugation efficiency. To reduce the DNA, 2 nmol of DNA primer are incubated with a 20:1 molar excess of Tris (2-carboxyethyl)phosphine (TCEP; Acros Organics, Morris Plains, NJ) at 40°C for 90 min.<sup>115</sup>

Protein polymer drag-tags are activated with a maleimide by the addition of sulfosuccinimidyl 4(*N*-maleimidomethyl)cyclohexane-1-carboxylate (Sulfo-SMCC; Pierce Biotechnology, Rockford, IL). A mixture of a 10:1 excess of Sulfo-SMCC to 1.2 mg of protein polymer in 80  $\mu$ L of 100 mM sodium phosphate buffer (pH 7.2) is vortexed for 1 h at room temperature. Excess Sulfo-SMCC is removed from the activated protein polymer drag-tag by gel filtration with a Centri-Sep column (Princeton Separations, Adelphia, NJ). The activated, purified protein polymer is frozen, lyophilized and then resuspended to a concentration of 10 mg/mL.<sup>117</sup> Polypeptoid drag-tags are activated with a maleimide during the solid-phase synthesis on the peptide synthesizer before cleavage. To do this, a mixture of 500  $\mu$ L of 1.2 M maleimidopropionic acid (Fluka, Buchs, Switzerland) in DMF and 144  $\mu$ L of DIC is added to the resin and mixed for 45 min, then washed three times with DMF (Figure 12.14).<sup>73</sup> After cleavage and purification by HPLC, the peptoid is frozen, lyophilized to a golden, viscous oil and then dissolved in water to a concentration of 10 mg/mL.

To conjugate the activated drag-tag to the reduced DNA, 90 pmol of DNA is mixed with 2.5 nmol of drag-tag in a total volume of 10  $\mu$ L of sodium phosphate buffer at pH 7.2 (Figure 12.4). The mixture is then incubated at room temperature for 3–24 h.<sup>115,117</sup> A large excess of drag-tag to DNA is necessary to ensure nearly complete conjugation of drag-tags to each DNA molecule.

### 12.5.3 THERMAL CYCLING PROTOCOLS

Single-base extension (SBE) reactions are commonly used both for genotyping and also for testing drag-tag + DNA primer conjugations. Because neither the drag-tag nor the DNA primer is fluorescently labeled, one fluorescently labeled ddNTP is added to the DNA so the bioconjugate can be detected by laser-induced fluorescence (LIF). SBE reactions require a sequencing polymerase, polymerase buffer, dye-labeled ddNTPs, DNA primer, and DNA template. To this end, the SNaPshot Multiplex Kit (ABI) has been frequently used for SBE reactions. The SNaPshot kit premix includes a sequencing polymerase, reaction buffer, and dichlororhodamine (dRhodamine) dye-labeled ddNTPs. SBE reactions are prepared by mixing 2.5  $\mu$ L of the SNaPshot premix, 1 pmol of primer + drag-tag conjugate, 0.025–0.10 pmol of template DNA, 0.5  $\mu$ L of 125 mM HCl, and sufficient water for a total volume of 5  $\mu$ L. The mixture is then thermocycled for 5 cycles at 96°C for 2 s (denaturation), 51.5°C for 5 s (annealing), and 60°C for 10 s (extension). Centri-Sep gel filtration columns are then used to remove excess dye terminators and buffer salts from the reaction mixture before electrophoresis.<sup>72,115</sup>

DNA sequencing reactions differ from SBE reactions in that they also include dNTPs in the reaction mixture to extend the chain further than just one base by Sanger sequencing. For ELFSE sequencing, the following reaction mixture is used: 5  $\mu$ L of SNaPshot premix, 8 nmol of dNTPs, 4.2 pmol of M13 primer (5'-**X**<sub>1</sub>GTTTTCCCA-GTCACGAC, where **X**<sub>1</sub> is a 5'-C6 thiol linker) conjugated to a drag-tag, 0.16  $\mu$ g of M13mp18 control DNA template (Amersham Biosciences, Piscataway, NJ), and sufficient water for a total volume of 10  $\mu$ L. The mixture is then thermocycled for 26 cycles at 96°C for 5 s (denaturation), 50°C for 5 s (annealing), and 60°C for 30 s (extension). For purification, Centri-Sep gel filtration columns are used to remove excess dye terminators, buffer salts, and dNTPs before electrophoresis.<sup>117</sup>

### 12.5.4 ELECTROPHORESIS CONDITIONS

Capillary electrophoresis separations of DNA + drag-tag conjugates are performed in a denaturing buffer: 1  $\times$  TTE (89 mM Tris, 89 mM TAPS, 2 mM EDTA) with 7 M urea and a 0.5–1% (v/v) POP-5 or POP-6 polymer solution (ABI) for a dynamic wall coating agent to suppress electroosmotic flow (EOF) and prevent adsorption to capillary walls. Filtering the buffer with a 0.45  $\mu$ m filter before loading it into the capillaries and buffer reservoirs reduces noise. In theory, any capillary array instrument with LIF detection (preferably 4-color) can be used for ELFSE separations. Capillaries with an effective length from inlet to detector of 36, 50, and 80 cm have been used to separate both ELFSE sequencing and genotyping fragments. Before analysis by electrophoresis, samples

should be denatured at 95°C for 30–60 s and snap-cooled on ice for 2–5 min. Typical electrophoresis conditions include electrokinetic injection with a potential of 1–2 kV applied for 5–30 s and running voltage of 15 kV, all at 55°C.<sup>68,115,117</sup>

## 12.6 FUTURE DIRECTIONS

In order for DNA sequencing by FSCE to make an impact on the sequencing field, sequencing of at least 400 bases at a time is necessary. At present, a monodisperse drag-tag with a significantly larger effective drag  $\alpha$  is the major obstacle blocking long-read sequencing by free-solution electrophoresis of DNA + drag-tag conjugates. Long protein polymers of the PZ-8 family are currently the most promising large drag-tags because the (GAGTGSA) sequence has proved amenable to this method. Research is also underway to investigate the possibility of achieving drag-tags with appropriate  $\alpha$ -values for long-read sequencing by attaching very large branches to peptoid backbones.

As can be seen in Figure 12.11, the final peaks of FSCE sequencing are over-separated while the beginning peaks are under-separated. For long-read sequencing to be efficient and competitive, the smaller molecules (final peaks) need to be less resolved, and the large molecules (first peaks) need better resolution. The over-separation of the last peaks does not limit the read-length of the sequencing but does increase the separation time. The number of bases of sequencing read by FSCE is, however, limited by the under-separation of the first peaks. FSCE separations have always been performed under conditions to minimize EOF; however, strong EOF should cause rapid elution of small DNA fragments with inherently low electroosmotic mobility. Therefore, performing FSCE separations in the presence of strong EOF was predicted to reverse the migration order of DNA fragments so that they elute in order from smallest to largest, like CGE. The possibility of performing FSCE with EOF was examined theoretically to determine if it would also slow down the longer molecules and speed up the smaller ones when the migration order was reversed.<sup>66</sup>

A theoretical study of FSCE with EOF showed that FSCE in the presence of EOF mobility exactly equivalent to the free-solution mobility of DNA (scaled EOF mobility = 1) will more than double the

**FIGURE 12.15** Graph of size resolution factor as a function of the number of ssDNA bases that are sequenced. When the size resolution factor is  $\leq 1$ , single-base resolution of ssDNA fragments is possible. The scaled EOF mobility is the EOF mobility divided by the free-solution mobility of DNA. Therefore, the read-length is predicted to be the longest when the EOF mobility exactly equals the free-solution mobility of DNA. (Reprinted with permission from McCormick, L. C. and Slater, G. W. *Electrophoresis* 27, 1693–1701, 2006.)

read-length of sequencing. The counterflow of EOF not only reverses the migration order of DNA fragments but also speeds up small fragments while slowing down long fragments. The impact of the scaled EOF mobility on read-length in bases of ssDNA is shown in Figure 12.15, which used the effective drag of streptavidin as a comparison. According to these results, approximately 100 bases of ssDNA that were sequenced in Figure 12.3 could actually have been 235 bases of ssDNA if the EOF mobility was accurately tuned to be equal to the mobility of DNA in free-solution.<sup>66</sup> According to this theory, FSCE with a scaled EOF mobility of 1 could be a significant contributor in the search for long-read free-solution sequencing. The combination of FSCE with EOF, a drag-tag with a significantly large  $\alpha$ -value, and electrophoretic separations on a microfluidic device offers the opportunity for sequencing by FSCE to be competitive with current methods of DNA sequencing. Both glass and plastic microfluidic devices can be easily functionalized with different coatings, allowing EOF to be tuned for FSCE separations to test how experimental data compare to the theory of FSCE with EOF. Once long-read sequencing by FSCE is achieved, FSCE has the potential to be seamlessly integrated into a “lab-on-a-chip” integrated microfluidic device.<sup>25–37,40,41,123,124</sup> If long-read sequencing in free-solution can be incorporated into a fully integrated microfluidic device, it has the chance to be competitive in the race for the \$100,000 genome.

## ACKNOWLEDGMENT

The authors would like to thank Louisa R. Carr for her help in the preparation of this manuscript.

## 13.1 INTRODUCTION

The detection of material in a capillary column has proven to be interesting and dynamic over the years.<sup>1</sup> Ultimately, the ability to detect a given analyte comes down to the amount of material in the cross-sectional area of the capillary at the detector location. For example in ultra violet (UV) detection, the absorbance of light,  $A$ , is related to three terms in the Beer–Lambert law,<sup>2</sup>

$$A = \epsilon lc. \quad (13.1)$$

The molar absorptivity,  $\epsilon$ , is an intrinsic property of the analyte, the second term,  $l$ , is the path length the light will travel through the medium; for capillary electrophoresis (CE), the second term is small (25–100  $\mu\text{m}$ ) and cannot be easily change without impacting the resolution of the separation process. Thus, manipulation of the third term,  $c$ , the concentration of the analyte of interest, has evolved into a topic of significant interest.

### 13.1.1 THE KOHLRAUSCH REGULATION FUNCTION AND STACKING

While there are a number of methods by which analytes can be stacked or preconcentrated in CE, ultimately, all stacking phenomena require a change in analyte velocity as the analyte transitions from the sample zone to the background electrolyte (BGE).

The capillary can be viewed as a wire, which will carry current when a potential is placed across it. The amount of potential drop is related to the resistivity of the cross-sectional area of the column. In a wire, the free electrons move from one end of the wire to the other and their ability to move freely is a measure of the resistance of the wire. In the liquid domain where CE resides, each ionic species has the ability to carry a part of the current based on its charge,  $z$ , and concentration,  $c$ . Since each ion has a unique mobility, the sum of all the ionic species in the cross-sectional area is a measure of the resistance. Before the application of potential, the Kohlrausch regulation function (KRF)<sup>3</sup> for a given point in the capillary is defined by the following equation:

$$\omega = \sum_i \frac{c_i z_i}{|\mu_i|}, \quad (13.2)$$

where  $c_i$  is the concentration of a given ion,  $z_i$  is the relative charge of strong electrolytes, and  $\mu_i$  is the mobility. For any given point in the capillary, the KRF value,  $\omega$ , will remain constant. With that in mind, upon application of voltage, species will move in and out of said cross-sectional area and increase (stack) or decrease (destack) in concentration in order to satisfy this function. For example, if the whole column was filled with a single mono electrolytic compound like sodium chloride dissolved in water, Equation 13.2 would allow the calculation of the Kohlrausch value at all points from one end of the capillary to the other like a wire. As different ions are added to the system, the equation becomes a summation of all the ions and their mobilities as they move into and out of the analysis point. It must be noted that each time the electric field is broken; the ionic composition at the time of reconnection will generate a new Kohlrausch value. Thus, an injection potential will have one Kohlrausch value and separation will have a second Kohlrausch value. The delta in values between the two events can help further stack the samples into tighter bands.<sup>4</sup>

### 13.1.2 THREE SOLUTIONS TO THE KRF

#### 13.1.2.1 Continuous Systems

There exist three types of states for the regulation function to operate. State 1 is where the BGE is continuous throughout the capillary. It is assumed that in this state a low analyte concentration is present in the sample plug and the presence of analyte does not affect the Kohlrausch value anywhere throughout the capillary. Put simply, the sample plug has the same Kohlrausch value as the BGE region surrounding it, thus, has no boundary. The flux of ions in and out of the cross-sectional area is uniform. This state is known as zone electrophoresis. Upon application of voltage, the sample compounds move out of the sample region as a function of their intrinsic mobilities and more importantly, no velocity difference exists between analyte in the sample zone and analyte in the BGE. Thus, the back end of the sample maintains equidistance from the front end of the sample. That velocity,  $v$ , is a function of the ions mobility and is given in the following equation:

$$v = \mu E, \quad (13.3)$$

where  $E$  is the electric field across the capillary. The width of the peak for each compound in the sample would be as narrow as the first original injection plug barring the diffusion process. Figure 13.1 shows several mobility markers from a short electrokinetic injection. The peak widths are becoming wider as the amount of time spent in the column increase due simply to longitudinal diffusion.

The second state is where the sample plug is higher or lower in BGE concentration than that of the surrounding BGE. If the sample plug is lower in concentration, the back of the sample plug will migrate rapidly toward the front of the plug because the Kohlrausch value at the boundary would decrease the sample ion velocity whereas the rest of the sample is still under the original Kohlrausch

**FIGURE 13.1** An electropherogram of 13 mobility markers run on a MegaBACE 4000. Injection voltage 8 kV, 20 s, run voltage 8 kV, 60 min, and oven temperature is 44°C. Mobilities calculated using a 60 cm long capillary, 43 cm to the detector. Concentration of each marker is 5 nM.

value. This difference in velocity is directly related to the difference in the concentrations as seen in the following equation:

$$v = \mu E = \mu IR = \mu I/c. \quad (13.4)$$

The resistance ( $R$ ) is inversely proportional the concentration ( $c$ ) of the electric field carrying ions. Thus, sample is stacked into a small region and the concentration increases, which allows a lower concentration sample to be detected. The front boundary (or the detector side of the sample plug) is a stable stationary boundary and does not move; only the sample moves through it. This stacking mechanism (see Figure 13.6) is commonly referred to as field-amplified sample stacking (FASS). If the sample plug is higher in concentration than the surrounding BGE, the plug will spread out, as the front of the plug has a higher velocity than the back end. The front boundary is a function of the Kohlrausch value calculated at the time of electric application and will cause mixing of the sample with the BGE to maintain the Kohlrausch value. This effect is known as electrodispersion and often presents as analyte fronting, and is typically considered undesirable. In continuous systems, the boundaries are stable and stationary and will not move except by electroosmotic flow (EOF).

### 13.1.2.2 Discontinuous Systems

The third state requires a multi-ion sample matrix (SM). In this system, there are several ions present of varying mobilities at high enough concentrations to affect the electric fields. For example, the column matrix can include an ion with a greater mobility than those in the sample. In effort to satisfy the KRF, this ion with the greatest mobility will have the ion next largest mobility ion to stack up behind it. The third ion and so further will fall in line; the ions are stacked into regions where the concentration/mobility (KRF) equals the leading electrolytes value. Thus, low concentration ions would stack into very narrow bands and higher concentration ions will be broader. This state is commonly known as isotachopheresis (ITP). There are several review articles,<sup>5-7</sup> which explain the

various states in more detail. In a discontinuous system, the boundaries between the ion species are moving but stable through the system. They will move from one end of the column to the other and are called system peaks.

Another version of a discontinuous system is called sample self-stacking.<sup>8,9</sup> In this system, a co-ion is placed into the sample matrix, which acts like the leading electrolyte in ITP but only during the injection phase. After injection, the sample will continue to stack until the stacking ion leaves the sample zone. In Reference 9, an equation is presented to calculate a stacking ratio known as  $a_{\text{crit}}$ .

$$a_{\text{crit}} = [(\mu_b + \mu_r)/(\mu_a + \mu_r)] \times [(\mu_a - \mu_x)/(\mu_x - \mu_b)] \quad (13.5)$$

where  $\mu_x$  is the mobility of the last ion to be stacked,  $\mu_a$  is the mobility of the major stacking co-ion,  $\mu_b$  is the mobility of the sample BGE (which may not be the same as the separation run buffer), and  $\mu_r$  is the mobility of the counter ion of the system.  $\mu_a$  is the same as the leading electrolyte in ITP and  $\mu_b$  is the trailing electrolyte. Thus, a temporary ITP event is setup in the sample during electrokinetic injection and during the first moments of the separation time.<sup>9</sup>  $a_{\text{crit}}$  is the theoretical value at which the major co-ion in the sample system is proposed to self-stack the slower ions,  $\mu_x$ , in a transitory ITP fashion.

In addition, in Reference 9, a value related to the major ion concentrations is give.

$$a = C_s/C_b \quad (13.6)$$

where  $C_s$  is the concentration of the sample-stacking co-ion,  $C_b$  is the concentration of the sample BGE. The value of “ $a$ ” will indicate if the sample system is near or at a self-stacking domain. If the “ $a$ ” value is greater than or equal to  $a_{\text{crit}}$  then self-stacking can occur. If not, then other stacking or destacking conditions are the driving force for the analysis.

## 13.2 EXAMPLES OF LONG INJECTION STACKING

In general, sample stacking will occur when a boundary exists between the sample regions and the surrounding electrolyte (BGE). This boundary must be stable for the length of time such that the concentration of the sample of interest can be increased. When the boundary has passed on, stacking will stop and normal zone electrophoresis occurs. Several standard methods for boundary formation and use are described elsewhere<sup>1,4</sup> like FASS, capillary ion electrophoresis,<sup>10</sup> and ITP to name a few.

Several novel stable pseudostationary boundary techniques have appear, one technique dubbed moving chemical reaction boundary<sup>11</sup> forms a neutral zone in the column were the  $\text{H}^+$  ions combine with the  $\text{OH}^-$  ions to make a water zone. This zone is stable and leads to stacking across it. A second method uses EOF balanced against back-pressure to hold the stacking boundary in a fixed location.<sup>12</sup> The stability of the boundary allows for injections up to 3 h to be made.<sup>13</sup> The most robust method for long injects has arguably been electrokinetic injection out of a sample vial in which the column has one Kohlrausch value and the vial a lower value. This method has shown to improve sample injection by 1000 fold.<sup>14</sup>

When considering long electrokinetic injections, it becomes necessary to carefully consider the ionic species included in the sample matrix and the BGE. Figure 13.2 illustrates the importance of matching the composition of the ions in the sample matrix to the BGE. In this case, 4-Morpholinepropanesulfonic acid was added to the sample matrix in order to achieve a desired pH for purposes of a reaction; thus creating a discontinuity between the sample matrix and the BGE (100 mM TAPS). Consequently, a stable moving boundary (or system peak) results between the MOPS in the sample matrix and *N*-[Tris(hydroxymethyl)methyl]-3-aminopropanesulfonic acid in the BGE (noted in Figure 13.2 by arrows). With increasing injection time, this system peak becomes more obvious, and more importantly, significant destacking of analytes that have to migrate through this

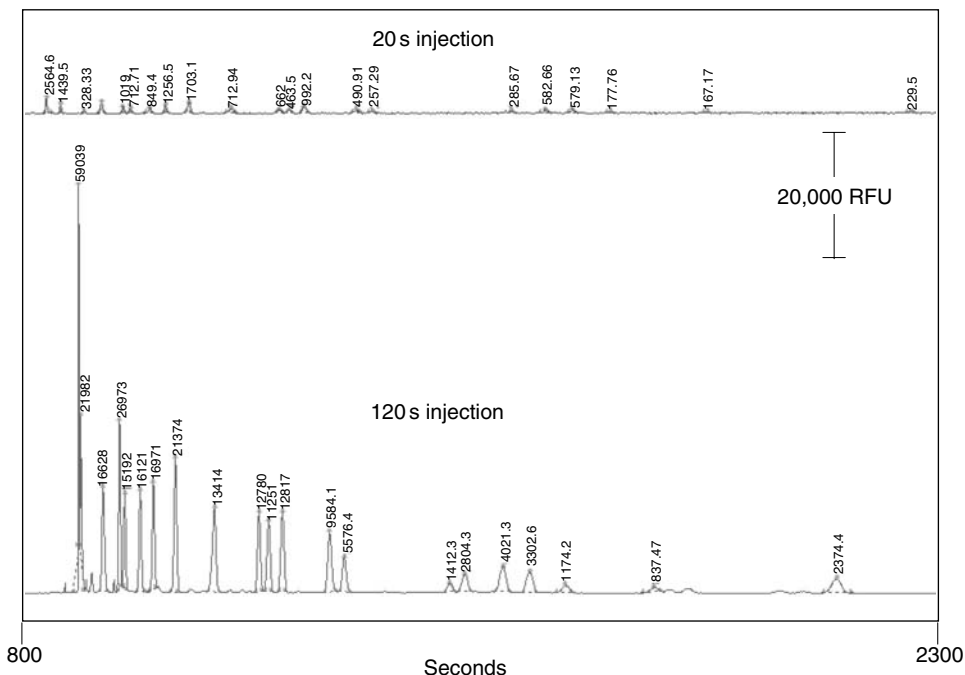

**FIGURE 13.2** Injection of mobility markers prepared in a 100 mM MOPS buffer system (pH 7.9). The injection time ranged from 20 s in the top image to 120 s in the bottom image. The separation was done on a MegaBACE 1000, injection voltage was 15 kV, run voltage 15 kV, run time 45 min, oven is set to 44°C. The MOPS system peak is located at about 28 min and indicated by an arrow.

boundary is observed. If the sample matrix composition is changed such that TAPS is in both the sample matrix and BGE (Figure 13.3), the injection time can be increased to 120 s and the system peak is located at the interface of the column and the sample vial.

To further push the limits of long injections a mobility difference between the major current carrying ionic species is required, resulting in the formation of a stable moving boundary; sample will stack in the plug during the time it takes to establish steady-state conditions. The leading or terminating electrolyte serves to define the electric field that each of the analyte zones experience such that band width will adjust itself to have the same concentration per cross section as the leading or terminating ion (isotachopheresis). Using a self sample-stacking ion in the sample plug at the appropriate “ $a$ ” value can generate a transient ITP event to occur during the injection and the first part of the separation time. The sample compounds isotachopheretically stack as the leading ion is slowed down by the mismatch at the moving boundary between the sample plug and the BGE. After the leading ion moves into the separation part of the column, the self-stacked stops and the sample begins to separate as if under zone electrophoresis and the resolution are preserved.

Close proximity to  $a_{crit}$ , as determined by the ratio of the concentration of the sample-stacking co-ion to the sample BGE (Equation 13.6), will result in a steady-state ITP effect before the leading ion is out of the sample zone. For the set of mobility markers shown in this work, a range of  $a_{crit}$  can

**FIGURE 13.3** Comparison of a 20 s injection with a 120 s injection using 100 mM TAPS buffer (pH 8.3) instead of 100 mM MOPS (pH 7.9) buffer in the sample.

be determined from Equation 13.5. On the basis of the use of chloride (from  $\text{MgCl}_2$ ) as the leading electrolyte and TAPS as the trailing electrolyte; a range of  $a_{\text{crit}}$ 's from 1.23 to 34.24 can be calculated. Figure 13.4 illustrates the difference between an “ $a$ ” value (ratio of chloride concentration to TAPS concentration) close to  $a_{\text{crit}}$  versus not close to  $a_{\text{crit}}$ . In the top trace, “ $a$ ” is 0.5; it is apparent that the mobility markers with  $a_{\text{crit}}$  values closest to 0.5 are stacked more efficiently (peaks A and B with  $a_{\text{crit}}$  values of 1.23 and 1.43, respectively). Decreasing the TAPS concentration relative to the chloride concentration to yield an “ $a$ ” value of 4.0 drastically improves the efficiency of stacking for markers with much higher  $a_{\text{crit}}$  values, allowing injection times up to 150 s long with no loss in resolution or distortion in peak shape. However, there is a functional limit to the amount of self-stacking that can occur as determined by the time it takes the leading electrolyte to migrate out of the sample zone. If electrokinetic injection continues beyond this point significant, destacking can occur as illustrated by Figure 13.5.

Whether the stacking technique is called field-amplified stacking, transient isotachopheresis, or sample self-stacking, the driving force in on-column sample preconcentration for charges species is the need to satisfy the initial KRF conditions. Under separation and sample matrix conditions where the KRF is difficult to determine, simply calculations such as  $a_{\text{crit}}$  and “ $a$ ” offer a rapid evaluation of conditions for optimal transient ITP.

### 13.3 SAMPLE STACKING IN MICELLAR ELECTROKINETIC CHROMATOGRAPHY

Micellar electrokinetic chromatography (MEKC) is a mode of CE primarily used in the separation of neutral molecules. Since a mixture of neutral molecules will all migrate with EOF, it becomes necessary to include a proxy within the BGE to afford a separation. This proxy is typically a micelle—an

**FIGURE 13.4** Electropherogram of the mobility markers run under different sample self-stacking conditions as defined by the concentration of chloride. The background buffer was 100 mM TAPS with 25 mM  $\text{MgCl}_2$  for an “ $a$ ” value = 0.5 and 12.5 mM TAPS BGE with 25 mM  $\text{MgCl}_2$  for an “ $a$ ” value = 4.0. The  $x$ -axis is setup as a relative scale in which the MF is set at zero and the ML peak is set as 1.0. All the other peak mobilities are calculated relative to this unit scale. The data were generated on a MegaBACE 4000 under the same condition as Figure 13.1.

**FIGURE 13.5** Electropherogram of the mobility markers at 150 s versus 300 s injection time. Data were generated on a MegaBACE 4000 as per Figure 13.1.

aggregate of surfactant molecules. Neutral analytes migrate into and out of the micelle, and when in the micelle, briefly take on the electrophoretic mobility of the micelle.

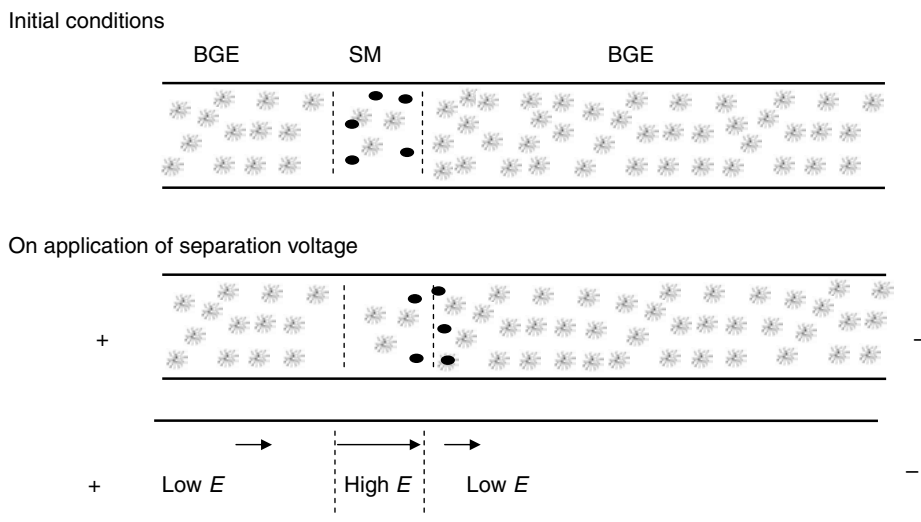

In the previous sections, several methods of sample preconcentration were described. Regardless of the mechanism, every example of sample stacking requires a change in the velocity of the analyte as determined by the drive to maintain the KRF value. Unfortunately, neutral analytes do not contribute to the KRF and a different perspective on sample stacking must be taken. There are a number of stacking methods available when using MEKC. This section will describe the fundamental mechanism and conditions by which sample preconcentration of neutral molecules occurs.

### 13.3.1 MODES OF SAMPLE STACKING IN MEKC

#### 13.3.1.1 Field-Amplified Stacking

Field-amplified stacking is made possible by preparing sample in diluted surfactant solution such that the conductivity of the sample matrix is lower than that of the BGE.<sup>15</sup> This results in localized higher electric field in the sample zone. When using normal polarity with a high-EOF velocity, this will result in analyte and micelle in the sample zone to rapidly travel toward the negative electrode due to the increased field strength in the sample zone. On entering the BGE, the analyte will experience a lower electric field, resulting in stacking. This mechanism is illustrated in Figure 13.6.

Throughout this section, electropherograms illustrating the effectiveness of the various modes of sample stacking will be presented. Figure 13.7 shows the electropherogram resulting from preparing sample in a dilute micelle solution, thus under FASS-like conditions. The analyte set is a mixture of neutral alkaloids. The bottom trace shows the separation resulting from preparing sample in BGE, thus under normal zone electrophoresis conditions, the middle trace shows the resulting electropherogram when sample is prepared in  $0.1 \times$  BGE, and the top trace shows the resulting electropherogram when sample is prepared in  $0.05 \times$  BGE. Experimental details are included in the figure legend. It is clear from the figure that the peak height of several analytes increase, however, some tailing is observed indicating that this method of preconcentration may be inefficient for this specific analyte set.

**FIGURE 13.6** Illustration of the mechanism of field-amplified stacking. In this case, the SM is dilute BGE typically between  $0.05 \times$  and  $0.1 \times$  BGE.

**FIGURE 13.7** Separation of 10 alkaloids. Bottom trace: sample matrix is BGE. Middle trace: sample matrix is  $0.1 \times$  BGE. Top trace: sample matrix is  $0.05 \times$  BGE. Experimental conditions:  $50 \mu\text{m}$  internal diameter,  $L_T = 60 \text{ cm}$  (50 cm effective length),  $l_{\text{inj}} = 10 \text{ mm}$  ( $20 \text{ s} \times 0.5 \text{ psi}$ ),  $V = 25 \text{ kV}$  ( $47 \mu\text{A}$ ), UV absorbance at 214 nm. BGE: 10 mM  $\text{Na}_2\text{B}_4\text{O}_7$ , 80 mM sodium cholate.

### 13.3.1.2 Sweeping

Sweeping was originally defined as “the picking and accumulating of analytes by the pseudo stationary phase that fills the sample zone during application of voltage.”<sup>16</sup> Sweeping was initially implemented by preparing analytes in a sample matrix of equal conductivity to the BGE, but devoid of surfactant sodium dodecyl sulfate.<sup>16,17</sup> Terabe and coworkers<sup>18</sup> later expanded the definition of “sweeping” to include any situation in which the BGE contains a separation vector and the sample matrix does not. The mechanism of stacking for an equal conductivity sample matrix is presented in Figure 13.8 for a system with negatively charged micelles and normal EOF. Briefly, under a homogeneous electric field, neutral analytes are carried toward the negative electrode only to be swept up in the micelles at the boundary of the sample region. The effectiveness of the stacking is dependent on an analytes affinity for the micelle, the higher affinity of the micelle the larger the extent of stacking. Terabe derived the following equation representing the extent of stacking as a function of an analytes affinity for the micelle

$$l_{\text{sweep}} = l_{\text{inj}} \left( \frac{1}{1+k} \right), \quad (13.7)$$

where  $l_{\text{sweep}}$  is the length of the swept analyte,  $l_{\text{inj}}$  is the length of the injected plug, and  $k$  is the retention factor for a given analyte. Figure 13.9 shows the effectiveness of sweeping on the alkaloid separation. Note that peaks 1 and 2 are not well stacked. This is expected as they have the lowest affinity ( $k$ ) for the cholate micelle.

**FIGURE 13.8** Illustration of the mechanism of sweeping. In this case, the ionic strength of the sample matrix, devoid of micelle, is adjusted such that a continuous field strength is achieved.

**FIGURE 13.9** Separation of 10 alkaloids. Bottom trace: sample matrix is BGE. Top trace: sample matrix is 30 mM  $\text{Na}_2\text{B}_4\text{O}_7$ . Experimental conditions: 50  $\mu\text{m}$  internal diameter,  $L_T = 60$  cm (50 cm effective length),  $l_{inj} = 10$  mm (20 s  $\times$  0.5 psi),  $V = 25$  kV (47  $\mu\text{A}$ ), UV absorbance at 214 nm. BGE: 10 mM  $\text{Na}_2\text{B}_4\text{O}_7$ , 80 mM sodium cholate.

### 13.3.1.3 High-Salt Stacking

High-salt stacking is a mechanism of analyte preconcentration afforded by the stacking of micelles at the negative electrode side of the sample plug.<sup>19</sup> Analyte migrates into the stacked micelle region experiencing a locally high retention factor due to the high micelle concentration. The nomenclature “high-salt stacking” comes from the fact that in order to stack micelles the conductivity of the sample

**FIGURE 13.10** Illustration of the mechanism of high-salt stacking. In this case the ionic strength of the sample matrix is adjusted such that it is 1.5–2.5 times the ionic strength of the BGE.

zone is typical  $1.5\text{--}2.5\times$  that of the BGE. High-salt stacking requires the following conditions be met:

$$\mu_{\text{sample}} E_{\text{sample}} < \mu_{\text{ev}} E_{\text{ev}} \quad (13.8)$$

$$\mu_{\text{sample}} > \mu_{\text{ev}}, \quad (13.9)$$

where  $\mu_{\text{sample}}$  is the mobility of the sample stacking co-ion,  $E_{\text{sample}}$  is the electric field in the sample zone,  $\mu_{\text{ev}}$  is the mobility of the electrokinetic vector (micelle), and  $E_{\text{ev}}$  is the field in the BGE. The condition that the mobility of the sample stacking co-ion be greater than the mobility of the micelle requires that the field in the BGE be greater than that in the sample zone, this is the need to significantly increase the conductivity of the sample zone relative to the BGE. The stacking mechanism is summarized in Figure 13.10. Note that the illustration shows micelles concentrating at the detector side of the sample plug upon application of a separation voltage. The effectiveness of high-salt stacking for the analysis of the alkaloid samples is shown in Figure 13.11. In this example, peaks 1 and 2 are well stacked demonstrating the power of high-salt stacking for analytes with low  $k'$ s.

#### 13.3.1.4 Electrokinetic Injection

Field-amplified stacking, sweeping, and high-salt stacking all require a discrete hydrodynamically injected sample plug. Alternatively, electrokinetic injections can be utilized to introduce sample to the column. Landers and coworkers<sup>20</sup> presented electrokinetic stacking under continuous conductivity conditions. Sample is injected with EOF and interacts with micelles included in the BGE. The analytes concentrate at the sample zone/BGE interface. Provided a large enough difference between the velocity of EOF and the net velocity of the micelle, it is possible to inject the equivalent of multiple column volumes of analyte. This stacking scheme is illustrated in Figure 13.12, and the corresponding example using this method for the alkaloid separation is shown in Figure 13.13.

#### 13.3.1.5 Field-Enhanced Sample Injection

While the above method of electrokinetic injection requires only a single step, it is possible to couple electrokinetic injections with a brief hydrodynamic injection of water.<sup>21</sup> The column is initially full of BGE, followed by a hydrodynamic injection of water. Analyte is then electrokinetically injected until the measured current through the column is approximately 70–90% of the column when filled

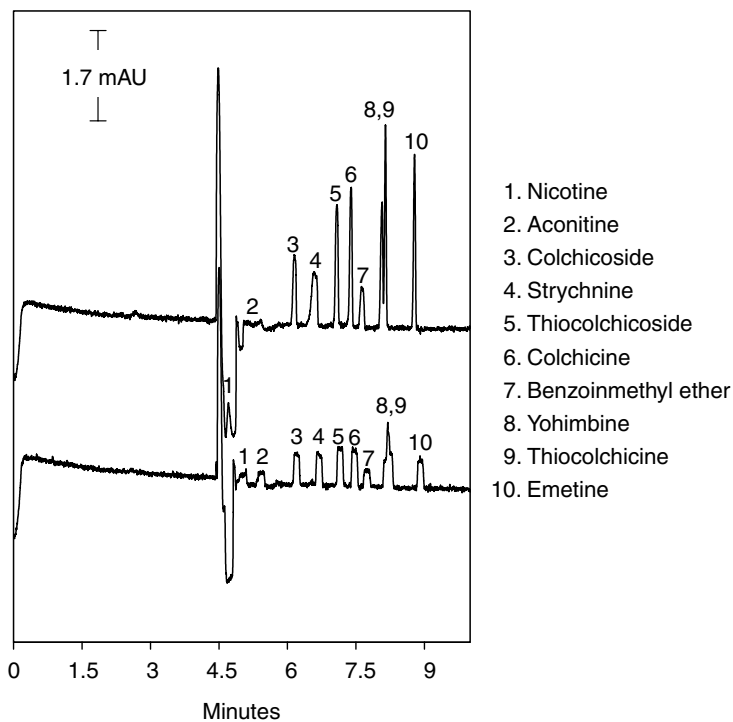

**FIGURE 13.11** Separation of 10 alkaloids. Bottom trace: sample matrix is BGE. Top trace: sample matrix is 150 mM NaCl. Experimental conditions: 50  $\mu\text{m}$  internal diameter,  $L_T = 60$  cm (50 cm effective length),  $l_{\text{inj}} = 10$  mm (20 s  $\times$  0.5 psi)  $V = 25$  kV (47  $\mu\text{A}$ ), UV absorbance at 214 nm. BGE: 10 mM  $\text{Na}_2\text{B}_4\text{O}_7$ , 80 mM sodium cholate.

**FIGURE 13.12** Illustration of the mechanism of electrokinetic stacking injection. The sample matrix is prepared devoid of micelles to an equal conductivity of the BGE.

exclusively with BGE. Upon application of voltage, analyte migrates into the water plug. As potential continues to be applied across the capillary the water plug compresses—narrowing the analyte plug. This scheme is shown in Figure 13.14. A separation of a mixture of alkylphenyl ketones using this method is shown in Figure 13.15.

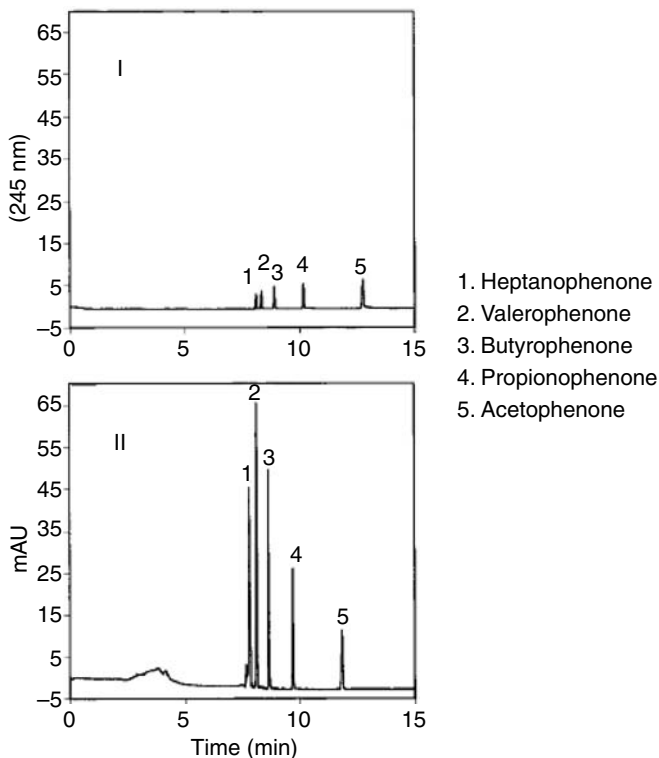

**FIGURE 13.13** Separation of 10 alkaloids. Bottom trace: sample matrix is BGE. Top trace: sample matrix is 30 mM Na<sub>2</sub>B<sub>4</sub>O<sub>7</sub>. Experimental conditions: 50 μm internal diameter,  $L_T = 60$  cm,  $t_{inj} = 20$  s at 10 kV,  $V = 25$  kV (47 μA), UV absorbance at 214 nm. BGE: 10 mM Na<sub>2</sub>B<sub>4</sub>O<sub>7</sub>, 80 mM sodium cholate.

**FIGURE 13.14** Illustration of the mechanism or field-enhanced sample injection.

**FIGURE 13.15** Separation of five alkyl phenyl ketones. Sample matrix is 8.3 mM SDS, 16.7 mM phosphate buffer (pH 2.5) (I). Water plug length of 8.7 cm for FESI (II). Experimental conditions: 50  $\mu\text{m}$  internal diameter,  $L_T = 64.5$  cm (56 cm effective length),  $t_{inj} = 2$  s at 50 mbar,  $V = -20$  kV, UV absorbance at 245 nm. BGE: 100 mM phosphate buffer (pH 2.25), 50 mM SDS. (Reprinted with permission from Quirino, J.P. and Terabe, S., *Am. Chem. Soc.*, 70, 1893, 1998. Copyright 1998.)

### 13.4 CONCLUSIONS

The goal of this chapter was to present some of the basic concepts of online sample preconcentration in capillary electrophoresis. The relationship between large volume injections of charged analytes and the Kohlrausch regulation function were discussed in Section 13.2. Irrespective of whether one chooses a continuous or discontinuous buffer system, careful consideration of the background electrolyte and sample matrix components and the formation of a long-term stable Kohlrausch boundary are absolutely necessary for efficient large volume injections. Rapid evaluation of the potential for sample stacking is made possible by calculations for “ $a$ ” and  $a_{crit}$ , precluding the sometimes cumbersome KRF calculation. Stacking of neutral analytes, which do not contribute to the KRF, was presented in Section 13.3. The mechanism and effect of several sample stacking modes were presented. The underlying phenomenon common to each mode of sample stacking in MEKC is that the analyte experiences a velocity change on partitioning into the micelle. In this regard, preconcentration efficiency in MEKC is, at the very least, dependent on the analyte affinity for the micelle and the mobility of the micelle. Ultimately, whether analytes are neutral or charged, successful optimization of online preconcentration is made possible with a complete understanding of the system components including the analytes of interest, sample matrix, and background electrolyte.

## 14.1 INTRODUCTION

Conventional analysis of biological specimens typically involves sampling from populations of cells (e.g., tissue homogenates). The heterogeneity of these populations, however, often yields information averaged over various types of cells. Single-cell sampling, on the other hand, allows researchers to study fundamental processes, which may not be observed in a heterogeneous cell population. To look at these processes at the single-cell level, analytical techniques must have the capability to utilize small volumes and investigate a variety of compounds concurrently. Obtaining both quantitative and qualitative information from single cells in complex biological environments allows researchers to learn more about basic cellular function as well as the mechanisms of drugs and toxins.

Capillary electrophoresis (CE) is an analytical technique ideally suited for studying the small volume contents of single cells, sampling whole cell and subcellular volumes on the femtoliter scale.

In addition, high separation potentials can be applied when using small inner diameter capillaries with CE since Joule heat can be rapidly dissipated. The use of high potentials results in fast, efficient separations of over  $10^6$  theoretical plates. Furthermore, CE is compatible with a diverse array of detectors including laser-induced fluorescence (LIF), ultraviolet (UV) absorbance, electrochemical, mass spectrometric, and radiochemical. This chapter builds upon the previous two editions of this book discussing advances in sampling techniques and detectors used for analyzing individual cells with CE. Furthermore, applications of single-cell CE analysis in the areas of neuroscience, immunology, nucleic acids and gene expression, as well as enzymology are also presented. The use of microfabricated devices for cellular analysis has become a popular area of research and is covered elsewhere in this book.

## 14.2 METHODOLOGY

### 14.2.1 SAMPLING TECHNIQUES

#### 14.2.1.1 Whole Cell Sampling

Sampling whole cells for CE involves either siphoning the cell by either applying a pressure differential or applying a potential across the capillary to electrokinetically inject the cell. In each case, a drag force is produced by the fluid flow, driving the cell into the capillary for lysis and the separation of its contents.<sup>1</sup> Though these schemes are the most simplistic forms of injection, there have been several recently developed complementary techniques for introduction of cells and their contents into capillaries.

##### *14.2.1.1.1 Continuous Cell Introduction*

Individually selecting cells for siphoning or electrokinetic injection is a time-consuming process, thereby limiting the number of samples that can be run in a given period of time. In an effort to increase throughput, Chen and Lillard<sup>2</sup> have created a two capillary scheme capable of continuously introducing cells for injection (Figure 14.1a). The thinner first capillary is immersed in a dilute cell suspension and cells are continuously pumped in single file by electroosmotic flow. Individual cells flow toward the lysis junction connecting the two capillaries where they are lysed by mechanical disruption. The lysate is then siphoned into the second capillary where separation takes place. This system reduces analysis time from 6 to 4 min for each cell<sup>2</sup> and is capable of repeatedly injecting cells for over 40 min before many of the cells descend to the bottom of solution and out of reach of the capillary.

##### *14.2.1.1.2 Laser Cavitation and Electrical Lysis*

Because removing a cell from its growth substrate alters many of the biological processes occurring in the cell, its detachment increases the difficulty in analyzing the cell and the variation from its normal function.<sup>3</sup> Thus, in order to obtain the most accurate portrait of the cell's internal environment, it must be sampled quickly after removal from the substrate. Two innovative techniques, laser cavitation and fast electrical lysis, allow for rapid sampling of substrate-bound cells.

Sims et al.<sup>4</sup> have exploited the production of a shockwave created by a laser beam for their laser cavitation scheme (Figure 14.1b). The shockwave generated by laser pulse is focused in close proximity to the cell to be analyzed, forming plasma at the focal point. A cavitation bubble is produced that subsequently collapses and causes a shockwave that ruptures the cell's membrane. Cellular contents can then be loaded rapidly after lysis, reducing the time available for deviation from standard cell function to occur.

To circumvent the expense and complication of using a pulsed laser, a fast electrical lysis procedure for single-cell analysis has also been developed (Figure 14.1c).<sup>3,4</sup> This setup takes advantage of gold conductivity, with both the capillary and the coverslip on which cells are grown coated

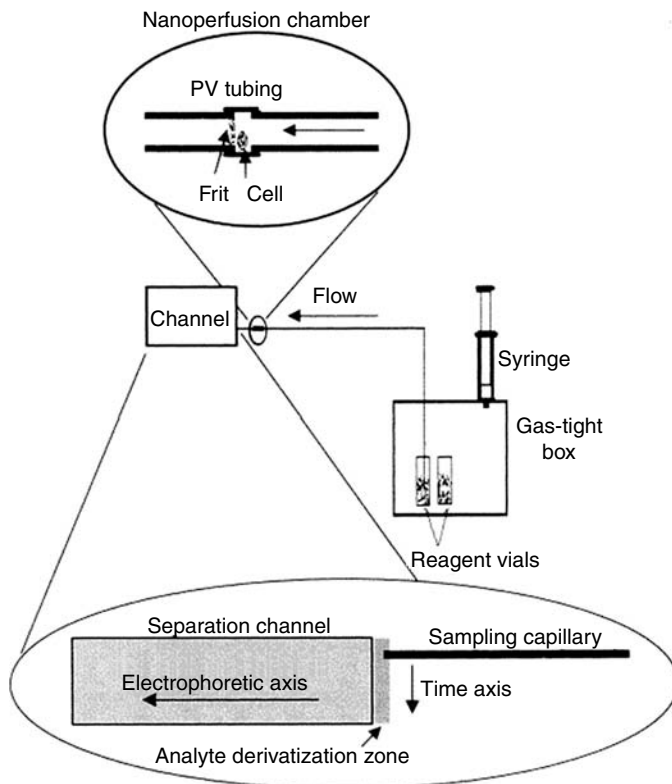

**FIGURE 14.1** Recently developed whole cell sampling schemes. (a) Continuous cell introduction. (From Chen, S. and Lillard, S.J., *Anal. Chem.*, 73, 111, 2001. With permission.) (b) Laser cavitation. (From Sims, C.E. et al., *Anal. Chem.*, 70, 4570, 1998. With permission.) (c) Fast electrical lysis. (From Han, F., et al., *Anal. Chem.*, 75, 3688, 2003. With permission.)

with gold prior to analysis. Once the tapered capillary is positioned above a chosen cell, a voltage pulse is applied between the capillary and the coverslip. The applied pulse passes through the cell concurrently lysing and injecting the contents into the capillary for separation.

#### 14.2.1.2 Release from Whole Cells

In addition to quantifying the amount of a compound within a whole cell, exocytosis can be monitored by the sampling, separation, and detection of compounds released following stimulation. Because this release often results in modifications in the environment surrounding the cell by initiating changes in adjacent cells, it is important to have the ability to sample releasate from single cells to further understand the effects of different compounds in a complex cellular environment. Direct monitoring of exocytosis was initially completed by Chen et al.<sup>5</sup> from the giant dopamine cell of the *Planorbis corneus* by manipulating the injection end of the separation capillary near the cell. After stimulation, a plug of secreted compounds was injected into the capillary, which was then returned to the buffer reservoir for separation. Since then, release from single mammalian cells has been achieved by Tong and Yeung.<sup>6</sup> In their setup, single bovine adrenal medullary cells were injected individually and allowed to adhere to the capillary wall. Subsequently, a plug of stimulant was injected and the separation run to quantify the amount of secreted catecholamines.

In order to maintain temporal resolution while obtaining chemical data, Liu et al.<sup>7</sup> have used a dynamic channel electrophoresis scheme to sample release from single cells. As shown in Figure 14.2, the sampling capillary is scanned across the entrance of a separation channel such that the position of the capillary at the channel inlet yields the temporal information of release. Single cells are placed in a “nanoperfusion chamber” for analysis within the sampling capillary (inset of Figure 14.2). Following

**FIGURE 14.2** Dynamic channel electrophoresis instrumentation. (From Liu, Y.-M. et al., *Anal. Chem.*, 71, 28, 1999. With permission.)

release of a plug of stimulant, secreted compounds flow through the frit into the separation channel, minimizing diffusion and increasing time resolution.

### 14.2.1.3 Subcellular Sampling

Sampling the cellular contents has become more prevalent as capillaries have become smaller and easier to position. Subcellular sampling allows only the cellular contents of interest to be analyzed, and offers the possibility to sample specific subcellular compartments, minimizing interference from the extracellular environment. In this manner, the function or dysfunction of different compartments can be investigated, simplifying the information being obtained and yielding a more basic understanding of the mechanisms occurring during fundamental cellular processes.

#### 14.2.1.3.1 Cytoplasmic Sampling

The synthesis, storage, and metabolism of different compounds are regulated by levels found in cellular cytoplasm. Sampling the cytosol of an intact cell can thus yield about the use of various chemical species. A microinjector having a tip tapering to 8–10  $\mu\text{m}$  o.d. was previously created to sample cytoplasm directly from single neurons in *P. corneus*.<sup>8</sup> The size of this injector, though suitable for large invertebrate cells, is not compatible for use with single mammalian cells, which average 15  $\mu\text{m}$  in diameter.<sup>9</sup> To probe smaller rat adrenal cells, Woods et al.<sup>10</sup> have fabricated microinjectors from 770 nm i.d. capillaries with tips narrowing to 2.5  $\mu\text{m}$  o.d. to use in conjunction with electroporation. As transient pores are created in the cell by electroporation, the microinjector

can be inserted with minimal perturbation. The voltage pulse used to electroporate is also used to electrokinetically inject cytoplasm into the capillary before the tip is removed and the separation is carried out.

#### 14.2.1.3.2 Optical Trapping

The utility of optical trapping for manipulating subcellular contents into a capillary was initially demonstrated using single vesicles from the *Aplysia californica*, which were lysed and their contents separated.<sup>11</sup> Optical trapping has since also been employed to maneuver nuclei,<sup>12</sup> mitochondria,<sup>13,14</sup> and various other organelles<sup>15</sup> into capillaries for separation. This noninvasive and sterile manner of sampling subcellular contents utilizes a single beam laser diode focused through a high numerical aperture objective onto the desired specimen.<sup>11,16</sup> The “scattering force” produced from the scattering of the light upon encountering the organelle is able to move the organelle along the direction of light propagation, in this case into the capillary for lysis and separation.<sup>17</sup>

#### 14.2.1.3.3 Organelle Separations

Much of the study of different organelles by single-cell CE has been completed by the Arriaga group, particularly focusing on acidic organelles and nuclei. In both cases, the organelles of interest were labeled with fluorescent tags for ease in detecting the desired species. During the analysis of single acidic organelles, populations of cells were first incubated with fluorescent microspheres, which were endocytosed and transported to these organelles. Cells were then lysed in a buffer solution and the fluorescent “organelle fraction” obtained prior to injection and separation.<sup>18</sup> For the investigation of nuclei, individual nuclei were tagged with a fluorescent nuclear-targeted protein in order to determine their presence with LIF detection. Analyzed cells were subsequently chosen based on observed fluorescence with a microscope and injected individually into the capillary. Following injection, the cell was lysed with digitonin and its cellular components separated.

## 14.2.2 DETECTION METHODS

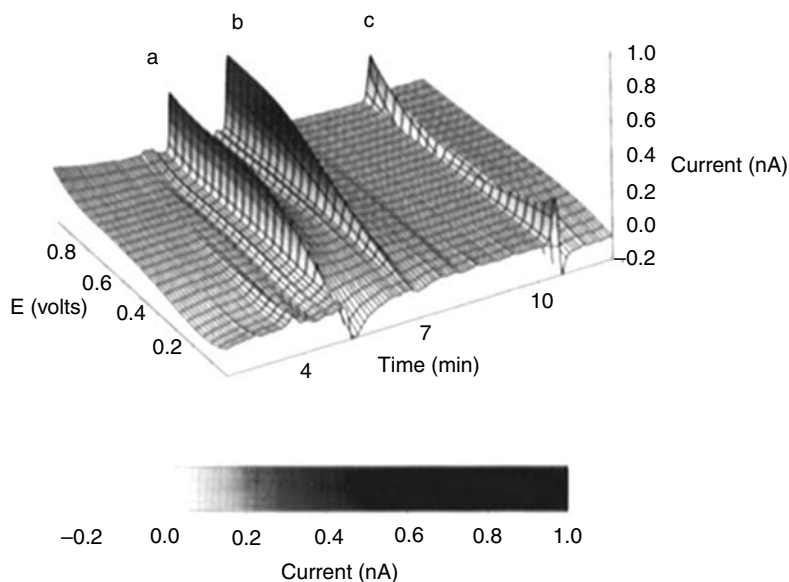

CE systems can be coupled to many detectors, allowing a variety of different molecules to be separated and quantified. UV absorbance, LIF, electrochemistry, radiochemistry, mass spectrometry, and refractive index are all detectors that have been successfully coupled to CE. However, electrochemical and LIF detection are the two most commonly used detectors for single-cell CE due to their high sensitivity. There have also been reports of using mass spectrometry and radiochemistry in single-cell CE analyses, though their use is not as widespread.

### 14.2.2.1 Electrochemistry

Electrochemical detection has found widespread use for single-cell studies with CE owing to both its selectivity and sensitivity. Though once hampered by the presence of a high voltage electric field, innovations such as the porous glass coupler for off-column detection and development of an end-column conical detector have been used to isolate the microelectrode from the potential field used for separation.<sup>19,20</sup> Electrochemical detection is typically carried out in the amperometric mode with the applied voltage held at a constant overpotential versus a reference electrode. Most often, carbon fiber working electrodes are used since they can be easily coupled at the ends of capillaries. As analytes encounter the working electrode surface following separation, they are either oxidized or reduced to produce a measurable current.

Scanning electrochemical detection has also been employed for single-cell CE separations.<sup>21</sup> In contrast to amperometry, scanning electrochemical detection varies the voltage of the working electrode. As separated species pass the working electrode, a voltammogram is obtained for each

**FIGURE 14.3** Electropherogram of the separated contents from a single dopaminergic neuron obtained using CE with scanning electrochemical detection and plotted in three dimensions. Peaks “a” and “b” correspond to dopamine that was immediately released during lysis and dopamine located deeper in the cell, respectively. Peak “c” represents a neutral electroactive species in cellular buffer. (From Swanek, F.D. et al., *Anal. Chem.*, 68, 3912, 1996. With permission.)

analyte and a three-dimensional surface is constructed showing current versus voltage and time (Figure 14.3). This unique detection mode allows eluted substances to be identified according to their characteristic voltammogram as well as retention time. Thus, scanning electrochemical detection offers enhanced selectivity since co-eluting peaks can be further resolved by their unique oxidation potentials. Scanning electrochemical detection has been utilized to detect dopamine at the femtomole level from single *P. corneus* neurons.<sup>22</sup>

#### 14.2.2.2 Laser-Induced Fluorescence

Along with amperometry, LIF is the most popular mode of detection in single-cell CE experiments owing to its high sensitivity. Most CE-LIF systems employ visible argon ion lasers; however, UV lasers have also been used for fluorescence excitation.<sup>23,24</sup> One problem with LIF is that not all species are natively fluorescent, so labeling is often required. Although LIF detection most often involves a single emission wavelength, Sweedler has demonstrated simultaneous multiwavelength detection (Figure 14.4).<sup>25</sup> Over 30 compounds containing aromatic amino acids in an individual neuron were separated and detected using native LIF with a UV laser, and a unique fluorescence emission spectrum was obtained for each eluted species.

#### 14.2.2.3 Mass Spectrometry

Mass spectrometry (MS) has perhaps the most potential as a detector since it can provide detailed chemical information to identify separated species, particularly molecules with high molecular weights like polypeptides. Unfortunately, mass spectrometers have not been widely used in single-cell CE experiments as detectors due to their relatively poor sensitivity compared to LIF. Nonetheless,

**FIGURE 14.4** (See color insert following page 810.) CE system with simultaneous multiwavelength fluorescence detection. Cellular samples were electrokinetically drawn into a capillary (1) from a steel microvial (2). The analytes were separated in the capillary, and eluted into a square-cuvette sheath-flow cell (3) where fluorescence was induced with a laser beam (4). The fluorescent light was collected orthogonally and directed into a spectrograph and CCD where a complete spectrum was obtained for each separated analyte (5). (From Fuller, R.R. et al., *Neuron*, 20, 173, 1998. With permission.)

**FIGURE 14.5** CE coupled to a MALDI-TOF-MS system for detecting neuropeptides. As the contents of a single cell were separated in the capillary, the separated species were collected as fractions deposited onto a MALDI-MS target. (From Page, J.S. et al., *Analyst*, 125, 555, 2000. With permission.)

there have been a few interesting papers using mass spectrometric detection for single-cell analysis. One early application of CE-MS for single-cell analysis demonstrated the use of electrospray ionization and Fourier transform ion cyclotron resonance mass spectrometry to detect the  $\alpha$  and  $\beta$  chains of hemoglobin in a single human erythrocyte.<sup>26</sup>

Sweedler and coworkers<sup>27</sup> have developed a novel system coupling CE to matrix-assisted laser desorption-ionization time-of-flight mass spectrometry (MALDI-TOF-MS) to study peptides (Figure 14.5). In some initial work, the contents of a single cerebral ganglion cell from *A. californica* were separated and mixed with MALDI matrix after exiting the capillary; every 30 s, a new fraction was deposited onto the MALDI target plate for mass spectrometric analysis. In following work, using an instrumentation setup similar to Figure 14.5, MALDI-TOF-MS was coupled with CE to identify neuropeptides and hormones released from individual *A. californica* cells.<sup>28</sup> Although MALDI-TOF-MS is excellent for qualitative chemical identification of high molecular weight species, it lacks the ability for quantification. Sweedler and coworkers,<sup>29</sup> however, complemented CE-MALDI-TOF-MS with radiochemical detection to achieve both chemical identification and successful quantification of hormones and neuropeptides from individual cells.

#### 14.2.2.4 Radiochemistry

Radiochemistry has not been extensively used for single-cell CE systems because of the cumbersome nature of working with radioactive elements and lengthy time involved in collecting an image of radiolabeled eluents. A postcolumn radionucleotide detector has been developed in which radiolabeled eluents are deposited onto a membrane with a scintillator, and then imaged with a charge-coupled device (CCD). This unique system had limits of detection of 88 zmol for  $^{32}\text{P}$ -labeled analytes, 17 amol for  $^{35}\text{S}$ , and 8 fmol for  $^3\text{H}$ , which were found in peptides.<sup>30</sup> An improvement of the previous system was made by using a commercial phosphor plate and photomultiplier tube, which yielded even lower limits of detection (4.9 zmol for  $^{32}\text{P}$  and 0.13 amol for  $^{35}\text{S}$  found in peptides), and was successfully applied to detecting radiolabeled peptides single buccal ganglion cells in *A. californica*.<sup>31</sup>

### 14.3 APPLICATIONS

#### 14.3.1 NEUROSCIENCE

Single-cell CE experiments in neurochemistry were first performed in the late 1980s with initial cytoplasmic sampling from *P. corneus* completed in 1988<sup>32</sup> and whole cell injection of *Helix aspersia* in 1989 to separate fluorescently labeled amino acids.<sup>33</sup> Since these pioneering studies, many different small molecule neurotransmitters and other related species have been detected in single cells by CE.

Serotonin is a monoamine neurotransmitter believed to regulate physiological functions such as appetite and sleep. Most importantly, decreased serotonin transmission in the brain has been implicated in playing a role in depression and other related mood disorders, making it an important focus of research in the contemporary neuroscience community. In one study, individual *Aplysia* metacerebral cells were electrically stimulated, followed by separation by CE and fluorescence detection with a UV laser.<sup>23</sup> Each cell soma contained approximately 450 fmol of serotonin with a limit of detection for the experiment of 39 nM. A later report<sup>34</sup> investigated serotonin metabolism in *Aplysia*. Single cells from different locations of the *Aplysian* nervous system were incubated with serotonin with two new serotonin catabolites discovered. Interestingly, it was recently shown that electrokinetic injection of serotonin results in the formation of a serotonin dimer artifact, but when hydrodynamic injection is used, the dimer is not present.<sup>35</sup>

Like serotonin, the amino acid D-aspartate is a small molecule neurotransmitter and is present in the central nervous system of both invertebrates and vertebrates. While most proteins and polypeptides contain only amino acids of the L-enantiomer, mounting evidence suggests that the D-enantiomer of aspartate plays a role in intercellular signaling. The addition of cyclodextrin to the separation buffer in CE allows these two enantiomers to be separated and individually quantified.<sup>36–38</sup> When individual *Aplysian* cell processes and soma were analyzed separately by CE-LIF, it was shown that D-aspartate was not only located in the nucleus but also in the processes and the amount of D-aspartate in different processes of the same cell was similar.<sup>37</sup> In a subsequent experiment, CE-LIF was used to show that the amounts of D-aspartate varied among different clusters from single *A. californica* neurons, D-aspartate is synthesized endogenously from its L-enantiomer, and it travels long intracellular distances to its release sites.<sup>38</sup> In addition to aspartate, the addition of cyclodextrin has allowed fluorescently labeled D-glutamate and L-glutamate to be separated from an individual cell of *Aplysia*.<sup>39</sup> Neuropeptides may also contain D-amino acids with the importance of peptides containing D-amino acids illustrated with the discovery of a neuropeptide containing D-tryptophan in a single cell of *A. californica*.<sup>40</sup>

Nitric oxide (NO), a more recently discovered neurotransmitter and regulator of other physiological processes, has been indirectly quantified by CE of its primary metabolites. Because of the ephemeral nature of NO, nitrate and nitrite, two products of NO oxidation, have been assumed to be good indicators of NO synthase activity. These anions in single *Pleurobranchaea californica* and *A. californica* neurons have been separated by CE and quantified with UV absorbance detection.<sup>41</sup>

The limits of detection were less than 200 fmol and the concentrations of nitrite and nitrate were typically 2 and 12 mM, respectively. A more recent report involved CE separations of arginine, citrulline, nitrate, and nitrite with LIF and conductivity detection.<sup>42</sup> Contrary to previous results, it was determined that nitrates are not always reliable indicators of NO synthase activity. Similarly, other metabolites associated with NO—arginine, citrulline, arginosuccinate, ornithine, and arginine phosphate—were quantified in *Pleurobranchaea* and *Aplysia* with limits of detection ranging from 5 nM to 17  $\mu$ M.<sup>43</sup>

*In vivo* detection of NO is commonly accomplished using the fluorophore 4,5-diaminofluorescein (DAF-2). When the fluorophore reacts with  $N_2O_3$  (a species related to NO), it is converted to a triazole derivative, DAF-2T. Dehydroascorbic acid present in cells also reacts with DAF-2 and forms a complex with an emission spectrum similar to that of DAF-2T, thereby interfering with NO detection. The separation of the interfering species with CE-LIF has allowed quantification of NO in single cells,<sup>44</sup> along with ascorbic acid and dehydroascorbic acid,<sup>44,45</sup> which both play important roles in cellular metabolism.

### 14.3.2 IMMUNOLOGY

For years, enzyme-linked immunosorbent assays (ELISA) have been the standard method for investigating antibody–antigen interactions. The time-consuming nature of ELISA, however, has led to the development of single-cell CE for the rapid analysis of the reaction of antibodies and target antigens. One such study has utilized single-cell CE-LIF to analyze human interferon-gamma ( $IFN-\gamma$ ), which provides antiviral, anticell proliferation, and immunity adjustment effects as support for other cells.<sup>46</sup> Though initially employing on-capillary immunoreactions, where the contents of a lysed natural killer (NK) cell could interact with fluorescently tagged anti- $IFN-\gamma$  monoclonal antibody (Ab\*) prior to the separation,<sup>46</sup> Zhang and Jin<sup>47</sup> further optimized sample preparation by loading Ab\* into cells via electroporation prior to entering the capillary. Single cells were subsequently washed and lysed on-capillary following a short incubation time prior to analysis by CE-LIF. Labeled antibodies for both  $IFN-\gamma$  I and II were detected in the cell electropherograms with increases in the relative fluorescence intensity observed for each form of the protein–antibody complex with the electroporated loaded cells versus those that had undergone the on-capillary reaction due to a decrease in Ab\* dilution during the intracellular immunoreaction (Figure 14.6). In addition, the average value determined for total  $IFN-\gamma$  concentration in NK cells (98 pM) corresponded well with the value acquired from an ELISA assay (99 pM),<sup>47</sup> demonstrating the utility of the CE technique in performing immunoreaction assays rapidly while maintaining accuracy.

In another investigation, the role of P-glycoprotein (PGP) in imparting multidrug resistance to tumor cells by functioning as transmembrane drug pump was examined.<sup>48</sup> Two groups of single cells—those that were drug resistant and those drug sensitive—were incubated with primary (JSB-1, a mouse raised antibody that binds to PGP) and secondary [goat antimouse IgG-fluorescein isothiocyanate (GAMIF), an antimouse antibody tagged with fluorescein isothiocyanate (FITC)] antibodies prior to analysis with CE-LIF. Owing to the minimal nonspecific binding of JSB-1, its quantity in a single-cell was taken as the total amount of PGP present on the cell since the antibody reacts with the protein epitope on a 1:1 ratio. When comparing the amount of PGP expressed in each cell group, a larger quantity was present on the drug resistant cell line, with 157,000 molecules of PGP present versus 47,000 molecules present on the drug sensitive cell line.

### 14.3.3 NUCLEIC ACIDS AND GENE EXPRESSION

A popular technique used to observe gene expression is reverse transcriptase-polymerase chain reaction (RT-PCR). RT-PCR works by reverse transcribing mRNA to a complementary DNA sequence that corresponds to the gene of interest. Several years ago, Zabzdyr and Lillard<sup>49</sup> showed that CE could be used to separate and detect RT-PCR products corresponding to  $\beta$ -actin in individual

**FIGURE 14.6** Electropherograms detailing IFN- $\gamma$ –antibody complex (IFN- $\gamma$ -Ab\*) content in NK cells using on-capillary immunoreaction (a) and intracellular immunoreaction (b) for both IFN- $\gamma$  I and II. (From Zhang H. and Jin, W., *J. Chromatogr. A*, 1104, 346, 2006. With permission.)

human prostate carcinoma cells, which was similar to an earlier study done by Li and Yeung<sup>50</sup> who detected PCR products corresponding to  $\beta$ -actin from lymphoblast cells. The cells were lysed with detergent or by a freeze-thaw method and a primer and other PCR reagents were added. The resulting PCR products were complexed with ethidium bromide and were separated by CE-LIF. The freeze-thaw lysing method yielded a better signal-to-noise ratio versus the use of detergent, and limits of detection corresponded to 133 initial molecules of  $\beta$ -actin mRNA per nL. Yeung and coworkers<sup>51</sup> successfully developed a microthermocycler for integrated cell lysis and RT-PCR in which the PCR products of  $\beta$ -actin were measured from a group of 16 cells, demonstrating the possibility of using this novel system for single-cell analyses. Lillard and coworkers<sup>52</sup> more recently used CE-LIF to detect RT-PCR products corresponding to  $\beta$ -actin and the  $\alpha$  estrogen receptor simultaneously from single human breast carcinoma cells (Figure 14.7). Surprisingly, only a single round of RT-PCR amplification was necessary, but additives were needed to enhance the low signals for the analytes. It is hypothesized that the signals were low because two primers were used simultaneously, and it is thought that they formed dimers thereby lowering the amplification efficiency.

In addition to using CE for detecting single-cell RT-PCR products, CE has also been used to detect RNA in individual cells without the need for extraction. Lillard and coworkers<sup>53</sup> injected single Chinese hamster ovary cells into a capillary, where the cells were lysed and the RNA complexed with ethidium bromide for LIF detection. Only rRNA and tRNA were detected, which was verified by monitoring changes in the peak patterns after adding RNase. mRNA was not detected because it is more unstable than the other forms of RNA with the buffer conditions used in these experiments. The total amount of RNA in individual cells was calculated to be approximately 10–20 pg.<sup>53</sup> Since aging, carcinogens, and other toxins cause damage to nucleic acids, single-cell CE was also used to observe changes in peak patterns of nucleic acids after single cells were incubated with hydrogen peroxide.<sup>53</sup> In addition to monitoring changes in nucleic acids following chemical damage, single-cell CE-LIF has also been used to look at changes in RNA during cell division.<sup>54</sup> Single Chinese hamster ovary cells were taken from different phases of the cell cycle, injected individually

**FIGURE 14.7** Electropherogram of multiplex RT-PCR products corresponding to  $\beta$ -actin and the  $\alpha$  estrogen receptor from single human breast carcinoma cells. (From Zabzdyr, J.L. and Lillard, S.J., *Electrophoresis*, 26, 137, 2005. With permission.)

via suction into a capillary, followed by lysis and detection with LIF. The total RNA content increased after each phase in the cycle, while the rates of RNA synthesis varied between the steps in the cycle.<sup>54</sup>

#### 14.3.4 ENZYMOLOGY

Understanding the mechanism behind the interaction between enzymes and substrates in a biological system is inherently difficult because of the variation that exists in enzyme expression and function across a population of cells. The use of single-cell CE, however, is particularly suited to enzymology as the activity of individual cells can be assayed alone. In one study, for example, post-translational enzymes have been investigated at potential targets for cancer therapy. The role of Ras proteins in cell growth and differentiation, as well as the presence of their mutated forms in human cancers, has made them a particularly interesting area of study for understanding how cancer proliferates and spreads. In efforts to target possible mechanisms for thwarting the function of mutated Ras proteins, the activity of three enzymes required to create functional proteins—farnesyltransferase, endoprotease, and methyltransferase—was evaluated.<sup>55</sup> Immortalized mouse cell lines were incubated with a peptide analog of the Ras protein to evaluate the function of each enzyme. Three enzyme products, two found in extracellular media and one intracellularly, were detected using CE-LIF upon lysis of single incubated cells. Disappointingly, comparison of the experimental product migration times did not correspond with those of the known products of the enzymes with the substrate, so no conclusion could be made as to the identity of the experimental compounds. However, the protocol developed was clearly shown to be compatible with single-cell CE.

While simply investigating the action of an enzyme in a cell at a single time point can provide a great deal of information, the ability to monitor how a reaction proceeds over time would also be advantageous. Shoemaker et al.<sup>56</sup> have developed nanoliter reaction vessels to sample the contents of a single lysed cell over time. Intracellular enzymes, such as  $\alpha$ -galactosidase, from the lysed cell are capable of interacting with a particular substrate in the vessel. In the case of  $\alpha$ -galactosidase, a disaccharide substrate,  $\alpha$ Glc(1  $\rightarrow$  3) $\alpha$ Glc-TMR, was utilized as the substrate and nanoliter aliquots were sampled for analysis by CE-LIF over several hours to detect the presence of the enzymatic product (Figure 14.8). A heterogeneity in enzyme function was observed with average conversion

**FIGURE 14.8** Electropherogram of an  $\alpha$ -glucosidase II single-cell (Cell 7) reaction aliquot taken after incubation (a). Percent conversion of the disaccharide (DG-TMR) substrate by  $\alpha$ -glucosidase II in single cells and control assays (b). Percent conversion was calculated by comparing the DG-TMR peak to that of the monosaccharide product MG-TMR. (From Shoemaker, G.K. et al., *Anal. Chem.*, 77, 3132, 2005. With permission.)

of  $20.9\% \pm 9.4\%$  of substrate to product and is attributable to differences in cell age, cell cycle, and cell size.<sup>55,56</sup>

#### 14.4 FUTURE PROSPECTS

Capillary electrophoresis of single cells has been employed in many scientific areas such as neuroscience, immunology, gene expression, and enzymology in the past 20 years. Though numerous developments have been made, many avenues are still left to pursue. One area that can be developed further is sample acquisition. The Chiu group, for instance, utilizes nanosurgery to choose which subcellular component (organelle) to analyze, using a combination of optical trapping and electroporation<sup>15,57</sup> to remove it from the cell. Other organelle types can be studied by pairing this technique with CE separations to better elucidate their functions. In addition, although continuous sampling from a single cell has already been achieved to study enzyme activity, it would be beneficial to maintain an intact cell while sampling to gain a more accurate picture of what is occurring in terms of cellular function. Further, sampling single cells within a population simultaneously will give clues about intercellular interactions in tissues and organs. In this manner, one can determine how a stimulus to one affects the others.

As always, separation conditions are constantly being optimized to gain the best resolution between analytes. For instance, when analyzing single whole cells, both lipids and proteins are capable of adsorbing to capillary walls, reducing peak resolution, and separation efficiency. Thus, it is imperative to reduce adsorption to the capillary walls to maintain the advantages of using CE over other techniques. Further, to lower detection limits, more sensitive detectors must be developed. Also, since LIF and electrochemistry are most common detection methods, but most analytes are

not natively fluorescent or electroactive, derivatization of analytes must be optimized so that all compounds present can be adequately measured.

While new innovations in sampling schemes and detectors will further increase its use for the analysis of single cells, CE has shown great promise as a tool to study single cells. The key advantages of CE are small volume capability combined with rapid and efficient separations. In addition, the diversity of detectors that can be coupled to a CE system further increases its versatility as a variety of analytes can be investigated. With continued use of CE to study individual cells, more information can be learned about the basic function of cells as well as their interactions with each other and different chemical species.

## 15.1 INTRODUCTION

Many chemical and biological events are dynamic in nature and rapid analytical techniques are required to monitor their occurrence. For example, reaction intermediates may be unstable and only present for milliseconds. Similarly, receptor binding and affinity complex formation or dissociation occurs on a rapid time scale. Neurotransmission and other cellular signaling processes are fast, with rapid release and clearance of signaling compounds. In addition, high-throughput analyses such as DNA analysis or drug screening require repetitive and rapid observations. Fast analytical techniques are therefore needed to better understand the time course of these phenomena.

Separations have often been considered a slow step in analysis, unsuitable for monitoring rapid processes. The first demonstration of an electrophoretic separation was achieved in hours<sup>1</sup> and today, conventional capillary electrophoresis separations are typically completed in around 10 min, depending on the sample. Other analytical methods, such as spectroscopy or electrochemistry, have therefore been used to obtain dynamic information about chemical changes. However, separations provide chemical information that may not be obtained with other techniques. Fast separations that allow simultaneous collection of temporal and chemical information would be advantageous for monitoring many of the real-world examples given above. Electrophoretic separations performed in capillaries or planar substrates have advantages over high-performance liquid chromatography (HPLC) and gel electrophoresis because rapid separations can be achieved without a loss of separation efficiency. Advances in electrophoresis instrumentation have reduced separation times from the minute to the

second time scale, and even to microseconds in some applications. The improved temporal resolution is leading to a better understanding of rapid chemical and biological processes. In this chapter, we will outline the theory, technological advances, and practical aspects of performing ultrafast capillary and microfluidic electrophoresis.

## 15.2 THEORY

When examining the theoretical basis of rapid separations, it is important to balance the considerations of temporal resolution with well-resolved separations. The fundamental equations defining electrophoresis show that it is possible to increase both the speed and efficiency of a separation by increasing the voltage.<sup>2,3</sup> The migration time ( $t_{\text{mig}}$ ) is given by

$$t_{\text{mig}} = \frac{L^2}{V \times \mu_{\text{ep}}} \quad (15.1)$$

where  $L$  is the separation length (and length to the detector),  $V$  is the separation voltage, and  $\mu_{\text{ep}}$  is the electrophoretic mobility of the analyte. Because the migration time is inversely proportional to voltage, higher voltages lead to shorter migration times. The equation for theoretical plates ( $N$ ) is

$$N = \frac{L^2}{\sigma_{\text{tot}}^2} = \frac{\mu_{\text{ep}} \times V}{2D} \quad (15.2)$$

where  $D$  is the diffusion coefficient and  $\sigma_{\text{tot}}^2$  is the total zone variance due to band broadening. If band broadening is limited to diffusion, then the equation simplifies to the term on the right, which shows that  $N$  is proportional to voltage. This reveals that more efficient separations will result from high applied voltages. Shorter separation lengths will result in faster separations, given the  $L^2$  proportionality to migration time, but with no loss in separation efficiency since  $N$  is not dependent on separation length. In contrast, in chromatography, shorter column lengths lead to faster separations but also result in a lower number of theoretical plates. Therefore, the strategy for fast, efficient electrophoretic separations is clearly high voltages and short separation distances.

The above analysis assumed that the only source of band broadening was diffusion, but other sources of band broadening can occur in an experiment. The total variance is given by

$$\sigma_{\text{tot}}^2 = \sigma_{\text{diff}}^2 + \sigma_{\text{heat}}^2 + \sigma_{\text{inj}}^2 + \sigma_{\text{det}}^2 + \sigma_{\text{ads}}^2 + \sigma_{\text{ED}}^2 \quad (15.3)$$

where variances are due to diffusion, joule heating, injection, detection, adsorption, and electro-migration dispersion, respectively. Joule heating increases with high voltages, which is problematic for fast separations where electric field strengths are often greater than  $1000 \text{ V cm}^{-1}$ . Heat is only dissipated through the surface of the separation path and radial temperature gradients between the inside and outside of the separation path result. The temperature gradients can lead to band broadening due to convection or differences in temperature-dependent variables that control the migration rate, such as viscosity. The effect of Joule heating on plate height has been quantified and the parameters can be predicted where heating will have a deleterious effect on efficiency.<sup>4</sup> The temperature difference between the wall and the middle of the separation path is proportional to the radius ( $r$ ) of the capillary inner diameter (i.d.) to the second power (i.e.,  $r^2$ ), so to reduce the effects of Joule heating most fast electrophoretic studies employ small i.d. capillaries ( $<10 \mu\text{m}$  i.d. compared to the standard  $50\text{--}100 \mu\text{m}$  i.d. capillaries) or shallow microfluidic channels. Joule heating can also be reduced by using low conductivity buffers.<sup>5</sup>

Small i.d. capillaries (or shallow microfluidic channels) present experimental challenges, particularly for injection and detection techniques. Band broadening due to adsorption is also a

prominent mode of dispersion in small i.d. capillaries due to high surface area to volume ratios, but covalent or dynamic coatings can be used to reduce this effect.<sup>6,7</sup> When small i.d. capillaries are used, lower amounts of analyte must be injected to avoid band broadening due to sample overloading. Therefore, injection instrumentation must reproducibly inject small plugs of sample; however, if smaller quantities are being injected, then high-sensitivity detectors are needed to detect the analytes. Typically, ultraviolet (UV) detectors are not sensitive enough, and so most fast separations rely on high-sensitivity detection methods such as laser-induced fluorescence (LIF). Advances in injection and detection methodologies for ultrafast separations will be described more in the Section 15.3.

Another parameter to consider in electrophoresis is electroosmotic flow (EOF), which is present in most examples of rapid electrophoretic separations. Therefore,  $\mu_{ep}$  in Equations 15.1 and 15.2 must be replaced with the sum of electrophoretic mobility and the electroosmotic mobility ( $\mu_{EOF}$ ):

$$t_{mig} = \frac{L^2}{V \times (\mu_{ep} + \mu_{EOF})} \quad (15.4)$$

$$N = \frac{L^2}{\sigma_{tot}^2} = \frac{(\mu_{ep} + \mu_{EOF}) \times V}{2D}. \quad (15.5)$$

At first glance, EOF appears to be favorable for both migration time and efficiency. However, while EOF mobilizes the analytes off the column faster, allowing less time for diffusional band broadening and an improvement in  $N$ , it is a nonselective mode of transport. As a result, if EOF is in the same direction as the ion mobility, two analytes have less time to be separated and a loss of resolution results. This fact is shown in the equation for resolution ( $R_s$ ) of two compounds:

$$R_s = 0.177 (\Delta\mu_{ep}) \left[ \frac{V}{D (\bar{\mu} + \mu_{EOF})} \right] \quad (15.6)$$

where  $\Delta\mu_{ep}$  is the difference in the electrophoretic mobilities of two analytes and  $\bar{\mu}$  is the average electrophoretic mobility of two analytes. Thus, the highest resolution is attained when  $\bar{\mu}$  is approximately equal and opposite to  $\mu_{EOF}$ ; however, this situation is at the cost of increased analysis time (see Equation 15.4).<sup>2</sup> Methods to reduce EOF, such as wall coatings and buffer additives, promote better resolution while maintaining fast separations.<sup>8</sup>

## 15.3 METHODS DEVELOPMENT

Examining the theory for electrophoresis reveals that high voltages and small separation lengths are two strategies primarily involved in ultrafast separations, for both capillary and microfluidic formats. However, most commercial instruments are incompatible with short separation distances and are not equipped with the fast injection devices and sensitive detectors needed for rapid separations. Therefore, methods development for both ultrafast capillary and microfluidic separations has gone hand-in-hand with instrument development. Instrument development has focused on methods to maximize voltages, minimize injection volumes, detect small amounts of analyte, and automate data analysis.

### 15.3.1 APPLIED VOLTAGE

Typical separations might employ electric fields from 100 to 300 V cm<sup>-1</sup> while electric fields in the 1000–5000 V cm<sup>-1</sup> range are common for fast separations. Ultrafast separations on the millisecond or microsecond timescale can require fields up to MV cm<sup>-1</sup>. These high voltages are a safety risk and the user should be properly isolated from the voltage. Proper care must also be taken to ensure that there are no additional pathways to ground for the applied voltage besides the capillary.

**FIGURE 15.1** Schematic representation of a microchip used for high-speed electrophoretic separations. Narrow channels were etched in the injection and separation areas, while wide channels were fabricated for all other sections. These differential channel widths ensured the majority of the potential was applied across the narrow channels. Owing to the high separation field strengths (up to  $6.1 \text{ V cm}^{-1}$  per volt of applied potential), subsecond separations were possible. (Reproduced from Jacobson, S. C. et al. *Anal. Chem.*, 70, 3476, 1998. With permission from American Chemical Society.)

Extremely high voltages (greater than 30 kV) can lead to breakdown of the material in the separation path and research with ultrahigh voltages has shown that shielding, such as immersion in a weakly conducting solution, will help prevent material breakdown.<sup>9</sup> The Jorgenson lab has applied ultrahigh voltages to increase the temporal response when analyzing tryptic digests of proteins by capillary electrophoresis.<sup>9</sup> High voltages yield faster, more efficient separations but a complicated separation can still take over an hour, even with 120 kV applied. The technology could be applied to making second or even subsecond separations in the future.

Amplified electric fields have been obtained by changing the geometry of a capillary as well. Pulling a capillary to an hourglass shape gives amplified fields in a  $50 \mu\text{m}$  region where the inner diameter is thinnest. Fields of up to  $0.15 \text{ MV cm}^{-1}$  were obtained by applying 5–20 kV potentials.<sup>10</sup> In the same vein, microfluidic devices have been fabricated that use differential channel widths to apply a large percentage of the separation voltage across the appropriate channel. For example, Ramsey and coworkers<sup>11</sup> applied 8.7 kV across a narrow injection valve design (Figure 15.1) and obtained a  $53 \text{ kV cm}^{-1}$  electric field in the separation channel, while 71 kV would have been required if all channels had the same cross-sectional area.

### 15.3.2 INJECTION METHODS

Injection technology is also crucial for achieving efficient separations. A thin plug of analyte must be injected because the band broadening caused by injection is proportional to the width of the sample plug squared. Sample overloading, or electromigration dispersion, can also occur due to differences in the electric field between the sample and the separation buffer if the plug is too wide. Thin plug injections onto small i.d. capillaries or shallow microfluidic channels require that low volumes of sample are loaded. Injection methods for microfluidic devices will be outlined at the end of this section; however, the two most common injection methods for capillary electrophoresis systems are hydrodynamic and electrokinetic injections. Modifications of hydrodynamic injections and electrokinetic methods are necessary to obtain thin plugs.

Injection valves have been used to introduce samples into a capillary electrophoresis instrument.<sup>12</sup> The injection system is similar to a six-port valve used in a conventional HPLC instrument, where the sample can be loaded into a sample loop on the valve, then the valve actuated to inject the plug onto the capillary. The size of the injection is determined by the plug size and flow rate. This system is not the fastest or most reproducible, but it relies on fairly simple technology. Valved injections have been used in conjunction with separation times down to 10 s.<sup>13</sup>

Flow-gated injection is also a common method of injection. Pioneered by Jorgenson, this method involves a cross intersection between the reagent capillary and the separation capillary.<sup>14</sup> During the separation, a cross-flow buffer sweeps the continuously flowing sample out to waste. However, to make an injection, this cross-flow buffer is stopped, the sample builds up in the gap at the middle of the cross, and then sample is injected electrokinetically. The disadvantages are the same as normal electrokinetic injections, as sampling biases occur due to differences in analyte electromigration rates. However, the reproducibility of injections is good, with relative standard deviations of 4% between runs. A range of flow rates can be used and the injection voltage can be varied to control the injection volume. Flow switching on a very rapid scale is difficult to achieve, so flow-gated injection is not useful for the fastest microsecond separations. However, it has been routinely used for multidimensional separations of 2–3 s<sup>15</sup> and coupling to *in vivo* monitoring with 10 s separations.<sup>16,17</sup>

Optical gating is an extremely fast method of injection for CE. The sample is fluorescently tagged and a separation voltage is applied to allow a continuous stream of sample to be electrokinetically injected.<sup>18</sup> An intense gating laser beam near the entrance to the capillary is applied to photobleach the fluorophore and render the analyte undetectable with LIF at the probe beam (Figure 15.2). Only when the gating beam is pulsed “off” is an injection made, allowing tagged molecules to be separated and detected by LIF. The gating laser beam can be pulsed quickly, on the microsecond

**FIGURE 15.2** Instrumental diagram for optical gating. The gating laser beam photobleaches the sample most of the time. To make an injection, the gating beam is pulsed off, and analytes can then be detected by LIF at the probe beam. (Reproduced from Monnig, C. A. and Jorgenson, J. W. *Anal. Chem.* 63, 802, 1991. With permission from American Chemical Society.)

level, making optical gating methods faster than fluid switching methods. However, effectively photobleaching the fluorescent tags can be difficult and incomplete photobleaching can lead to high background light levels.<sup>18</sup> The separation voltage is continuously applied to the capillary, so capacitive charging when applying a voltage does not limit the sample plug sizes. The sample plug is limited by the dimensions of the laser focus, the time for switching and the velocity of the sample migrating through the gate. A concern is that the sample is continuously being injected onto the column. If the sample adsorbs to the capillary or contains high salt levels that alter EOF, poor separations may result. Optical gating has the advantage of being amenable to fast, repeated injections. Therefore, it has been used to apply pulse profiles for multiple injection methods such as Hadamard transform.<sup>19</sup>

A twist on optical gating, which photodestroys most analytes, is optical generation of fluorescent products. For example, multiphoton-excited photoreactions have been used to generate fluorescent products from thermally labile, nonfluorescent reactants.<sup>20</sup> As with optical gating, the laser beams needed for the reaction can be pulsed, so the fluorescent products are only produced for a very short period. Another approach is to generate a fluorescent analyte to photoactivate a caged fluorophore.<sup>21</sup> Caged fluorescein can be photolyzed below 365 nm yielding a fluorescent species that can be detected using the 488 nm line of an Ar ion laser. Therefore, a UV laser beam can be used as a gate to activate a small plug of sample, making it fluorescent and detectable with LIF. This method has lower noise than traditional optical gating because it does not suffer from the background currents caused by incomplete photobleaching.

Injection methods for microfluidic experiments are different, but often based on similar principles. For example, gated injections (either via a perpendicular cross-flow or via an optical gate) that are similar to their CE counterparts are used for high-speed separations on microdevices. Often these injection times are fast, less than 5 s is typical, and since the sample remains close to the injection intersection, serial injections can be easily attained.

A tee intersection,<sup>22</sup> double tee,<sup>23</sup> or a tee intersection operated in a pinched format<sup>24</sup> are the most popular choices for injection schemes in microfluidic formats due to their simplicity and ability to deliver time-independent concentrations of samples. These types of injection formats are unique to microfluidic devices. While short and rapid injections are needed in CE experiments, long loading times are regularly used with these injection systems even with high-speed separations since (ideally) no sample enters the separation channel until analysis begins.

The downside to these methods is that sample often diffuses out of the loading channel during the analysis, which leads to increased band broadening. One method to reduce this effect is to apply “pullback” voltages. In this way, the analyte is driven away from the injection intersection after separation commences to ensure no diffusion of sample into the separation channel. The disadvantage of the pullback method is that the sample is moved away from the injection intersection making it difficult to achieve rapid serial injections. To alleviate this problem, a double-tee format has been used with one tee in the sample channel (allowing the sample to remain close to the injection cross while the pullback voltage was applied), and a second tee in the separation channel (which enabled loading of subsequent injections during the analysis).<sup>25</sup> With this design, repetitive injections up to 10 Hz could be achieved, although the method was not coupled to a separation.

In gated injections the sample is shunted away from the separation channel using a perpendicular flow.<sup>26</sup> To perform an injection, the perpendicular flow is stopped for a specific amount of time and the sample is allowed to fill the injection cross before reinitiating the perpendicular flow. If the sample is being driven by application of an electric field, the injection is biased toward analytes with the highest mobilities. This type of injection is similar to conventional flow-gate injections in capillary systems. Often the injection times are fast, less than 5 s is typical, and since the sample remains close to the injection intersection, highly reproducible serial injections can be easily attained (Figure 15.3).<sup>27</sup>

**FIGURE 15.3** Series of 110 consecutive separations performed in a microchip to monitor insulin secretion via a competitive immunoassay. Fast monitoring can be achieved by increasing the rate at which a reaction is sampled (e.g., 1 s injections with a 5 s separation time). The gated injection scheme used in these separations enabled rapid sampling, resulting in high temporal resolution of insulin secretion. The black line through the peaks shows the bound/free ratios for each electropherogram; reproducibility ranged from 2% to 6% over the course of 30 min. (Reproduced from Roper, M. G. et al. *Anal. Chem.*, 75, 4711, 2003. With permission from American Chemical Society.)

### 15.3.3 DETECTION METHODS

Absorbance detection is frequently utilized with capillary electrophoresis but is difficult to use in conjunction with rapid separations. While most molecules absorb in the UV, small capillaries or shallow channels entail small pathlengths, resulting in high limits of detection. Detection cells that lengthen pathlengths, such as Z-shaped cells and bubble cells, are incompatible with fast separations and can lead to band broadening. Signal averaging can boost signal-to-noise (S/N) ratios but is inconsistent with rapid detection because it is time consuming.

The most common detection method for fast separations with CE or microfluidic platforms is LIF. With this method, molecules are usually derivatized with a fluorescent moiety, then a laser is used to induce fluorescence and the resultant light intensity measured. Lasers can be focused into small beams, minimizing band broadening due to the length of the detector. On-column detection is popular because it limits band broadening after the separation. A detection window is created on the capillary by removing the protective polyimide coating; however, scattering of light from the capillary can cause noise and decrease S/N ratios. Dovichi and coworkers<sup>28</sup> designed a sheath-flow cell for off-column detection that concentrates the analyte into a Taylor cone after the capillary. The sheath-flow detection cuvette was square, eliminating the light scattering caused by the round capillary. A schematic diagram of an LIF instrument is shown in Figure 15.4a with a close-up of the sheath-flow cell for LIF detection in Figure 15.4b.<sup>29</sup> Sheath-flow cells are used to increase S/N ratios by a factor of 10 over on-column detection.

Similar to capillaries, the most common detection method for high-speed separations on microdevices is fluorescence, yet few methods have matched the limits of detection found in sheath-flow formats routinely used in capillary systems. This is due in part to the microfluidic substrate being in a planar format and therefore difficult to reproduce the three-dimensional Taylor cone found in sheath-flow capillary systems. The most simple and common method for high-sensitivity detection in microdevices is the use of a confocal detection scheme.<sup>30</sup>

Native-fluorescent LIF has been used to detect proteins with high tryptophan levels<sup>31</sup> and serotonin.<sup>32</sup> However, most molecules are not fluorescent and must be derivatized with a fluorescent moiety in order to be detected. Derivatization has been achieved both with covalent attachments and affinity agents such as aptamers.<sup>33,34</sup> The limitation for LIF as a detection technique for rapid separations is usually the chemistry of the derivatization reaction. First, the kinetics of the tagging reaction should be fast, especially for online analysis systems. Some fluorophores such as fluorescein

**FIGURE 15.4** Instrumental diagram of a flow-gated injection CE instrument for monitoring neurochemicals. (a) Schematic diagram of the optical setup for the detection of analytes after OPA derivatization online. (b) Schematic diagram of the flow-gated interface and sheath-flow cuvette for detection. A cross-flow buffer between the reaction and separation capillary normally sweeps the sample to waste. An injection is made by stopping the cross-flow, allowing sample to build up in the gap, then applying a voltage for an electrokinetic injection. The sheath-flow cuvette has a sheath buffer flowing around the capillary to concentrate the sample into a Taylor cone and facilitate off-column detection. (Reproduced from Bowser, M. T. and Kennedy, R. T. *Electrophoresis*, 22, 3668, 2001. With permission from WILEY-VCH.)

isothiocyanate (FITC) can take 6–12 h to react completely,<sup>35</sup> making them incompatible with methods requiring fast analysis. However, a few tags for primary amines, such as *o*-phthalaldehyde (OPA)<sup>36</sup> and naphthalene dicarboxylic acid (NDA)<sup>37</sup> can react within a few minutes. The classes of compounds that can be detected are limited by the chemical reactions. Methods for derivatizing primary amines,<sup>33</sup> thiols,<sup>38</sup> and carboxylic acids<sup>39</sup> have been developed, but secondary amines, for example, have slower kinetics and are much more difficult to rapidly detect. Also problematic is that derivatization of real-world samples in complex matrices with nM concentration is difficult.<sup>40</sup> Despite the drawbacks of the chemical reaction, LIF is popular because the spectral properties of the fluorescent tag can be tuned and high mass sensitivity detection can be obtained. Detection of yoctomoles of analyte has been reported using LIF.<sup>41</sup>

Electrochemical detection has also been used for rapid electrophoretic separations.<sup>42,43</sup> The main challenge of electrochemical detection after electrophoresis is separating the electrode from the high voltage applied for the separation. Noise at the electrode from the separation voltage must be minimized for efficient, rapid separations. This is usually accomplished by detecting on-column after a decoupler that grounds the separation voltage before the electrode or by end-column detection after the capillary.<sup>44</sup> Because there is no EOF after the column, care must be taken to avoid band broadening during end-column detection. Electrochemistry can provide high sensitivity and low mass detection limits. Electroactive molecules can be detected without derivatization, an advantage over LIF. Microelectrodes are compatible with small i.d. capillaries and the small size of electrodes makes them particularly attractive for interfacing with microchips where miniaturization is a goal. Electrodes can even be fabricated into chips. Because mass limits of detection are not as good as with LIF, electrochemical detection has been used with separations in the minute time frame<sup>45</sup> but it has not been used for ultrafast, subsecond separations.

Mass spectrometry (MS) is especially useful for monitoring changes in peptides and proteins.<sup>46</sup> MS can be coupled to fast separations;<sup>47</sup> however, there are multiple challenges including detection of low mass samples inherent to rapid electrophoretic separations (see previous section) and coupling the separation eluent to the mass spectrometer for detection. Electrospray detection has primarily been used as the interface method, but the separation voltage and electrospray voltage are of different magnitudes (kV and V, respectively). Coupling of nanospray and CE has been achieved to allow faster separations.<sup>48</sup> Ideal mass analyzers for rapid separations would make measurements several times a second, making ion traps and time-of-flight analyzers preferred. Quadrupoles are more sensitive but have slower scan speeds. MS coupled to CE has not been used for ultrafast microsecond separations, but could be useful for proteomics and other applications that require separations of tens of compounds. These separations could normally take hours, but could be reduced to the minute time scale with rapid capillary electrophoresis procedures outlined here.

#### 15.3.4 ELECTRONICS AND DATA ANALYSIS

Analysis of ultrafast separation data requires a consideration of instrumentation electronics and data analysis. High collection frequencies are needed to sample sharp analyte peaks. In addition, filtering cutoffs and rise times must be ample to allow fast signals to pass.<sup>49</sup> Fast sampling rates, while providing a better description of the peak shape, require larger bandwidths and can lead to greater noise from environmental sources. For subsecond separations, sampling rates greater than 1000 Hz and filter rise times less than 1 ms are needed. Often, high-speed separations are used for monitoring purposes. In these cases, methods to analyze a large number of electropherograms in a reasonable time are indispensable.<sup>50</sup>

A simple approach to increasing S/N ratios for samples, thereby lowering detection limits, is to average multiple electropherograms from the same sample. The difficulty of this approach with rapid separations is that performing multiple separations increases the analysis time and sample consumed. Mathematical multiplexing approaches such as Hadamard transforms allow multiple separations to

be performed at once, increasing throughput and improving S/N. Aspinwall has designed a fast Hadamard transform injection profile that when coupled with low volume optical gating injections yields separations with ninefold enhancement in S/N in less than 10 s.<sup>19</sup> This is the first multiplexing method that is amenable to fast monitoring.

## 15.4 PRACTICAL APPLICATIONS

For ease in presenting literature examples of rapid electrophoretic separations, this section is broken into examples using capillary and microfluidic electrophoresis systems.

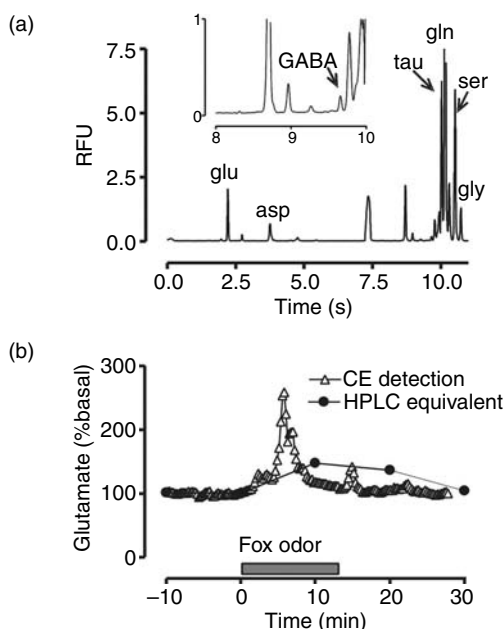

### 15.4.1 CAPILLARY ELECTROPHORESIS

The fastest separation to date is the separation of 5-hydroxytryptamine (5-HT) and 5-hydroxytryptophan (5-HT<sub>trp</sub>) in 20  $\mu$ s (Figure 15.5).<sup>10</sup> Multiphoton excitation was used to create the fluorescent, highly unstable photoproducts.<sup>20</sup> Short injection pulses were achieved by pulsing the laser on for 200  $\mu$ s to achieve a femtoliter reaction plug. Separation of these products could be achieved in a 4.7  $\mu$ m i.d. traditional capillary with a separation distance of 15  $\mu$ m in under 10 ms. Different reaction products were observed than when the separation products eluted 0.1–1.0 s after pulse, indicating the reaction occurs in less than 0.1 s and the products were very unstable. To achieve microsecond separations, higher electric fields were needed. This was accomplished by pulling capillaries into an hourglass shape to create extremely high electric fields (MV  $\text{cm}^{-1}$  range) in the pulled region.<sup>10</sup> With a separation distance of 10  $\mu$ m, separations could be performed in these high fields in 20  $\mu$ s. This experiment demonstrated that capillary electrophoresis could be used to analyze short-lived reaction products. The intermediates have similar spectroscopic properties, but different electrophoretic mobilities that are probed with CE. The technological advances of both the geometry of the capillary and the width of the injection pulse will allow faster probing of a variety of reactions.

The Kennedy lab has been at the forefront of using rapid capillary electrophoresis to measure neurochemical changes. Optically gated injection of OPA-derivatized amino acids has been achieved in less than 2 s.<sup>33</sup> However, the high salt concentrations of physiological samples, such as cerebral spinal fluid, can reduce EOF, and make separations slower. Still, 10 s temporal resolution for online monitoring of directly sampled and microdialysis samples were obtained. An instrument has been developed in the Kennedy lab for online analysis of microdialysis samples after precolumn

**FIGURE 15.5** Microsecond separation of 5-HT and 5-HT<sub>trp</sub>. The capillary was pulled to an hourglass geometry to achieve an electric field of 0.15 MV  $\text{cm}^{-1}$  over the 10- $\mu$ m separation distance. (Reproduced from Plenert, M. L. and Shear, J. B. *Proc. Natl Acad. Sci. USA*, 100, 3853, 2003. With permission.)

**FIGURE 15.6** Use of rapid CE for neurochemical monitoring during a behavioral experiment. (a) Example electropherogram of a rapid separation of OPA-derivatized amino acids in a microdialysis sample. Overlapping injections were used, so glutamate (glu) and aspartate (asp) are from the previous injection. Also separated were taurine (tau), glutamine (gln), serine (ser), and glycine (gly). The enlarged inset shows a clear peak for GABA. (b) Average peak height for glutamate changes during presentation of a predator fox odor to a rat ( $n = 14$  animals, fox odor present during gray bar). The CE data (triangles) collected a point every 14 s and revealed that changes in glutamate were fast and large. Averaging the data to show the equivalent 10 min temporal resolution of HPLC experiments show that both the magnitude and the width of the peak are distorted with slower temporal resolution techniques. (Adapted from Venton, B. J. et al. *J. Neurochem.*, 96, 236, 2006. With permission.)

derivatization with OPA or NDA (Figure 15.4).<sup>29,37</sup> With flow-gated injection, short, small i.d. capillaries, and electric field strengths of  $2000 \text{ V cm}^{-1}$ , separations of amino acids were achieved in less than 15 s. Sheath-flow detection with LIF allowed low nM detection limits of real samples. An example electropherogram from a behavioral experiment using this instrumentation is shown in Figure 15.6a. With overlapping injections, six amino acids were detected every 10 s. Plotting the peak current for glutamate revealed large, fast amino acid changes in response to a predator fox odor (Figure 15.6b).<sup>16</sup> Conventional detection by HPLC would allow only 10 min temporal resolution, and grouping the rapid CE data in 10 min bins to mimic that temporal resolution reveals that fast detection is needed to characterize both the time course and magnitude of the changes. Capillary electrophoresis has also been used to demonstrate that glutamate and  $\gamma$ -aminobutyric acid (GABA) transients correlate with behavioral changes during stereotypic mouse behaviors<sup>51</sup> and fear conditioning.<sup>52</sup> The application of fast CE separations to neurochemical monitoring is allowing a better picture of the dynamics of neurotransmission in the rat brain.

Others have also demonstrated fast separations that could be useful for neurochemical monitoring. Shear's laboratory has detected cyclization reactions of catecholamines to form trihydroxyindoles that allowed them to be detected with two photon fluorescence.<sup>53</sup> Their method allowed separation of norepinephrine and epinephrine within 80 s and cofactors such as FADH and NADH within 4 min. Bowser and coworkers<sup>54</sup> have developed rapid chiral CE separations for D-serine in salamander retinas and rat brain samples. Fast separations of nitrate and nitrite in rat brain perfusates have been

achieved using UV detection in under 1.5 min.<sup>55</sup> Multiplexing rapid separation using Hadamard transforms has improved the detection limits of amino acids.<sup>19</sup> Monitoring of amino acid mixtures at low nM concentrations indicates that this method may be beneficial for neurochemical monitoring of compounds such as GABA and dopamine, which are usually present at low concentrations.

Conventional capillary electrophoresis is useful for separating small inorganic ions in a complex mixture. CE with a contactless conductivity detector has been utilized to separate solutions of cations or anions in under 20 s.<sup>13</sup> Together, inorganic ions and cations were detected in under 2 min.<sup>56</sup> The conductivity detector allows detection of ions that are not UV active. Small anions and cations have also been separated from the complex solutions blood serum and milk.<sup>57</sup>

Rapid separations of DNA fragments in conventional capillaries have been demonstrated. Commercial instrumentation commonly used to sequence DNA is not equipped to use small diameter, short length capillaries so extremely fast separations have not been extensively utilized. Boček and coworkers<sup>58</sup> have shown that CE-LIF detection of denatured DNA fragments can be achieved in 2.5 cm capillaries in less than 45 s. Comparable separations on a traditional CE-UV instrument with 50 cm capillaries required 23 min. Short tandem repeat polymorphisms could be detected because baseline separation of DNA fragments differing by two nucleotides was possible in under a minute. In another study, narrow electrophoretic injections were the key to minimizing dispersion and obtaining fast, efficient separations of DNA. Here, short capillaries were used to demonstrate separations of double-stranded fragments of DNA within 30 s.<sup>59</sup> Fast mutation detection was achieved of a single base pair mutation in double-stranded mitochondrial DNA in 72 s.

Separations of peptides and proteins are not routinely performed in under a minute. However, the Jorgenson lab has used rapid CE to investigate isomerization between *cis* and *trans* peptide bonds.<sup>60</sup> Isomerization of proline-containing peptide bonds from *cis* to *trans* can occur in a few seconds. The multiple peaks detected with CE for peptides containing more than one proline are thought to be due to differential migrations of the *cis* and *trans* conformations. Optical gating injections combined with a 6  $\mu\text{m}$  i.d. capillary was used to separate *cis* and *trans* isomers in 2 s, less than the rate of the conformational shift. Longer peptides could be separated in 5 s. These studies show that rapid CE is useful for studying fast isomerization rates for optical isomers.

Affinity probe capillary electrophoresis (APCE) uses a fluorescently labeled ligand to bind a receptor. Separation of the bound and free affinity probe has been achieved with CE with LIF detection. One advantage of the rapid CE method is that if the separation is rapid compared to the dissociation time, affinity constants can be determined.<sup>61</sup> Competition experiments can be performed to observe the conditions of complex formation. For example, a fluorescent GTP analog was used as an affinity probe and G protein receptor subunits as the ligand.<sup>62</sup> The complex and free fluorescent probe were separated within 20 s and Ras-like G protein complexes could be separated in less than 15 s. The rapid separations allowed kinetics of binding to be studied.

APCE has also been used to investigate the fast kinetics of peptide–protein interactions.<sup>63</sup> A fluorescently labeled phosphorylated peptide was mixed with a Src homology 2-domain protein and separations of complex and free probe could be achieved in less than 4 s. These rapid separations were necessary, because no complex peak was observed with 8 s separations, presumably because it had dissociated. Estimated dissociation constants for the complex were obtained from peak areas and results were similar to constants from fluorescence anisotropy data. Aptamers have also been used as affinity ligands for fast separations. Separations as short as 30 s were accomplished with a fluorescently labeled aptamer against IgE.<sup>34</sup> APCE has also been used to detect nM concentrations of digoxin in less than 1 min.<sup>64</sup>

The rapid separations offered by capillary electrophoresis have made it amenable as a detector in hyphenated techniques. For LC-CE, the total analysis time is usually governed by the LC separation, which generally takes minutes. However, capillary electrophoresis detection adds more peak capacity because of a second and orthogonal dimension for separation, and shorter separation conditions for LC can often be tolerated. For example, a 2.5 min reversed-phase liquid chromatography gradient was used in conjunction with 2.5 s CE separations for the detection of a tryptic digest of cytochrome *c*.<sup>65</sup>

The experiment used optical gating for injections, but flow-gated injections were actually developed to interface the two separation techniques. For example, using a capillary LC column, flow-gated injections of LC eluent onto the CE capillary were performed every 30–60 s.<sup>14</sup> Fluorescently labeled phenylalanine and glutamate could be separated in 35 s. A more complicated analysis of fluorescently labeled urine required longer separations, up to 1 min. However, overlapping electrokinetic injections were made before one run finished, allowing 30 s temporal resolution.

### 15.4.2 MICROFLUIDIC APPLICATIONS

Owing to the numerous examples of microfluidic separations in the literature, we have attempted to limit the applications reviewed to those where the separation was performed in less than 30 s.

As an example of utilizing the gated methodology for rapid, sequential sample introduction, Roper et al.<sup>27</sup> made 1 s injections every 15 s over the course of 30 min to monitor secretion of a peptide hormone from a single islet of Langerhans on a glass microfluidic chip. During the 15 s separation, free FITC-insulin and FITC-insulin bound to an insulin antibody were separated and used to quantify the amount of insulin released from the islet. The Kennedy and coworkers<sup>66</sup> have continued to expand on this initial work by improving the throughput using 0.5 s injections every 5.5 s. These rapid serial injections and separations were used to monitor insulin secretion from an islet for over 2 h.

Gated injections have also been used in several applications where microdialysis sampling was coupled to microfluidic devices for separation. For example, Lunte and coworkers<sup>67</sup> coupled the outlet of a microdialysis sampling probe to a microfluidic chip and used the inherent flow resistances within the device to split a portion of the dialysate to the separation channel. Their device was used to monitor the product of an enzyme reaction using 1 s injections every 30 s and could observe a decrease in the substrate peak with a concomitant increase in the product peak. Sandlin et al.<sup>68</sup> have also coupled a microdialysis probe to a microfluidic chip and used this device to monitor changes in neurotransmitter levels in the brains of anesthetized rats. In this report, the dialysate was mixed and reacted on-chip with OPA, before a 0.1 s gated injection with a 25 s separation. With this protocol, sequential injections were made every 130 s over the time course of 100 min while obtaining high efficiency separations ( $N = 156,000$  for glutamate).

Lapos and Ewing<sup>69</sup> have performed 80 ms injections every 5 s for the separation of 4-chloro-7-nitrobenzofurazan (NBD)-labeled amino acids. They have continued to improve upon this method by utilizing optical gating to inject analytes in a parallel channel format<sup>70</sup> and have achieved five serial separations of four NBD-labeled amino acids in four parallel channels every 10 s. In addition, they have performed three serial separations of five fluorescein-labeled oligonucleotides (10, 20, 30, 60, and 80 basepairs in length) within 20 s.<sup>71</sup>

Li and coworkers<sup>72</sup> described the separation of FITC and FITC-labeled antihuman IgG by zone electrophoresis in a glass microchip. The two compounds were electrokinetically injected into the separation channel for 2 s and separated in less than 12 s. A comparison between the separation performance in capillary and microchip showed that higher efficiency was achieved in the microchip format due to the shorter separation length and the higher electric field that were applied in microfluidic structures.

Belder and coworkers<sup>73</sup> reported the fast chiral separation of acidic and basic compounds using a commercially available quartz microchip with a simple cross-tee design and linear imaging UV detection. Highly sulfated cyclodextrins were added to the separation medium to improve selectivity and samples were loaded for 60 s using the pinched injection mode. The chiral separation of norephedrine was achieved in 2.5 s, and a mixture of three basic drugs was resolved in 11 s.

The same microchip electrophoresis system was used by the Takeda and coworkers<sup>74</sup> to separate phenolic compounds [bisphenol A, 4-nonylphenol, 4-(1,1,3,3-tetramethylbutyl)phenol and 4-*tert*-butylphenol] by micellar electrokinetic chromatography (MEKC). The samples were loaded for 25 s using a pinched injection scheme.  $\beta$ -Cyclodextrin was added to the MEKC buffer to further improve

the separation and the four phenolic compounds were resolved in 13 s in a 25 mm separation channel using an electric field of  $450 \text{ V cm}^{-1}$ .

The requirement for low sample injection volumes in microchip electrophoresis often leads to problems in detection sensitivity. In cases where the analytes of interest are present in low amounts, sample concentration techniques are typically applied before separation. deMello and coworkers<sup>75</sup> has reported performing in-column field-amplified sample stacking (FASS) for the separation and detection of low concentrations of biogenic amines. A hybrid PDMS/glass device patterned with a narrow sample channel tee-injector design allowed the sample to be directly injected into the separation channel without leakage control. The separation length was 30 mm and the sample was loaded into the separation channel for 10 s. The extent of the sample plug was defined by the chip design, more specifically by the distance between the injection intersection and the inlet buffer reservoir, which enabled reproducible injections. Stacking occurred on application of the separation voltage, and separation of putrescine and tryptamine was performed in less than 20 s. Limits of detection for putrescine and tryptamine using FASS were 20 and 25 pM, respectively.

Several research groups have investigated the use of polymeric materials to fabricate microfluidic devices, which can help reduce production costs compared to glass or quartz materials. Henion and coworkers<sup>76</sup> reported the use of Zeonor (a polymer commonly used to manufacture CDs and DVDs) as the analytical platform for the separation of carnitine derivatives by microchip electrophoresis-MS. Using a double-tee junction design for sample injection (15 s loading time), carnitine, acetylcarnitine, and butyrylcarnitine were separated in a 3.5 cm long separation channel in less than 10 s, with an applied electric field of  $2 \text{ kV cm}^{-1}$ .

Nagata et al.<sup>77</sup> reported the use of a polyethylene glycol-coated poly(methyl methacrylate) (PMMA) microchip for microchip gel electrophoresis separations. Trypsin inhibitor, bovine serum albumin (BSA) and  $\beta$ -galactosidase (labeled with Alexa Fluor 488) were electrokinetically loaded for 60 s. The sodium dodecyl sulfate (SDS)-protein complexes were then separated and baseline resolved in 8 s using a 5% linear polyacrylamide/0.1% (w/v) SDS-based separation buffer, 3 mm separation channel, and  $303 \text{ V cm}^{-1}$  electric field.

Fast microchip electrophoresis in polymeric devices was also applied to multiplex enzyme assays, which enabled high-throughput screening of one or several substrates against multiple enzymes targets. One particular advantage of this technique is that the activity, specificity, and cross-reactivity of enzymes for drug candidates may be monitored as well as protein-protein interactions in a single fast separation. Gibbons and coworkers<sup>78</sup> performed a fourplex protein kinase assay in a PMMA chip patterned with a double-tee injection (150  $\mu\text{m}$  offset) design. The separation was performed in a buffer containing 1% polyethylene oxide (PEO) to suppress EOF. Three substrate peaks and four product peaks were separated in less than 25 s.

The fabrication of separation platforms from less common materials has also recently been described. Wirth and coworkers<sup>79</sup> performed electrophoretic separations inside silica colloidal crystals. The advantages of this separation medium include fast mass transport, high electric field resistance, and chemically modifiable surfaces. The silica colloidal crystals were treated and reacted with chloro-dimethyl-octadecyl silane to form a  $\text{C}_{18}$  stationary phase. The system differed from traditional electrochromatography in that EOF was negligible. In such a system, separation occurred through both adsorption and electrophoresis phenomena. A comparison between the Van Deemter plots obtained from the silica colloidal system (obtained using an unretained dye since there was no flow) and from a commercial monolithic column showed that the colloidal phase produced much smaller plate heights due to smaller  $A$  (Eddy diffusion) and  $C$  (mass transfer) terms. Fast mass transport was also beneficial to produce fast separations. Three hydrophilic peptides, labeled with rhodamine and electrokinetically injected for 5 s, were separated in less than 10 s using an electric field of  $800 \text{ V cm}^{-1}$  in a 6-mm-long separation channel.

More complex experimental designs have also been described. Hyphenation of microchip electrophoresis with an orthogonal separation technique was reported by Zhang and coworkers.<sup>80</sup>

A two-dimensional HPLC/electrophoresis device (fabricated in glass) was used to separate FITC-labeled peptides. To interface the two techniques, a microchip design similar to a cross-tee was used, containing a hole in the sample-loading channel that connected the outlet end of the HPLC capillary column to the microchip channels. The HPLC effluent was continuously introduced into the sample-loading channels and was repeatedly injected (pinched injection for 3 s) into the separation channel every 20 s. The peptides were separated in a 40-mm-long separation channel using an electric field of  $635 \text{ V cm}^{-1}$ . The partial profile of a tryptic digest of BSA was obtained from 10 consecutive injections and separations of the HPLC effluent, with eight FITC-labeled peptides being separated and detected in a total analysis time of 230 s. With these experimental conditions (i.e., sampling and separation times), two peptides were detected per electrophoretic separation (20 s analysis time).

Ramsey and coworkers<sup>11,81</sup> were one of the first groups reporting subsecond separation in a microfluidic device. A simple cross-T design, etched into a planar glass chip, was used to separate rhodamine B and fluorescein in 150 ms, in a 0.9-mm-long separation channel.

Liu et al.<sup>82</sup> also reported the microchip electrophoretic separation of three flavin metabolites (riboflavin, flavin-adenine dinucleotide, flavin mononucleotide) in less than 1 s using a pinched injection scheme. The experimental conditions were optimized to achieve ultrafast separation, by shortening the separation channel length and increasing the electric field. The separation quality was also improved by controlling the sample injection size by optimizing sample pinching dispensing factors.

Subsecond chiral separations of DNS-labeled amino acids were also reported by Belder and coworkers<sup>83</sup> using quartz microchips. Highly sulfated  $\gamma$ -cyclodextrin was added to the separation buffer as a chiral selector and the samples were loaded for 20 s using the pinched injection mode. The separation length and electric field strength (1.5 mm and  $2012 \text{ V cm}^{-1}$ , respectively) were optimized to achieve baseline resolution of DNS-norleucine enantiomers in 720 ms, and DNS-tryptophan enantiomers in 800 ms (Figure 15.7). The authors also showed the baseline separation of a more complex sample consisting of three amino acids (DNS-phenylalanine, DNS-norvaline, and DNS-glutamic acid) in 3.3 s using a 7 mm separation length and  $2012 \text{ V cm}^{-1}$  electric field.

**FIGURE 15.7** Subsecond chiral separation of DNS-norleucine achieved using a simple cross-injector quartz microchip. The separation was performed in a 1.5-mm-long channel, using an electric field of  $2012 \text{ V cm}^{-1}$  and 2% highly sulfated  $\gamma$ -cyclodextrin, 25 mM triethylammonium phosphate buffer, pH 2.5, as the separation buffer. ## 15.5 METHODS DEVELOPMENT GUIDELINES

In this section, it is our goal to provide a brief procedure that may be followed to produce successful ultrafast separations.

### 15.5.1 CAPILLARY ELECTROPHORESIS

Rapid capillary electrophoresis measurements in general require small i.d., short length capillaries with fast injection and sensitive detection techniques. One example of a successful implementation of all these principles is a rapid capillary electrophoresis instrument developed by Bowser and Kennedy<sup>29</sup> to analyze online microdialysis samples for *in vivo* monitoring (Figure 15.4). This instrument used small, 10  $\mu\text{m}$  i.d. capillaries that were 10 cm long. Applied voltages were 20,000 V, or 2000  $\text{V cm}^{-1}$ .

Analysis of amino acid neurotransmitters was achieved by online, precolumn derivatization with OPA. The reaction of OPA with primary amines occurs in less than 2 min. An online reactor was created by inserting a smaller capillary with the analyte into a larger capillary through, which the OPA was pumped. After the end of the smaller capillary, the analyte would be mixed with OPA and derivatized. A flow-gated interface was used for injection. The sample was swept to waste by a cross-flow buffer except when an injection was made. Then analyte was allowed to accumulate in the gap (30–50  $\mu\text{m}$ ) between the reaction and separation capillaries. A small voltage, less than the separation voltage, was applied for only 200 ms to perform an electrokinetic injection. This allowed very efficient separations with only 30 ms wide peaks.

Separations were performed with 40 mM borate buffer. One key is to filter all solutions so that no dust particles are present that can clog the small capillaries. Hydroxypropyl- $\beta$ -cyclodextrin was added to the separation buffer to increase the selectivity and was useful for the separation of isomers  $\alpha$ - and  $\beta$ -aminobutyric acid from GABA. In addition, side chains of the amino acids differentially interact with the hydroxyl groups on the cyclodextrin, allowing more separations that are efficient. Overall, efficiencies as high as 500,000 theoretical plates were obtained with separation times less than 20 s. Overlapping injections, where the separation is stopped (i.e., the voltage turned off) and more sample injected before the first separation is finished, allowed separations every 10 s (Figure 15.6a). Limits of detection for glutamate were less than 50 nM.

LIF in a sheath-flow cuvette allows detection of small amounts of analyte with high S/N ratios. The sheath-flow cuvette improved S/N ratios 15 times over conventional on-capillary detection. The end of the separation capillary was inserted into a square, quartz cuvette. Buffer was siphoned around the outside of the capillary end, which had been ground to a point. This created a Taylor cone of analyte. For OPA, excitation was with a 351 nm line of an Ar ion laser and emission at 450 nm was collected at a 90 angle using an objective to focus it on a photomultiplier tube. Collection of light at this angle avoids interference from the light of the incident beam. Software programs automated data collection and allowed the analysis of hundreds of electropherograms simultaneously.

To summarize

1. High voltages are needed for rapid separations (electric fields greater than 1000  $\text{V cm}^{-1}$ ).
2. Short separation distances are crucial for fast analyses.
3. Small i.d. capillaries reduce band broadening due to joule heating.
4. Precolumn derivatization with a fast reaction eliminates band broadening issues with postcolumn derivatization.
5. Short injection times, less than a second, yield narrow peaks and efficient separations.
6. A flow-gated interface allows sampling and injection from a continuous flow stream.
7. LIF is a high-sensitivity detection scheme for low quantities of analyte.
8. A sheath-flow cuvette increases S/N ratios and decreases detection limits.
9. Rapid, batch analysis of hundreds of electropherograms enables fast data analysis.

### 15.5.2 MICROFLUIDIC CHIPS

As detailed in Section 15.4, there are multiple examples of fast separations performed in microfluidic devices and the channel design and speed of the separation is ultimately dictated by the analytes to be separated. In one example, Roper et al.<sup>27</sup> detected insulin secretion from islets of Langerhans using a combination of several factors designed for rapid separations. These factors included the use of shallow channels, 1 s gated injections, 15 s separations, and high-speed data processing.

Use of shallow channels reduces current (and therefore, Joule heating) by increasing the overall resistance of the device. Unfortunately, these type of channels were also easy to clog with dust particulates, salt, or cellular debris so a thorough cleaning procedure before and after experiments was outlined in a subsequent paper.<sup>67</sup> This cleaning method included flushing the channels with NaOH, followed by multiple buffer rinses. In addition, caps were placed on top of microfluidic reservoirs to reduce dust and particulate entry into the device over a day of experimentation. With these types of precautions in place, separations every 10 s over a period of several hours could be performed.

Gated injections were used in this example since a pullback flow would perturb the insulin concentration upstream that was being monitored. With 1 s injections, the absolute number of analytes being detected was relatively low; however, the concentration being detected, approximately 100 nM FITC-insulin was high for LIF detection. The separation buffer was also optimized for high-speed separations by using a zwitterionic buffer. Zwitterionic buffers or separation buffers with added organic modifiers allow the application of high separation voltages while maintaining a low current, essential for rapid separations.<sup>7</sup> Finally, a software program was written to analyze the large amount of data being produced from these rapid separations.<sup>50</sup> Without this specialized software, data analysis was orders of magnitude longer than the separation time, limiting the utility of the method.

An analogous circuit diagram should be produced while the fluidic architecture is being designed. With this diagram, the distribution of the separation voltage over the channel network can be tested using relative resistance values<sup>84–86</sup> before spending the time and money fabricating the photomask or device. Through careful consideration of the relative resistances, the majority of the separation voltage can be applied to specific areas within the channel network, such as across the separation channel, leading to decreased separation times.

To summarize

1. Fabrication of analogous circuit diagram ensures proper channel lengths and widths (relative resistances) so that if only 3000 V is applied across the entire device, most of the voltage is dropped across the separation channel.
2. Production of a glass microfluidic device with shallow channels. These two features allow for high EOF rates while maintaining a low current.
3. Extensive cleaning of the channel surfaces before and after experiments with NaOH and buffers.
4. Use a high concentration of zwitterionic buffer to allow application of a high voltage while maintaining a low current.
5. One-second gated injections using a computer-controlled high voltage relay followed by a 10–15 s separation allows rapid, serial monitoring.
6. LIF in conjunction with an epifluorescence microscope facilitates sensitive detection of low mass, low volume injections.
7. High-throughput data program allows for efficient postprocessing of collected data.

## 15.6 CONCLUSIONS

Capillary electrophoresis has continuously demonstrated that short analysis times are compatible with well-resolved separations. With the use of microfluidic devices, more integrated sample processing

and handling is possible while maintaining the benefits associated with rapid separations. The major obstacles to performing rapid separations are nondiffusional sources of band broadening (i.e., large injection amounts and finite detection zones). With the proper choice of instrumentation and analytes, separation time scales could be readily achieved below 1 s. The development of commercial instrumentation is needed for widespread implementation of rapid electrophoresis methodologies. It will be interesting to observe if technology development in the areas of injection and detection techniques paves the way for new applications, or if the applications drive the development of new technologies. Certainly now it appears that technology is at the forefront as many examples of high-speed separations are performed on fluorescent dyes. When the reverse is true, the true power of rapid separations may be observed. Thus, the research field of rapid electrophoretic separations is expected to be active for quite some time.

## 16.1 INTRODUCTION

The cell is the basic functional unit of all living systems and the instruction set required to manage all cellular activities is contained within the biopolymer known as deoxyribonucleic acid (DNA). The sequential ordering of paired bases within the DNA polymer codes for the exact instructions that define an organism and determine its ability to survive and reproduce. DNA sequencing is the process of determining the unknown locations and ordering of bases within an organism's genome. Identifying and understanding sequence changes or "DNA variations" among individuals can lead

to significant improvements in the way physicians diagnose, treat, and take measures to prevent the large number of disorders that affect us.

In the late 1980s and early 1990s, when laboratories involved in DNA sequence analysis were still using labor-intensive, manually loaded slab gels, many people in the biotechnology field recognized several potential process improvements offered by capillary electrophoresis (CE). The most highly valued potential improvement areas include increased throughput, process simplification through automation, and sequencing cost reduction achieved through minimizing the consumption of key reagents. The promise of these significant improvements drove substantial R&D investment in CE and as a result, rapid technological advances were made during the 1990s in the development of replaceable gels, capillary surface chemistries, and sensitive optical detection methods (the reader is directed to several informative references [1–9]). Table 16.1 provides an approximate time-line for several of the advances made in the field of CE that would ultimately prove to be key elements to improving the field of automated DNA sequencing.

At a very simple level, current state-of-the-art sequencing methodology may be viewed to involve two fundamental steps. In the first step, an enzyme catalyzed reaction is utilized to create a complicated mixture of molecules that are structurally very similar to one another. Then, in the second step, these molecules must be rapidly size-sorted and accurately identified at low concentration levels. None of the advances made in the field of CE were more important than the development of robust, high-resolution separation matrices required to size-sort these mixtures and the degree of success quickly realized in this area was quite impressive. Figure 16.1 illustrates rapid progress made during the 1990s in our ability to resolve single-stranded DNA fragments of increasing size using CE. Over roughly a 5 year period, reported read-lengths progressed from a “proof-of-principle” few hundred bases to a much more impressive range of 600–900 bases and commercial efforts in CE ultimately played a significant role in the early completion of the human genome sequencing initiative [10,11]. Today, automated DNA sequencing is the largest single commercial application of CE and CE has effectively displaced slab gel based sequencing methodologies. Significant improvements have been demonstrated in all three of the earlier mentioned process improvement areas, though one may argue that significant opportunity remains for the reduction of expensive reagent consumption.

The key technology areas involved in the maturation of CE-based DNA sequencing can be broken down into the following major categories:

- Sequencing reaction chemistry
- Separation matrix and surface coatings

**FIGURE 16.1** Graph showing literature reports of single-stranded DNA fragment lengths resolved by capillary gel electrophoresis versus publication year. The area between the two dashed lines identifies the current read-length range typically achieved using commercial capillary-based DNA sequencing systems. Reference numbers are provided above the data points.

- Sample introduction and separation methods
- Excitation/detection systems
- Algorithms

Advances were required in all of these areas in order to make reliable and competitive CE-based DNA sequencing a reality and in the following sections of this chapter we describe fundamental progress made in each of these areas as we survey the related literature.

## 16.2 CORE CAPILLARY ELECTROPHORESIS SEQUENCING SYSTEM TECHNOLOGIES

### 16.2.1 DNA SEQUENCING REACTION CHEMISTRY

#### 16.2.1.1 Sequencing Chemistries

All current CE-based DNA sequencing systems utilize chemistry based on the chain termination method originally described by Sanger et al. [12]. In this approach, a DNA polymerase enzyme is used, in the presence of chain-terminating dideoxynucleoside triphosphates, to catalyze the extension of an oligonucleotide primer hybridized to target DNA, as illustrated in Figure 16.2. As chain extension progresses, a subset of the original target pool is terminated at each base position thus creating a nested set of single-stranded fragments in the denatured reaction product. These fragments range in length from that of the primer (plus one nucleotide) to a few thousand bases, well beyond the upper resolution limit of sequencing matrices developed to date (generally in the range of 1200 bases). Fluorescent reporter molecules are integrated into the sequencing reaction at either the primer or

**FIGURE 16.2** Graphical depiction of Sanger–Coulson chain terminator sequencing chemistry.

the dideoxy chain terminators. Once the extension reaction is complete, the mixture of fluorescently labeled fragments is purified to remove unincorporated reagents, denatured to free-labeled fragments from the template strand, and loaded into the inlet end of a gel-filled capillary. Under the influence of an applied electric field, the carefully formulated sieving matrix contained within the capillary allows smaller fragments to migrate more freely along the capillary length and so the migrating fragments become size ordered by the time they reach the detection region located near the capillary outlet. The identity of the 3' terminal base of each migrating fragment is associated with the corresponding fluorescent reporter signal and this signal, combined with the ordering of migration, is used for algorithm-based sequence calling.

During the 1990s, several variations of the chain terminator chemistry were utilized in CE-based sequencing studies. The first of these variations is known as fluor-primer sequencing. Here, a single fluorescently labeled primer is elongated during four separate extension reactions in which only one of the four dideoxy chain terminators is present. The reaction products from each reaction are separated electrophoretically in a capillary, yielding "one-color primer-labeled" sequencing data [13]. The one-color primer sequencing chemistry was widely utilized in separation optimization and gel matrix development studies but was not popular for actual CE-based sequencing of DNA because four separate reactions and separations would have been required to read sequence. In an alternate approach, four separate extension reactions are run, each employing one of the four dideoxy chain terminators and a primer labeled with one of four different fluorophores. The reactions are then combined and separated in a capillary, yielding "four-color primer sequencing" data [14–25]. This approach was more acceptable as it required only one separation be performed, but it still suffered from the requirement of running four separate reactions.

A fundamentally different variation of the dye-primer chain termination chemistry, originally suggested by Tabor and Richardson [26], was explored by several CE groups in the 1990s. Here, relative

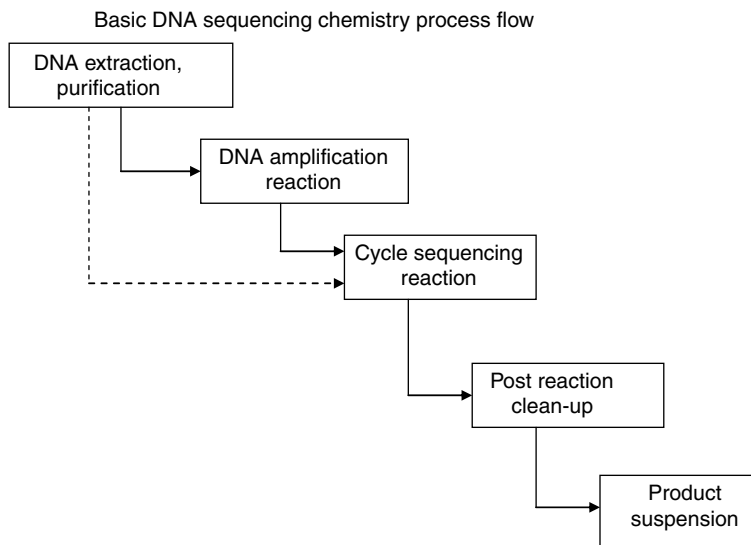

peak height, rather than the spectral identity of the fluorescent labels, was used to determine sequence. This approach offered the hope of simplified instrumentation and chemistry since only one channel of fluorescence needed to be monitored from a single separation of labeled fragments produced in a single reaction. Tabor and Richardson [26] showed that incorporation of  $Mn^{2+}$  into sequencing reaction buffers using T7 DNA polymerase nearly eliminated template sequence-dependent variability in dideoxynucleotide triphosphate (ddNTP) incorporation and thereby resulted in vastly improved peak height uniformity. They exploited this observation in a slab-based sequencing protocol using a single fluorescently labeled primer and different concentrations of the four ddNTPs to determine sequence using relative peak intensity. Ansorge et al. [27] also described using a similar strategy. Using this approach, the advantages of single-lane sequencing were realized without the associated use of four different fluors. Pentoney et al. [28] and Dovichi et al. [29,30] investigated the possibility of adapting the Tabor–Richardson type approach for DNA sequence determination for capillary gel electrophoresis (CGE) with laser-induced fluorescence (LIF) detection [31,32].

Pentoney et al. [28] demonstrated that Tabor–Richardson type sequencing could be effectively utilized in combination with a relatively simple and inexpensive CE/LIF system. Here the authors modified the Tabor–Richardson approach so that only three ddNTPs are included in the sequencing chemistry. Each template was sequenced twice using two different sets of terminator concentrations and both reactions were analyzed simultaneously. The position of the fourth nucleotide in the sequence was determined from the location, size, and shape of gaps appearing in the electropherogram in between peaks produced by the three ddNTP terminators present in the reaction. This simplified the software task of discerning between the different intensity levels and more efficiently utilized the available system dynamic range. The authors found that careful selection of the terminator concentrations and algorithm-based comparison of the two complementary data sets resulted in a robust sequence determination.

The current state-of-the-art chemistry approach utilizes four dideoxynucleotides, each labeled with a different fluorophore, to generate fragments from a single reaction [33], which are also analyzed in one capillary (four-color dye-terminator or “single tube” sequencing) [34]. This approach eliminates the need to fluorescently label and purify different primer sets, the sequence of which varies with each target. Note that slab gel based automated sequencers using one or more of these chemistry approaches were originally developed by Pharmacia, Hitachi, EG&G, Applied Biosystems, and Du Pont. CE-based automated DNA sequencers have now been commercialized by Applied Biosystems, Beckman Coulter, Inc., and GE Healthcare. All the CE-based systems currently utilize the four-color dye-terminator chemistry in combination with nondiscriminating thermal stable DNA polymerases that allow linear amplification of reaction product via a chemistry protocol known as “cycle sequencing.” Cycle sequencing refers to a modified version of the above described Sanger–Coulson sequencing chemistry in which a thermal stable DNA polymerase is used in order to repetitively run the extension reaction in a cyclic fashion. The thermal stable DNA polymerases used today can be repeatedly heated to 95°C and still retain their enzymatic activity. Through the use of repeated temperature cycles (annealing, extension, denaturation), it becomes possible to repeat the extension reaction over and over again in the same reaction vessel, each time generating more reaction product from the same sample target. This cycle sequencing method results in an  $n$ -fold increase in reaction product, where  $n$  is the number of times the cycle is repeated. Figure 16.3 depicts today’s typical DNA sequencing chemistry process flow.

### 16.2.1.2 Fluorescent Dyes

Fluorescent dye sets used in capillary sequencing attached to either primers or terminators have been developed for gas, solid state, and diode lasers, and they span the spectral range from roughly 488 to 800 nm. The basic requirements of a fluorescently labeled set of four terminators are demanding and include high-extinction coefficients at wavelengths for which reasonably low-cost lasers exist, high-quantum yields for fluorescence, sufficient separation of emission maxima for confident identification, reasonable aqueous buffer solubility, good photostability, minimal impact on enzyme

**FIGURE 16.3** High-level graphical depiction of the steps involved in running a typical Sanger–Coulson sequencing chemistry.

incorporation efficiency, and uniform mobility effects upon labeled fragments generated in the Sanger–Coulson chemistry. No truly perfect set of fluorophores has been developed for DNA sequencing and algorithm-based data correction is utilized to compensate for some of the above concerns.

Four-color DNA sequence determination involves the accurate recognition of one of four different emission profiles at each base position. In addition, in some instances, such as the sequencing of mixed viral strains, it is necessary to identify the presence of two or more bases at a single-base location in the electropherogram. To minimize spectral cross talk, families of four dyes have generally been selected to have emission maxima that differ by about 30 nm. Two different approaches have been developed to efficiently excite these four-dye families. The first approach is to assign two pairs of dyes to two different laser excitation sources. This allows the excitation wavelength that is used to stimulate each dye pair to be located reasonably near the corresponding dye absorbance maxima. The two laser excitation lines are usually alternately modulated in this scheme. A second approach is to exploit the use of fluorescence energy transfer [16,35–37]. Here, a common absorber molecule is used to efficiently couple each of the four labels with a single laser line and a large fraction of the absorbed laser energy is then rapidly transferred to one of four different acceptor dyes. In this manner, a single laser source can be used to sensitively address four different labels having very different emission maxima.

## 16.2.2 SURFACE COATING AND SEPARATION MATRIX

### 16.2.2.1 Capillary Characteristics and EOF Suppression

Most CE-based DNA sequencing separations are performed using fused-silica capillaries and some have been reported for channels etched into glass plates. Since DNA sequencing separations are performed at alkaline pH ( $\sim 8.5$ ) to provide a negatively charged DNA phosphate backbone, the acidic capillary surface silanol groups will also be ionized. This leads to the formation of negatively charged surface silanol groups and a charge imbalance near the capillary inner wall. Mobile, hydrated cationic species attracted to this negatively charged zone define a region of net positive charge density that decreases in magnitude with increasing distance from the capillary wall. Under the influence

**FIGURE 16.4** Inner surface of a capillary derivatized using the chemical method described by Hjertén to eliminate electroosmosis and surface adsorption of solutes.

of an applied electric field, the hydrated cationic groups near the capillary wall will migrate toward the cathode (negatively charged electrode) and will effectively drag bulk fluid along with them in an interesting pumping phenomenon known as electroosmotic flow (EOF) [38]. Unless eliminated, EOF will lead to gel movement and results in very poor separation quality.

Several methods exist to suppress EOF. The earliest method, described by Hjertén in 1985, involved covalent attachment of a hydrophilic masking layer of noncross-linked polyacrylamide to the inner capillary wall in order to prevent both EOF and solute adsorption in free zone and isoelectric focusing separations of proteins. In this original work, the bifunctional compound  $\gamma$ -methacryloxypropyltrimethoxysilane was covalently bonded to the inner surface of a glass capillary and the other end of this bridging molecule was then reacted with acrylamide (AA) monomer undergoing linear polymerization, as illustrated in Figure 16.4 [39]. Several other combinations involving bifunctional bridging groups and noncross-linked polymers may be used in a similar manner. Additional covalent attachment chemistries have since been developed to mask the surface silanol groups [40–43].

A second simpler method that has been used to eliminate EOF is to mask the surface silanol groups using an adsorbed polymer. This “self-coating” or “dynamic-coating” method will be discussed in more depth in a later section of this chapter.

### 16.2.2.2 Role of the Separation Matrix

The separation matrix truly lies at the core of CE-based DNA sequencing. Since DNA fragments have constant size to charge ratios (each additional base adds another phosphodiester linkage and hence another unit of charge), both the force acting upon each fragment and the frictional drag experienced by each fragment increase linearly with size during electrophoresis performed in free solution. This effect causes the DNA mobility to be size-independent [44], and so a sieving matrix is required in order to separate DNA fragments of differing lengths from one another. We should keep in mind that the basic separation requirement in DNA sequencing is to rapidly resolve single-stranded DNA over a range of approximately 20 bases to more than a thousand bases with single-base resolution. This is a well-defined nucleic acid mixture, but a very demanding separation indeed.

One of the most important technical hurdles to overcome was the development of a practical solution to the capillary separation matrix problem. Early capillary gel work involved the adaptation of cross-linked polyacrylamide gels, used for years in slab-based DNA sequencing separations, to the capillary format. In cross-linked gels, a DNA mixture is sieved through pores formed by a network of polymer branches that are covalently fixed. The size selectivity of this network is tuned through variation of both the monomer (%T) and cross-linker (%C) concentrations. Cross-linked

gels were introduced into capillaries by initiating polymerization in an external vessel and then driving the flowable, prepolymerized solution into the capillary with a simple syringe. These “fixed” capillary matrices were capable of resolving DNA fragments but suffered from frequent failure modes including sharp current drops due to intermittent bubble formation. As a result, use-lives were often as short as one or two runs [45,46] and fixed capillary gels proved to be an impractical solution for automated DNA sequencing.

The development of replaceable noncross-linked or linear polyacrylamide gels for DNA sequencing was probably the single most significant advance made in the field of CE during the 1990s [45–48]. In replaceable gels, a dynamic network of entangled linear polymers forms the pores through which the DNA mixture is sieved. The size selectivity of this noncross-linked network is tuned through variation in the length and concentration of the polymers defining the replaceable matrix. Replaceable gel matrices for CE were described in 1991 for the separation of oligodeoxycytidylic acids (“poly-C”) 10–15 and 24–36 bases long [47] and analysis of double-stranded restriction digest products [49]. These gel matrices were not only capable of resolving sequencing fragments with single base resolution over a wide size range but also easily replaced, thereby eliminating the need for frequent capillary removal or capillary inlet trimming. A number of reviews provide detailed discussions of the theory of DNA separation in gels as well as a description of the various separation matrices that have been evaluated for DNA sequencing [2,44,50–52], especially in References 53–56.

But what characteristics or physical properties of a replaceable sieving gel are most important in terms of resolving single-stranded DNA over such a wide size range? And what metrics have proven useful in the optimization of gel formulations and separation parameters? Quesada and Menchen [55] have published a helpful theoretical discussion of the parameters affecting the performance of semi-dilute replaceable polymer systems used in capillary-based DNA sequencing. It turns out that for a given separation matrix polymer, the separation speed and resolving power of the entangled gel matrix are generally dependent on polymer concentration. Below a critical or “overlap” concentration  $c^*$ , little or no interaction between matrix polymer strands exists. The overlap concentration is generally reached when the space volume  $4\pi(R_G^3)/3$  (where  $R_G$  is the radius of gyration of the polymer) is occupied by exactly one polymer strand [55,57]. Above  $c^*$ , the polymers begin to impinge upon one another and the mesh size of the gel matrix becomes inversely proportional to polymer concentration. Mesh size in an entangled polymer system may be thought of as the average distance between polymer–polymer entanglements. For linear polyacrylamide studied at different concentrations above  $c^*$  ( $C > c^*$ ), the mesh size was observed to follow the relationship

$$\xi = 2.09C^{-0.76 \pm 0.03}, \quad (16.1)$$

where  $\xi$  is the mesh size (in angstroms) and  $C$  is the polyacrylamide concentration (in gm/mL) [2,58]. As an example, a 3.5% noncross-linked linear polyacrylamide (LPA) gel would correspond to an estimated average pore size of  $\sim 27\text{\AA}$  using Equation 16.1.

The past 10 years of capillary gel research has indicated that optimum separation efficiency and maximum read-length are achieved through the use of highly entangled systems of hydrophilic, high-average molecular weight polymers. Typical replaceable gel systems utilize polymer molecular weights on the order of 1–8 million Da and concentrations on the order of 2.5–6%. The polymer molecular weight distribution, polymer concentration, column length, field strength, and separation temperature are typically settled upon empirically to yield an optimum compromise between separation quality and analysis time.

Several models exist to describe the migration of DNA fragments through the separation matrix. In the Ogston model [59], often applied to cross-linked gels, the DNA fragments are treated as migrating rigid spheres traversing variously sized pores within the matrix; smaller “spheres” encounter more pores with equal or greater diameters and migrate more quickly than larger “spheres.” The DNA

**FIGURE 16.5** Graph showing the proportional relationship between migration time and DNA fragment length for a replaceable capillary gel separation of dye-terminator labeled sequencing fragments. (pUC 18 template DNA, 1009 bases called to 98% accuracy, run on a CEQ analysis system from Beckman Coulter).

fragment mobility in the separation matrix is approximated by the following equation:

$$\mu = \mu_0 \exp(-K_r C) \quad (16.2)$$

where  $\mu$  is the mobility in the separation matrix,  $\mu_0$  is the mobility in free solution,  $K_r$  is the retardation factor and is proportional to both the radius of the matrix polymers and the radius of gyration of the DNA fragment, and  $C$  is the polymer concentration. This model is valid only for DNA fragments in the approximate size range of 50–300 bases in polyacrylamide gels [56,60].

A second model known as biased reptation with fluctuations (BRF) is an extension of the biased reptation model (BRM), and treats the DNA fragment not as a solid sphere but as a long flexible tube that snakes through the pores of the separation matrix [61,62]. The electrophoretic migration times are predicted to be directly proportional to DNA fragment size, as observed experimentally [50] and illustrated in Figure 16.5. A large number of reports have confirmed empirically that DNA fragment mobility in well-formulated and properly run gels is inversely related to molecular weight over a size range of roughly 20–1000 bases, after which mobility asymptotically approaches a minimum and the remaining fragments are observed to comigrate. Interested readers are directed to Viovy [54] for a detailed description of the physical mechanisms of DNA separations.

Another important feature of the separation matrix is its ability to relieve any secondary structure that arises due to intramolecular base pairing in the single-stranded DNA molecules. The presence of such regions of secondary structure leads to increased electrophoretic mobility of DNA fragments and hence congested regions in the electropherogram known as “compressions.” These compressed regions make accurate base-calling difficult or impossible. To alleviate this problem gels are typically formulated with the addition of urea, formamide, or other denaturing compounds [25,63]. The use of elevated temperature also helps to disassociate the regions of secondary structure.

### 16.2.2.3 Evolution of Separation Matrices

#### 16.2.2.3.1 Cross-linked versus Linear Acrylamides

Capillary gel electrophoretic separation of DNA fragments at single base resolution was first demonstrated by Karger and coworkers in 1988 [64] and this work was expanded in 1990 [65]. Extending

**FIGURE 16.6** Capillary electrophoretic separation with single base resolution of poly-A 40–60 bases long. (Reprinted with permission from Cohen, A.S., et al., *Proc. Natl Acad. Sci. USA*, 85, 9660, 1988.)

what had been learned from slab gel work, a cross-linked polyacrylamide gel ( $T = 7.5\%$ ,  $C = 3.3\%$ ) was formed in a  $75\ \mu\text{m}$  i.d. column having an effective length of 13 cm. Using an absorbance-based detector, the individual fragments in a sample containing polydeoxyadenylic acid homopolymers (poly-A) 40–60 nt in length were resolved from one another with efficiencies equivalent to  $5 \times 10^6$  plates per meter in less than 8 min (Figure 16.6). Because of this high-resolving power, the authors accurately predicted that “capillary gel electrophoresis [may] be used as a tool for oligonucleotide sequencing” as well as a tool for “rapid assessment of purity” [65]. Paulus et al. [66] demonstrated single base resolution for samples containing polydeoxythymidilic acid 20–160 nt long using a cross-linked  $T = 2.5\%$ ,  $C = 3.3\%$  matrix. Subsequent work using fluorescence detection also demonstrated DNA fragments with single base resolution [15,29,67–71]. These separation gels typically consisted of a Tris–borate buffer at pH values  $>8.0$  and with 7–8 M urea used as a denaturant.

However, the cross-linked nature of these separation matrices limited reuse since the polyacrylamide degraded, bubbles or voids tended to form in the gels and impurities injected with the sample accumulated in the capillaries, all leading to instability and unacceptably short average use-life [45,46]. In an attempt to improve capillary use-life, Righetti and coworkers [72] polymerized AA in a capillary without a cross-linker ( $T = 10\%$ ,  $C = 0\%$ ) and then treated the resultant media with cysteine to scavenge any remaining monomer, since this monomer is both toxic and potentially reactive. The walls of the capillary were pretreated such that during matrix polymerization, polyacrylamide strands were also bonded to the inner wall thus eliminating EOF. The authors reported that these matrix-filled capillaries were expected to have an improved use-life of approximately 2 weeks.

The use-life issue was resolved by replacing the medium within the capillaries after each use using a non cross-linked gel. Bocek separated a sample of poly-C 10–15 and 24–36 bases long in a replaceable gel created from a solution containing 10% AA [47] while Karger and coworkers

[45] used replaceable gels to analyze dye-primer labeled DNA sequencing reaction products. In the latter work, Karger and coworkers [45,46] polymerized a degassed solution containing 6% w/v AA monomer in a Tris–borate–EDTA (TBE) buffer containing 7 M urea with ammonium persulfate (APS) and *N,N,N',N'*-tetramethylethylenediamine (TEMED) in 100  $\mu$ L syringes. Linear polyacrylamide (LPA) viscosities, ranging from 160 to 3600 centipoise, as measured with a falling ball viscometer, were found to be inversely proportional to the radical initiator concentration while migration times were found to be proportional to viscosity, reflecting the size (or molecular weight) of the LPA strands. LPA in this viscosity range required pressures of the order of 1200 psi to be forced through capillaries 33 cm long with an inner diameter of 75  $\mu$ m, well within the range of a syringe pump [45], thus allowing the matrix to be replaced after every run. Using LPA with an average molecular weight of approximately  $1 \times 10^6$  Da (determined via light scatter) and fluorescently labeled primer samples, fragments >370 bases in length could be identified using capillaries that were modified via the covalent masking method of Hjertén [39].

Subsequent work using noncross-linked LPA matrices and run under more optimized conditions led to incremental increases in read-length. Although the separation medium was not replaced after each run, Dovichi and coworkers [73] reported reads of up to 570 bases in less than 140 min when a primer-labeled sample was separated at room temperature using a matrix created from a 6% AA solution polymerized directly in capillaries treated with a solution of [ $\gamma$ -methacryloyloxy] propyl] trimethoxysilane to bind a surface layer of polyacrylamide to the capillary walls, similar to the method of Hjertén [39]. Read-lengths of up to 640 bases were achieved in 2 h run times at 60°C using a capillary containing a matrix consisting of a 5% AA solution [17].

Karger and coworkers [18] using a replaceable separation matrix introduced into the capillary before each run, performed separations at 50°C at a field strength of 150 V/cm using a 2% AA solution that yielded >1000 bases for a set of dye primer-labeled sequencing reaction fragments. Separations performed in the temperature range 50–60°C were reported to yield higher resolution for large fragments, decreased separation times, and longer read-lengths [19]. A separation matrix created by mixing LPA of two different molecular weight distributions, 0.5% (w/w) of 270 kDa and 2% (w/w) 17 MDa, operated at 70°C with a field of 125 V/cm yielded read-lengths of  $\sim$ 1300 bases in just over 2 h for primer-labeled sequencing reaction fragments [24].

Synthetic procedures incorporating inverse emulsion polymerization were later used to create a fine powder of high-purity LPA with a molecular mass of 9 MDa [20]. Separations performed using a matrix created from a combination of this powder and polymer having a molecular weight of 50 kDa resulted in read-lengths of greater than 1000 bases in runs requiring less than 60 min [21]. More recently, Barron and coworkers [74,75] showed promising results using very sparsely cross-linked “nanogel” matrices. The authors used very low concentrations of methylene bisacrylamide (Bis) cross-linker ( $\sim 10^{-4}$  mol%) in an emulsion polymerization of AA, to produce polymers with molecular weights of  $\sim$ 10–11 MDa. The low level of cross-linking was carefully controlled to retain polymer solution fluidity, but was apparently high enough to stabilize pores within the matrix, thereby allowing separations of large DNA fragments to occur with higher resolution than is typically observed using noncross-linked LPA [75]. The authors reported that the improvement in separation quality for the larger single-stranded fragments led to an increase in read-length of approximately 19% [75].

To date, LPA remains a very popular separation matrix for DNA sequencing, and is used on the family of sequencers and genetic analyzers available from both Beckman Coulter and GE Healthcare. Figure 16.7 illustrates a typical separation of dye terminator-labeled DNA sequencing reaction products performed using the CEQ<sup>TM</sup> system from Beckman Coulter and a linear polyacrylamide based replaceable gel matrix. In this run, 1009 bases were called with 98% accuracy.

#### 16.2.2.3.2 Other Matrix Materials

A gel matrix based upon the use of polydimethylacrylamide (PDMA) has also enjoyed great commercial success [76,77]. Developed by Madabhushi and coworkers at Perkin Elmer Corporation (now Applera Corporation) and used in their family of high-throughput DNA sequencers, PDMA

**FIGURE 16.7** (See color insert following page 810.) Analyzed four-color dye-terminator sequencing from a CEQ analysis system (Beckman Coulter): 1009 bases called to 98% accuracy.

polymers of various molecular weights were created by polymerization of *N,N*-dimethylacrylamide (DMA) solutions with APS and TEMED at 50°C and purification by precipitation. The resulting polymer had molecular weights in the range 20–200 kDa. A 6.5% PDMA (98 kDa) solution was reported to have a low viscosity of 75 cP and yielded read-lengths of 600 bases. In addition, since PDMA is reported to be more hydrophobic than LPA, the segmental adsorption energy of PDMA onto fused silica is greater than that of LPA [76]. Consequently, PDMA will adsorb to capillary walls and mask the surface silanol groups, significantly reducing EOF and eliminating the task of having to chemically modify the capillary walls. Madabhushi [76] reported performing over 100 runs, replenishing the gel before each run, without ever having to recondition the capillary. Heller [78,79] performed a detailed study of the utility of PDMA in DNA separations by creating polymers with various molecular weights for use in optimizing polymer concentration, polymer chain length, and electric field strength. Chu and coworkers [80] achieved read-lengths of up to 1000 bases in 96 min at room temperature using 2.5% w/v PDMA with a molecular weight of 5.2 MDa. Although the added analysis time would be impractical, preconditioning of PDMA, by subjecting the gel medium to an electric field strength of 162–320 V/cm for at least 6 h before separation, was reported to improve peak separation and was predicted to extend the read-length [81].

Barron and coworkers [82] reported success using replaceable poly *N*-hydroxyethylacrylamide (PHEA) as both a separation matrix for DNA sequencing and a dynamic coating that eliminated EOF. Using bare fused-silica capillaries, 4–6% solutions of PHEA with a molecular weight of ~5.2 MDa and field strengths ranging from 40 V/cm to 117 V/cm, read-lengths of 445–750 bases were achieved with 98.5% accuracy. Separation times of 1–5 h were reported in this study.

Chu and coworkers [83] combined LPA and PDMA in an attempt to obtain a gel with the best properties of each polymer, namely high-quality separations using uncoated capillaries. They observed that mixtures containing PDMA with high molecular mass or in high concentrations adversely affected the quality of separations. A mixture of 2.5% (w/v) of LPA with mass 2.2 MDa and 0.2% PDMA with mass 8 kDa resulted in a matrix that produced read-lengths of  $\sim 700$  bases using bare (untreated) capillaries [83]. To more intimately entangle the LPA and PDMA polymers, the group polymerized PDMA monomer in a homogeneous solution of LPA, thus creating a “quasi-interpenetrating network” or quasi-IPN [84]. Using single-color dye-primer separations, they reported sequencing up to 1200 bases in less than 60 min at 65°C using 2% quasi-IPN formed by LPA with a molecular weight of 9.9 MDa and an AA to DMA ratio of  $\sim 11:1$ .

Although AA-based matrices dominate the commercial field of DNA sequencing today, other polymers have been tested with varied results. Bashkin et al. [85], Marsh et al. [86], and Dolnik and Gurske [87] reported having some success using hydroxyethylcellulose (HEC), with Bashkin et al. reporting base calls to 500 bases in less than 60 min using a matrix composed of 2% HEC in the molecular weight range 90,000–105,000 using Hjertén-modified capillaries [85]. Kheterpal and Mathies [88] compared the read-lengths achieved using HEC matrix and LPA matrix in sequencing and found LPA read-lengths to be  $\sim 1000$  bases while that of HEC was limited to approximately 600 bases.

Yeung and coworkers [34,89–93] demonstrated success using poly(ethyleneoxide) (PEO) as a sieving matrix. PEO is an attractive alternative to LPA in the sense that PEO is available commercially over a broad and high-molecular weight range, eliminating the need to synthesize the long chain polymer [89]. Similar to PDMA, PEO polymer adsorbs to the capillary walls and masks the surface silanol groups. However, Yeung’s group [90,94] found that periodic capillary regeneration with HCl or polyvinylpyrrolidone (PVP) [93] was required to maintain good performance. The authors reported separations of  $>900$  bases in less than 110 min using a 2.5% solution of PEO with a molecular weight of 8 MDa and separation performed at 40°C using a capillary effective length of 40 cm, an inner capillary diameter of 75  $\mu\text{m}$  and a field strength of 160 V/cm [93]. Yeung and coworkers [95,96] also reported using PVP as the separation matrix in uncoated capillaries and demonstrated read-lengths approaching 350 bases. PVP-based separation media have the dual advantage of masking surface silanol groups and possessing an extremely low viscosity ( $<30$  cP) [76,93].

Dolnik and coworkers [97] used a novel, natural material to create a sieving matrix for capillary sequencing. Guar gum, or guaran, is a polysaccharide originating from the endosperm portion of the legume seed (*Cyamopsis tetragonoloba*) that grows mainly on the Indian subcontinent and in some parts of Texas and Oklahoma and contains 75–85% galactomannan. In this sequencing application, purified 2.1 MDa guaran was dissolved to a final concentration of 15 g/L in a urea/Tris/HEPES buffer, pumped into a capillary array and run using the MegaBACE system available from GE Healthcare. Separation of sequencing fragments using this matrix, as well as matrices using galactomannan from tara gum and locust bean gum exhibited poorer efficiencies than did separations performed using LPA; read-lengths were generally in the range of 600–700 bases (98.5% accuracy) [97].

Menchen et al. [98] created self-assembling polymers for sieving DNA by capping polyethylene glycol (PEG) molecules with micelle forming fluorocarbon tails. In solution just above the critical micelle concentration, these molecules are believed to form intramolecular micellular structures and, at even higher concentrations, intermolecular micellular structures are believed to form. Reasonably good resolution was obtained for fragment lengths up to  $\sim 500$  bases using a 6% solution of a 1:1 mixture of polymers created from PEG35000 end-capped with  $(\text{C}_6\text{F}_{13})_2$  and PEG35000 end-capped with  $(\text{C}_8\text{F}_{17})_2$  [98].

Several new copolymer formulations have recently been created [99]. In the first type of copolymer, AA monomer was copolymerized with a second monomer type, creating a polymer with units of the two monomers randomly distributed. Chu and coworkers [100] created AA/DMA random copolymers with molecular weights of  $\sim 2.2$  MDa, starting with 3:1, 2:1, and 1:1 molar ratios of AA and DMA. Using a 2.5% w/v copolymer created with either 3:1 or 2:1 molar ratios, reasonably

**FIGURE 16.8** Viscosity change as a function of temperature for thermal associating gels with different additives. (Reprinted with permission from Sudor, J., et al., *Electrophoresis*, 22, 720, 2001.)

good resolution up to 700 bases, with visual identification of  $\sim 900$  bases, was achieved in room temperature separations of primer-labeled fragments using uncoated, bare fused-silica capillaries. Barron and coworkers [101] copolymerized DMA with *N,N*-diethylacrylamide (DEA) at different molar ratios. These copolymers generally performed poorly in comparison to either LPA or PDMA homopolymers in terms of resolution, with performance suffering as the relative amount of DEA increased, indicating the role that polymer hydrophobicity plays in separation quality [102]. Although performance suffered with increasing amounts of DEA, the viscosities also decreased, possibly indicating a tradeoff in performance and ease-of-use [101].

A second class of copolymer is the “thermo-associating” or “thermo-gelling” copolymer [103–107]. These are made up of two polymers, one of which exhibits a phase change across a critical temperature known as the lower critical solution temperature (LCST). This phase change is characterized by a change in turbidity and/or viscosity [103,105]. These thermo-associating matrix materials have the interesting and useful property of switching from a low-viscosity state to a high-viscosity state upon increasing temperature from ambient (Figure 16.8). This facilitates easy matrix replenishment at ambient temperature while providing a good separation environment at higher temperatures, where DNA sequencing separations are normally performed. Examples include the “comb-like” copolymers consisting of poly (*N*-isopropylacrylamide) (PNIPAM) groups [106] or PDMA groups [107] grafted onto an LPA backbone and copolymers of *N*-ethoxyethylacrylamide and *N*-methoxyethylacrylamide [105]. The thermal-thickening behavior of the comb-like copolymers is primarily attributed to the behavior of the LCST units: at lower temperatures, little interaction between or within the backbones or grafts exists. As the temperature approaches the LCST, the grafted units begin to associate with one another, forming the aggregates that provide sieving during separation (Figure 16.9). Presumably due to interactions of the grafted PNIPAM or PDMA units with the capillary walls [107], the comb-like polymers may be run on bare fused-silica capillaries. Separations made with the PDMA grafts yielded resolutions and migration times comparable to those of LPA [107].

### 16.2.3 EXCITATION/DETECTION METHODS: THE ROAD TO FOUR-COLOR MULTICAPILLARY SYSTEMS

The detection of DNA fragments in a capillary separation channel is a challenging proposition [5,108]. Injected sample quantities for each (ultimately) resolved band are typically in the sub nanomolar to picomolar range and detection volumes are on the order of a 100 pL. Peak efficiencies

**FIGURE 16.9** Simplified depiction of the mechanism for thermo-thickening. Upon heating above the LCST, grafted side chains become less soluble and tend to aggregate with one another thereby forming a transiently cross-linked structure. (Reprinted with permission from Sudor, J., et al., *Electrophoresis*, 22, 720, 2001.)

of  $\sim 10^5$ – $10^6$  are required for single base resolution. For a 30 cm capillary, these high-efficiency numbers correspond to peak widths of approximately 500  $\mu\text{m}$  at the detector window. LIF detection [31] is the method of choice for capillary-based DNA sequencing because it extends to extremely low limits of detection, is compatible with the narrow capillary bore confines, is easily extended to multiwavelength monitoring, and is readily compatible with Sanger–Coulson sequencing chemistries (both primer and terminator labeling). For example, the CEQ-family of four-color DNA analysis systems (Beckman Coulter) utilizes diode lasers that are focused to an elliptical spot approximately 60  $\mu\text{m}$  in length along the capillary axis. Within the corresponding 120 pL illuminated volume, approximately 220 molecules of fluor-labeled DNA in 120 pL illuminated volume may be detected at a signal-to-noise ratio (SNR) of 2 using LIF detection (unpublished data).

### 16.2.3.1 Single-Capillary On-Column Detection Systems

Several groups have designed on-column LIF detection systems for capillary-based sequencing. Excitation and emission light is typically passed through a short portion of the capillary from which

**FIGURE 16.10** Single-color on-column CE/LIF detection system. (Reprinted with permission from Drossman, H., et al., *Anal. Chem.*, 62, 900, 1990. Copyright 1990 American Chemical Society.)

the polyimide cladding has been removed, usually by burning or charring. The effective separation length of the column is defined as the distance from inlet tip of the capillary to this detection window.

Zagursky and McCormick [109] provided the first report of DNA sequencing performed in a capillary-like format. The authors modified a commercial automated slab-gel sequencing system (Genesis 2000 DNA Analyzer from E. I. DuPont) to accommodate up to 12 polyacrylamide gel-filled, 530  $\mu$ m i.d. by 40 cm long (effective length) columns. The separation of dye-terminator labeled sequencing reactions was performed using the Genesis 2000 system equipped with an argon-ion laser and two-color LIF detection optics and sequencing calls to 500 bases with 96% accuracy were performed in 9.5 h. This work was performed using low field strength but conversion to capillary dimension tubing (i.e., <200  $\mu$ m i.d.) was expected to allow the use of higher voltage with a resulting decrease in separation time.

Smith and coworkers [67] designed one of the first on-column, single-capillary, single-wavelength systems used to detect primer-labeled DNA sequencing reaction fragments (Figure 16.10). The output beam of a 40 mW argon-ion laser was passed through a 488 nm bandpass filter, expanded, and then focused into a 50  $\mu$ m i.d. capillary to excite fluorescein-labeled DNA sequencing fragments. Emission light was collected normal to the excitation direction using a 40 $\times$ , 0.65 NA microscope objective. Slits placed at the objective plane reduced background interference from excitation light scattered at the capillary walls. A bandpass filter placed just in front of a photomultiplier tube (PMT) further eliminated scattered light and selected the appropriate detection wavelength range. The detection limit for this system, determined using vacuum injection of known concentrations of fluorescein-labeled primers, was estimated to be 60,000 molecules (at a SNR of 2:1). Swerdlow and Gesteland [68] and Karger and coworkers [69], working in parallel with comparable CE/LIF systems, reported detection limits of  $10^{-11}$  M for a solution of fluorescein, at a SNR of 3:1 and 5:1, respectively. Swerdlow and Gesteland [68] reported focusing the laser to a spot size of approximately 20  $\mu$ m diameter, corresponding to an illumination volume of 30 pL and a reported detection limit of <200 molecules.

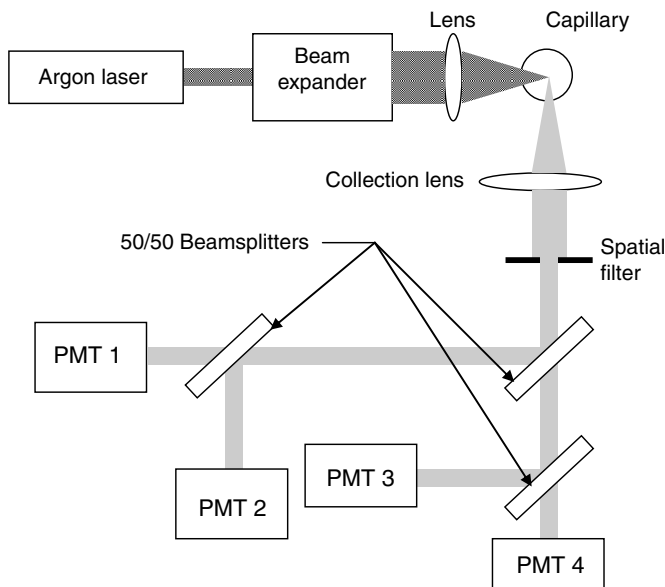

Pentoney et al. [28] used a 543 nm HeNe laser to excite primer-labeled sequencing reaction fragments. The capillary was threaded through a simple aluminum parabolic reflector and the portion of the capillary with the polyimide cladding removed to allow detection was located at the focal point of the reflector (Figure 16.11). The collimated light exiting the reflector passed through several optical filters to eliminate scattered light before detection using a PMT. A scattering block was placed across the mouth of the parabolic reflector to reject the intense plane of scattered light that surrounds the capillary. Detection limits in the low  $10^{-11}$  M range for solutions of fluor-labeled primers were reported [28].

**FIGURE 16.11** A single-color CE/LIF detection system utilizing a parabolic reflector for capturing and collimating fluorescence. (Reprinted with permission from Pentoney, S.L., Jr., et al., *Electrophoresis*, 13, 467, 1992.)

Recognizing the need to perform multicolor detection for truly robust DNA sequencing, a number of groups devised methods to perform single-capillary four-color detection. Smith and coworkers [15] expanded their single detector system by incorporating 50/50 mirrors in the emission path in order to split the emission from four fluorophores and direct it toward four optically filtered PMTs (Figure 16.12). The four fluorophores, FAM, JOE, TAMRA, and ROX, from Applied Biosystems (now part of Applera) were coupled to primers and used in four separate chain extension reactions. These four fluorophores can all be stimulated by a common argon-ion laser, allowing detection in all four channels to occur simultaneously. However, since 50/50 mirrors were used in the emission path, only 25% of the original emission intensity for any channel actually reached the detector. Dovichi and coworkers [29] opted for an alternate time sharing approach in a similar system by placing a spinning filterwheel, containing four bandpass filter segments, before the detector. Dovichi used two lasers, an argon-ion laser at 488 nm and a HeNe laser at 543 nm for excitation of the same family of fluorophores used by Luckey [15], because the 543 nm HeNe laser is a better spectral match with the absorbance profile of TAMRA and ROX fluorophores. The two lasers were modulated with a two-sector chopping wheel, with 488 nm light used to stimulate FAM- and JOE-labeled primers while the 543 nm laser was used to stimulate TAMRA- and ROX-labeled primers. Synchrony between the two spinning wheels allowed assignment of the emission collected at the PMT to a particular spectral channel and hence to a specific fluor-labeled primer. Since the single detector is now temporally shared among the four dyes, sensitivity will depend on the integration time for each channel. This, in turn, will depend on the data acquisition rate, typically set to 2 Hz or greater due to peak width and sampling considerations [29].

Gesteland and coworkers [71] eliminated the need to split the fluorescence emission or time-share the detector to obtain multicolor data by using a spectrometer to disperse the emission from the four Applied Biosystems fluors before imaging onto a charge-coupled device (CCD) camera. Quantum yield in the 500–600 nm range was 1.6–2.5 $\times$  greater for the CCD camera than for the PMT which made this imaging detection system quite attractive. However, the need to place multiple mirrors, with a composite efficiency of  $0.94^4 = 0.78$ , and the 0.70–0.75 efficiency of the grating employed reduced the light levels directed toward the detector by 50%. Sensitivities using this CCD-based optical system with a 500 ms integration time were reported to be comparable to PMT-based systems [71]. Karger also eliminated the emission splitting/time sharing issue by using a 488 nm laser and a 543 nm laser focused to two different points on the capillary that were separated by approximately

**FIGURE 16.12** Four-color on-column detection system utilizing four dedicated PMTs. A 540 nm bandpass filter was placed in front of PMT1; a 560 nm bandpass filter was placed in front of PMT2; a 580 nm bandpass filter was placed in front of PMT3; and a 610 nm bandpass filter was placed in front of PMT4. All pass bands are 10 nm. (Reprinted from Luckey, J.A., et al., *Nucleic Acids Res.*, 18, 4417, 1990. With permission from Oxford University Press.)

2 cm [110]. Two collection objectives were used in this study, one for each detection window, to bring the emission to different regions of a diode array detector. A grating placed before the diode array dispersed the emission from each of the detection windows, with a resolution of 1 nm per pixel in the 555–700 nm range. Monitoring different portions of the array gave excitation wavelength-associated spectral information about the emission and thus about the primer-labeled fragments as they migrated through the capillary.

### 16.2.3.2 Multicapillary On-Column Detection Systems

The systems described above may all be regarded as important steps or feasibility demonstrations in the development of CE-based optical systems for DNA sequencing. The use of capillaries, with their small cross-sectional areas and high surface-to-volume ratios permitted the use of significantly higher field strengths than had typically been used in slab gel separations but the corresponding increase in separation speed was not so great as to give single-capillary sequencing systems a throughput advantage over slab-based systems where many parallel lanes were run simultaneously. Therefore, in order to significantly improve sequencing throughput over that already realized with slab-based systems, many researchers developed fluorescence optical approaches that allowed simultaneous monitoring of multiple capillaries run in a parallel format. Mathies and coworkers [13,112] and Mathies et al. [111] developed a multicapillary DNA sequencing system in which a linear array of capillaries, placed on a moving stage, is scanned under a stationary confocal microscope head, as displayed in Figure 16.13. In their first report [13], 25 capillaries (100  $\mu\text{m}$  i.d., 200  $\mu\text{m}$  o.d.) were bundled into a linear array. An array holder, mounted to a motor driven translation stage, held the capillary windows in optical alignment. For excitation, the output beam of an argon-ion laser was expanded, collimated, and reflected through a long pass dichroic mirror to a  $32 \times 0.4$  NA microscope objective, which focused the beam to a 9  $\mu\text{m}$  spot at the plane of the arrayed capillaries. A portion

**FIGURE 16.13** Multicapillary detection system utilizing a planar capillary array arrangement. Although two detectors are shown, one- and four-color detection systems have also been implemented. (Reprinted with permission from Huang, X.C., et al., *Anal. Chem.*, 64, 2149, 1992. Copyright 1992 American Chemical Society.)

of the fluorescence originating from the capillaries was captured by the same microscope objective used to focus the laser (confocal arrangement) and transmitted back through the long pass dichroic mirror to reduce background laser interference at the detector. The fluorescence emission was focused through a  $400\ \mu\text{m}$  pinhole spatial filter, a  $488\ \text{nm}$  rejection filter, and a long pass filter, all to further reduce laser scatter. The initial system contained a single PMT and monitored one or two colors, but later systems reported by the same group used either two or four detectors for multicolor monitoring [111–113]. In those systems, the emissions from different fluorophores were split and directed to the appropriate PMTs using dichroic beam splitters. The translation stage, with the capillary array holder mounted to it, was scanned beneath the microscope objective at  $1\ \text{Hz}$ . During a sweep, the velocity of the translational stage was  $20\ \text{mm/s}$  while data were collected at  $2000\ \text{Hz}$ ; thus, an image resolution of  $10\ \mu\text{m}$  per data point was achieved [13]. Since  $100\ \mu\text{m}$  i.d. capillaries were used in this work, 10 points defined the inner bore of the capillary. These 10 measurements were co-added to yield a single intensity measurement for that capillary and that scan. A detection limit of  $\sim 2 \times 10^{-12}\ \text{M}$  ( $\text{SNR} = 3$ ) was reported using solutions of fluorescein that were flowed through the system (so-called flowing stream characterization measurements) [13].

Bashkin et al. [86,114] modified this system by placing the microscope objective on a translation stage: the position of the 48-capillary array in their system was fixed and the objective was translated above the array. The capillary signals were sampled unidirectionally at a sampling rate of  $38\ \text{kHz}$  for each of two PMTs, yielding a spatial resolution of  $37.5\ \mu\text{m}$  per pixel, and a temporal resolution of  $1\ \text{Hz}$ . Flowing stream detection limits of  $10^{-12}\ \text{M}$  were reported using solutions of BODIPY505/515 (Molecular probes) prepared in methanol [114]. Automated replacement of the hydroxyethyl cellulose (HEC) gel separation matrix used in their studies was accomplished via a

stainless steel pressure manifold/anode assembly [114]. In the upper part, four ports were available for arrays of 16 capillaries to be inserted while one port introduced a common electrode and another port allowed high-pressure nitrogen to be introduced. The lower part of the manifold assembly contained a 25 mL beaker that contained either the separation matrix or water. Pressurization of up to 1000 psi allowed water or matrix to be pushed out the distal end of the capillary. This system was extended to four PMTs and eventually commercialized by Molecular Dynamics (now part of GE Healthcare) as the MegaBACE DNA sequencing system [114,56].

Mathies and coworkers [115] also developed a highly multiplexed system, with the potential to monitor 1000 capillaries. In this "rotary capillary array electrophoresis scanner," the capillaries were supported in grooves on the outside of two coaxial  $\sim 4'$  diameter cylinders (see Figure 16.14). A microscope objective, designed to deliver excitation light and collect the resulting emission, was placed between the two cylinders and mounted on a central shaft that was driven by a stepper motor to rotate at 2–4 revolutions per second. Light traveled bidirectionally along the axis of the rotating shaft between the dichroic beam splitter located just outside the top of the shaft and a diagonal mirror located within the shaft. Simultaneous replacement of separation matrix in all capillaries was achieved by placing matrix in an O-shaped well, where the capillary tips reside, and pressurizing with helium. During a sequencing run, buffer and the high voltage electrode were placed in this same well.

Yeung and coworkers [116–119] studied several on-column excitation and detection schemes and developed several multicapillary systems. In one scheme [117], the windows of 96 capillaries, with an i.d. of 75  $\mu\text{m}$ , were aligned in a plane oriented at  $45^\circ$  with respect to a CCD camera detector. A sheet of 514 nm excitation light, oriented perpendicular to the viewing axis of the CCD camera was focused into the windows of the capillary array. Emission was collected through a holographic filter to reduce background laser scatter. Two-color fluorescence detection was obtained by directing one image of the array onto a portion of the CCD chip through a 630 nm longpass filter and directing a second image of the array onto another region of the CCD chip through a quartz plate without additional optical filtering. The 1.5 cm range of capillaries imaged covered 300 pixels on the CCD with each individual capillary window encompassing three pixels in one image. An integration time of 300 ms was used to acquire each frame at 1.75 frames per second and good uniformity in migration time was observed. Cross talk in this sheet illumination approach, arising from emission in an adjacent capillary being refracted by the capillary walls into the CCD camera and appearing in the electropherogram of the second capillary, was estimated to be  $<10\%$ . Automation of matrix replenishment was discussed in this work but not implemented. Heller and coworkers [120] developed a similar system, but used a grating to disperse the emission onto the CCD camera. Intercapillary cross talk was estimated to be 1–2% in their system. This system was coupled to a stacker that held up to forty 96-well microtiter plates, allowing up to 15,000 samples to be run without reloading. However, no automated matrix replenishment system was described.

Yeung and coworkers [121,122] also developed a side-entry illumination system for exciting up to 24 capillaries. In this work, capillaries with either round or square bores were used. After windowing, the capillaries were packed side-by-side with the windows aligned and fixed into place using epoxy. Fused-silica plates were used to create a cell for the windowed region of the capillaries; this cell was then filled with index-matching fluid to reduce laser light loss at the capillary interfaces. The 514 nm line of an argon-ion laser was focused through the side of the array and transferred through the detection bores of all capillaries. Because of the refractive index-matching fluid, negligible light loss was observed across the array and the authors predicted that greater than 34% of the incident laser power would be available in the 500th capillary of a hypothetical 500-capillary array [122]. Detection was made above the plane of the capillary array with a CCD camera. A 514-nm notch filter was used to reduce scattered light while an image splitter, consisting of a 610- or 630-nm long pass filter and a quartz plate, allowed two-color imaging onto two regions of the CCD chip. Detection limits of 90 pM were reported from long injections of fluorescein dissolved in run buffer, to eliminate stacking. Two-color DNA sequencing was demonstrated in this work.

**FIGURE 16.14** Illustration showing a 1000 capillary, four-color detection rotary capillary array electrophoresis scanner device. (From Mathies and Scherer, US Patent 7,090,758.)

Quesada and Zhang [123] and Quesada et al. [124] performed detailed ray tracing and also demonstrated success using a side illumination scheme. A planar 12 capillary array was created and the windowed region was placed in index-matching fluid. The output of a 488 nm laser was split into two fiber-optic transmitters and delivered to either end of a planar array, thus reducing variation in laser intensity across the array. Emission was collected with 12 optical fibers, each placed against one capillary detection window, normal to the direction of laser excitation. The emission was dispersed using a spectrograph and imaged onto a CCD camera, thus providing spatial and four-color spectral information. Cross talk between adjacent capillaries was estimated to be  $\sim 1\text{--}2\%$  while a detection limit of  $\sim 3.7$  pM at a SNR of 2, derived from flowing stream measurements using fluorescein, was reported. Simultaneous four-color dye-terminator sequencing for all 12 capillaries was demonstrated in this work [124]. Since the number of capillaries that could be used was generally limited by laser attenuation due to beam divergence, glass rods were placed between capillaries by Anazawa et al. [125]. This allowed them to achieve detection limits of  $< 1$  pM of flowing fluorescein solution in the 45th capillary, furthest away from the illumination source.

Recently, Roeraade and coworkers [126,127] developed a detection scheme in which each capillary acted as a waveguide to direct the emitted fluorescence to the capillary tip, where it was collected with a CCD camera. Strip illumination of up to 91 capillaries was made in a region where the capillaries are arranged in a planar array; these capillaries were externally coated with a fluoropolymer that did not require removal for use in LIF detection. Approximately 15 cm downstream from the excitation region, the capillaries were cast into a two-dimensional hexagonal array with black epoxy and placed into a container consisting of buffer and the electrode. Fluorescence emitted from the ends of the capillaries transmitted through the glass wall of the container was collimated, passed through two bandpass filters to eliminate 488 nm scattered light, and was then dispersed with a prism onto a cooled-CCD camera. This arrangement yielded spatial and spectral information about the fluorescence emitted from the capillary outlets. Cross talk between capillaries, arising from emission from one capillary being captured and transmitted by a second capillary, was found to be less than 0.4%. A detection limit of 2.7 pM fluorescein measured in flowing stream mode was reported, but this sensitivity measurement was made without use of the prism to disperse the light [126].

The parabolic reflector concept developed by Pentoney et al. [28] was extended to a scanning eight-capillary system, which was commercialized by Beckman Coulter in their family of four-color, eight-capillary DNA analysis systems. In this work, two diode lasers, also used in References 128 and 129, were alternately modulated and the beams directed to a precision rotating mirror positioned on a galvanometer. This mirror sequentially directed the focused laser beams into each capillary window in the planar array. The windows were centered about the focus of a parabolic reflector, which collimated and directed the emission through a four-quadrant spinning filter wheel, a dual-notch filter (designed to reduce scatter from each laser) and then through a focusing lens and onto a PMT (Figure 16.15). The mouth of the parabolic reflector again had a black bar placed across it to block the intense plane of laser scatter. The spinning filter wheel was synchronized with the modulation of the two diode lasers and the galvo scanner such that when the first laser was striking the capillary, the first two filter quadrants passed in front of the detector. Similar interrogations of the capillaries were made for laser 2 and filter wheel quadrants 3 and 4. To ensure high sensitivity, the diode lasers were optically filtered to remove low level emission (“diode wings”) overlapping those of the detection wavelengths. Detection limits below 10 pM at a SNR of 2 were determined from flowing stream measurements using proprietary dye-labeled terminator solutions (unpublished data, Beckman Coulter).

An interesting aspect of this step-scanned system is the automated optical alignment feature. To maximize duty cycle, the galvo mirror rapidly advances from one capillary bore to the next and then pauses during data acquisition. In order to predetermine the location of the capillary bores, an automated scan was made before every run. In this prescan, which was completed in less than 2 min, the first laser was scanned across the entire region where the array was believed to reside. An autoalignment photodiode, placed behind the array, facing the laser but off axis to the laser, detected light refracted from the capillaries and an auto-alignment spectrum was obtained, such as the one displayed in Figure 16.16. The peaks seen in this spectrum contain the information required to direct the galvo to position the beams at the capillary bore centers. This process was repeated for the second laser, yielding a second set of eight peaks corresponding to the galvo positions required to send the second laser to each of the capillary bores. The 16 positions (eight-capillary positions for each of the two lasers) were saved in a lookup table and used during the separation to place the first laser in the first capillary, the second laser in the first capillary, the first laser in the second capillary, and so on. Experience has shown that the positions of the capillary bores with respect to the laser positions do not change during the course of the run.

### 16.2.3.3 Sheath-Flow Detection

Dovich and coworkers [29,70,130] developed a high-sensitivity fluorescence detection system for DNA sequencing based on a detection scheme borrowed from flow cytometry and previously

**FIGURE 16.15** Illustration of the galvanometer scanner based, eight-capillary DNA sequencer optics employed in the Beckman Coulter DNA analysis system.

**FIGURE 16.16** Capillary auto-alignment spectrum used to determine the capillary bore center positions.

developed by the same group for CE separations of labeled amino acids [131]. To minimize or eliminate background scattered light arising from the excitation source striking the curved capillary surface, the separated DNA fragments were carried away from the capillary outlet before detection. This was accomplished by placing the end of a 1 m  $\times$  50  $\mu$ m i.d. capillary in a flow cytometer cell (Figure 16.17): the labeled sequencing fragments eluting from the end of the capillary were entrained

**FIGURE 16.17** Postelectrophoresis sheath-flow detection of DNA fragments. (Reprinted with permission from Zhang, J.Z., et al., *Clin. Chem.*, 37/9, 1942, 1991.)

and carried down the flowcell by sheath fluid, flowing at 0.16 mL/h, into a square detection region. The sample stream was illuminated with a focused laser and fluorescence from the labeled sequencing products was collected, filtered to eliminate potentially interfering Rayleigh and Raman scatter and passed on to a PMT [17,29,30,70,73,130,132–134]. Two-color detection was achieved either using a dichroic beam splitter to separate the emission from two fluorors [29,30,73,134] or by detection on both sides of the sheath-flow cuvette [30], facilitating two-label peak-height encoded DNA sequencing. A detection limit of less than 60 molecules of Rhodamine 6G injected into the system was reported [133].

Four-color sequencing in a single capillary using this sheath-flow concept was also demonstrated [17]. Two alternately modulated lasers, an argon-ion laser and a green helium-neon (HeNe) laser, were combined using a dichroic filter. The collinear beams were focused onto the sheath flow entraining the separated four-color primer-labeled DNA fragments. To spectrally resolve the emission, a four-sector filter wheel spinning at 2 Hz was placed between the flow cell and a microscope objective, which in turn coupled the emission into an optical fiber mated to an avalanche-photodiode operated in single-photon-counting mode. With the argon-ion laser on, the first two quadrants of the filter wheel, containing bandpass filters centered at 540 nm and 560 nm, respectively, passed in front of the microscope objective. Similarly, excitation with the green HeNe laser was synchronized to detection through the 580 nm and 610 nm quadrants of the spinning filter wheel. Read-lengths of 640 bases in 2 h were reported for fluorescently labeled primers [17]. A multicolumn approach soon followed [22] and with a planar array of five capillaries, the lasers were focused to illuminate across the outlets of the capillary array, exciting all five sheath-entrained samples in the cuvette simultaneously approximately 100  $\mu\text{m}$  below the ends of the capillaries (Figure 16.18). Emission was collected normal to the direction of the sheath flow and excitation laser direction using a microscope objective (20 $\times$ ,

**FIGURE 16.18** A five-capillary sheath-flow CE/LIF detection scheme. (Reprinted from Zhang, J., et al., *Nucleic Acid Res.*, 27, e36, 1999. With permission from Oxford University Press.)

0.5 NA) and was passed through a spinning filter wheel. At the image plane, five gradient refractive index lenses, each coupled to a fiber optic, brought the emission from the five spots onto five dedicated avalanche photodiodes [22]. The implementation of a micromachined sheath-flow cuvette for capillary alignment extended multiplexing to 16 capillaries [135] while a two-dimensional capillary array scheme using 32 capillaries, with illumination by a “sheet” of laser light and detection in the sheath stream at the exit tips of the capillaries using a CCD camera, suggested feasible scaling to “several thousand capillaries” [136].

Kambara and Takahashi also employed the sheath-flow technique for the interrogation of 20 capillaries using a CCD camera [137]. In that work, the 20 capillaries were aligned into a linear array, with the outlet end of all capillaries engulfed by a sheathing fluid, in this case, a TBE buffer. No flow cell was used in this work. A laser was directed through the sheath fluid carrying the sample, normal to the direction of the sheath flow, allowing sample from all 20 capillaries to be illuminated simultaneously (Figure 16.19). A cylindrical lens followed by a prism was used to disperse the fluorescence from all 20 capillary bores onto a CCD camera. One axis of the CCD image yielded spatial information about the interrogated capillaries and the other axis of the CCD yielded spectral information. No moving parts was required in this approach. In addition, since excitation and detection for all capillaries and fluors occur simultaneously, no time sharing was required, improving duty cycle and greatly increasing the capability of this system for multiplexing. PE Biosystems Inc. (now part of Applera) has commercialized a similar sheath-flow design on several of their high-throughput DNA sequencing systems [6,56,127].

#### 16.2.3.4 Other Detection Schemes Explored

The detection methods thus far described focus on measuring the intensity of fluorophores at one to four wavelengths. For multicolor work, an important requirement is that the fluorophores are spectroscopically unique. To obtain spectroscopic information, the emission is either monitored using one time-shared detector, split among several detectors, or dispersed with a grating or prism, all resulting in reduced light levels and lower SNR.

One alternative method is to use differences in fluorescence lifetime as the metric to discriminate between the fluor-labels [138,139]. Several potential benefits of measuring lifetimes for DNA sequencing have been described [140,141]. Lifetimes may be accurately determined in the absence of spectral discrimination; thus, discrete lifetimes may be determined for mixtures of fluors coeluting in a single peak. Lifetimes are also independent of intensity even at concentrations where relatively poor SNR may lead to an erroneous fluorescence intensity-based call. In addition, since scattered light has an effective lifetime of zero, scatter may be temporally rejected and is thus less of an issue. However, this method requires a family of fluors in which the lifetimes are resolvable [141–143] and the use of relatively complex electronics [141].

There are two methods that have been used to determine fluorescence lifetimes in DNA sequencing. In the first method, known as the frequency-domain or phase-modulation method, the excitation beam is intensity modulated. The a.c. portion of the resulting emission is phase-shifted relative to the laser modulation; this phase-shift contains information about the fluorescence lifetime, or lifetimes if more than one fluor is present [140]. McGown and coworkers [144,145] used this method for four-color sequencing. In that work, 488 nm or 514 nm laser light was electronically modulated with a Pockels cell before being focused onto a capillary column. Detection, made normal to the laser direction, was optically filtered to reduce laser scatter and was focused onto the detector of a

fluorescence lifetime instrument (Model 4850 MHF from Spectronics Instruments, Rochester, NY). Fluorescence lifetimes of 1.7, 2.5, 2.9, or 3.5 ns were measured and assigned to primers labeled with either CY3, the energy transfer dye fluorescein-dTMR, rhodamine green, or BODIPY-fluorescein, respectively. Recent advances using acridone dyes with more resolvable lifetimes of 4, 6, 11, and 14 ns have been reported [143].

The second method of determining fluorescence lifetime is to modulate the excitation source with a very short pulse width and measure the decaying fluorescent emission with high-temporal resolution when the laser is off. Soper and Mattingly [146] constructed a near-infrared detection system with picosecond resolution. In this study, an argon-ion pumped Ti:sapphire laser generated 210 femtosecond excitation light pulses at 76 MHz. They found a strong dependence of fluorescence lifetime on sieving matrix material. Detection of separated dye-primer labeled fragments was demonstrated [147]. Wolfrum and coworkers [138] used a single 630 nm diode laser, pulsed at 22 MHz with 500 picosecond on durations, to excite a family of fluor-labeled primers. The lifetimes of the four fluorophores studied were 3.7, 2.9, 2.4, and 1.6 ns. Emission, filtered with a dichroic lens (required in their confocal illumination/detection setup) and a 675 nm bandpass filter, was monitored using an avalanche photodiode. This work was expanded by placing up to 16 capillaries onto a translation stage and scanning them under the confocal excitation/detection system [23]. In all cases, relatively complex curve fitting of the fluorescence decay was required to extract the lifetime values. Detection limits were not reported for any of the fluorescence lifetime-based capillary sequencing studies probably because that was an area of difficulty relative to conventional fluorescence approaches.

Another detection scheme, studied by Gorfinkel and coworkers [148,149] with capillary-based DNA sequencing in mind, was based on single-photon detection. In this approach, the output beams from four lasers were combined in a single optical fiber and used to excite the labeled fragments in the CEQ DNA test sample (Beckman Coulter) as they migrated through the detection window of a capillary. Each laser, selected to preferentially excite one of the four BCI fluors at 635, 675, 750, and 810 nm, was modulated at a different frequency, in the range 1–2 Hz. Collection was made via a fiber receiver connected to a single-photon PMT detector. Four stacked notch filters were used to eliminate scatter from each of the lasers. Since the four dye-matched lasers were modulated at different frequencies, the fluorescence signal arising from each fluor was also modulated at a different frequency. A Fourier spectrum contained a peak or peaks corresponding to the fluorescence frequency of the fluor(s) present. Cross talk, corresponding to the emission from a fluor generated by excitation from a second laser, may be determined by running each fluor independently and determining the relative Fourier amplitude for each of the lasers. Although demonstrated only for sequencing in a single capillary, a multiplexed scheme to monitor separations in 32 capillaries was also described [149].

Metzker and coworkers [150] developed a “color-blind fluorescence detection” system using four fluorophores. In this system, each of the four fluorophores was stimulated primarily by only one of four lasers. The four lasers, at 399, 488, 594, and 685 nm, were modulated using mechanical shutters such that only one laser was striking the capillary at any time. These were used to excite Alexa Fluor 405, BODIPY-FL, 6-ROX, and Cy5.5, respectively. Emission was collected normal to the direction of excitation and was then transmitted through a long pass and several notch filters to block light scattered from any of the lasers before being focused onto a PMT. Since each of the four fluorophores is primarily stimulated by only one laser, fluorescence detected at the PMT was assigned to the DNA fragment labeled with the fluorophore primarily excited by the laser currently striking the capillary. In general, cross talk observed between lasers and fluorophores was in the range of 2–4%. However, Cy5.5 excited by 594 nm yielded an emission that was 20% of the emission generated upon excitation with 685 nm light. Mobility correction was required before good DNA sequence could be called.

An interesting nonoptical detection scheme for CE-based DNA sequencing was proposed by Brennan et al. [151]. In this approach to sequencing, capillary gel electrophoresis was coupled to

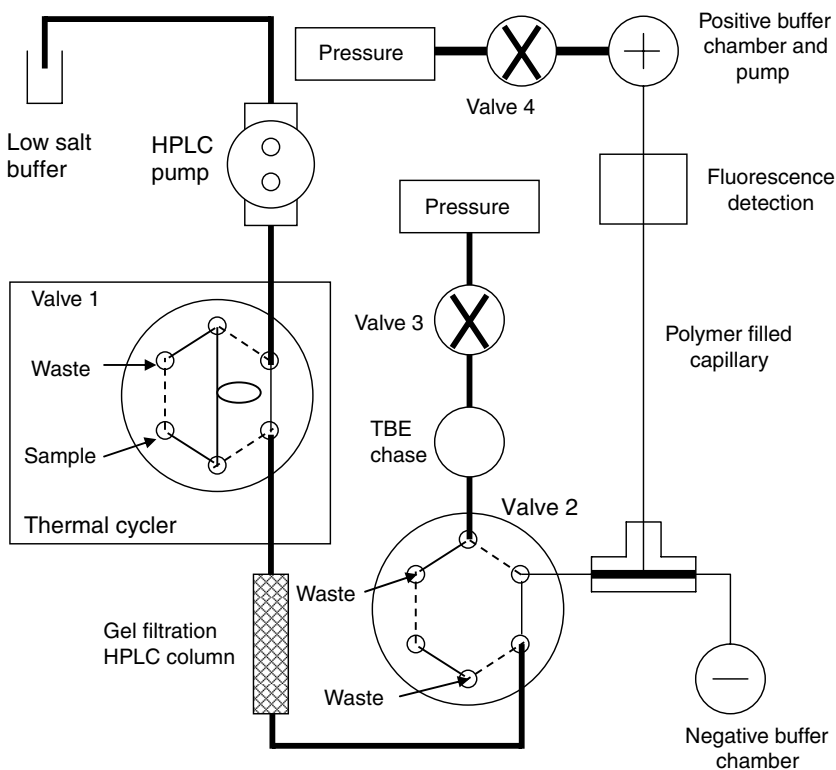

mass spectrometric detection. The idea was based on the use of four different sulfur isotopes, having masses of 32, 33, 34, and 36 to establish the terminal base identity of Sanger–Coulson sequencing fragments eluting from the capillary. The labels were incorporated in the form of thiophosphate analogues. Described advantages included the possibility of internal labeling, which would produce an increase in signal with increasing fragment length, and the elimination of spectral overlap issues that exist with fluorescent labeling schemes. The novel proposition involved a CE/MS interface in which capillary effluent droplets were created using a piezo-electric dispenser similar to those used in ink-jet printers. The small, picoliter volume droplets were to be combusted and transferred to a mass dedicated spectrophotometer tuned over the small mass range required to differentiate the four sulfur isotopes.

### 16.2.3.5 Integrated Sample Processing and Detection

The systems described thus far addressed only a portion of the individual tasks required to elucidate DNA sequence. A more efficient process would fully integrate the tasks of DNA extraction, purification, template preparation, and amplification with sequencing reaction chemistry, post reaction cleanup, separation, and detection [152]. Several groups have explored partially integrated systems intended to streamline various steps in this process [152–156].

Swerdlow et al. [153] developed a system for DNA sequencing that integrated the cycle sequencing reaction, post reaction sample cleanup, sample injection, CE separation, and LIF detection. A schematic representation of the system is displayed in Figure 16.20. Cycle sequencing reaction components and sample were loaded by syringe into a temperature programmable rotary valve. Once the cycle sequencing reaction was completed, the reaction product was directed to a gel filtration HPLC column for cleanup. Their system allowed “heart cutting” of the product peak that eluted from the gel filtration column and this purified aliquot of the product peak was then electrokinetically injected into a gel-filled capillary using the “Tee” injection scheme depicted in Figure 16.20. After a 10 s injection, pressure drove a stream of TBE buffer through valve 2 and into the “T” in order to chase away any remaining sample. Once the “T” had been filled with TBE buffer, electrophoresis was initiated. On-column detection was made using a single PMT to monitor one-color fluorescence induced by 532 nm laser excitation. The entire process was completed in 90 min [153].

Yeung and coworkers devised a similar scheme to integrate thermal cycling and purification followed by injection, separation, and detection, first in a single capillary [157] and then in eight capillaries [154]. In the multicapillary work, multiplexed freeze/thaw valves (MFTV) were used to simplify the manipulation of samples during the thermal cycling process. In the MFTV, an array of eight capillaries was threaded through two stainless steel tubes; the length of capillary between the tubes was placed in a thermalcycler and was used as the reaction vessels. When liquid nitrogen was flowed through the two stainless steel tubes, the liquid in the capillary portions within the steel tubes froze, thus “closing” the valves and forming an immobile volume of liquid between the two frozen plugs. Passage of warm air through the steel tubes melted the plugs, opening the “valves.” Figure 16.21 displays the operation of the MFTV for a single capillary. A pump was used to draw thermalcycling reagents from a well in a microtiter plate into the portion of the capillary within the thermalcycler. With valves 1 and 2 in the closed position, the cycle sequencing reaction was performed, thereby creating the labeled DNA fragments (Figure 16.21a). With 1 and 2 in the open position, and valve 3 in the closed position, the pump drew the sample above the “T” (Figure 16.21b). The sample was then pushed into the size exclusion column for sample purification by closing valves 1 and 2 and opening valve 3 (Figure 16.21c). After this, sample purification and capillary loading/separation occurred in much the same manner as described by Swerdlow et al. [153]. Detection of separated DNA fragments was made via side illumination of all eight capillaries via the method described above [122]. This method was later expanded to include sequence determination directly from single bacterial colonies [155].

## 16.2.4 SEPARATION METHODS

### 16.2.4.1 Sample Injection

In terms of sample loading, capillary-based DNA sequencing systems have a fairly narrow window of stable operation. This window ranges on the low injection end, from the minimum amount of sample required to produce sufficient signal to reliably call bases throughout the sequencing run (note that signal strength generally declines with increasing base number) to the high injection end of the window, where sample overloading results in resolution losses and/or current instabilities. Several complicating factors can further reduce the width of this stability window including residual template DNA, protein contaminants in the sample, excess salts and unincorporated nucleotides, and the unintentional introduction of air into the gel upon executing electrokinetic injection. The ideal sample loading process, speaking strictly from a separations perspective, would introduce nothing but labeled sequencing fragments onto the gel, and those fragments would be introduced over a column length that contributed nothing to total peak variance at the detector. The fragments would furthermore be introduced onto the gel at concentrations that were electrically transparent relative to the conductive gel medium. Obviously, practical considerations having to do with post sequencing reaction cleanup and low level fluorescence detection prevent us from completely realizing this ideal injection goal.

In 1998, Karger and coworkers [158,159] published a two-part study on the role of sample matrix components and post reaction sequencing product cleanup. In this study, the authors used ultra-filtration to remove template DNA and gel filtration to reduce salt concentration in the sample

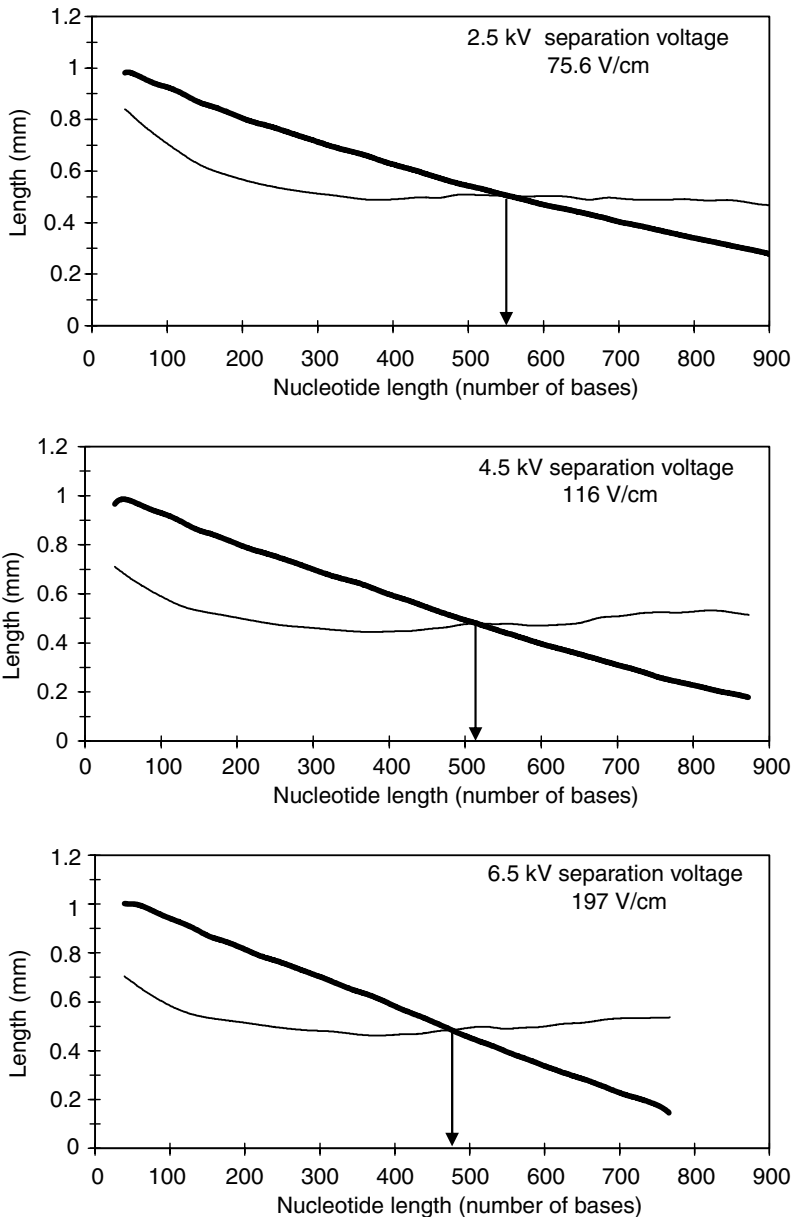

**FIGURE 16.21** Multiplexed freeze/thaw valves used to isolate sample during thermalcycling. (Reprinted with permission from Tan, H. and Yeung, E.S., *Anal. Chem.*, 70, 4044, 1998. Copyright 1998 American Chemical Society.)

loading matrix. The cleanup procedure was reported to be very reproducible, resulted in a 10- to 50-fold increase in the amount of sequencing fragments loaded onto the gel, and facilitated the realization of read-lengths in excess of 1000 bases.

Manufacturers of commercial systems generally recommend a spin-column cleanup method or an ethanol precipitation/washing cleanup protocol that must then be followed by suspension of the lyophilized DNA pellet in a sample loading matrix designed to optimize or enhance sample loading. Note that separating DNA sequencing fragments generated from polymerase chain reaction (PCR) amplicons is generally less problematic than when larger template DNA is sequenced, thus supporting the idea that the presence of template DNA in the sample often leads to poor performance.

#### 16.2.4.2 Separation Parameters

Several groups have searched for optimum run parameter settings in an attempt to maximize sequencing rates and read-lengths in both fixed and replaceable gels [15,18,21,24,50,67,73,80,160]. Rather than provide an exhaustive review of those studies here, we describe a few metrics that we have found useful in the optimization of separation conditions. The first of these is the “cross-over plot” in which peak width and adjacent peak spacing are plotted against base number [55]. Figure 16.22 shows cross-over plots for the separation of dye-terminator labeled sequencing fragments run at three different field strengths using a CEQ system (Beckman Coulter) and a linear polyacrylamide gel. A qualitative resolution limit is visible in these plots as the point where the two curves cross. At that point in the separation, the peak-to-peak spacing has dropped to the level where it is equal to the peak widths. Beyond this intersection point, discerning individual bands becomes increasingly difficult. Note that the cross-over point in these figures is observed to occur at decreasing base number as the field strength is increased and so any increase in speed realized by using higher voltage is offset by a loss in read-length.

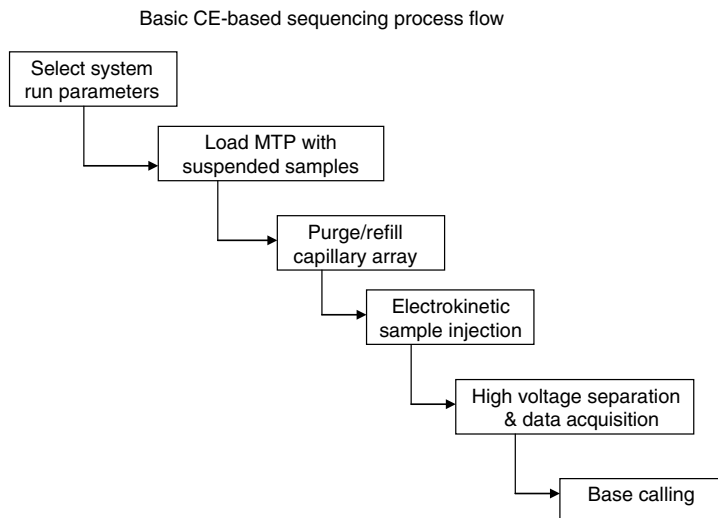

**FIGURE 16.22** Peak-to-peak spacing (thick curves) and full-width at half maximum (FWHM) values (thin curves) as a function of nucleotide length for several run voltages.

Another useful, and perhaps more significant, metric to monitor as run conditions are varied is the “98% cutoff” or “length of read” number. This refers to the length of read achieved before the cumulative errors reach a value equal to or greater than a prespecified value of 2%.

A third metric that has proven useful in the optimization of run parameters and gel formulations is the “first base called” (FBC). This is the first position in the sequence that is correctly called and it is located typically 5–15 bases from the 3' end of the primer used in the extension reaction. Factors affecting the FBC include the gels ability to sieve over a wide range of sizes, including the smaller extension products and congestion that often occurs early in the electropherogram due to coelution of unincorporated terminators, salts, and unextended primer.

**FIGURE 16.23** High-level graphical depiction of the steps involved in CE/LIF-based DNA sequence determination.

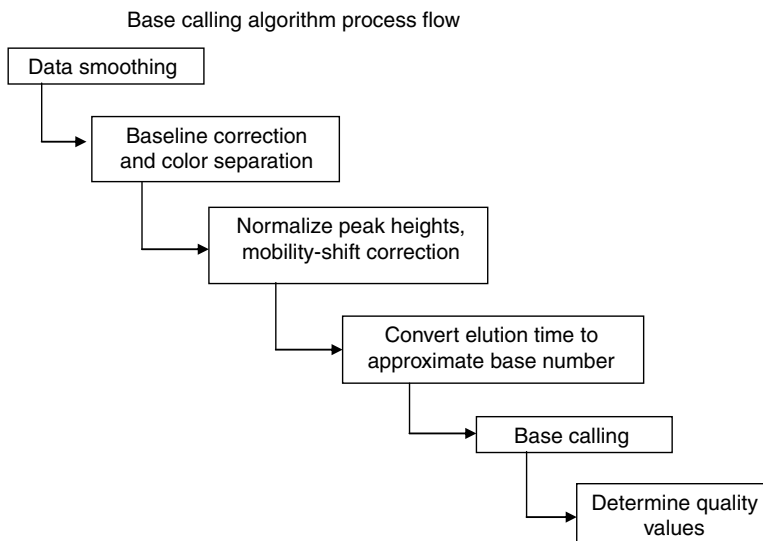

A fourth metric that we have found useful is to track resolution and/or base-calling accuracy over short stretches of sequence “known to be difficult” (KD stretches). This term refers, for example, to regions in electropherograms where anomalous migration occurs due to either secondary structure or the presence of salt fronts.

Figure 16.23 illustrates the steps involved in executing a typical CE-based DNA sequencing separation using one of today’s automated sequencers. Run parameters such as injection voltage and duration, capillary temperature, denaturation time and temperature, separation voltage and duration, and sample well assignments are pre-programmed using simple graphical user interfaces. After cleanup, sequencing reaction samples are suspended in a suitable loading matrix and are transferred to appropriate wells in a 384- or 96-well microtiter plate. Fresh gel is automatically introduced into the capillaries of the array, optical alignment is verified, samples are denatured and then electrokinetically loaded into the capillaries. Recommended injection parameters vary somewhat but generally involve loading the samples onto the gel at low voltage ( $\sim 60$  V/cm) for approximately 30 s. Separation is initiated, often with the voltage ramped up over a prespecified time interval, to a final separation voltage on the order of 100–200 V/cm. Higher field strengths will result in faster separations but often at the cost of shorter read-lengths and/or reduced system stability. Multicolor detector output signals are acquired at data rates suitable to accurately represent the corresponding peak profiles (generally in the range of 2–4 Hz). Individual capillary current profiles, which are a useful diagnostic, are also often collected throughout the injection and separation process.

## 16.2.5 ALGORITHMS

### 16.2.5.1 Basic Sequence Calling Steps

The importance and value of base-calling algorithms that have been developed for automated DNA sequencing cannot be overstated. Figure 16.24 graphically depicts the major steps involved in the analysis of raw detector output signals from today’s capillary-based sequencers. Raw LIF signals are collected at a data acquisition rate sufficient to adequately represent the true concentration profiles of the narrow bands migrating through the beam. The raw data is generally smoothed to reduce noise and is baseline corrected to reduce drift. Color separation refers to dealing with the fact that fluorescence emissions typically exhibit some degree of overlap in the spectral channels monitored for

**FIGURE 16.24** Graphical depiction of the steps involved in analyzing CE/LIF sequencing data for base calling.

each of the four fluorescent labels. Manufacturers of these systems understand the degree of spectral overlap that exists in these measurements and are able to mathematically eliminate this concern so that an unambiguous base assignment is made at each position. Peak-height uniformity has seen improvements over the years, owing both to improved sequencing reaction chemistry (e.g., the role played by pyrophosphatase in References 26 and 161) and algorithm-based mathematical normalization for differences in response across the dye set and for signal decay with increasing base number. The four different dyes attached to the terminators can also have an impact on fragment mobility and thus can complicate the clear size ordering assumed to be provided by the gel matrix. This issue has also been minimized through both chemistry improvements (similarity of dye structures, common degree of sulfonation, etc.) and mathematical algorithm corrections.

### 16.2.5.2 Quality Values

Phred is a base-calling algorithm, developed by Ewing and Green [162,163] that reads DNA sequence data files in a variety of formats, makes base call assignments, and also associates a highly accurate, base-specific quality score with each base call. The reported Phred quality scores are logarithmically related to error probabilities as shown in Table 16.2. Manufacturers of commercial sequencing systems also incorporate similar base-specific quality scores into their base-calling algorithms.

## 16.3 THE NEXT GENERATION: SEPARATIONS IN MICROFLUIDIC SYSTEMS

With replaceable gel CE now having effectively displaced all slab-based DNA sequencing, many have speculated that the next generation of fully automated, high-throughput DNA sequencing systems will be based on the use of microfluidic technologies such as compact plates or discs that are channel etched and micro-plumbed at high density [7,8,164–171]. Using technologies such as photo and chemical etching, originally developed for the microelectronics industry, features much smaller than those required for conventional CE may be created directly in fused silica or other materials. This technology could allow for significant miniaturization of multicolumn systems, more control options

**TABLE 16.2**  
**Error Probability for Various Phred Quality Scores**

Phred Quality Score	Probability of Error at That Base Call	Basecall Accuracy at That Base (%)
10	1 in 10	90.0000
20	1 in 100	99.0000
30	1 in 1000	99.9000
40	1 in 10,000	99.9900
50	1 in 100,000	99.9990
60	1 in 1,000,000	99.9999

for sample introduction, and simplification of fluid handling in even more highly paralleled systems. The ability to reliably introduce much smaller sample plugs into the separation channels (reduced injection variance) may one day allow even faster separations to be run using significantly shorter separation channels. As demonstrated below, plug lengths as short as 30  $\mu\text{m}$  may be introduced in microfluidic channels. Low signal-to-noise issues anticipated with reduced sample loading may be resolved using innovative solutions such as brighter fluorophores and increasing channel depths in the detection region.

The first DNA separation with single base resolution performed in a microfluidic device was reported by Effenhauser et al. [172]. Using standard photolithographic techniques channels were etched into a polished glass plate over which a second plate containing micromachined holes was thermally bonded (Figure 16.25). Both thin channels (50  $\mu\text{m}$  wide and 12  $\mu\text{m}$  deep) and broad channels (1000  $\mu\text{m}$  wide and 12  $\mu\text{m}$  deep) were created in this study. Before use, all the channels were filled with a 10% AA solution that was allowed to polymerize *in situ*. Pipette tips were glued to the holes in the covering plate and acted as reservoirs. Referring to Figure 16.25, sample was injected from reservoir 1 into the main separation channel by applying a field across 1 and 5. The loaded sample plug was 150  $\mu\text{m}$  long with a volume of 90 pL [164]. Separation of this plug was achieved by switching the field to ports 3 and 7. LIF detection of the fluorescein-labeled fragments was made 3.8 cm downstream of the injection manifold and single base resolution of fragments 10–25 bases long was achieved in less than 45 s [172].

Mathies and coworkers [173] developed a similar system to separate double-stranded DNA restriction fragment digests. Standard photolithography techniques were also employed here [174]. Specifically, the channels were etched into a glass slide by first covering the slide with a photoresist film and then transferring the channel pattern to the film by exposing UV light through a patterned mask. The photoresist film exposed to the UV light dissolved while the remaining film hardened. The exposed glass region was then chemically etched with solutions of  $\text{NH}_4\text{F}/\text{HF}$  to form the appropriate channels and the remaining photoresist film was removed with  $\text{H}_2\text{SO}_4/\text{H}_2\text{O}_2$ . A glass plate with access holes drilled into it was then thermally bonded to the etched plate. Channel widths of 30–120  $\mu\text{m}$  were created. To prepare the channels for electrophoresis and eliminate EOF, the surfaces were treated using a modified version of the Hjertén protocol. A general scheme for sample injection and separation is displayed in Figure 16.26. Low-viscosity HEC separation matrix was placed in the separation channel by applying vacuum to opening 4. The cross channel regions were filled with TBE buffer. Electrodes, buffers, and sample were placed in reservoirs numbered 1 through 4. Two injection types were explored. For “stack” injection, sample was placed in 3 while a field was applied across 3 and 4. For “plug” injection, sample was placed in 3 and a field was applied across 1 and 3 to move sample across the intersecting separation channel. In either case, once sample was injected, separation occurred by applying the field across positions 2 and 4. Initially, single-color detection was made using an optical arrangement similar to that described for multicapillary work, as illustrated in Figures 16.13 and 16.14.

The first reported DNA sequencing separation with this system utilized plug injection of primer-labeled fragments onto an LPA matrix in a channel having an effective separation length of 3.5 cm and resulted in a four-color basecall of  $\sim 150$  bases at 97% accuracy in 540 s [175]. Further work using a replaceable 4% LPA matrix, delivered via a high-pressure loader [176], and the “twin-T” injection scheme used earlier by Effenhauser [172], yielded read-lengths of 500 bases at 99.4% accuracy in less than 20 min [177]. Microfluidic chips containing 12 [178], 16 [179], 96 [180–183], 188 [184], and 384 [185,186] separation channels have since been reported. Linear 96-channel systems were constructed [179,180] as were novel radial microplates for 96- and 384-channel systems [181–183,185,186], although no sequencing was demonstrated with the 384-channel system. Figure 16.27 displays a system with 384 channels etched into a 20 cm diameter wafer; lanes were  $\sim 60 \mu\text{m}$  wide and  $30 \mu\text{m}$  deep, with an effective separation length of 8.0 cm. A multicapillary array loader was created to transfer sample (via pressure) from a microtiter plate to the radial microplate [181]. For detection, a rotary scanning confocal fluorescence detector was created [181,182]. Similar to the linear scan head developed to interrogate a multicapillary array (see Figure 16.13), the objective is placed on a rotating scan head (Figure 16.28) [181]. This system was capable of collecting data at 200 revolutions per second, with 5000 data points collected per revolution for each color. Given that the scanning diameter was 2 cm, a spatial resolution of  $\sim 12.6 \mu\text{m}$  was achieved. A detection limit of  $\sim 1 \text{ pM}$  at a SNR of 2 was reported using this system [182]. Simultaneous four-color sequencing of primer labeled DNA fragments yielded an average of 400 high-quality bases in each of the 95 channels (one channel failed due to a defect in the photolithography) [183].

Ehrlich and coworkers [187] performed a systematic study of LPA polymer concentration and composition, device temperature, effective channel length, and electric field strength for microfluidic-based DNA sequencing platforms. They determined that separations performed in an 11.5 cm channel (the longest used in this work) at  $50^\circ\text{C}$  using a field strength of 125 V/cm and a separation matrix consisting of 3.0% (w/w) 10 MDa plus 1.0% (w/w) 50 kDa LPA were most optimal, yielding a read-length of 640 bases at 98.5% accuracy in  $\sim 30$  min for primer-labeled DNA fragments. Very long read-lengths required an extension of the column length and separations in 40 cm channels ( $40 \mu\text{m}$  deep and  $90 \mu\text{m}$  wide at the top) yielded reads  $>800$  bases at 98% accuracy in 80 min at  $50^\circ\text{C}$  [188]. Comparable results required 180 min of run time on the MegaBACE 1000 system (GE Healthcare) [188,189].

In addition to the advantages of performing separations in microfluidic channels presented at the beginning of this section, several others are now evident. For example, in all microfluidic systems in which the sample is loaded through a gel-filled “T” region before separation, “preseparation” is occurring. With judicious injection timing, unwanted materials contained in the sample solution may be prevented from entering the separation zone, thereby increasing separation quality [190,191]. For example, fragments contained in the sample that are larger than the upper resolving limit of the gel normally coelute as a large unresolved “blob” at the end of the electropherogram. This signal can be completely eliminated from the analysis by running sample through the T junction just long enough to allow the largest resolvable fragments to transit the intersection. Once the high-voltage contacts are switched from injection to separation positions, only the resolvable fraction of the sample will be directed on for separation and analysis.

In addition, such injection methods have also been reported to enhance loading of larger fragments relative to direct electrokinetic sample injection onto a gel-filled capillary [179,192]. Finally, because there is no analogy to the polyimide cladding protecting capillaries in microfluidic channels, the entire chip process may be monitored with a CCD camera, yielding information about sample injection and providing flexibility in detection [193,194].

Ehrlich and coworkers [188] found that long channel lengths yielded longer read-lengths, with a channel 40 cm long yielding reads of greater than 800 bases at 98% accuracy in 80 min. However, long straight channels are difficult to create primarily because of the special equipment needed to etch large plates [184,191]. To remedy this situation, some groups have created channels with several turns (i.e., serpentine channels) to increase column length. However, dispersion effects degraded

**FIGURE 16.27** (a) Layout of 384-channel microfluidic electrophoresis device. (b) Expanded view of a single quartet of channels with their injectors. (c) Expanded view of a quartet of individual sample reservoirs. (Reprinted with permission from Emrich, C.A., et al., *Anal. Chem.*, 74, 5076, 2002. Copyright 2002 American Chemical Society.)

the individual bands because the path-length within the channel varied depending on whether the molecules traveled along the interior or exterior radius [195,196]. New designs implemented with unique channel geometries in the turn regions have minimized this problem [197,198].

To circumvent the drawbacks associated with the etching of long straight channels on large glass plates, Liu [191] created a hybrid capillary/microchip design. In his work, twin-T injectors with round channels as well as round capillary connection channels were created using very narrow line-width isotropic etching (Figure 16.29). The chip was then diced and a 75/200  $\mu\text{m}$  capillary inserted along the chip edge into the connection channel, mating with the twin-T region (Figure 16.29b). Hybrid 16-capillary chips were created and used on a modified MegaBACE 1000 system (GE Healthcare) for multicapillary detection [199]. Sample loaded in the twin-T was then separated in the 40 cm long capillary, resulting in  $>800$  bases read to 98.5% accuracy in 56 min. Comparable capillary-only runs with electrokinetic injection yielded only  $\sim 650$  bases [191].

The use of microfluidics in a commercial DNA sequencing system has yet to be demonstrated. This is likely due to the lack of a compelling driver. Capillaries are still relatively inexpensive in comparison with etched plates and schemes have been engineered to allow fairly cost effective replacement of subgroups of capillaries, even in the high-throughput systems employing hundreds of

separation channels. Future improvements in the field of microfluidics may result in a transition from capillaries to etched substrates but competitive sequencing technologies that seem to have finally eliminated the need for electrophoresis are now on the horizon [200–203] and progress in this area will likely redefine the role of CE in DNA sequencing.

## 16.4 OTHER NUCLEIC ACID APPLICATIONS

Although the focus of this chapter has been on capillary-based DNA sequencing, it is important to point out that the same systems originally developed for DNA sequencing are also capable of supporting a wide variety of other important electrophoresis-based assays. Methods and kits have been developed for applications such as gene expression, heterozygote detection, mutation analysis, allele identification, single nucleotide polymorphism screening, microsatellite instability, and amplified fragment length polymorphism (AFLP) fingerprinting and these applications are now finding widespread acceptance in a variety of fields of science including biomedical research, human and animal diagnostics, and agriculture.

## 16.5 CONCLUSIONS

Clearly, a remarkable amount of progress has been made over the past two decades in the area of automated DNA sequencing. Early sequencing methodologies were slow, tedious, labor-intensive, and riddled with error-making opportunities. Until the late 1980s, slab gels were manually poured, samples were loaded by hand, and images created using X-ray film were painstakingly read by eye. Automated film readers were introduced to improve the manual reading process but their utility was short lived as better technologies were soon developed. The late 1980s and early 1990s saw important improvements as the manual sequencing process was partially automated. Radio isotopic tags were displaced by the use of fluorescent labels and the process of reading slab gels was automated using multilane fluorescence slab gel readers and powerful base-calling algorithms. The initiative to sequence the human genome drove the development of faster, high-throughput sequencing technologies, and CE emerged in the late 1990s as that decade's winner. Slab gels were displaced by capillary arrays filled with replaceable gels and sensitive fluorescence technologies were successfully adapted to the more challenging multicapillary format. Current large-scale sequencing projects would be slowed unthinkably without automated capillary sequencing machines, which became commercially available in the late 1990s and have now made DNA sequencing much quicker and more reliable. Today, one automated capillary DNA sequencing system can produce data at a rate of approximately 1 million bases of raw sequence per day with as little as 15 min of user intervention required. Without question, the works cited in this chapter and the authors who performed those studies have all contributed to a technology and field that has enjoyed impressive progress.

New technologies involving nonelectrophoretic, massively paralleled sequencing strategies now seem poised to deliver the next significant improvement in the area of lower cost, high-throughput DNA sequencing. These systems are targeting single platform throughput levels of tens of millions of bases per hour and may make whole genome sequencing more affordable.

## ACKNOWLEDGMENTS

The authors wish to thank Cynthia Johnson, Clarence Lew, Feng Liu, Lucy Liu, Paul Kraght, Veronica V. Colinayo, and Christopher Pentoney for their assistance in creating this chapter and Dr James C. Osborne for his support.

## 17.1 INTRODUCTION

Since the early 1980s, the use of computers within society has increased at a significant rate. They are now involved in almost every aspect of modern day life, and it is therefore not surprising that this prevalence has transferred into the professional field of the modern day scientist. Of particular interest in this chapter is the use in capillary electrophoresis (CE) to model or “simulate” the myriad of chemical and physical processes that occur during an electrophoretic separation. This is achieved through a series of model equations derived from the transport concepts in solution under the influence of a d.c. electric field together with user-inputted experimental conditions, such as concentrations, mobilities, field strengths or currents, capillary lengths, and so on, and a theoretical separation is calculated. One of the potential advantages of a simulation is the possibility of determining appropriate separation conditions well before any laboratory experiments are undertaken, making method development a simpler task, although it must be noted that this can currently only be done with limited capacity. Simulations can also provide detailed insight into the processes involved

in the separation allowing the researcher to understand the result of a particular combination of experimental conditions, and with this information design new superior systems, and this has been the major area in which simulation software has been used to date. In addition, simulations can be employed for educational purposes.

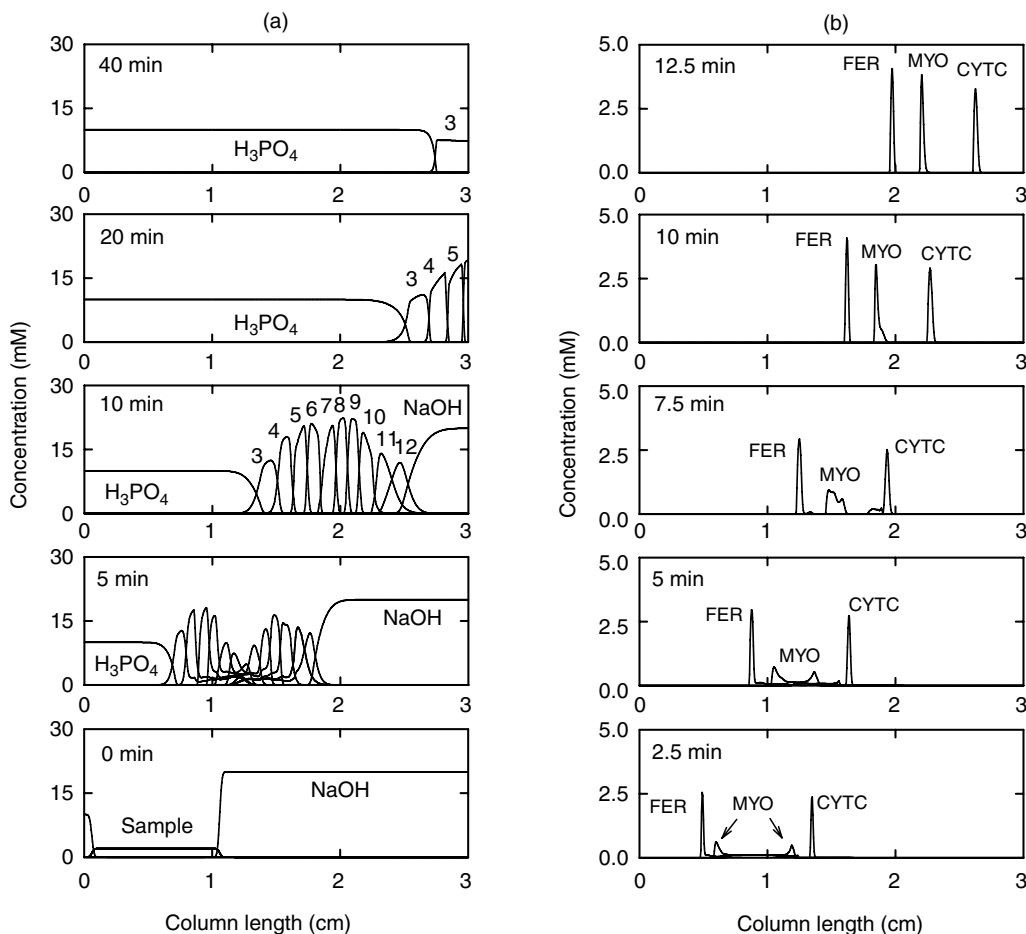

The result sought by the researchers will quite often dictate the simulation approach to be used, and in this regard it is necessary to distinguish the different types of computer models for electrophoresis. The most important for CE are (1) the dynamic models providing complete sets of concentration, conductivity, pH, and flow profiles as a function of time and location (e.g., at the point of detection along the capillary) for zone electrophoresis (ZE), moving boundary electrophoresis (MBE), isotachopheresis (ITP), and isoelectric focusing (IEF) [1,2]; and (2) the models for rapid assessment of ZE buffer systems and analyte separability [3–6] with a comprehensive program available for free (Peakmaster 5.1, <http://www.natur.cuni.cz/Gaš>). An overview of other models, including the steady-state models for ITP and IEF, which can predict the shape but not the evolution of steady-state electrophoretic boundaries, is given in [7], and a survey of training software for electrophoresis is provided in [8]. Computer simulations using dynamic models are more powerful than the other alternative as they are applicable to any buffer configuration and follow the entire separation at every step from start to finish according to the underlying transport laws. This not only yields the end result but also provides snapshots along the way, which can be used to monitor and understand the evolution of a particular process. While this is a huge advantage, it has one main disadvantage, namely that the algorithms are much more complicated and therefore requires more computer power. Furthermore, in contrast to high-performance liquid chromatography (HPLC) [9–12], electrophoretic simulations are much more computationally intense in three distinct ways: (1) electrophoresis usually has more components to deal with, (2) the separation efficiency is much higher requiring that component concentrations be updated more often and at more numerous column positions, and (3) the equations required to describe the processes are more numerous. This is less of an issue today than it was 20 years ago as computer hardware technology has developed significantly since then. Simulations that used to take several days can now be performed within several hours, allowing more complex and realistic simulations to be undertaken. It has only been within the past 5 years, over 20 years since the first reports on computer simulations, that it is possible to simulate simple CE separations under conditions that approximate those routinely employed in the laboratory.

In this chapter, we will discuss the theory underlying the use of dynamic simulation software and the benefits that the use of simulations can provide, illustrated through a number of simulated examples and examples taken from the literature over the past two decades. Finally, the most common computer simulation software will be contrasted and discussed from a practical perspective providing some guidelines as to the best way to approach a simulation problem.

## 17.2 BACKGROUND

Simulators with dynamic models are based on the description of algebraic acid–base equations and continuity equations, which are partial differential equations in time and space that can only be solved numerically using computers. Such models calculate the transport of each component through the electrophoretic space as a result of electromigration, diffusion, imposed and/or electrically driven bulk flow, solution-based chemical reactions such as protolysis and, if incorporated, also interaction of solutes with the capillary walls. An example is presented in Figure 17.1. A complete analysis of the temporal behavior of an electrophoretic system is thereby obtained and such models are thus often referred to as dynamic or transient state models. The numerical solutions are called dynamic simulations or dynamic modeling. Many dynamic models of various degrees of complexity have been described in the literature [13–46]. Only two of them are mostly used these days, namely the generalized PC-based models developed by Gaš and coworkers [30] and Mosher and coworkers [34–36], models that permit simulation of the transient states in all major electrophoretic modes

with predictive values for MBE, ZE, ITP, and IEF and are referred to as SIMUL5 and GENTRANS, respectively, in the remainder of this chapter. Furthermore, the construction of a three-dimensional stochastic simulation model for electrophoretic separations has been reported [47]. In contrast to the dynamic models referred to above, this approach is based on the modeling of the trajectories of each individual molecule, requires extremely powerful computers in order to compute the motion of a statistically significant number of molecules, and is not further considered in this chapter. The

**FIGURE 17.1** Computer predicted IEF of 10 carrier components and 3 proteins between 10 mM  $H_3PO_4$  (anolyte) and 20 mM NaOH (catholyte) in a bare fused-silica capillary using GENTRANS with (i) the electroosmosis model that considers electroosmosis as function of pH and ionic strength according to experimental data (electroosmosis model V of Reference 54), (ii) a 3 cm column divided into 600 segments ( $\Delta x = 50 \mu\text{m}$ ), (iii) boundary conditions with open column ends, (iv) a constant voltage of 10 V, and (v) data smoothing. (a) Concentration profiles of carrier ampholytes at 0, 5, 10, 20, and 40 min of current flow. (b) Dynamics of the three proteins at 2.5, 5, 7.5, 10, and 12.5 min (from bottom to top, respectively). (c) Column properties at 10 min (solid lines) and 0 min (dotted lines) for component distributions, ionic strength, pH, conductivity, and electroosmotic flow (from bottom to top, respectively). (d) Temporal behavior of current density, pH at two column locations (70 and 100% of column length), detector profiles for the proteins at the two detector locations, and detector profiles for all carriers and proteins for the two column locations (from top to bottom, respectively). For constructing the detection traces, all analytes had a detector response of 1. The cathode in panels a–c is to the right. The numbers in panel c refer to the pI values of the carrier ampholytes. S in panel c denotes the initial sample and C, F and M in panel (d) refer to CYTC, FER, and MYO, respectively.

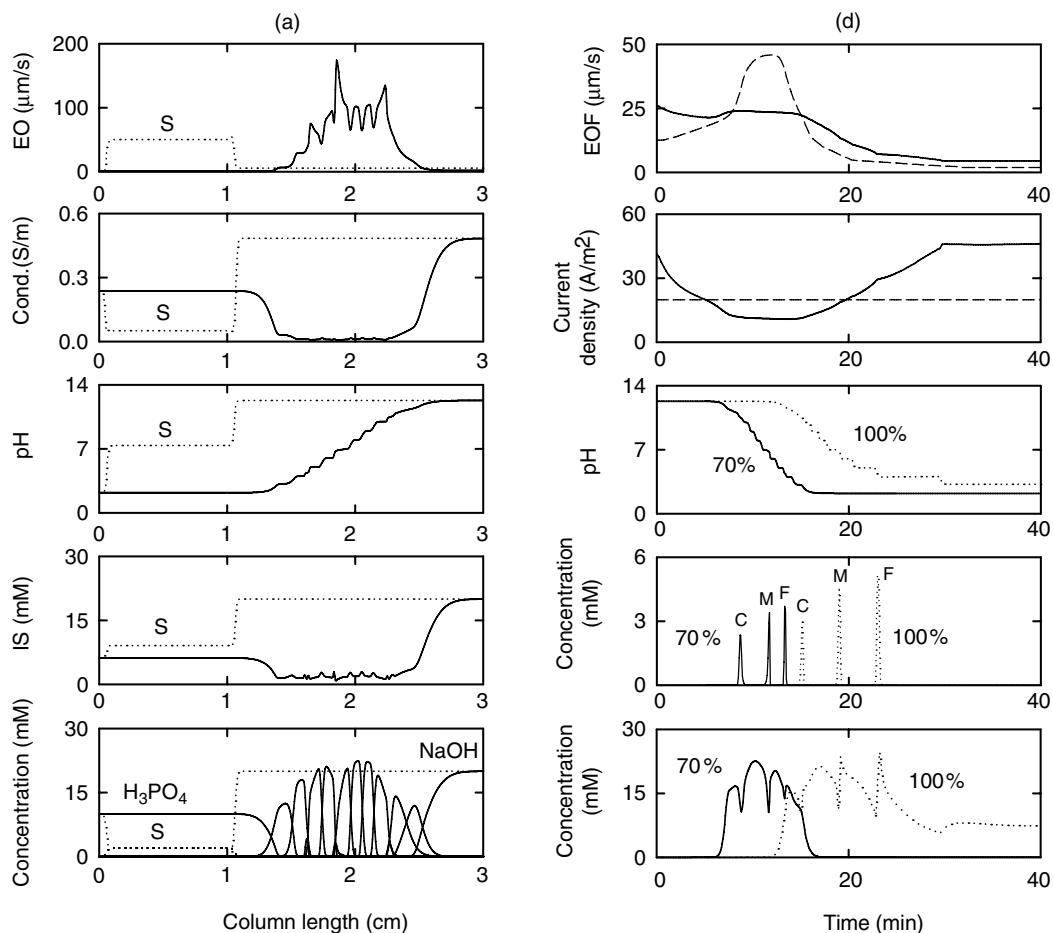

FIGURE 17.1 (Continued)

same is true for all multidimensional models that describe electrokinetically driven mass transport in microfabricated chip devices, such as those of Ermakov et al. [48], Bianchi et al. [49], Chatterjee [50], and Sounart and Baygents [51], as well as predict sample zone distortion in continuous flow electrophoresis [52].

Dynamic simulation provides plentiful data of any given CE system. This is illustrated here with the IEF separation example presented in Figure 17.1, which is performed in a fused-silica capillary and comprises a sample composed of ten hypothetical biprotic carrier ampholytes and three proteins [cytochrome *c* (CYTC, pI of 10.49), myoglobin (MYO, pI of 6.80), and ferritin (FER, pI of 4.40)] bracketed between 10 mM phosphoric acid (anolyte) and 20 mM sodium hydroxide (catholyte). A 3 cm separation space divided into 600 segments of equal length, 33% initial occupation of the sample at the anodic capillary end (panel a, bottom graph), and a constant voltage of 10 V were used. The pI values of the carrier ampholytes uniformly span the range 3–12 ( $\Delta\text{pI} = 1$ ). For each ampholyte,  $\Delta\text{pK}$  was 2, the ionic mobility was  $3 \times 10^{-8} \text{ m}^2/\text{Vs}$  and the initial concentration was 2.0 mM. The initial concentrations of the three proteins were 0.1 mM each. Physico-chemical input properties were the same as used before [32,53] and the input data for the calculation of electroosmosis are those for a fused-silica capillary and consideration of the impact of the ionic strength on electroosmosis according to model V [54]. Simulation reveals that the carrier ampholytes are completely separated within about 10 min of current flow (panel a) and the pH gradient is therefore established within

that time period (center graph of panel c). The data shown also reveal that carrier ampholytes at the interfaces to anolyte and catholyte (nicely seen with the pI 3 and pI 12 carriers, respectively) become gradually isotachophoretically adjusted and somewhat removed from the gradient. Owing to electroosmosis, the liquid and thereby the whole zone structure is being transported toward the cathode. With time, the catholyte and most carrier compounds are swept out at the cathodic capillary end and the net cathodic transport is decreasing and eventually disappearing completely [53]. A stationary steady-state zone configuration, which is characterized by an equilibrium between anodic isotachophoretic zone transport and cathodic electroosmosis, is produced. Under the employed conditions, the boundary between anolyte (phosphoric acid) and the most acidic carrier ampholyte is predicted to become immobilized at 91% of column length (top graph in panel a). The graphs presented in panel b depict the dynamics of the protein separation and are essentially those that are seen in whole column imaging [36]. The data of panel c represent zone properties predicted for the 10 min time point (solid line graphs) compared to the corresponding initial distributions (dotted line graphs). Data of other time points are not displayed, as this would complicate the figure. The electroosmotic data of each column segment presented in the top graph of panel c illustrate that the IEF gradient functions as the driving fluid pump of the capillary. These data do not reflect a real physical distribution of that property, but provide insight into the pumping activity of each zone. The electroosmotic pumping activity within anolyte and catholyte are predicted to be significantly smaller compared to that within the gradient system. Furthermore, computer-predicted temporal data for the net electroosmotic flow (EOF), current density, and various detector profiles are given in panel d. EOF is thereby shown to vary with time (even when the separation is executed under a constant current density, as is shown with the broken line graph, which was obtained for a constant  $20 \text{ A/m}^2$ ). The same is true for the current density under the simulation conditions of constant voltage. Detector profiles for pH, the proteins (e.g., absorbance at 280 nm), and the carriers and proteins (e.g., absorbance at 200 nm) are given for two column locations, namely 70% of column length (solid line graphs) and the cathodic capillary end (100% of column length, dotted line graphs). The entire IEF zone structure is detected at the first location (and this can be obtained with a detector placed between about 70% and 90% of column length), whereas at the end of the column, the anolyte and the most acidic part of the gradient is not detectable at this location. Information of this kind is useful for designing experiments with detection at the capillary end, most notably with mass spectrometry (MS). It should be appreciated that without the use of computer simulation software, it would be very difficult to discern and delineate the different electrophoretic phenomena involved in the system in Figure 17.1.

### 17.3 HISTORICAL CONTEXT

Shortly after computers became available to University-based research entities, separation scientists at universities in the Czech Republic (Prague, supervision of J. Vacík), Switzerland (Bern, E. Schumacher), and Arizona, USA (Tucson, M. Bier) began to construct dynamic computer models for electrophoresis with the goal of exploring the basics of electrokinetic separations in solution. The early models of Moore [13], Ryser [14], Gaš [15], and Vacík and coworkers [16–18], although restricted to strong electrolytes, allowed the simulation of ZE, ITP, and MBE configurations and can be regarded as the first dynamic electrophoretic models. These efforts were associated with the CE studies of the 1960s and 1970s, which led to ITP analyses in polymer capillaries. First dynamic models predicting the behavior of strong and weak electrolyte systems were developed in the 1980s, including those of Bier et al. [1,19,20], Radi and Schumacher [21,22], Roberts [23,24], and Schafer-Nielsen [25]. Except for [21,22], they were applied to all basic electrophoretic modes, including IEF. The model of Radi and Schumacher [21,22] is unique in using the kinetic constants of the association and dissociation reactions to describe a chemical equilibrium. The model of Bier et al. [1], which led to a unified view of all basic electrophoretic modes, was extensively used to characterize

a large number of electrophoretic configurations (for overviews see [7] and the detailed monograph of Mosher et al. [2]) and also simulates the behavior of proteins using effective and mean square valences that are determined from titration data [26]. Furthermore, the first model with incorporated EOF together with the transport based on electromigration and diffusion is that of Dose and Guiochon [27]. This approach, in which strong electrolytes are considered only and EOF is treated as constant plug flow, has been applied to the modeling of capillary ZE and ITP. The model of Roberts includes two spatial dimensions, whereas all others are one-dimensional approaches [23,24]. It is important to note that all these efforts were undertaken with hybrid or digital mainframe computers.

With the advent of PCs and the increasing popularity of capillary electrophoretic separations and analyses in fused-silica capillaries, many other dynamic simulators were developed in the 1990s, including those of Gaš et al. [28–30], Mosher and Thormann [31–36], Ermakov et al. [37–39], Shimao [40,41], Schafer-Nielsen [42], Martens et al. [43], Beckers and Boček [44], Ikuta and Hirokawa [45], and Sounart and Baygents [46]. Gaš et al. [28,29] extended their early model with incorporation of weak electrolytes, an approach that recently resulted in a comprehensive package that can account for any number of mono- and multivalent electrolytes and ampholytes (SIMUL5, [30]). The PC adapted model of Mosher and Thormann, GENTRANS, which is based on the dynamic simulator of Bier et al. [1,19,20] and was extended for a more realistic treatment of proteins [31], application of plug flow [32] and *in situ* calculation of EOF using wall titration data as input [33,34], can handle strong and weak electrolytes, simple univalent ampholytes, peptides and proteins (currently limited to 150 components total), and be executed at voltage gradients that are typically employed in experimental work [35,36]. It is interesting to note that the models in current use are again promoted by researchers from the same regions from which the early dynamic models originated, namely Prague, Czech Republic (B. Gaš), Bern, Switzerland (W. Thormann), and Tucson, Arizona, USA (R.A. Mosher).

## 17.4 THEORETICAL ASPECTS OF SIMUL5 AND GENTRANS

### 17.4.1 MATHEMATICAL MODEL

The generalized models SIMUL5 and GENTRANS are simulation programs that predict the impact of current flow on a specified distribution of electrolytes. They are composed of a set of balance laws governing the transport of components in electrophoretic separations as was originally developed in the 1980s by Bier et al. [1,19,20], later detailed in the monograph of Mosher et al. [2] and recently reported by Hruška et al. [30]. They comprise a coupled set of nonlinear partial differential equations describing the appropriate balance laws and algebraic equations describing chemical equilibria, which includes an unsteady electromigration–diffusion equation for each component, a charge balance with inclusion of the diffusion current (for importance, see [55]), the electroneutrality approximation, expressions for dissociation–association equilibria of weak electrolytes and amphoteric compounds, and a model for calculating protein mobilities as a function of pH and ionic strength (GENTRANS only). Because dissociation–association reactions are fast compared with the mass transport [22], ion concentrations are constrained by a coupled set of mass action relations, namely the dissociation of water, and the dissociation–association equilibria of the components. Flow (constant or time dependent) is incorporated by adding an additional term to the flux equation. The assumed plug flow with cross-sectional uniformity does not contribute to any boundary and zone dispersion. GENTRANS also includes *in situ* calculation of electroosmosis using wall titration data as input [33,34]. For each column segment, electroosmosis is calculated with the use of a pH and ionic strength dependent electroosmotic mobility and the voltage gradient. Then, in analogy to Darcy's equation, which is valid for pressure-driven flow, the bulk capillary flow is taken to be the average of all of the segment flows.

Both models are one-dimensional and based on the principles of electroneutrality and conservation of mass and charge. Isothermal conditions are assumed and relationships between the

concentrations of the various species of a component are described by equilibrium constants. Component fluxes are computed on the basis of electromigration, diffusion, and convection (imposed flow and/or electroosmosis). In GENTRANS, electrophoretic mobilities of small molecular mass components are considered to be independent of the ionic strength and temperature, but vary as a function of pH. SIMUL5 has an optional feature to account for the influence of the ionic strength on ionic mobilities and electrolyte activities. Furthermore, to save computational time, SIMUL5 calculates only the part of the column where considerable changes from the initial values are expected.

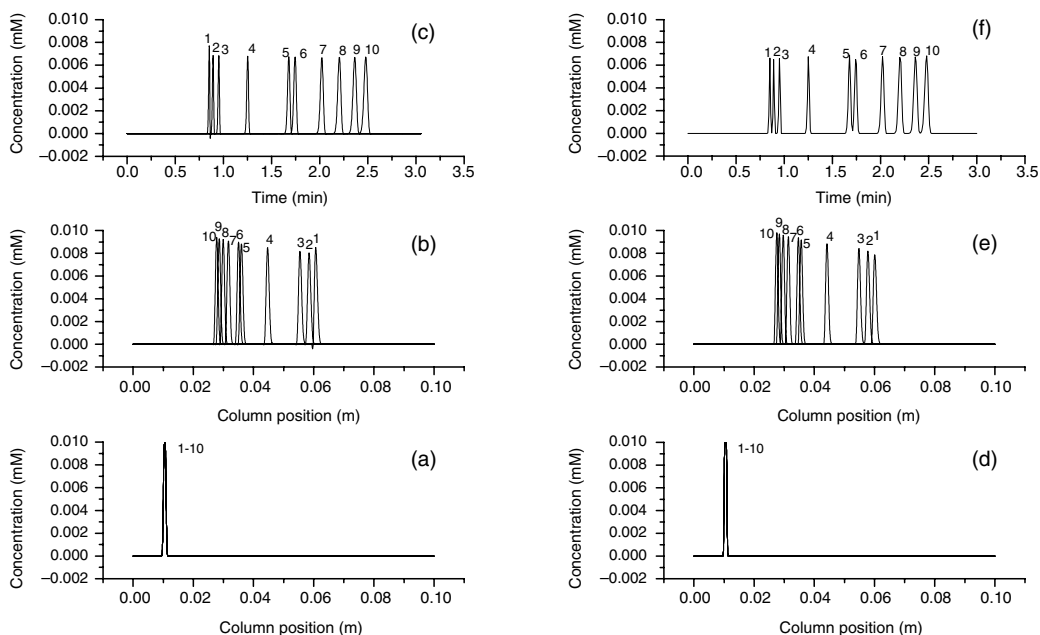

### 17.4.2 NUMERICAL IMPLEMENTATION

The complete partial differential equations are solved numerically. The spatial region is overlaid with a uniform set of grid points or segments of length  $\Delta x$  for which all properties are calculated for each time step. The numerical treatment involves replacing the spatial derivatives in the partial differential equations by finite difference approximations that yields a set of ordinary differential equations with time as the independent variable. These equations are solved using sophisticated algorithms and computer codes that enable one to use variable step sizes for the time discretization and thus control error growth. SIMUL5 solves the equations using the Runge-Kutta and predictor-corrector method by Hamming [30], whereas GENTRANS is based on the fifth order Runge-Kutta-Fehlberg time step and second order central difference spatial discretization using DAREP simulation language [2,20], an approach that was later referred to as CSD algorithm in the work of Sounart and Baygents [46]. In both models, the algebraic equations are treated with the Newton's iteration method. Eventual differences in performance of the two simulators have not been elucidated thus far although there appears to be no major difference in the predictions between the two systems for a relatively simple simulation of the capillary ZE separation of a number of inorganic and organic anions as shown in Figure 17.2. It should be noted, however, that there are some practical differences, namely the actual simulation time using GENTRANS was approximately 40 min, with another 20 min required to process the data and import it to graphing software, while SIMUL5 required approximately 3 h to perform the same simulation, although did not require postsimulation data processing to visualize the results.

### 17.4.3 BOUNDARY CONDITIONS

For each simulation, the boundary conditions have to be specified. As the models rely on cross-sectional uniformity, there is only one spatial dimension, the separation axis  $x$  to be considered. For a constant voltage simulation, the boundary conditions on the potential  $\phi(x,t)$  are  $\phi(0,t) = V$  and  $\phi(L,t) = 0$  where  $V$  is the potential and  $L$  the column length. Boundary conditions on the component concentrations at the column ends, that is, the permeabilities for the components, vary with electrophoretic technique. Both models feature the conditions for open column ends, which allow mass transport into and out of the separation space. After each step and for each component, the implemented algorithm sets the concentration at the first (last) mesh point equal to that of the second (next-to-last) mesh point. This approach accounts for changing boundary conditions at the column ends that occur when, for example, sample components are leaving the separation space. Simulations with GENTRANS can also be executed with fixed concentrations at column ends. Experimentally, this is equivalent to the presence of large electrolyte reservoirs at each column end. This choice is generally used (1) for ZE, ITP, and MBE simulations in which no sample components reach the column ends; (2) for ITP and MBE in which no buffer constituents from one electrode vessel reach the opposite side of the separation space; and (3) for IEF simulations in the presence of anolyte and catholyte whose concentrations remain unchanged at the column ends during the investigated time interval. Conditions with column ends that are impermeable to any buffer and sample compounds can also be selected. It represents a configuration having the column ends only permeable for  $\text{OH}^-$  and  $\text{H}^+$  at cathode and anode, respectively, and is equivalent to an IEF experimental system in which

**FIGURE 17.2** Simple capillary ZE separation of a mixture of inorganic anions and carboxylic acids in a MES/HIS electrolyte using SIMUL5 (panels a–c) and GENTRANS (panels d–f) under identical conditions (no EOF, same PC). Data were produced using a 10 cm length that was divided into 4000 segments ( $\Delta x = 25 \mu\text{m}$ ) with the simulation in GENTRANS featuring variable column ends and smoothing. A constant voltage of  $-2000 \text{ V}$  ( $200 \text{ V/cm}$ ) was applied and the sample initially occupied 1% of the capillary length. Panels a and d show the initial distribution of the inorganic and organic anions. Panels b and e show the column distributions 30 s after application of the voltage. Panels c and f show the detector trace constructed with the detector placed 9.5 cm from the injection end (segment 3800). For constructing the detection trace in GENTRANS, all analytes had a detector response of 1. The electrolyte consisted of 20 mM MES ( $\text{p}K_{\text{a}} = 6.095$ ,  $\mu_{\text{ep}} = 28 \times 10^{-9} \text{ m}^2/\text{Vs}$ ), 20 mM HIS ( $\text{p}K_{\text{a}} = 6.04$ ,  $\mu_{\text{ep}} = 44.7 \times 10^{-9} \text{ m}^2/\text{Vs}$ ), pH 6.06. The sample consisted of 0.01 mM of the following anions prepared as sodium salt ( $\mu_{\text{ep}} = 51.9 \times 10^{-9} \text{ m}^2/\text{Vs}$ ) in BGE. Analytes are 1 = sulphate ( $\mu_{\text{ep}} = 82.9 \times 10^{-9} \text{ m}^2/\text{Vs}$ ), 2 = chloride ( $\mu_{\text{ep}} = 79.1 \times 10^{-9} \text{ m}^2/\text{Vs}$ ), 3 = nitrate ( $\mu_{\text{ep}} = 75.1 \times 10^{-9} \text{ m}^2/\text{Vs}$ ), 4 = formate ( $\text{p}K_{\text{a}} = 3.752$ ,  $\mu_{\text{ep}} = 56.6 \times 10^{-9} \text{ m}^2/\text{Vs}$ ), 5 = iodate ( $\mu_{\text{ep}} = 42.0 \times 10^{-9} \text{ m}^2/\text{Vs}$ ), 6 = acetate ( $\text{p}K_{\text{a}} = 4.756$ ,  $\mu_{\text{ep}} = 42.4 \times 10^{-9} \text{ m}^2/\text{Vs}$ ), 7 = propanoate ( $\text{p}K_{\text{a}} = 4.874$ ,  $\mu_{\text{ep}} = 37.1 \times 10^{-9} \text{ m}^2/\text{Vs}$ ), 8 = butyrate ( $\text{p}K_{\text{a}} = 4.820$ ,  $\mu_{\text{ep}} = 33.8 \times 10^{-9} \text{ m}^2/\text{Vs}$ ), 9 = valerate ( $\text{p}K_{\text{a}} = 4.842$ ,  $\mu_{\text{ep}} = 31.6 \times 10^{-9} \text{ m}^2/\text{Vs}$ ), and 10 = caproate ( $\text{p}K_{\text{a}} = 4.857$ ,  $\mu_{\text{ep}} = 30.2 \times 10^{-9} \text{ m}^2/\text{Vs}$ ).

electrodes are used to define the ends of an electrophoresis chamber. It is also quite similar to an IEF arrangement in which (1) a cation exchange membrane is used to isolate the anode chamber from the separation space, and the analyte is an acid, and (2) an anion exchange membrane is used to isolate the cathode chamber from the separation space, and the catholyte is a base. Furthermore, GENTRANS also permits the specification of mixed boundary conditions. This selection allows the user to specify a boundary condition, either no transport or free transport of each component at both left and right boundaries.

#### 17.4.4 EXECUTION OF A SIMULATION

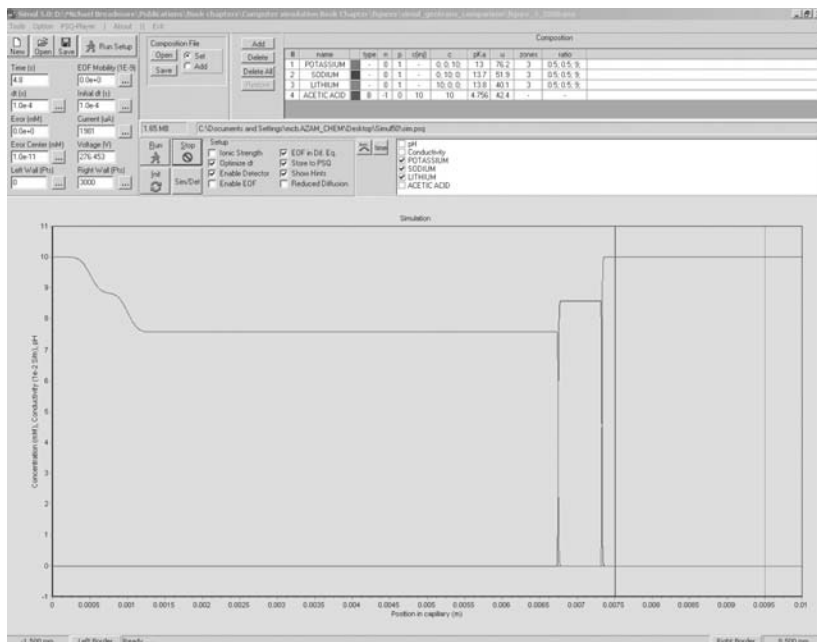

Initial conditions that must be specified for a simulation include (1) the distribution of all components, (2) the  $\text{p}K$  and mobility values of the buffer and sample constituents, (3) the diffusion coefficients and charge tables of the proteins (GENTRANS only), (4) the electroosmotic input data [constant velocity

**FIGURE 17.3** Execution time of GENTRANS under MS-DOS (MS Fortran version) as function of chip and clock speed assessed with PCs that were equipped with Intel chips for a 40 min simulation of the IEF example of Figure 17.1 under a constant current density of  $10 \text{ A/m}^2$ , a constant net EOF of  $15 \text{ }\mu\text{m/s}$  toward the cathode and fixed concentrations at column ends. A 350-fold decrease in execution time was observed with the PCs purchased during the 11-year time period. Using the FTN77 Fortran version on the Pentium PCs, execution time was found to be about half compared to that with the MS Fortran version.

value (SIMUL5 and GENTRANS) or as wall titration data for *in situ* calculation of electroosmosis (GENTRANS only)], (5) the magnitude of constant voltage or constant current density, (6) the duration of power application and the number of time points (frequency) of data storage, (7) the column length as well as its segmentation, and (8) the species permeabilities (boundary conditions) at the ends of the separation space (GENTRANS only). The programs output concentration, pH, conductivity, ionic strength, and flow (GENTRANS only) distributions, and allow the presentation of these data either as profiles along the column at specified time intervals or as temporal data, which would be produced by detectors at specified column locations, that is, segment numbers. Furthermore, they output the current density and the net flow (GENTRANS only) as functions of time. SIMUL5 also has the added option of viewing the results as an animation allowing simple visualization of the progression of the electrophoretic system.

The programs are executed on Pentium computers typically running at 233–3000 MHz. Execution time, which can vary between a few seconds and a full month, mainly depends on the PC's clock speed (Figure 17.3), the complexity of the electrophoretic situation (mainly the number of components), the applied power level, and the number of column segments. SIMUL5, which is free and can be downloaded from the web (<http://www.natur.cuni.cz/Gaš>), features a comfortable windows environment for data input, data evaluation, and visualization of the ongoing simulation, as illustrated in Figure 17.4. Furthermore, SIMUL5 features an inbuilt database of mobilities and  $\text{p}K_{\text{a}}$  values of common components as well as visualization of a completed simulation in a movie format. The GENTRANS program is somewhat older, runs in the DOS environment and exists as two versions, a low-resolution version for up to 600 segments (written in MS FORTRAN), and a high-resolution version for up to 100,000 segments (FTN77 FORTRAN). The use of GENTRANS can be learned in our research laboratories at the Universities of Bern and Tasmania.

**FIGURE 17.4** Screen capture of the windows environment of SIMUL5 performing exactly the same simulation as displayed in Figure 17.11 with a current density of  $0.0075 \text{ m}^2$ . The main panel displays the current simulation progress, and is currently only displaying the column distributions for potassium, sodium, and lithium. The vertical line at a column position of  $0.0075 \text{ m}$  is the right-hand calculation boundary, with the left-hand calculation boundary at a position of  $0 \text{ m}$ . The second vertical line at  $0.0095 \text{ m}$  is the position of the detector. The top left corner features the simulation parameters, such as time, voltage, current, and so on. The top right displays the physico-chemical properties of the buffer and sample components.

## 17.5 PRACTICAL APPLICATIONS

A considerable proportion of the published reports on the use of dynamic computer simulation software have been on the development of the simulation software itself and the agreement of the simulation with real experimental data. This is an important and essential part of the development of any theoretical system for without agreement between what is obtained in the laboratory, the knowledge gained from the simulation becomes meaningless. These applications will not be discussed here, instead, we will focus on the way in which computer simulations have been used to increase our understanding of the system and the field of electrophoretic separations. The early work is summarized in [7] and the book of Mosher et al. [2], which appeared in 1992. In examining the literature published thereafter, it has been dominated by application into a number of key areas, particularly in ITP and MBE, IEF and ZE, as well as in understanding various forms of stacking in ZE, and will be discussed under these categories. It is interesting to note that the application of simulation software seemed to peak in the mid 1990s with a number of groups working in this field, with a noticeable decline after this, until a few years ago when there was renewed interest around the world. While one may speculate about the causes, it is worthwhile noting that the past few years have seen an increasing number of applications of computer simulations in electrophoresis for two main reasons. First, with the advent of faster computers, it is possible to simulate more realistic and complex separations thus improving the quantitative prediction ability of the software and the ability to simulate a range of separations that were previously not possible. Second, the development of simple to use windows based software, such as SIMUL5, means that computer simulations are no longer restricted to highly trained researchers, but can be used by almost anyone with a basic

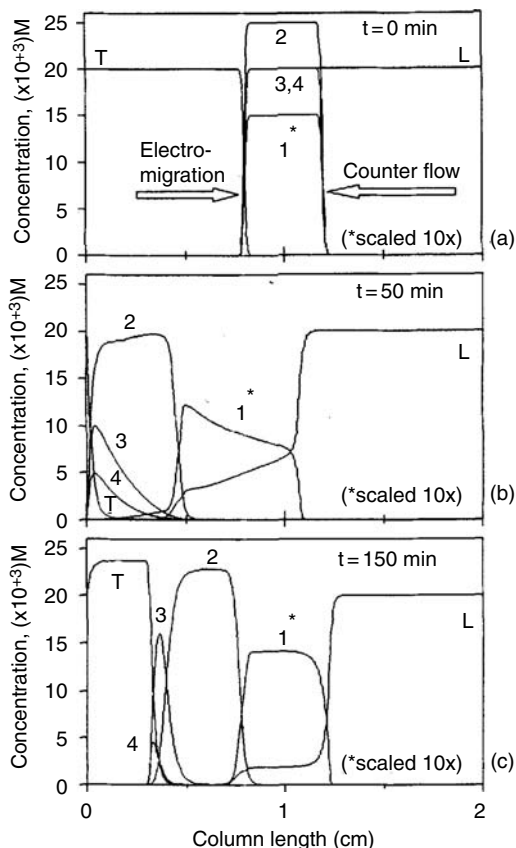

knowledge of electrophoresis. It is anticipated that this area will see considerable growth over the next few years as new and more powerful computers are used in conjunction with more sophisticated simulation software.

### 17.5.1 ISOTACHOPHORESIS AND MOVING BOUNDARY ELECTROPHORESIS

ITP is one of the oldest electrophoretic separation techniques, and as such there have been a number of simulations on ITP and the behavior of the boundaries, although many of these have been used for the verification of the simulation software and for educational purposes [2,7,8]. In one of the first nontrivial studies on ITP boundaries, Mosher et al. [56] provided the first precise description of enforced migration due to changes in pH between the leading and terminating electrolyte. A boundary with self-sharpening properties was created by a conductivity decrease across the boundary in the direction of migration due to the pH gradient, which could be used to force analytes to migrate between the two electrolytes as a result in changes in ionization (and hence, mobility). They also showed that experimentally observed “bumps” were not necessarily artifacts due to adsorption/desorption phenomena, but were due to changes in conductivity and hence a change in electric field. A similar study was later undertaken by Gaš et al. [28] using an early version of the SIMUL5 software. They also simulated the occurrence of “bumps” due to the presence of  $H^+$  or  $OH^-$  and the migration inversion of analytes depending on the pH of the electrolytes used. They concluded that in a well-buffered system, migration inversion could occur only for analytes that had a  $pK_a$  difference of approximately 0.3–1.0 pH units.

The impact of hydrodynamic flow upon the formation and stabilization of ITP zones has been examined by Deshmukh and Bier [57]. They modified the GENTRANS software to account for the addition of counter flow and found that it had no significant impact on the shape of the ITP boundary, but did have an impact on the position and could be used to effectively immobilize a particular ITP boundary. This, however, can be a problem when the counter flow is applied at the beginning of the separation as forming zones that migrate with a velocity lower than the counter flow were found to be pushed from the capillary, as illustrated in Figure 17.5. This explained experimentally observed results for the ITP stacking of serum components in which some components were not stacked appropriately. Subsequently, Mosher et al. [33] introduced equations to account for EOF, and in contrast to other available software, to also account for the variation of EOF with pH by using titration data. This was later used by Thormann et al. [58] to examine the effect of EOF on ITP and illustrate the difficulties of performing anionic ITP in unmodified fused-silica capillaries. Particularly interesting was the generation of a stationary anionic ITP boundary in which the boundary velocity was perfectly balanced by the EOF. Subsequent work by Caslavská and Thormann [59] simulated bidirectional ITP in which the EOF was used to mobilize the zones past the detector. The use of high pH electrolytes allowed both cationic and anionic ITP zones to be detected, but using a lower pH caused the formation of stationary anionic ITP zones that could not be detected without the application of hydrodynamic flow. Importantly, simulation data agreed well with the results obtained by experiment. The same was found to be true for the prediction of ITP in polymethylmethacrylate (PMMA) capillaries [54]. Furthermore, very recent work by Caslavská and Thormann [60] revealed that fused-silica capillaries double coated with Polybrene and poly(vinylsulfonate) feature a strong cathodic EOF across the entire pH range such that bidirectional ITP zone patterns at acidic pH reach the detector without the addition of imposed flow.

In a series of work, Mosher et al. [26,31,61] expanded GENTRANS to be applicable for proteins. As proteins are complicated molecules with a large number of ionizable groups, the mobility changes significantly as a function of pH and as such a table of pH titration data and diffusion constants is necessary to calculate the mobility of the protein [26]. After their initial work demonstrating the applicability to proteins, two algorithms to account for the influence of ionic strength on protein mobility were evaluated [31] with the best system subsequently used to examine the feasibility of using titration data generated from the amino acid composition and free amino acid  $pK_a$  values

**FIGURE 17.5** Selective washout of sample components during ITP due to application of a counter flow. The counter flow applied was sufficient to immobilize the leading front. For the first 50 min, the bands are pushed to the left due to the counter flow, followed by a movement to the right due to ITP adjustment. Leader (L): 20 mM cacodylic acid/Tris, pH 7.1; Terminator (T): 20 mM  $\beta$ -alanine/Tris, pH 9.1. The four sample components were (1) albumin, (2) Gly-Gly, (3) Asn, and (4) Gln. Their initial concentrations were 1.5 mM, 25 mM, 20 mM, and 20 mM, respectively. Simulation was performed under constant current density of  $20 \text{ A/m}^2$  with a separation length of 4 cm with 400 segments and an applied counter flow of  $0.47 \times 10^{-5} \text{ m/s}$ . (Reproduced from Deshmukh, R.R. and Bier, M., *Electrophoresis*, 14, 205, 1993. With permission.)

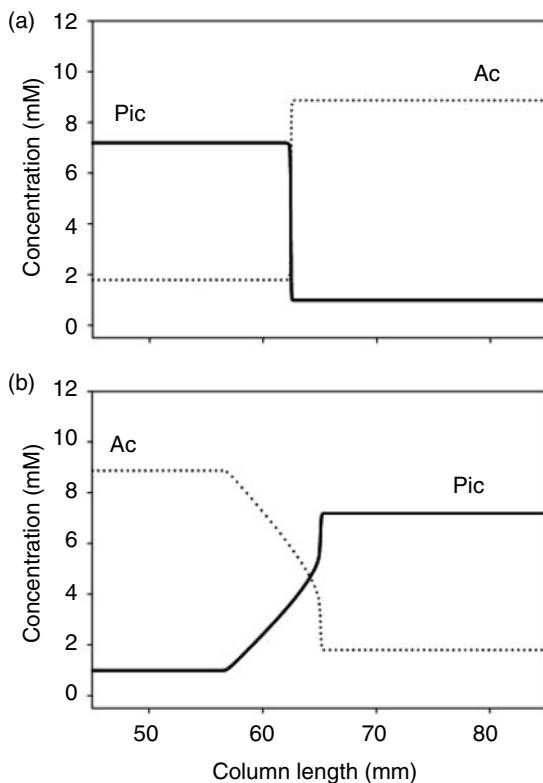

[61]. When using theoretical titration data, a different ITP order of several proteins was obtained to that observed by experiment, although this could be rectified by shifting the pH data to correct for differences between theoretical and experimental pIs. Thormann and Mosher [62] simulated two different anionic ITP systems and one cationic ITP system for the separation of proteins. In all cases, there was qualitative agreement with experimental data, although the plateau concentrations were typically lower than those observed experimentally. This was attributed to additional protein interactions that are not considered in the model. In subsequent work, Thormann et al. [63] performed simulations of ITP separations of serum albumin and compared these with experimental capillary ITP, continuous flow ITP, and recirculating flow ITP in various instruments. Distortion of protein zones found in the collected fractions of continuous flow ITP, which was not observed for low molecular mass compounds and was not observed in the simulations, was attributed to various instrument properties, such as high density/viscosity gradient formed at the buffer interfaces as well as the design of the outlet ports. This was not observed in recirculating flow ITP where faster fluid flows appeared to alleviate this problem.

In a different application, Dubrovčáková et al. [64] performed simulations of ITP separations in which a neutral complexing agent (a cyclodextrin in this case) was added to the electrolytes. Mechanistic insight into the movement of the ITP boundaries with addition of the cyclodextrin to the sample, leading and terminating electrolyte, and various combinations, was gained. Simulations also provided insight into the optimum concentration of cyclodextrin required to separate two analytes with particular interaction constants.

Assessment and characterization of the evolution of moving and stationary electrophoretic boundaries is another topic of interest in simulation [2,7,44]. As an interesting application, Foret et al. [65] investigated with GENTRANS the formation of a moving boundary induced by the liquid sheath in coupling of CE with electrospray ionization MS. When the buffer in the capillary and the liquid sheath contain different counterions, a boundary migrating from the capillary tip into the capillary is formed. Before reaching the MS interface, analytes will suddenly face another buffer composition (difference in pH, conductivity, ionic strength, etc.) and thus a change in migration that can result in delays, loss of resolution, or inversion of migration order. The authors showed that the migrating boundary can be either diffuse or sharp, depending on whether the effective mobility of the sheath liquid counterion is higher or lower than that of the buffer in the capillary. In the most recent application, Gebauer and Boček [66] used SIMUL to evaluate a new type of boundary that shows both steady-state (sharp) and nonsteady-state (diffuse) properties. After discussing the theory behind the new boundary, simulation results of a simple system comprising picrate and acetate were used to demonstrate the validity of their theory, with the new type of boundary shown in Figure 17.6b. Figure 17.6a depicts conditions in which a normal steady-state boundary is formed.

### 17.5.2 ISOELECTRIC FOCUSING

The unique and powerful nature of IEF, which comprises a complex discontinuous configuration, has ensured that there have been a number of simulations of IEF, again with the majority of those being used to validate the simulation software and to ensure that there was reasonable agreement with experimental data. The majority of these simulations were performed with a current density typically much lower than that employed in the laboratory, which provided qualitative information about the system, but could not be used in any quantitative capacity. Nevertheless, these simulations provided new insights into the separation, stabilizing, and destabilizing processes of IEF in closed columns without electrolytes, in configurations with acid and base as anolyte and catholyte, respectively, and in systems with immobilized pH gradients (for a review of that simulation work see Mosher et al. [2]). Simulations also revealed the basics of one-step capillary IEF performed in the presence of electroosmosis in fused-silica capillaries [32,53]. In 2000, Mao et al. [35] presented the first results with a new version of GENSTRANS that could handle up to 150 components and simulate IEF at experimental current densities. This allowed the simulation of a pH gradient spanning 7 pH units from 3 to 10, with the pH gradient made from 140 ampholytes, and low molecular mass amphoteric dyes as sample constituents. These simulation data were used in conjunction with whole column capillary imaging to examine the mechanism and quantitative agreement between the two. Both systems demonstrated the well-known transient “double-peak” approach to focusing with the simulation software predicting complete focusing being achieved 5 min after current application, while experimentally it was observed to be 6 min. This was remarkable agreement given that the input data (pK and mobility values) of carrier ampholytes and the dyes used were not accurately known and that the composition of the commercial ampholyte mixture is largely unknown. A subsequent study by Mosher and Thormann [67] revisited the focusing and stabilization phases of IEF. The simulation results performed at 300 V/cm suggested that focusing is complete within less than 10 min and is followed by a lengthy stabilization phase (up to 7000 min), which is characterized by changes that progress from the column ends toward neutrality and the formation of nonlinear pH gradients, as illustrated in Figure 17.7. The presence of electrolytes at the column ends disrupts the stabilizing phase, with the degree of disruption being dependent on the concentrations of the acid and base

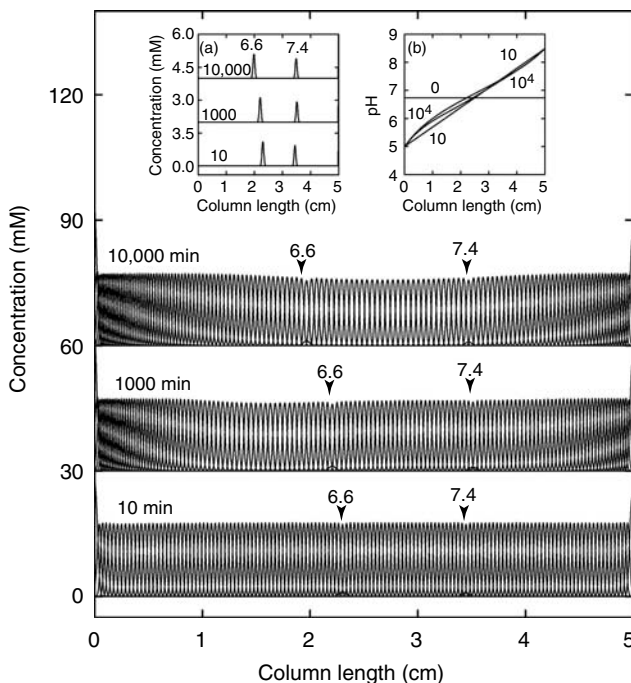

**FIGURE 17.6** Simulated picrate (solid line) and acetate (dotted line) concentration profiles evolved after 25 s of electrophoresis from initial sharp boundaries between solutions in which the molar fraction of picrate in the front and rear zone was (a) 0.1 and 0.8 and (b) 0.8 and 0.1, respectively. The simulation was performed with 6000 segments ( $\Delta x = 16 \mu\text{m}$ ) at a current density of  $4000 \text{ A/m}^2$ . (Reproduced from Gebauer, P. and Boček, P., *Electrophoresis*, 26, 453, 2005. With permission.)

of anolyte and catholyte, respectively. The data suggest that it is impossible to reach a completely stationary steady-state pH gradient when using carrier ampholyte solutions, and that the only way to achieve this is through the use of immobilized pH gradients such as those of Immobiline gels.

As GENTRANS can also handle proteins, Thormann et al. [36] performed simulations of the IEF focusing of hemoglobin variants and compared these with whole column imaging IEF (both approaches at 300 and 600 V/cm). They simulated a broad range pH gradient from 3 to 10 with 20 ampholytes per pH unit (140 ampholytes over the entire gradient) and a short-range pH gradient from 5 to 8 with 40 ampholytes per pH unit. In contrast to IEF simulations of small molecular mass compounds, the number of segments had to be increased from 1000 to 8000 in order to get smooth protein peaks, which was due to the sharper peaks produced by proteins. The authors also noted that in order to establish a smooth stepless pH gradient at experimental field strengths, it was necessary to use 40 ampholytes per pH unit to establish the focusing gradient, while previously most simulations had used at most 20. Again, agreement between experimental results with whole column imaging was obtained supporting the use of this software for studying IEF.

In their latest work, Thormann and Mosher [68] have used GENTRANS to examine IEF when sodium chloride is added to the catholyte at the beginning of the separation. This approach is a single-step approach to post focusing mobilization of the IEF gradient by the addition of salt to the cathode. Results were shown to demonstrate that proteins still focus at a pH near their pI, but that the anion flux from the addition of chloride caused the pH to be slightly lower giving all ampholytes a

**FIGURE 17.7** Computer-simulated distributions of the 140 carrier components and the three dyes for the pH 5–8.5 gradient system after 10, 1000, and 10,000 min of constant voltage application. The numbers refer to the pI values of the dyes and the arrowheads mark their locations. Successive graphs are presented with a y-axis offset of 30 mM. The insets a and b depict the concentration profiles of the pI 6.6 and 7.4 amphoteric dyes and the pH profiles, respectively, at the indicated time points. Simulations were performed with  $\Delta x = 50 \mu\text{m}$  and having column ends that are impermeable to any sample and carrier compounds. (Modified from Mosher, R.A. and Thormann, W., *Electrophoresis*, 23, 1803, 2002. With permission.)

slight positive charge and hence movement toward the cathode. The rate of movement was found to be dependent on the concentration of chloride added, with high concentrations causing more rapid movement. This also caused a gradual pH loss at the anodic end, while the cathodic end (where the salt was) remained unchanged causing a change in the profile of the pH gradient.

### 17.5.3 ZONE ELECTROPHORESIS

Simulations of capillary ZE where the sample is the only discontinuity present have appeared in the literature, but the reports are fewer than those of ITP and IEF, and are dominated by confirming the validity of the simulation model, showing the property changes across ZE zones and demonstrating the effect of electrophoretic sample concentration when the sample is administered in a matrix of reduced ionic strength [2,7,33,34,54]. Simulation of ZE is useful for designing configurations with indirect detection, for the assessment of system zones and the investigation of unusual peak forms or peak shape distortions that cannot be handled with Peakmaster [30,69–72]. Particular worthy of discussion here is the work of Ermakov et al. [73–75] on developing algorithms to describe interaction of analytes with the capillary wall and the effect that this has on peak shapes in capillary ZE. Simulations were undertaken with different levels of adsorption and desorption at different concentrations of analytes and also as a function of the adsorption capacity of the surface. Peaks shapes were then compared with experimental results to gauge the source of interaction of analytes. Small monovalent cations were found to have minimal interaction with the wall (symmetrical peak shapes and no baseline shift) while large polycations were found to have slow desorption and produced

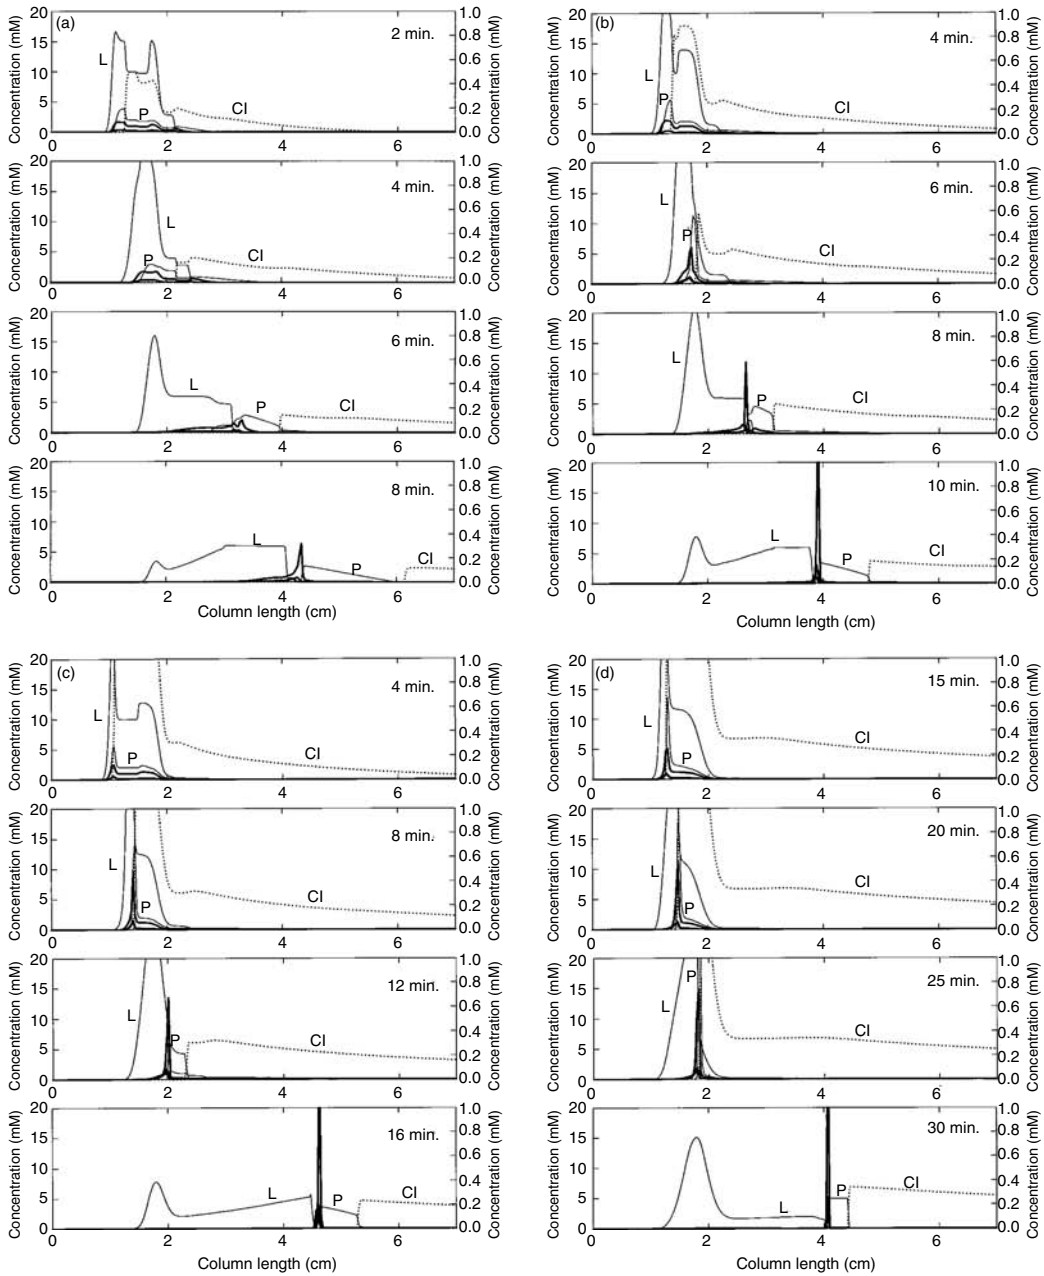

a tailed peak with a shift in baseline after the peak, consistent with simulation data in which analytes showed very slow, almost irreversible, desorption. Independent from the work of Ermakov et al., Gaš et al. [76] studied the dynamics of peak dispersion in capillary ZE with wall adsorption using a simulation model that accounts for linear and nonlinear adsorption isotherms together with slow and fast sorption rates. Furthermore, options in electrolyte systems for online combined capillary ITP and ZE were investigated theoretically and verified by computer simulation using GENTRANS [77].

#### 17.5.4 tITP STACKING

The combination of capillary ITP and ZE has long been recognized as an ideal approach to improve the sensitivity of problematic samples, particularly those with significant ionic strength. For biological and environmental samples such as serum, urine, and seawater, the presence of high concentrations of chloride is perfect to function as a suitable leading electrolyte for the ITP step, and all that is required is to ensure that an appropriate terminator is used and that there is sufficient time to complete the ITP stage and then to destack and separate the components by capillary ZE. tITP systems with samples naturally abundant in chloride have been the basis of several significant experimental and computational studies, the most significant belonging to Gebauer et al. [78] for the analysis of biological samples by tITP, or sample self stacking as referred to by these authors. Their first report in 1992 presented a simple theory to provide explicit description of various zone parameters such as detection time, variance, and resolution, which was confirmed by computer simulation using the GENTRANS software. This was later continued to look at the concentrations of components required to induce tITP stacking, with the concentration of the sample macrocomponent or stacking ion required to be above a critical concentration [79]. This concentration is a function of the buffer co-ion concentration in the sample and the mobilities of the buffer co-ion, sample macrocomponent, sample minor component, and the counterion. Simulations were undertaken to show when stacking does and does not occur as a function of this ratio. Results were also presented illustrating that the closer the mobility of the minor component to the stacking macrocomponent, a higher critical concentration of macrocomponent is required to induce efficient stacking. Later work focused on simulating the effect of multiple macrocomponents upon stacking and conditions under which one of them would function as a destacker [80]. There was again found to be a critical concentration of both the stacking and destacking macrocomponents, with this ratio only a function of the mobilities of the ions within the system. Above this ratio, the destacker is actually stacked also facilitating stacking of the minor components. Using the concepts of this system, Křivánková et al. [81] performed simulations to examine the conditions required to induce tITP stacking of minor components in serum (citrate, maleate, and acetoacetate), at various ratios of the destackers (phosphate and lactate), with simulation results for different amounts of salt in the sample shown in Figure 17.8. Simulation data demonstrated that 50 mM Cl or more was sufficient to induce ITP stacking in all possible phosphate and lactate concentrations found in human serum and could therefore be used for the analysis of plasma and serum samples from patients with a number of disorders. Their latest work used SIMUL to examine the properties of borate buffers and ways in which tITP stacking could be induced for samples with a high concentration of NaCl [82]. They examined two approaches, first, the addition of a suitable terminating ion (MOPS) to allow borate to function as the leader, and second, the use of ammonium as the counterion that reduced the mobility of hydroxide, allowing chloride to function as the leader, and borate to function as the terminator. Both approaches were able to provide suitable tITP stacking of minor components and were found to agree well with experimental approaches.

In the area of environmental analysis, Hirokawa et al. [83] used SIMUL to simulate the electrokinetic injection of cations with and without the hydrodynamic injection of potassium acetate. Not

**FIGURE 17.8** Simulated concentration profiles at the given four time points for the sample containing (a) 10 mM, (b) 20 mM, (c) 40 mM, and (d) 100 mM chloride. Left concentration axis relates to the macrocomponents chloride (Cl, dotted line), phosphate and lactate (P and L, respectively, both thin lines). Right concentration axis relates to the microcomponents citrate, malate, and acetoacetate (thick lines). Simulations were performed with  $\Delta x = 62 \mu\text{m}$  at a field strength of 40.54 V/cm. (Reproduced from Křivánková, L., et al., *Electrophoresis*, 24, 505, 2003. With permission.)

surprisingly, much better preconcentration was obtained for cations with a mobility faster than the mobility of the electrolyte co-ion with the injection of potassium as this functioned as a leading ion for tITP. Following this, they presented results for the simulation tITP stacking of iodide in seawater. Simulation data showed that the sample of unbuffered seawater maintains a high pH during ITP and therefore a suitable terminator with a low mobility at this pH was necessary, although it should be noted that practically seawater is actually buffered slightly by the presence of carbonate and borate. On the basis of these results, the authors used 500 mM MES at pH 6.0 as the terminating electrolyte that showed excellent stacking of an analyte with a mobility of  $30 \times 10^{-9} \text{ m}^2/\text{Vs}$  (approximating the mobility of iodide after ion association with CTAC).

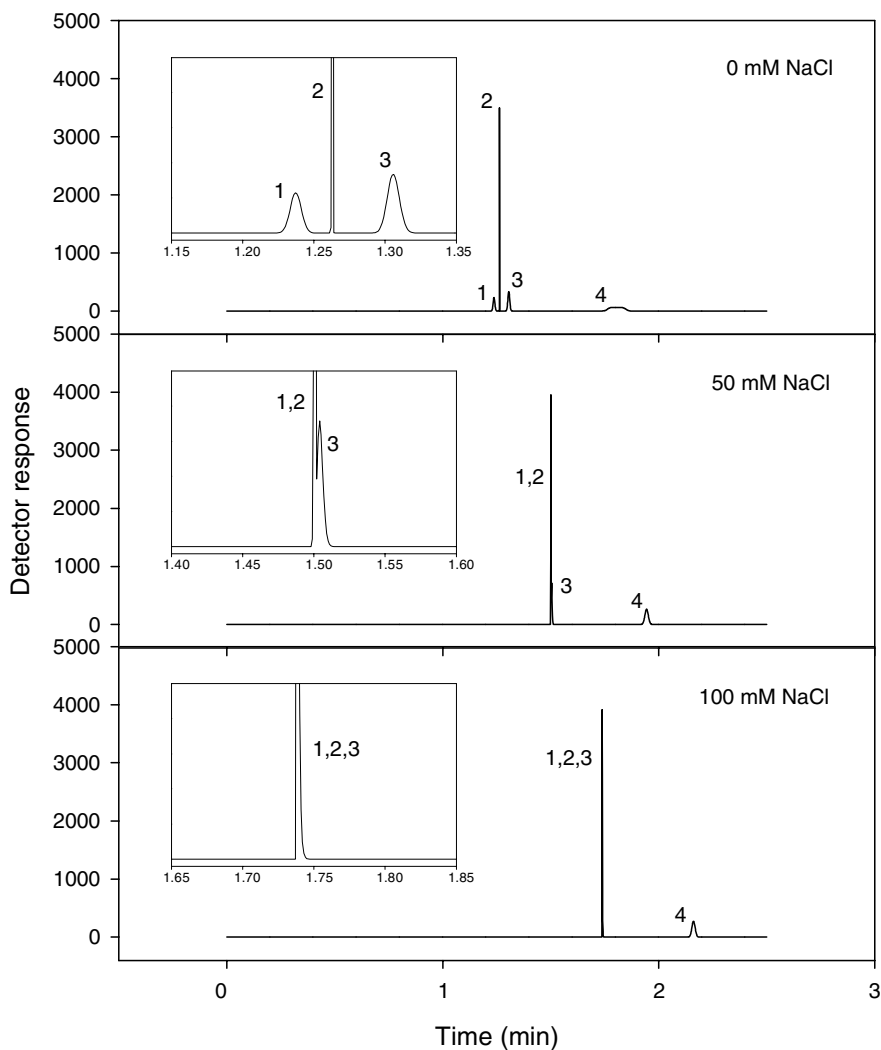

The only other report of note in the area of tITP is that by Schwer et al. [29] who used an early version of SIMUL to examine tITP stacking with a discrete pH difference between the leading and terminating electrolytes. Dissipation of the pH difference was used to increase the mobility of the cationic terminator thus shifting the separation from ITP stacking to ZE separation. A simplified system involving the injection of a high pH terminator before the sample using a low pH terminator was developed and showed to be suitable for the stacking of a tryptic digest of  $\alpha$ -caesin.

### 17.5.5 pH STACKING

An alternative approach to stacking components in highly saline samples is through the use of a pH discontinuity between the sample and the electrolyte to stack ionizable analytes. This is similar to the enforced migration method examined by Mosher et al. [56] discussed above, although in this case it is transient in nature and is destroyed before migration by capillary ZE. Kim et al. [84] used SIMUL to simulate the formation and movement of a pH boundary and its influence on stacking weak acids. The pH boundary eventually dissipates allowing stacked analytes to be separated according to their electrophoretic mobility. Simulations also explained the experimental observation of an improvement in stacking of *m*-nitrophenol with increasing injection volume, which was related to the velocity of the stacking pH boundary and the length of time before dissipation and hence, destacking of the analytes.

Shim et al. [85] used their own program for the simulation of stacking weak acids (such as fluorescein) in buffered and unbuffered saline samples. Buffered saline samples showed stacking via tITP, while in unbuffered samples (NaCl in water) the rapid exit of the matrix ions from the sample caused a localized pH change to maintain electroneutrality thus creating an additional pH boundary. This pH boundary was restricted to the initial position of the sample injection and merged with a migrating tITP boundary induced by the high concentration of Cl. Thus, analytes were initially stacked on both sides of the sample zone and merged into a single focused zone in a fashion similar to the transient “double peak” mechanism observed in IEF.

In the above two simulations, stacking was simulated for one analyte and the magnitude of the pH boundary was only several pH units. Breadmore et al. [86] used GENTRANS to simulate the stacking of 24 weak bases of different mobility and  $\text{p}K_a$  in which the sample had a pH almost 7 units higher than that of the electrolyte. The influence of the addition of a high concentration of sodium chloride to the sample was also examined, with simulation results demonstrating that the movement of the boundary can be influenced by the addition of sodium chloride to the sample. Upon the addition of 100 mM NaCl, a significant reduction in mobility of the boundary was observed allowing bases with a much lower mobility to be focused. However, one of the limitations of lowering the mobility of the boundary in this fashion is that it causes prolonged migration of the boundary itself, which can result in analytes migrating through the entire capillary as focused bands, as shown in Figure 17.9. Care must therefore be taken to allow sufficient time for the boundary to dissipate and the analytes to destack.

**FIGURE 17.9** Simulated detector response for the separation of four weak bases ( $pK_a = 4.5$ ) after stacking with a transient pH boundary without and with the addition of NaCl to the sample zone. Buffer: 65.6 mM formic acid, pH 2.85, with NaOH. Sample: 65.6 mM formic acid, pH 8.60 adjusted with NaOH, 0, 50, or 100 mM NaCl and the four bases ( $5 \mu\text{M}$  each). Insets show a close-up view of the peaks 1–3. Voltage 400 V/cm. Detector location 5 cm. Peaks are (1)  $25 \times 10^{-9} \text{ m}^2/\text{Vs}$ , (2)  $20 \times 10^{-9} \text{ m}^2/\text{Vs}$ , (3)  $15 \times 10^{-9} \text{ m}^2/\text{Vs}$ , and (4)  $10 \times 10^{-9} \text{ m}^2/\text{Vs}$ . ### 17.5.6 MISCELLANEOUS APPLICATIONS

Tesařová et al. [87] used a modified version of SIMUL, which they called SIMULMIC to simulate the separation of neutral analytes in a system with a neutral cyclodextrin and anionic micelles. A number of systems were examined in which various combinations of the inlet and outlet vials and the capillary itself were filled with cyclodextrin. Simulation results were used to examine the micellar/cyclodextrin boundary at various times and concentrations although no simulation results for a chiral separation were reported. To the best of our knowledge, this is the only dynamic simulation of an electrokinetic chromatography (EKC) separation to date.

Several reports have been presented to simulate capillary affinity electrophoresis (CAE) under equilibrium (complex is formed with ligand in the electrolyte and migrates in an equilibrium state) and nonequilibrium (ligand is not in the electrolyte allowing the complex to dissociate during separation) conditions [88–90] using binding constants and association/dissociation rate constants. Because of the added complexity of the additional equations, implementation often involves simplification by assuming no changes in the electrolyte macrocomponents and hence no change in pH or conductivity, thus only allowing more limited simulations to be performed. Nevertheless, these simulators can successfully predict peak shapes in CAE, and as was demonstrated by Okhonin et al. [90] can be used to determine the binding and rate constants by using nonlinear regression to fit the experimental separation to that predicted with the CAE software.

SIMUL5 has been used to study oscillation patterns that occur in background electrolytes with complex eigenmobilities when they are subjected to an electric field [91]. For a system composed of 0.21 mM sebacic acid and 0.323 mM imidazole, simulation revealed the production of local  $10^{-12}$  mM perturbations of the imidazole concentration, which exponentially grew as long as the system was in the region of complex eigenmobilities. This unusual behavior could be experimentally validated and is thus not a simulation artifact.

## 17.6 METHODS DEVELOPMENT GUIDELINES

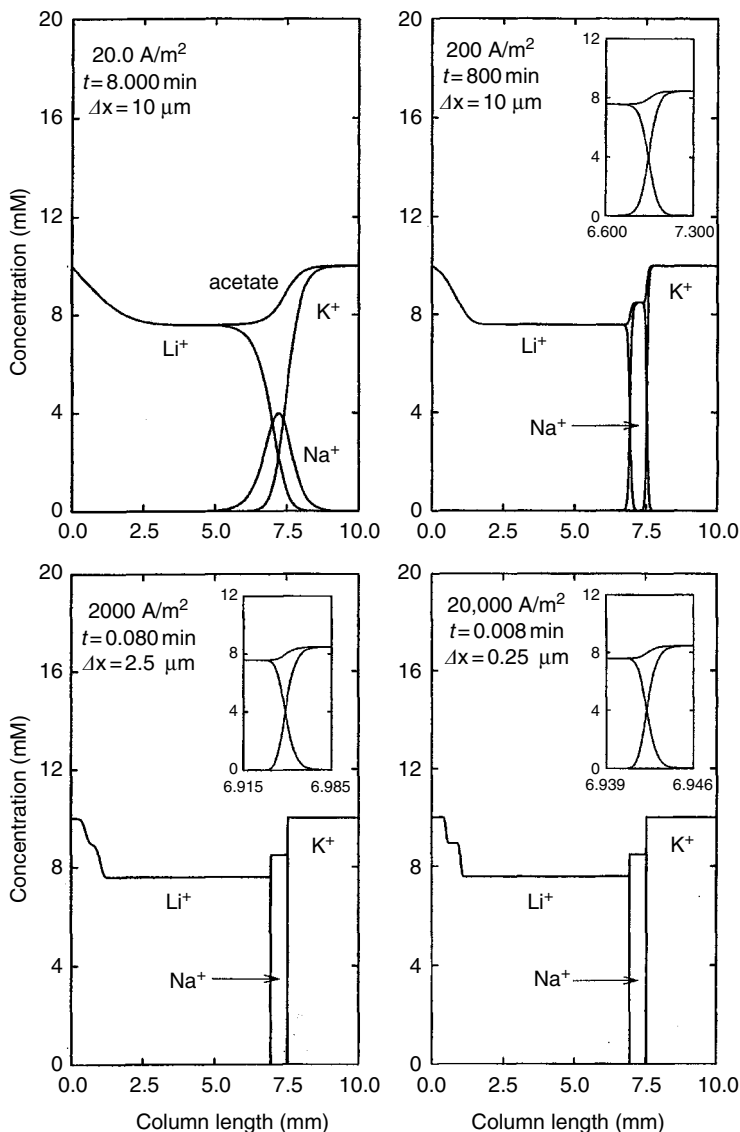

In performing a simulation, there are some points that the researcher must understand in order to maximize the utility of their simulation. Selection of the simulation parameters, such as the number of segments and the applied power level, is crucial for success. These aspects are visualized with the following simple example, which represents the simulation of the ITP zone formation of sodium between potassium (leader L) and lithium (terminator T) with acetate as the counterion (Figure 17.10). This simulation was performed in a 1 cm column that was divided into 2000 segments of equal length ( $\Delta x = 5 \mu\text{m}$ ) and having a constant current of  $200 \text{ A/m}^2$ . All initial concentrations are 10 mM and the sample occupies 5% of column length (between 5% and 10%, bottom graph of left panel of Figure 17.10). Upon application of power, the sodium zone becomes adjusted within about 0.1 min (right panel of Figure 17.10) to a concentration of 8.48 mM as it gradually penetrates into the space originally occupied by the leader where it continues to migrate between potassium and lithium. The same applies to lithium, the terminating constituent, which becomes adjusted to a concentration of 7.59 mM. Thereafter, the entire zone structure is migrating at a constant velocity and without change of the zone structure toward the cathode (left panel of Figure 17.10). The corresponding zone distribution after 0.08 min (4.8 s) at  $2000 \text{ A/m}^2$  obtained with SIMUL5 is shown in Figure 17.4. The migrating boundaries between the alkali metal ions are sharp, steady-state transitions whose widths are dependent on the applied power level. At a low power, electrophoretic boundaries are rather broad and easy to treat with a relatively low number of segments. Before the availability of fast computers, this was the rule rather than the exception [2,7]. SIMUL5 and GENTRANS are capable of handling high power levels. The example presented in Figure 17.11 illustrates the impact of current density on the ITP zone boundaries in the configuration of Figure 17.10. Having  $20 \text{ A/m}^2$  (electric field  $E = 1.79 \text{ V/cm}$ ) results in broad boundaries and simulation predicts that there is insufficient sodium to produce an ITP zone with a plateau concentration (upper left graph of Figure 17.11). The opposite is true with an increase of the current density to  $200 \text{ A/m}^2$  ( $E = 17.9 \text{ V/cm}$ , upper right graph),  $2000 \text{ A/m}^2$  ( $E = 179 \text{ V/cm}$ , lower left graph), and  $20,000 \text{ A/m}^2$  ( $E = 1787 \text{ V/cm}$ , lower right graph), conditions with much sharper boundaries and 10-, 100- and 1000-fold, respectively, faster solute transport. The latter two examples were simulated at power levels that are typically used in experiments. ITP boundaries between the alkali metal ions of our example are predicted to be in the order of 350, 35, and  $3.5 \mu\text{m}$ , respectively (Figure 17.11, insets depict the sodium–lithium transitions at elongated  $x$ -axis scales), that is, boundary width is indirectly proportional to the current density which is in agreement with previous knowledge [92]. The transition between potassium and

**FIGURE 17.10** Computer predicted ITP zone formation with sodium as sample (S) between potassium (leader L) and lithium (terminator T) and having acetate as counter component and no electroosmosis. Data were produced with GENTRANS using a column of 1 cm length that was divided into 2000 segments ( $\Delta x = 5 \mu\text{m}$ ), fixed concentrations at column ends and no data smoothing. A constant current density of  $200 \text{ A/m}^2$  was applied and the sample initially occupied 5% of column length. Left-hand graphs depict concentration distributions at 0, 0.2, 0.4, 0.6, and 0.8 min after current application. Right-hand graphs depict the dynamics of the formation of the migrating sodium ITP zone with concentration profiles after 0.02, 0.04, 0.06, 0.08, and 0.1 min. The cathode is to the right. The mobilities of potassium, sodium, and lithium were taken as  $7.91 \times 10^{-8} \text{ m}^2/\text{Vs}$ ,  $5.19 \times 10^{-8} \text{ m}^2/\text{Vs}$ , and  $4.10 \times 10^{-8} \text{ m}^2/\text{Vs}$ , respectively. The  $\text{p}K_a$  and mobility of acetic acid were 4.76 and  $4.12 \times 10^{-8} \text{ m}^2/\text{Vs}$ , respectively.

sodium is somewhat sharper than that between sodium and lithium. The reason for this is the smaller conductivity change across the latter boundary (Figure 17.12, right panel).

Using insufficient number of segments, there is a risk of numerical oscillations that are seen in all profiles, including concentration, conductivity, and pH distributions. This is illustrated with the data presented in Figure 17.12 that were generated with  $2000 \text{ A/m}^2$ . Strong oscillations are obtained for a simulation with 1000 segments ( $\Delta x = 10 \mu\text{m}$ , left graph in Figure 17.12). With 2000 segments ( $\Delta x = 5 \mu\text{m}$ , center graph in Figure 17.12), much smaller oscillations are predicted, whereas 4000 segments led to smooth transitions ( $\Delta x = 2.5 \mu\text{m}$ , right graphs in Figure 17.12). It is important to realize, however, that this is at the expense of simulation time. For a total of 0.1 min electrophoresis time, the simulations performed on a Pentium IV 2.4 GHz PC lasted 2.45, 7.20, and 20.68 min, respectively, suggesting that doubling the grid requires 2.9-fold longer simulation time intervals.

**FIGURE 17.11** ITP simulation of the system of Figure 17.10 at different constant current densities of  $20 \text{ A/m}^2$  (upper left graph),  $200 \text{ A/m}^2$  (upper right graph),  $2000 \text{ A/m}^2$  (lower left graph), and  $20,000 \text{ A/m}^2$  (lower right graph) with data shown for 8 min, 0.8 min, 0.08 min, and 0.008 min, respectively. The insets depict the sodium-lithium transitions on elongated  $x$ -axis scales. Data were produced with GENTRANS without smoothing using 1000, 1000, 4000, and 40,000 segments, respectively.

On the other hand, the simulation at  $200 \text{ A/m}^2$  and 1 min of electrophoresis time (Figure 17.10) executed on a Pentium 233 MHz PC with 1000, 2000, and 4000 segments required 0.27, 2.0, and 16.5 h, respectively. For this case, execution time was found to increase about eightfold with doubling of the mesh. This illustrates that simulation time intervals are also hardware dependent. It should also be noted that the alternative to increasing the mesh size is to restrict the magnitude by which the step size  $dt$  can change. This can be used successfully to overcome floating-point errors that result from numerical oscillations, however, this also obviously results in an elongation in simulation time.

**FIGURE 17.12** ITP simulation data at  $2000 \text{ A/m}^2$  of the system of Figure 17.10 using 1000 (left graphs), 2000 (center graphs), and 4000 (right graphs) segments. Concentration, pH, and conductivity data shown are for 0.08 min and were obtained with GENTRANS without application of data smoothing.

While no quantitative study has been undertaken, this approach can often be quicker than doubling the number of segments.

Instead of an increased mesh, other algorithms have been tested in various laboratories as is discussed in depth by Sounart and Baygents [46]. None of the proposed procedures, however, was found to provide data without undesired boundary distortions in a much reduced time interval. Instead, GENTRANS is having an optional smoothing algorithm that removes negative concentrations caused by numerical oscillations. Using smoothing will decrease accuracy and creates the potential for nonphysical results to be produced. If smoothing is used and data are obtained that are suspected to be nonphysical, that is, behavior not expected to occur in an experiment, the simulation should be repeated without invoking smoothing, and the results compared to the suspect data. The data presented in Figure 17.13 illustrate the impact of the smoothing option for the simulation of a ZE separation of five dipeptides that are negatively charged in the CHES buffer at pH 9.5. Without smoothing, peptides 2–4 show oscillations with negative concentrations at the rear ends of their peaks (shown for 10 and 20 min of power application, left-hand graphs). These are not observed anymore when smoothing is used (right-hand graphs). Smoothing is thereby shown that such a simulation can be executed with a relatively large mesh size ( $\Delta x = 166.7 \mu\text{m}$ ), that is, a low number of segments that results in a rather fast simulation.

While there has been a significant improvement in computer hardware over the past decade, it is still necessary to note that due to the intimate relationship between the length of the capillary, number of segments, and current density or applied electric field strength, there are still some laboratory experiments that are difficult to simulate. These are typically those that employ very high current densities (approaching  $45,000 \text{ A/m}^2$ , which translates to a current of  $88 \mu\text{A}$  in a  $50 \mu\text{m}$  ID capillary, or  $200 \mu\text{A}$  in a  $75 \mu\text{m}$  ID capillary) in which there is a self-sharpening discontinuity. These are frequently encountered when trying to simulate various stacking methods, which are difficult to simulate at realistic currents unless short capillaries, typically in the order of several cm, with several thousands (typically 20,000) segments, are used. Longer capillaries or fewer segments

**FIGURE 17.13** Simulation of the ZE separation of five dipeptides in a 20.0 mM CHES/9.457 mM NaOH buffer at pH 9.5 and without electroosmosis using GENTRANS without (left-hand graphs) and with (right-hand graphs) data smoothing. Data were produced using a column of 10 cm length that was divided into 600 segments ( $\Delta x = 166.7 \mu\text{m}$ ) and fixed concentrations at column ends. A constant voltage of  $-145 \text{ V}$  (current density of  $-100 \text{ A/m}^2$ ) was applied and the sample was applied as Gaussian peak (0.1 mM peak height each, half width of 10 segments) superimposed onto the buffer at 10% of column length. Sample distributions after 0, 10, and 20 min of power application are shown with a y-axis offset of 0.06 mM between graphs. The anode is to the right. Key: 1,  $\beta$ -ala-his ( $\text{p}K_{\text{a}}$  values: 2.73, 6.87, 9.73; mobility:  $2.14 \times 10^{-8} \text{ m}^2/\text{Vs}$ ); 2, lys-glu ( $\text{p}K_{\text{a}}$  values: 2.93, 4.47, 7.75, 10.5; mobility:  $1.96 \times 10^{-8} \text{ m}^2/\text{Vs}$ ); 3, his-gly ( $\text{p}K_{\text{a}}$  values: 2.40, 5.80, 7.82; mobility:  $2.26 \times 10^{-8} \text{ m}^2/\text{Vs}$ ); 4, asp-his ( $\text{p}K_{\text{a}}$  values: 2.45, 3.02, 6.82, 7.98; mobility:  $1.81 \times 10^{-8} \text{ m}^2/\text{Vs}$ ); 5, asp-gly ( $\text{p}K_{\text{a}}$  values: 2.10, 4.53, 9.07; mobility:  $2.46 \times 10^{-8} \text{ m}^2/\text{Vs}$ ). The  $\text{p}K_{\text{a}}$  and mobility values of the weak acid CHES were 9.55 and  $2.31 \times 10^{-8} \text{ m}^2/\text{Vs}$ , respectively. The mobility of sodium was  $5.19 \times 10^{-8} \text{ m}^2/\text{Vs}$ .

cause undesirable oscillations, and while this can be avoided by lowering the current density, it again deviates from the situation encountered in the laboratory. A version of GENTRANS has been created that can handle up to 100,000 segments while SIMUL has no apparent restriction on the number of segments, potentially allowing simulations to be performed with capillary lengths typically used in the laboratory at experimentally used electric field strengths (up to 1000 V/cm), however as noted above, doubling the number of segments increases the computational time by a factor of 4–8, meaning current simulations with 20,000 segments taking 18 days, would stretch out to 72–144 days (about 2.5–5 months!). While it is expected that the advent of newer computers will continue to push the boundaries of simulation software, it will necessitate revision of the software itself, particularly to make use of multiprocessor computers that are now becoming commonly available in desktop computers.

Finally, it should be noted that there are a number of essential requirements that need to be reported to allow others to repeat a particular simulation. Obviously, the software and the version are important as are the input data used to describe the components ( $\text{p}K_{\text{a}}$  values, mobilities, and concentrations), but it is often the overlooked parameters that can mean the difference between successfully repeating a simulation. The length of the capillary ( $L$ ) and number of segments (either as the number of segments,  $n$ , or the mesh size,  $\Delta x$ ), the current density and the voltage, and the initial step size ( $dt$ ) and whether there are any restraints on these should always be given. Also

important is the position and distribution of the components, particularly the presence of boundaries, which should be given with their position as well as their width. In principle, simulations can be performed at constant voltage or constant current density. For simulations comprising boundaries with a steady-state shape, such as ITP, simulations with constant current density rather than constant voltage might be preferred as the width of a steady-state boundary is current dependent.

## 17.7 CONCLUDING REMARKS

The state of dynamic computer simulation software has progressed significantly over the past two decades. Software is available that will simulate electrophoretic systems including MBE, ZE, ITP, and IEF under almost exactly the same conditions used in the laboratory, and this has been used to show the detailed mechanisms of many of the fundamental phenomena that occur in a simple electrophoretic separation. A detailed insight into a number of electrophoretic processes has been achieved and this is having a significant impact on designing new and improved electrophoretic systems. Noticeably absent is the inability of the current software to simulate EKC and electrochromatography (EC), and while the underlying algorithms of the current software is applicable to these forms of CE, the necessity of adding more equations and constants to describe the additional equilibria that necessitates an increase in computation time, and is likely to be the reason this has not been implemented to date. This will change over the coming years as improvements in computer hardware will result in a decrease in total simulation times and will make it feasible to complicate the system by introducing additional equilibria to account for other modes of electrophoresis making it possible to simulate even more varied and complex CE separations. Furthermore, two- and three-dimensional dynamic simulation models will have to be developed that permit simulations in capillaries and microchannels of different shapes and geometries.

It is important to mention that dynamic electrophoretic simulations are relevant for separations on any scale and instrumental format, including free-fluid preparative, gel, capillary, and chip electrophoresis. Separations in the minute to subsecond time domains (Figure 17.11) can thereby be assessed. Electrophoretic modeling is extremely flexible. In addition to the classical electrophoretic modes (MBE, ITP, ZE, and IEF), it has been used to examine the behavior of systems containing arrays of fixed charges such as immobilized pH gradients or the presence of ion exchange membranes [1,2]. CE performed in capillaries and microchannels (chips) benefits from computer modeling as simulation is well suited (1) to develop/modify buffer systems, including those employed for indirect and conductivity detection (determination of the impact of the sample on background buffer composition); (2) to study the effects of sample composition on sample concentration/migration for different injection procedures; (3) to determine the effect of a pH change on migration/separation; (4) to investigate system peaks, unusual sample peaks, and buffer oscillations; (5) to explore combinations of electrophoretic modes, including ITP/ZE separations and mobilization in IEF; and (6) to elucidate the impact of EOF on separations in discontinuous buffer systems (ITP and IEF), to name a few. Furthermore, it allows to predict the impact of various modifications on the electrophoretic behavior of peptides and proteins, including genetic mutations/modifications, chemical modifications such as deamidation during downstream processing, changes in amino acid composition, stripping of tightly bound, charged small ion cofactors, and binding of metal ions. This and other areas of application, including the prediction of enantioselective and other affinity separations, will be explored on a broad basis by dynamic electrophoretic simulation in the not too distant future.

## 18.1 INTRODUCTION

Joule heating is an unavoidable phenomenon in capillary electrophoresis (CE) and results from resistive heating that occurs when an electric current ( $I$ ) flows through the electrolyte when a potential difference is applied. The increase in conductivity with temperature results in a positive feedback

effect in which the current increases until a steady state is reached. This may even cause the electrolyte to boil or superheat: this is known as autothermal runaway [1]. Temperature control is usually employed in CE to aid heat dissipation and provide acceptable precision, but measurement of the electrolyte temperature is often overlooked. In some older systems, only ambient temperature operation was available, with or without fan-forced airflow. The temperature of the electrolyte affects its viscosity ( $\eta$ ), its dielectric constant ( $\epsilon_r$ ), and the zeta potential ( $\zeta$ ) [2], which affect the precision of migration times through the effect of  $\eta$ ,  $\epsilon_r$ , and  $\zeta$  on the electroosmotic mobility ( $\mu_{\text{eof}}$ ) and the electrophoretic mobility ( $\mu_{\text{ep}}$ ). Even small changes in temperature can cause significant deviations in migration times [3]. The electrolyte temperature also has a major influence on peak broadening [4–6], such that separation efficiency generally decreases with increasing temperature. Radial temperature differences in the electrolyte result in viscosity differences across the capillary with analytes traveling faster in the warmer, lower viscosity zone near the axis of the capillary than in the cooler zones near the capillary wall [5]. Axial temperature differences that result from the layout of the instrument [7], and differences caused by variations in conductivity as the sample migrates through the electrolyte, also increase dispersion effects [6].

This chapter discusses the phenomena of Joule heating, heat dissipation, estimation of the electrolyte temperature and its effects, and extends the discussion of Nelson and Burgi [3] provided in the first edition of this book. The focus of this chapter is on the use of simple methods to determine the temperature of the electrolyte, free from the influence of Joule heating. An improved understanding of the radial temperature profile that exists during electrophoresis [8] allows a simple technique to be introduced for evaluating the heat transfer coefficient for an instrument.

## 18.2 HEAT GENERATION

### 18.2.1 THEORY

A significant number of authors have modeled the theory of heat generation and heat dissipation in CE [4,9–13]. The rate of Joule heating ( $P$ ), which is the resistive heating power that occurs when an electric current ( $I$ ) flows through the electrolyte, can be quantified simply using the following equation:

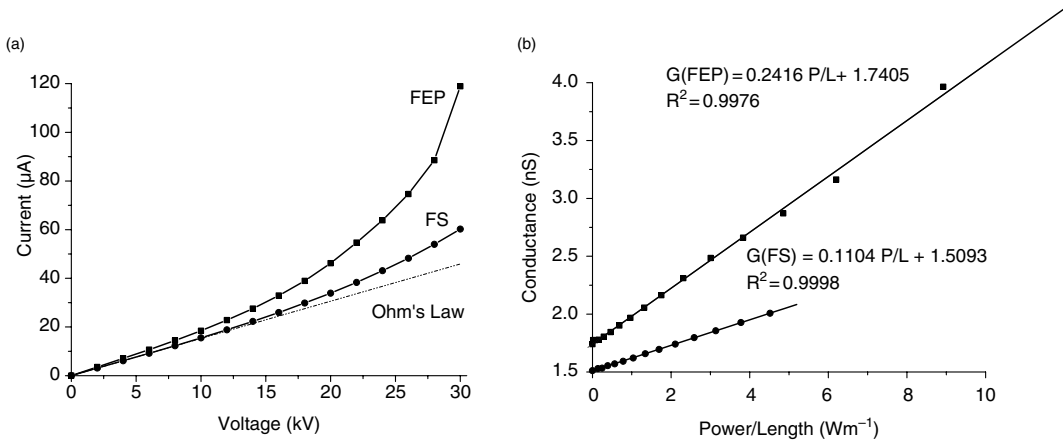

$$P = IV, \quad (18.1)$$

where  $V$  is the applied voltage. If the current is measured in microamperes ( $\mu\text{A}$ ) and the voltage is measured in kilovolts (kV),  $P$  will be measured in milliWatts (mW). Instead of  $P$ , the power per unit length ( $P/L$ ) is generally used to take the length of the capillary into account.

Traditionally, it has been suggested that a graph of current versus voltage should be constructed for an electrolyte to characterize the CE system. In Figure 18.1a, an Ohm's Law plot is given for a fused-silica (FS) capillary and for a fluorinated ethylene-propylene (FEP) capillary. The greater the deviation of the curve from the Ohm's Law plot, the less efficient is the cooling system. However, assignment of the voltage at which the deviation of the curve from the Ohm's Law plot becomes excessive is somewhat arbitrary, although this is sometimes used as a guide for maximum operating potential.

A more useful plot to characterize the CE system is a graph of conductance ( $G$ ) versus the power dissipated per unit length as this can provide information about the increase in the buffer temperature, the internal radius of the capillary, and the cooling efficiency of the instrument. Conductance varies linearly with temperature, making it very useful as a probe for the average electrolyte temperature in the capillary. A detailed description is provided in Section 18.4.2.

Equation 18.2 shows that conductance is the reciprocal of resistance and can be found by dividing the current by the voltage, parameters that can be easily monitored and recorded

**FIGURE 18.1** Graphs of (a)  $I$  vs.  $V$  and (b)  $G$  vs.  $P/L$  for different capillaries of equal length. Conditions:  $L_{\text{tot}} = 41.0$  cm fused-silica (FS)  $d_i = 74.0$   $\mu\text{m}$ ,  $d_o = 362.8$   $\mu\text{m}$  and fluorinated ethylene-propylene copolymer (FEP)  $d_i$  80  $\mu\text{m}$ ,  $d_o \approx 370$   $\mu\text{m}$ . Electrolyte: 10 mM phosphate buffer at pH 7.21.

during the course of a separation.

$$G = \frac{I}{V}. \quad (18.2)$$

If the current is measured in  $\mu\text{A}$  and the voltage is in kV, the conductance is determined in nanoSiemens ( $\text{nS} = 10^{-9} \text{AV}^{-1} = 10^{-9} \Omega^{-1}$ ). Plots of  $G$  versus  $P/L$  for a FS capillary and for a fluorinated FEP capillary are given in Figure 18.1b.

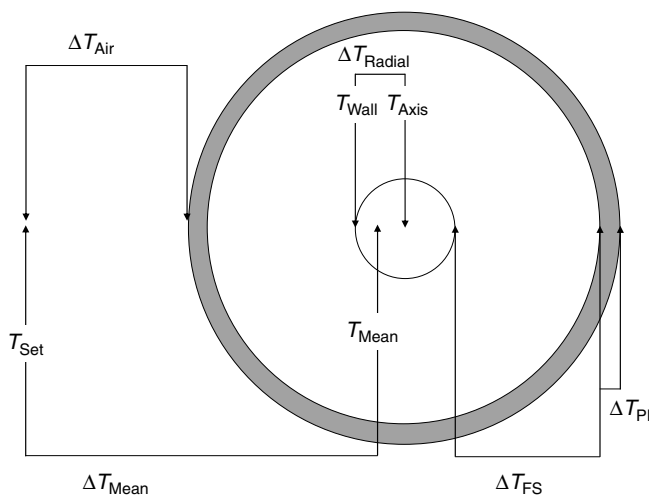

The later onset of deviation from Ohm's Law for the FS capillary as voltage increases in the Ohm's Law plot in Figure 18.1a demonstrates the superior heat dissipation of FS over FEP. This is confirmed by the smaller slope of  $G$  vs.  $P/L$  for the FS capillary in Figure 18.1b. The ratio of the gradient of the  $G$  vs.  $P/L$  graph to the intercept can be used to estimate the temperature increase of the electrolyte. A more detailed description of temperature calculation will follow in Section 18.4. In addition, the average internal diameter ( $d_i$ ) of the capillary can be derived from the conductance at zero power ( $G_0$ ). The intercept,  $G_0$ , is proportional to the cross-sectional area of the capillary. Provided that the lengths of the capillaries are equal, this allows one to use Equation 18.3 to calculate the internal diameter of an unknown capillary based on the internal diameter of another capillary [14].

$$\frac{G_{0(\text{FEP})}}{G_{0(\text{FS})}} = \frac{(d_{i \text{ FEP}})^2}{(d_{i \text{ FS}})^2}. \quad (18.3)$$

Figure 18.1b demonstrates that the FEP capillary has a larger internal diameter, as evident from its larger conductance at zero power ( $G_0$ ). On the basis of the  $d_i$  of the FS capillary, the diameter of the FEP capillary can be calculated as illustrated in the following equation:

$$d_{i \text{ FEP}} = \sqrt{\frac{G_{0(\text{FEP})}}{G_{0(\text{FS})}}} \cdot d_{i \text{ FS}} = \sqrt{\frac{1.7405}{1.5093}} \cdot 74.0 \mu\text{m} = 79.5 \mu\text{m}. \quad (18.4)$$

The possibility of determining the electrolyte temperature and the capillary diameter make the  $G$  versus  $P/L$  graph a superior method to the Ohm's Law plot for characterizing Joule heating.

**FIGURE 18.2** Schematic diagram showing the locations at which the temperature determinations are made, and definitions of temperature differences. (Reproduced with permission from Evenhuis, C. J., et al., *Anal. Chem.* 2006, 78, 2684–2693. Copyright 2006 American Chemical Society.)

Grushka et al. [4] have provided a useful rule of thumb that the radial temperature difference in the capillary ( $\Delta T_{\text{Radial}}$ , see Figure 18.2) should not be allowed to exceed 1.5 °C otherwise there is an unacceptable loss of efficiency due to peak broadening.

It has been shown that the radial temperature difference is directly proportional to the power per unit length and is independent of the cooling efficiency of the instrument. The following equation applies for aqueous electrolytes:

$$\Delta T_{\text{Radial}} = \frac{1}{4\pi\lambda} \cdot \frac{P}{L} = 0.1315 \text{ } ^\circ\text{C W}^{-1}\text{m} \cdot \frac{P}{L}, \quad (18.5)$$

where  $\lambda$  is the thermal conductivity of the electrolyte ( $\lambda_{\text{water}} = 0.605 \text{ W m}^{-1} \text{ K}^{-1}$ ). To avoid excessive peak broadening  $P/L$  should not be allowed to exceed  $11 \text{ W m}^{-1}$ . For nonaqueous electrolytes, which tend to have lower thermal conductivities, or electrolytes containing organic constituents, it is wise to calculate or estimate the maximum value of  $P/L$ [15]. For example, for methanol ( $\lambda_{\text{MeOH}} = 0.202 \text{ W m}^{-1} \text{ K}^{-1}$ ) the maximum power level would be  $3.8 \text{ W m}^{-1}$ .

A number of other problems are associated with working at high values of  $P/L$ . McCormick [16,17] observed that if the electrolyte heated up too quickly, part of the sample could actually be expelled from the capillary by the rapid expansion of the buffer. The formation of bubbles or even boiling of the electrolyte can also occur at high power levels, resulting in a sudden decrease of the current. Microbubbles formed by outgassing of dissolved air allow the current to continue but can often be detected as random sharp peaks (spikes). To avoid these spurious peaks, it is good practice to degas the electrolyte in an ultrasonic bath before its use.

### 18.2.2 FACTORS AFFECTING HEAT GENERATION

The flowchart (see Figure 18.3) demonstrates that the capillary, electrolyte, and instrumental parameters all have an influence to a varying degree on the overall temperature rise of the electrolyte ( $\Delta T_{\text{Mean}}$ , see Figure 18.2). An explanation of the terms used is shown in Table 18.1. Key parameters are discussed in detail in the following sections.

**FIGURE 18.3** Flowchart showing the influences of various experimental variables on the electrolyte temperature.

### 18.2.2.1 Buffer Composition

Figure 18.4 illustrates that  $\Delta T_{\text{Mean}}$  increases linearly with the power per unit length ( $P/L$ ). The buffer composition and concentration affect its conductivity and therefore the rate of heat generation during a separation. Equation 18.6 illustrates the principle that the use of a lower conductivity buffer results in a smaller increase in temperature for the same electrical field strength ( $E$ ).

$$\frac{P}{L} = \frac{\kappa AV^2}{L^2} = \kappa AE^2. \tag{18.6}$$

As conductivity depends on the mobility of the ions involved (see Equation 18.7), the use of counterions of lower mobility can reduce the current.

$$\Lambda^0 = \sum_i \frac{\mu_i F}{z_i}, \tag{18.7}$$

**TABLE 18.1**  
**Explanation of Terms**

Abbreviation	Quantity	Unit
$\Delta T_{\text{Air}}$	Temperature difference across air layer surrounding capillary (see Figure 18.2)	$^{\circ}\text{C}$
$\Delta T_{\text{Wall}}$	Temperature difference across the capillary wall [sum of $\Delta T_{\text{FS}}$ and $\Delta T_{\text{PI}}$ (see Figure 18.2)]	$^{\circ}\text{C}$
$\Delta T_{\text{FS}}$	Temperature difference across fused-silica wall (see Figure 18.2)	$^{\circ}\text{C}$
$\Delta T_{\text{Mean}}$	Change in mean temperature of the electrolyte as a result of Joule heating (see Figure 18.2)	$^{\circ}\text{C}$
$\Delta T_{\text{PI}}$	Temperature difference across poly(imide) coating (see Figure 18.2)	$^{\circ}\text{C}$
$\Delta T_{\text{Radial}}$	Radial temperature difference across electrolyte (see Figure 18.2)	$^{\circ}\text{C}$
$\gamma$	Thermal coefficient of electrical conductivity	$^{\circ}\text{C}^{-1}$
$\eta$	Viscosity of electrolyte	$\text{kg m}^{-1} \text{s}^{-1}$
$\Lambda^0$	Limiting ionic conductivity	$\text{Sm}^2 \text{mol}^{-1}$
$\Lambda_{\text{m}}$	Molar conductivity	$\text{Sm}^2 \text{mol}^{-1}$
$\varepsilon$	Electrical permittivity of the electrolyte	$\text{F m}^{-1}$
$\zeta$	Zeta potential	V
$\kappa$	Electrical conductivity of electrolyte	$\text{S m}^{-1}$
$\lambda$	Thermal conductivity of electrolyte	$\text{Wm}^{-1} \text{K}^{-1}$
$\lambda_{\text{Wall}}$	Thermal conductivity of wall	$\text{Wm}^{-1} \text{K}^{-1}$
$\mu$	Limiting ionic mobility	$\text{m}^2 \text{s}^{-1} \text{V}^{-1}$
$\mu_i$	Limiting ionic mobility of $i$ species	$\text{m}^2 \text{s}^{-1} \text{V}^{-1}$
$\mu_{\text{ep}}$	Electrophoretic mobility	$\text{m}^2 \text{s}^{-1} \text{V}^{-1}$
$\mu_{\text{EOF}}$	Electroosmotic mobility	$\text{m}^2 \text{s}^{-1} \text{V}^{-1}$
$\mu_{\text{EOF}}(0)$	Electroosmotic mobility at zero power	$\text{m}^2 \text{s}^{-1} \text{V}^{-1}$
$\Phi$	Constant relating $\Delta T_{\text{Mean}}$ to $P/L$	$^{\circ}\text{C W}^{-1} \text{m}$
$A$	Cross-sectional area	$\text{M}^2$
$c$	Molar concentration	$\text{mol L}^{-1}$
$d_i$	Internal diameter of capillary	M
$d_o$	External diameter of capillary	M
$F$	Faraday's constant	$96,487 \text{ C mol}^{-1}$
$G$	Conductance	S
$G(0)$	Conductance at zero power	S
$h$	Heat transfer coefficient	$\text{Wm}^{-2} \text{K}^{-1}$
$I$	Electric current	A
$K$	Kohlrausch constant	$\text{Sm}^2 \text{mol}^{-3/2} \text{L}^{-1/2}$
$L$	Total length of the capillary	M
$P$	Power	W
$P/L$	Power per unit length	$\text{Wm}^{-1}$
$q$	Charge of ion	C
$r_h$	Hydrodynamic radius	M
$V$	Applied voltage	V
$z_i$	Valency of ionic species $i$	Dimensionless

where  $\Lambda^0$  is the limiting ionic conductivity,  $\mu_i$  is the limiting ionic mobility of species  $i$ , and  $z_i$  is its valency.

For example,  $\text{Na}^+$  should be used in preference to  $\text{NH}_4^+$  or  $\text{K}^+$  when counterions are being considered. Large organic counterions such as histidine can significantly reduce the current but one needs to be aware that separation selectivity can also be affected. Zwitterionic buffers such as

**FIGURE 18.4** Variation of mean increase in electrolyte temperature with power per unit length for capillaries made from different materials ●, FEP; ◆, PMMA; ▲, PEEK; and ■, FS. Conditions:  $h = 376 \text{ Wm}^{-2} \text{ K}^{-1}$ ,  $L_{\text{tot}} = 32.2 \text{ cm}$ ,  $d_i \approx 75 \text{ }\mu\text{m}$ ,  $d_o \approx 365 \text{ }\mu\text{m}$ . See Reference [14] for more details for each capillary. Electrolyte: 10 mM phosphate, pH = 7.21. (Reproduced with permission from Evenhuis, C. J., et al., *Electrophoresis* 2005, 26, 4333–4344. Copyright 2005 Wiley VCH.)

3-(*N*-morpholino)propanesulfonic acid (MOPS) and 2-(*N*-morpholino)ethanesulfonic acid (MES) have high buffer capacities with low conductivities; they tend to absorb at low ultraviolet (UV) wavelengths but may be used to advantage for UV detection above 210 nm [3].

### 18.2.2.2 Applied Voltage

The rate of Joule heating increases with the square of the applied voltage, so doubling the voltage increases  $P/L$  by a factor of 4 (see Equation 18.6). The voltage is usually optimized for maximum efficiency but a compromise between efficiency and heat generation can often lead to shorter analysis times if there is sufficient resolution and the analytes are not influenced by elevated temperatures [3].

### 18.2.2.3 Capillary Length

The rate of Joule heating ( $P$ ) is inversely proportional to the length of the capillary, so halving the capillary length increases both  $P/L$  and  $\Delta T_{\text{Radial}}$  by a factor of 4 (see Equation 18.6), but decreases the separation time by a factor greater than 4 due to the increased mobility of the analytes. Resolution can be improved by using a longer capillary if the same electrical field can be maintained [3].

### 18.2.2.4 Capillary Internal Diameter

As the conductance depends on the cross-sectional area of the capillary (see Equation 18.6), for a constant applied voltage,  $P/L$  increases with the square of the internal diameter ( $d_i$ ).

$$\frac{P}{L} = \frac{\pi \kappa d_i^2 V^2}{4L^2}. \quad (18.8)$$

Decreasing the internal diameter from 75  $\mu\text{m}$  to 50  $\mu\text{m}$  leads to a 56% reduction in  $P/L$ . It follows that the use of smaller bore capillaries enables higher conductivity buffers to be used at similar field strengths, which can significantly improve peak focusing. However, decreasing the internal diameter

of the capillary may result in a loss of sensitivity for concentration-sensitive detection techniques, such as UV absorption, due to the decreased detection pathlength.

### 18.2.2.5 Buffer Viscosity

Increasing the buffer viscosity ( $\eta$ ) affects the apparent mobility through the electrophoretic mobility ( $\mu_{ep}$ , see Equation 18.9) and electroosmotic mobility ( $\mu_{EOF}$ , see Equation 18.10) by increasing the resistance to movement

$$\mu_{ep} = \frac{q}{6\pi r_h \eta}, \quad (18.9)$$

where  $q$  is the charge on the solvated ion,  $r_h$  is its hydrodynamic radius,  $\epsilon$  is the electrical permittivity of the electrolyte, and  $\zeta$  is the zeta potential.

$$\mu_{EOF} = -\frac{\epsilon\zeta}{\eta}. \quad (18.10)$$

To a good approximation, there is an inverse relationship between the viscosity and the resulting current; doubling the buffer viscosity will halve the current and  $\Delta T_{Radial}$ . In nonaqueous solvents, electrical currents are generally lower than that for the same electrolyte dissolved in water, but predicting  $\Delta T_{Radial}$  becomes complex as one needs to take into account variations in the mobilities of species, dissociation equilibria, dielectric constant, zeta potential, and thermal conductivity [18].

## 18.3 HEAT DISSIPATION

### 18.3.1 THEORY

It is not surprising that since heat energy is generated in the electrolyte and the heat is conducted through the capillary walls, the electrolyte temperature is greater at the axis than at the inside wall. A temperature gradient therefore exists from the central axis to the outside wall of the capillary. The size of the radial temperature difference across the electrolyte ( $\Delta T_{Radial}$ ) and across the capillary wall(s) is dictated by the power generated per unit length ( $P/L$ ) and the thermal conductivity of each medium, but the overall increase in temperature of the electrolyte is determined by the cooling efficiency, which is characterized by the heat transfer coefficient at the outer surface ( $h$ ). A relatively straightforward method of finding  $h$  for a CE instrument is described in Section 18.5. It has been predicted that an approximately parabolic temperature profile exists within the electrolyte [9,12] and this has been verified using noninvasive methods, such as Raman Spectroscopy [19]. In FS capillaries, an exponential decrease in temperature occurs across the FS and poly(imide) layers. Interestingly, the magnitude of the temperature difference across the thin polymer layer is comparable to that across the FS. However, even when highly efficient cooling systems are in operation, the main temperature drop occurs from the outside surface of the poly(imide) coating to the set temperature [12] (see Figure 18.5).

### 18.3.2 FACTORS INFLUENCING HEAT DISSIPATION

#### 18.3.2.1 Type of Cooling System

The thermal conductivity of the cooling medium and the speed at which the medium flows over the capillary influence the cooling efficiency. For example, helium has been shown to be about six times more effective than air for capillary cooling due to its greater thermal conductivity [20]. As mentioned earlier, the elevation in electrolyte temperature is determined mainly by how efficiently

**FIGURE 18.5** Calculated average radial temperature profile for a FS capillary. Conditions:  $P/L = 1.00 \text{ Wm}^{-1}$ ,  $h = 376 \text{ Wm}^{-2} \text{ K}^{-1}$ ,  $L_{\text{tot}} = 32.2 \text{ cm}$ ,  $d_i = 74.0 \text{ } \mu\text{m}$ ,  $d_o = 362.8 \text{ } \mu\text{m}$ , thickness of poly(imide) layer =  $21.0 \text{ } \mu\text{m}$ . Electrolyte: 10 mM phosphate, pH = 7.21. (Reproduced with permission from Evenhuis, C. J., et al., *Anal. Chem.* 2006, 78, 2684–2693. Copyright 2006 American Chemical Society.)

heat is conducted from the outer surface of the capillary, and this is characterized by the heat transfer coefficient ( $h$ ).

Typical values for  $h$  in CE instruments are approximately  $50 \text{ Wm}^{-2} \text{ K}^{-1}$  for stagnant air [21],  $300\text{--}700 \text{ Wm}^{-2} \text{ K}^{-1}$  for fan-forced air depending on the speed of flow and the fraction of the capillary that is temperature controlled [8,21] and between  $700$  and  $1200 \text{ Wm}^{-2} \text{ K}^{-1}$  for liquid cooling [5,22]. The most effective cooling system to be demonstrated for CE used a Peltier thermoelectric device to cool an alumina block. The capillary was housed in a purpose built groove and thermal contact was enhanced using ethylene glycol. A heat transfer coefficient of  $h = 2600 \text{ Wm}^{-2} \text{ K}^{-1}$  was reported for this device [10].

Figure 18.6 illustrates that increasing the speed of the airflow becomes less effective at higher airflow rates, but that there is a large change in heat transfer at low flows.

### 18.3.2.2 Cooling System Design

Axial temperature differences are to be avoided. Ideally, the temperature of the whole capillary should be actively controlled to the same temperature. Unfortunately, the design of some commercial CE instruments is such that there are substantial portions of the capillary without temperature control. These portions of the capillary are surrounded either by stagnant air or by electrolyte in the vials. Without redesigning the instrument, areas with stagnant air cannot be avoided, but many instruments allow regulation of the temperature of the vials containing the sample and electrolyte vials, which allows significant improvements in the reproducibility.

### 18.3.2.3 Capillary Material

Although poly(imide)-coated FS accounts for the vast majority of applications in CE, polymeric materials have also been studied as materials for CE capillaries since these offer a variety of different

**FIGURE 18.6** Theoretical variation of the heat transfer coefficient with the speed of the airflow for a poly(imide) coated FS capillary with  $d_i = 75 \mu\text{m}$  and  $d_o = 375 \mu\text{m}$ .

surface physical properties. Examples include the following: poly(methylmethacrylate) (PMMA) [23,24], FEP [25], poly(propene) [26], poly(butylene-terephthalate) [26], poly(tetrafluoroethene) (PTFE) [27–30], and poly(etherether ketone) (PEEK) [31].

Generally speaking, the thermal conductivity of polymers is much less than FS (see Table 18.2) so that the temperature difference across the capillary walls and the rise in temperature of the electrolyte are both significantly greater for polymeric capillaries under the same conditions (see Figure 18.5) [14].

### 18.3.2.4 Capillary Outer Diameter

It has been noted that increasing the external diameter of the capillary by using a thicker layer of FS actually reduces the rise in temperature of the electrolyte [3,10]. Although the temperature gradient across the capillary wall increases, heat is removed more effectively from the larger surface area at the external surface. However, increasing the thickness of the polymer layer causes an increase in the temperature but can lead to a reduction in the optical baseline noise [3]. These authors suggested that the increased temperature of the electrolyte could be counterbalanced by reducing the temperature of the cooling system [3].

## 18.4 DETERMINATION OF THE AVERAGE ELECTROLYTE TEMPERATURE

A knowledge of the electrolyte temperature is important in CE as temperature changes in the electrolyte influence precision, accuracy, separation efficiency, and method robustness [7,14,32]. During the past two decades, a considerable amount of research has been conducted toward electrolyte temperature measurements in CE [1,14,19,21,32–42]. Early methods have included using the variation of electroosmotic mobility ( $\mu_{\text{EOF}}$ ), electrophoretic mobility ( $\mu_{\text{ep}}$ ), and electrical conductivity ( $\kappa$ ) to measure temperature [38,39]. More recently, techniques such as external thermocouples [21], Raman thermometry [19,40], NMR spectroscopy [32,35], thermochromic probes [41], and the variation in fluorescence response [42] have been used to measure temperatures. Most of these methods require the modification of the existing instrument and/or the purchase of additional equipment.

Two noninvasive methods of temperature measurement based on the electroosmotic mobility and conductance are discussed in further detail below. The linear relationships between both the electroosmotic mobility and the conductance versus  $P/L$  are illustrated in Figure 18.7.

### 18.4.1 ELECTROOSMOTIC FLOW METHOD

It should be noted that the electroosmotic mobility ( $\mu_{\text{EOF}}$ ) is not a measure of the average electrolyte temperature ( $T_{\text{Mean}}$ , see Figure 18.2) over the whole cross section; but instead reflects the average temperature of the electrolyte near the inner wall of the capillary ( $T_{\text{Wall}}$ ). This is because the electroosmotic flow is generated at the capillary wall. To determine the average temperature of

**FIGURE 18.7** Variation of electroosmotic mobility and conductance with power per unit length. Conditions as in Figure 18.5.

the electrolyte ( $T_{\text{Mean}}$ ), a correction of  $\frac{1}{2}\Delta T_{\text{Radial}}$  needs to be added to the wall temperature to take into account the radial temperature profile of the electrolyte [8].

$$T_{\text{Mean}} = T_{\text{Wall}} + \frac{1}{2}\Delta T_{\text{Radial}} = T_{\text{Wall}} + 0.066 \text{ KW}^{-1} \text{ m} \cdot \frac{P}{L} \quad (18.11)$$

The previous methods of using  $\mu_{\text{EOF}}$  as a temperature probe have assumed that changes in  $\mu_{\text{EOF}}$  were due solely to variations in viscosity. More recently, it has been shown that changes to the dielectric constant and zeta potential also influence  $\mu_{\text{EOF}}$  [8]. To obtain the most accurate results, an initial calibration curve for the variation of electroosmotic mobility with temperature is required for a specific electrolyte and capillary material. To make this calibration plot,  $\mu_{\text{EOF}}$  needs to be determined at three or more different values of  $P/L$  for a range of set temperatures using the instrument's temperature control system. At each temperature, the graph of  $\mu_{\text{EOF}}$  versus  $P/L$  is extrapolated to  $P/L = 0$  to find  $\mu_{\text{EOF}}$  free of the effects of Joule heating,  $\mu_{\text{EOF}}(0)$ . These values of  $\mu_{\text{EOF}}(0)$  can be used to prepare the calibration curve for the variation of electroosmotic mobility with temperature, as illustrated in Figure 18.8.

For the example illustrated in Figure 18.8, the electrolyte used was 10 mM phosphate buffer at pH = 7.21.  $\mu_{\text{EOF}}$  was found to increase at 2.22% per °C, that is, the temperature coefficient (or slope of  $\mu_{\text{EOF}}$  versus  $T$ ) was  $0.0222^\circ\text{C}^{-1}$ . Once the temperature coefficient for electrophoretic mobility is known, the electrolyte temperature can be easily determined for any value of  $P/L$  as long as the same capillary and electrolyte are used.

$$T_{\text{Mean}} = T_0 + \frac{\mu_{\text{EOF}} - \mu_{\text{EOF}}(0)}{0.0222\mu_{\text{EOF}}(0)} + 0.066 \text{ KW}^{-1} \text{ m} \cdot \frac{P}{L} \quad (18.12)$$

where  $T_0$  is the temperature set for the instrument,  $\mu_{\text{EOF}}$  is the electroosmotic mobility measured for the electrophoretic separation, and  $\mu_{\text{EOF}}(0)$  is the extrapolated value of  $\mu_{\text{EOF}}$  to zero power at ambient temperature.

**FIGURE 18.8** Calibration curve for  $\mu_{\text{EOF}}$  versus Ambient temperature. Conditions as in Figure 18.5. (Reproduced with permission from Evenhuis, C. J., et al., *Anal. Chem.* 2006, 78, 2684–2693. Copyright 2006 American Chemical Society.)

*Example:* If  $\mu_{\text{EOF}}(0) = 7.209 \times 10^{-8} \text{ m}^2 \text{ s}^{-1} \text{ V}^{-1}$  at  $25.00 \text{ }^\circ\text{C}$  and  $\mu_{\text{EOF}}(P/L = 4.625 \text{ Wm}^{-1}) = 9.179 \times 10^{-8} \text{ m}^2 \text{ s}^{-1} \text{ V}^{-1}$ , then

$$\begin{aligned} T_{\text{Mean}} &= 25.00 \text{ }^\circ\text{C} + \frac{9.179 \times 10^{-8} - 7.209 \times 10^{-8}}{0.0222 \text{ }^\circ\text{C}^{-1} (7.209 \times 10^{-8})} + 0.066 \text{ }^\circ\text{CmW}^{-1} \cdot 4.625 \text{ Wm}^{-1} \\ &= 25.00 \text{ }^\circ\text{C} + 12.31 \text{ }^\circ\text{C} + 0.30 \text{ }^\circ\text{C} = 37.61 \text{ }^\circ\text{C} \end{aligned}$$

The increase in mean temperature of the electrolyte ( $\Delta T_{\text{Mean}}$ ) is directly proportional to  $P/L$ .

$$\Delta T_{\text{Mean}} = \Phi \frac{P}{L}, \quad (18.13)$$

where  $\Phi$  is a constant relating  $\Delta T_{\text{Mean}}$  to the  $P$ .

For the example above,  $\Delta T_{\text{Mean}} = 12.61 \text{ }^\circ\text{C}$ ,

$$\Phi = \frac{\Delta T_{\text{Mean}} L}{P} = \frac{12.61 \text{ }^\circ\text{C}}{4.625 \text{ Wm}^{-1}} = 2.726 \text{ }^\circ\text{C W}^{-1} \text{ m}.$$

To obtain the most accurate results, the calibration process described above would need to be applied for each different electrolyte. This makes the method less attractive for routine use.

#### 18.4.2 CONDUCTANCE METHOD

Conductance ( $G$ ) can be calculated by simply dividing the current by the voltage (see Equation 18.2). Conductance can be used as a probe for the mean electrolyte temperature ( $T_{\text{Mean}}$ ). For most electrolytes, the thermal coefficient of electrical conductivity ( $\gamma$ ) varies from about  $0.019 \text{ K}^{-1}$  to  $0.021 \text{ K}^{-1}$  [43] at the concentrations used for CE. It is possible to calculate  $\gamma$  from first principles using the Debye–Hückel–Onsager equation [8] but this is far from being a trivial process. As a rule of thumb, using  $\gamma = 0.020 \text{ K}^{-1}$  gives values of  $\Delta T_{\text{Mean}}$  to within 5%, but for more accurate values a calibration process is necessary.

To measure  $\Delta T_{\text{Mean}}$ , the value of conductance at the ambient temperature is required without the influence of Joule heating [ $G(0)$ ]. This can be obtained by measuring  $G$  at 3 or more values of  $P/L$  and extrapolating to  $P/L = 0$  (see Figure 18.7).

$$\Delta T_{\text{Mean}} = \frac{G - G(0)}{\gamma G(0)}. \quad (18.14)$$

For example, 10 mM phosphate buffer at pH = 7.21 has  $\gamma = 0.0205 \text{ }^\circ\text{C}^{-1}$ . Using the data from Figure 18.7,  $G(0) = 1.935 \text{ nS}$  and  $G(4.625 \text{ Wm}^{-1}) = 2.441 \text{ nS}$ .

This value is within  $0.15 \text{ }^\circ\text{C}$  of the increase in temperature that was calculated above using  $\mu_{\text{EOF}}$ . The overall process is far more straightforward than the method based on  $\mu_{\text{EOF}}$  and is less sensitive to slight changes in wall chemistry that can occur over a period of time.

#### 18.5 DETERMINING THE HEAT TRANSFER COEFFICIENT ( $h$ )

As illustrated in Figure 18.5, the difference between the outer wall temperature and the ambient temperature (referred to as  $\Delta T_{\text{Air}}$ , see Figure 18.2) can easily account for 80% of the temperature increase of the electrolyte, even in an efficiently cooled instrument. The size of  $\Delta T_{\text{Air}}$  is determined by the size of the heat transfer coefficient, so it useful to be able to determine  $h$  experimentally rather than to assume that the instrument is still functioning according to the manufacturer's specifications.

It should be noted that it is not possible to calculate  $h$  for an instrument per se as the value calculated depends on the outer diameter of the capillary used. However as most practitioners use capillaries with  $d_o \approx 375 \mu\text{m}$ , this value will be used in the example below for the purposes of illustration.

$h$  is calculated from the difference in temperature between the outer wall and the ambient temperature of the coolant ( $\Delta T_{\text{Air}}$ )

$$h = \frac{1}{\pi d_o \Delta T_{\text{Air}}} \cdot \frac{P}{L}, \quad (18.15)$$

where  $d_o$  is the outer diameter of the capillary and  $P/L$  is the power dissipated per unit length.  $\Delta T_{\text{Air}}$  can be found from the rise in the mean temperature of the electrolyte and the temperature differences across the FS and poly(imide) layers (see Figure 18.2).

$$\Delta T_{\text{Air}} = \Delta T_{\text{Mean}} - 1/2 \Delta T_{\text{Radial}} - \Delta T_{\text{FS}} - \Delta T_{\text{PI}}. \quad (18.16)$$

For both FS and poly(imide) capillaries, the temperature difference across the wall is found using the following equation:

$$\Delta T_{\text{AcrossWall}} = \frac{1}{2\pi \lambda_{\text{Wall}}} \ln \left( \frac{d_o}{d_i} \right) \cdot \frac{P}{L}, \quad (18.17)$$

where  $\lambda_{\text{Wall}}$  refers to the thermal conductivity of the wall material. The thermal conductivities for FS and poly(imide) are  $\lambda_{\text{FS}} = 1.40 \text{ Wm}^{-1}\text{K}^{-1}$  and  $\lambda_{\text{PI}} = 0.155 \text{ Wm}^{-1}\text{K}^{-1}$ , respectively [12,21].

For convenience, the following calculations use  $P/L = 1.00 \text{ Wm}^{-1}$  but the calculations are applicable for any value of  $P/L$ . For the purpose of the calculation, the values used are internal diameter,  $d_i = 75.0 \mu\text{m}$ , diameter of FS  $d_{\text{FS}} = 335 \mu\text{m}$ , and outer diameter  $d_o = 375 \mu\text{m}$  (the thickness of the poly(imide) coating is  $20 \mu\text{m}$ ).

$$\Delta T_{\text{FS}} = \frac{1}{2\pi \times 1.40 \text{ Wm}^{-1}\text{K}^{-1}} \ln \left( \frac{335 \mu\text{m}}{75.0 \mu\text{m}} \right) \cdot 1.00 \text{ Wm}^{-1} = 0.170 \text{ K}$$

$$\Delta T_{\text{PI}} = \frac{1}{2\pi \times 0.155 \text{ Wm}^{-1}\text{K}^{-1}} \ln \left( \frac{375 \mu\text{m}}{335 \mu\text{m}} \right) \cdot 1.00 \text{ Wm}^{-1} = 0.116 \text{ K}$$

$$\frac{1}{2} \Delta T_{\text{Radial}} = \frac{1}{2} \times \frac{1}{4\pi \times 0.605 \text{ Wm}^{-1}\text{K}^{-1}} \cdot \frac{P}{L} = 0.066 \text{ KW}^{-1}\text{m} \cdot 1.00 \text{ Wm}^{-1} = 0.066 \text{ K}$$

Using the previously determined value of  $\Delta T_{\text{Mean}} = 2.726 \text{ K}$  for  $P/L = 1.00 \text{ Wm}^{-1}$  for a capillary with a total length of 32.2 cm,

$$\Delta T_{\text{Air}} = \Delta T_{\text{Mean}} - \frac{1}{2} \Delta T_{\text{Radial}} - \Delta T_{\text{FS}} - \Delta T_{\text{PI}}$$

$$= 2.726 \text{ K} - 0.066 \text{ K} - 0.170 \text{ K} - 0.116 \text{ K} = 2.374 \text{ K}$$

$$\therefore h = \frac{1}{\pi d_o \Delta T_{\text{Air}}} \cdot \frac{P}{L} = \frac{1}{\pi \times 375 \times 10^{-6} \text{ m} \times 2.374 \text{ K}} \cdot 1.00 \text{ Wm}^{-1} = 358 \text{ Wm}^{-2}\text{K}^{-1}.$$

It should be noted that the value of  $h$  calculated is an average over the whole length of the capillary and that the size of  $h$  will depend on the fraction of the capillary that is under thermostat control. Longer capillaries that have a larger fraction of the capillary under thermostat control will tend to give larger values of  $h$ .

**FIGURE 18.9** Variation of the mean rise in electrolyte temperature with heat transfer coefficient for  $P/L = 1.00 \text{ Wm}^{-1}$ .

## 18.6 ESTIMATING THE TEMPERATURE INCREASE OF THE ELECTROLYTE

The temperature rise of the electrolyte can be estimated using a combination of the heat transfer coefficient and the power per unit length using Equation 18.18. For the FS capillary described above [ $d_i = 75.0 \text{ }\mu\text{m}$ ,  $d_o = 375 \text{ }\mu\text{m}$ , thickness of poly(imide) =  $20 \text{ }\mu\text{m}$ ]:

$$\begin{aligned} \Delta T_{\text{Mean}} &= \Delta T_{\text{Air}} + \frac{1}{2}\Delta T_{\text{Radial}} + \Delta T_{\text{FS}} + \Delta T_{\text{PI}} = \Delta T_{\text{Air}} + 0.352 \text{ KmW}^{-1} \cdot \frac{P}{L} \\ &= \left( \frac{1}{\pi d_o h} + 0.352 \text{ KmW}^{-1} \right) \frac{P}{L} = \left( \frac{849}{h} + 0.352 \text{ KmW}^{-1} \right) \frac{P}{L} \end{aligned} \quad (18.18)$$

A graph of Equation 18.18 is shown in Figure 18.9.

For capillaries with  $d_o = 375 \text{ }\mu\text{m}$ , the error introduced by Equation 18.18 is less than  $0.4^\circ\text{C}$  for  $d_i = 50\text{--}150 \text{ }\mu\text{m}$ . For capillaries with narrower bores, the temperature rise is slightly greater than predicted and for wider bore capillaries the predicted temperature rise is smaller.

## 18.7 CONTROL OF THE CAPILLARY TEMPERATURE

When selecting the desired temperature of the capillary, consideration should be given to reproducibility of sample injection and migration times, optimization of resolution, the possibility of sample decomposition, and the minimization of analysis times [3].

### 18.7.1 REPRODUCIBILITY OF MIGRATION TIMES AND INJECTION VOLUMES

Both the electroosmotic mobility and electrophoretic mobility are temperature-dependent so it is not surprising that controlling the temperature of the capillary leads to improved intraday-, interday-, and interlaboratory-reproducibility of migration times. Nevertheless, it is possible to achieve acceptable run-to-run reproducibility using an instrument without temperature control if experiments are carried out in a laboratory in which the ambient temperature is maintained within a narrow range.

Since the viscosity of the electrolyte decreases with increasing temperature at a rate of approximately 2% per °C, the volume of sample injected using a particular pressure and time combination will increase with the ambient temperature. As a rule of thumb, the product of pressure and time should be reduced by 20% for each 10°C rise in the ambient temperature. Alternatively, peak areas can be normalized by multiplying them by the ratio of the viscosities at the different temperatures [3]. As mentioned earlier, where the facility exists, it is wise to control the temperature of the tray housing the electrolyte vials as this improves reproducibility of both injections and migration times.

### 18.7.2 OPTIMIZING RESOLUTION

Nelson and Burgi [3] observed that the relative migration times could be affected differently by changes to the ambient electrolyte temperature so that the order in which a range of anions is detected can be changed considerably. Ions that comigrate at one temperature can be well resolved at a different temperature. Although the mechanism for these changes is not well understood, changing the temperature may be an effective strategy to improve resolution. However, it should be noted that generally there is an increase in peak distortion that accompanies increases in temperature [5].

### 18.7.3 SAMPLE DECOMPOSITION

It is well known that biological samples may be sensitive to decomposition and/or conformational changes at elevated temperatures [10,44,45]. Such changes can be avoided by monitoring the electrolyte temperatures using the procedures described earlier or by controlling the electrolyte temperature at a lower value to counteract the effect of Joule heating.

### 18.7.4 BAND BROADENING

Joule heating is well established as a source of peak broadening. Petersen et al. [5] showed that a 10°C increase in temperature is associated with a 3.3% decrease in the number of theoretical plates due to increased axial diffusion. Radial temperature differences tend to be more significant; Grushka et al. [4] recommended that the radial temperature difference should not be allowed to exceed 1.5°C. Gobie and Ivory [1] found that thermally induced parabolic distortion of the migration velocity can be countered by applying an opposing laminar flow to the outlet end of the capillary. This method was found to be particularly effective in wider bore capillaries.

## 18.8 CONCLUSIONS

Although Joule heating is inevitable during electrophoretic separations, its magnitude is simple to quantify. Variation of the electrical conductance ( $G$ ) with the power per unit length ( $P/L$ ) is a simple and effective method of measuring the temperature increase of the electrolyte. An experimental method of determining the heat transfer coefficient ( $h$ ) for a capillary has been outlined, along with a simple equation to calculate the rise in the mean temperature of the electrolyte ( $\Delta T_{\text{Mean}}$ ).  $\Delta T_{\text{Mean}}$  increases linearly with the power per unit length and can be minimized by using narrow bore capillaries with low electrical conductivity electrolytes and by increasing the length of the capillary. Finally, the ambient temperature of the capillary during a separation should always be considered as a variable that must be optimized with respect to speed, efficiency, and resolution [3].

## 19.1 INTRODUCTION OF CAPILLARY ISOELECTRIC FOCUSING

Isoelectric focusing (IEF) [1] is a powerful electrophoretic method for characterizing proteins and other biopolymers. IEF separates amphoteric substances based on their isoelectric point (pI) differences. In an electric field, a charged particle is subjected to the force,  $F$  ( $F = QE$ ,  $Q$  is the charge of the particle and  $E$  the strength of the electric field). At the pI, where the charge of the particle equals zero, the mobility of the particle should be zero. IEF is a special electrophoresis performed in a pH

gradient. The result of an IEF separation is that amphoteric substances in a sample are separated and focused at the positions along the pH gradient where their pI equals the pH.

IEF has been applied mainly to two areas in the biological sciences: the analysis of complex protein mixtures and the characterization of purified proteins [2]. For the first application, IEF is used as a separation dimension in multidimensional electrophoretic methods, such as 2-D polyacrylamide gel electrophoresis (2-D PAGE). The 2-D PAGE is a common tool in proteomics. For the second application, IEF is one of the two most common methods (another one is ion exchange chromatography) to characterize a protein's charge heterogeneity. The charge heterogeneity of a protein is frequently caused by post-translational modifications. Thus, the IEF method is an important tool in the study of these modifications. Pharmaceutical companies utilize IEF methods to monitor product processing, study formulations, and perform quality control for their protein products.

As a major protein characterization tool in biotech laboratories, slab gel IEF is slow, labor intensive, and semiquantitative. In addition, the quality of the results depends on the skill of the analyst. It was recognized that if IEF could be performed in a column format, significant advantages over slab gel IEF could be realized, in terms of automation, speed, and quantification. In 1985, Hjertén and Zhu [3] first reported an IEF method performed in a capillary column format—capillary isoelectric focusing (cIEF). In the early years of cIEF, it was performed on commercial capillary electrophoresis (CE) instruments that were designed for multiple CE modes. cIEF was expected to have both the high resolution of slab gel IEF and the advantages of a column-based separation technology that include automation and quantification.

Despite the inherent appeal of cIEF, since it was first introduced more than 20 years ago, widespread acceptance of cIEF by biotechnology laboratories and the pharmaceutical industry as a substitute for slab gel IEF for protein characterization did not occur. The main factor for this slow acceptance by the industry was related to the difficulty in performing cIEF using general purpose CE instruments (conventional cIEF). Subsequently, the introduction of whole-column detection cIEF [4] and its commercialization [5] revolutionized cIEF technology. It has been quickly adopted by leading pharmaceutical companies and research laboratories. Many analysis methods based on the whole-column detection cIEF have been validated in laboratories regulated by the U.S. Food and Drug Administration (FDA) [6,7]. To our knowledge, the top 10 pharmaceutical companies in the world are using the whole-column detection cIEF technique for protein characterization, for drug discovery, product processing, including formulation development, and quality control (QC).

It has been almost 25 years since CE was first reported [8]. The late 1980s and early 1990s were CE's booming years. During that period, it was widely expected that CE would replace high-performance liquid chromatography (HPLC) for most HPLC applications, although this did not occur. After the 25 years, CE almost disappeared from industrial laboratories. Only two CE technologies survived and were accepted by biotech pharmaceutical companies, including CE-sodium dodecyl sulfate (SDS) and cIEF. CE-SDS could replace SDS-PAGE and cIEF could replace slab gel IEF for many applications, especially in protein characterization and QC. The speed of the acceptance of these two CE technologies in the biotech field has been accelerated in the past 5 years [9] due to the improvements in these two CE technologies.

In this chapter, a review of cIEF applications for protein characterizations performed by biotech and pharmaceutical laboratories will be presented.

## 19.2 REVIEW OF cIEF TECHNOLOGY

### 19.2.1 CONVENTIONAL cIEF

When a general purpose CE instrument is used to perform cIEF (conventional cIEF), as shown in Figure 19.1a, the separation column, which is usually a 50–100  $\mu\text{m}$  inner diameter, 25–60 cm long capillary, is filled with a mixture of a protein sample and carrier ampholytes (CAs). After the sample is injected, the two ends of the capillary column are dipped into the catholyte and the anolyte, as

**FIGURE 19.1** Steps involved in cIEF using general purpose CE instruments (conventional cIEF). (a) Sample injection, (b) focusing step, and (c) mobilization step.

shown in Figure 19.1b. A separation voltage (usually at 100–500 V/cm) is applied to the two ends of the capillary column. Under the separation voltage, a pH gradient is established along the capillary column from the anodic end of the column to the cathodic end of the column by isoelectric stacking of components in the CAs [10,11]. In the pH gradient, driven by the separation voltage, proteins in the sample migrate to the points within the capillary column where their isoelectric point (pI) values are equivalent to the pH values and the migration then stops. The proteins are focused into very narrow zones at their pI points.

There are three basic requirements of a separation column for cIEF; zero or substantially reduced electroosmotic flow (EOF), hydrodynamic flow, and interaction between protein samples and the column wall. Columns used in cIEF are usually coated on their inner wall with stable, neutral coatings to control for EOF and prevent the protein from interaction with the wall [10]. During the focusing process, the two ends of the separation column should be maintained at the same level to eliminate the hydrodynamic flow. Under these conditions, at the end of the focusing process, all protein zones are stationary or near stationary within the separation column [3].

Since general purpose CE instruments are only equipped with a single point on-column detector, which is usually located close to one end of the capillary column as shown in Figure 19.1c, these stationary protein zones within the column have to be mobilized past the detection point of the single point detector. For cIEF performed on these CE instruments (conventional cIEF), a mobilization process is necessary following the focusing process [10,11]. There are three ways of performing the mobilization: pressure-driven mobilization [11], salt mobilization [3], and EOF-driven mobilization [12]. These three methods can be used in any combination.

*Pressure* is often used for mobilization. As shown in Figure 19.1c, at the end of the focusing a low pressure (usually about 0.5 psi) is applied to one end of the capillary column to mobilize the entire pH gradient past the detection point. During the mobilization, the separation voltage remains to reduce the sample zone broadening.

With *salt mobilization*, at the end of the focusing process salts are added into one of the electrolytes. The addition of the salts creates a pH shift at this end of the column under the separation voltage, and then the shift gradually progresses deeper into the column. This causes the whole pH gradient within the column to shift toward this end of the column.

In *EOF-driven mobilization*, the EOF of the separation column is not totally eliminated, but is controlled with additives, such as methylcellulose (M.C.). Upon application of the separation voltage, the focusing process is initiated. Concurrently, the whole volume of solution within the column is mobilized toward the cathodic end of the column, driven by the EOF. In this way, the mobilization process is combined with the focusing process.

## 19.2.2 APPLICATIONS OF THE CONVENTIONAL cIEF

There are a range of applications of conventional cIEF to real-world analysis, including the characterization of protein samples in laboratories of biotech pharmaceutical companies, and clinical analysis. In the pharmaceutical industry, some methods have been developed based on this technology [13,14] and validated [15–17] as the identity assays in regulated pharmaceutical laboratories for the analysis of therapeutic monoclonal antibodies and glycoproteins. cIEF has also been used in clinical analysis for human hemoglobin analysis [18,19] and the analysis of proteins in cerebrospinal fluid [20]. There are several reviews on the applications of the conventional cIEF [10,21]. However, the pace of acceptance of conventional cIEF for the analysis of real-world samples is slow.

## 19.2.3 DIFFICULTIES ASSOCIATED WITH CONVENTIONAL cIEF

The mobilization process in conventional cIEF inhibits its widespread use. The process introduces many problems, such as poor resolution, poor reproducibility, and long sample analysis time (less than 2 samples/h). In conventional cIEF, the dynamic process of IEF within the separation column is not monitored, which makes it difficult to optimize focusing time and mobilization parameters. Focusing time is the most important parameter in cIEF. In addition, the real focusing time in conventional cIEF is equal to the focusing time and the mobilization time, since the separation voltage is always on during the mobilization process. This makes it almost impossible to optimize the focusing time because the mobilization time of a sample component depends on its pI value. It is also difficult to detect problems in the focusing process within the separation column, such as sample aggregation and precipitation.

## 19.2.4 WHOLE-COLUMN DETECTION cIEF

The introduction of whole-column detection cIEF technology [22,23] solved the problems caused by the mobilization process in conventional cIEF. Figure 19.2 illustrates the principle of whole-column detection cIEF. The separation column is a short capillary (typically, 50 mm long, 100  $\mu\text{m}$  inner diameter silica capillary). The inner wall of the capillary is coated to eliminate EOF and prevent

**FIGURE 19.2** Principle of whole-column detection cIEF.

proteins from interacting with the wall surface. The whole-column detection system is an ultraviolet (UV) absorption-imaging detector operated at 280 nm. During the operation of cIEF, the two tanks on the cartridge are filled with the catholyte and anolyte, respectively, as shown in Figure 19.2. A protein sample premixed with CAs is injected from the inlet of the column into the separation column between the two semipermeable membrane tubes. After the column is filled with the sample, the sample injection is stopped. A separation voltage, typically, 3 kV (600 V/cm), is applied across the two tanks. IEF only occurs within the separation column between the two semipermeable tubes. The structure of the separation column makes accurate sample injection unnecessary. As long as the separation column between the two semipermeable tubes is filled with the sample solution, the injection is quantitative. The IEF process within the entire length of the separation column is monitored by the whole-column detection system. At the end of the focusing, after recording the last image, the sample is washed out of the column by injecting a wash solution from the inlet, then, the separation column is then ready for the next sample.

Since the whole-column detector monitors the IEF process within the separation column in an online fashion, the focusing time can be determined in a single sample run. At the end of the focusing process, all sample zones within the capillary column are simultaneously recorded by the detector without disturbing the separation resolution. Any sample precipitation and aggregation during focusing can be observed and distinguished while focusing is in process. Sample precipitation and aggregation are the two most common problems in IEF faced while obtaining reproducible results. Different additives may be used to improve peak pattern reproducibility. These features facilitate fast method development. In turn, the commercialization of the whole-column detection cIEF technology accelerated the acceptance of cIEF technology by pharmaceutical companies.

## 19.3 THEORETICAL ASPECTS OF cIEF

### 19.3.1 NATURE pH GRADIENT AND STEADY-STATE IEF

The separation of ampholytes in a pH gradient formed by CAs was proposed by Svensson in the early 1960s [1,24–26]. It is known that the pH value of a pure ampholyte solution is approximately its isoelectric point [24]. In a Svensson's IEF system, the electrode reactions must be the electrolysis of water ions, which ensures that protons are produced at the anode and hydroxide ions are produced at the cathode. Before the electric field is applied, components of CA are uniformly distributed throughout the separation channel between the anode and the cathode. The pH along the channel is uniform, representing the average pH of the mixture of all of the components of the CAs. Upon the

application of electric field, influenced by the migration of protons from the anode and hydroxide ions from the cathode of the separation channel, the components of the CAs begin to separate. The components with pI values higher than the average pH are positively charged and migrate toward the cathode whereas the components with pI values lower than the average pH are negatively charged and migrate toward the anode. The components cease migrating when their net charge becomes zero, at the region where the pH equals their pIs. Consequently, a smooth and stable pH gradient, which is positive all the way from anode to cathode, can be “naturally” generated.

### 19.3.2 THE STABILITY OF pH GRADIENT

Svensson [24,25] regarded the natural pH gradient IEF as a true steady-state process and expected its unlimited stability. However, as noted by Svensson, a true steady state was never reached in gel IEF [27]. Instabilities of pH gradient, such as the plateau phenomenon, cathodic drift, anodic drift, or symmetric drift, were commonly observed [1,27–34]. There have been hypotheses to explain the instability of the pH gradient in IEF by isotachopheresis (ITP) mechanism [35,36] or stationary neutralization reaction boundary equilibriums (SNRBEs) [37]. Hjerten et al. [38] suggested, as he proposed the mechanism for chemical mobilization in cIEF, that pH instability is inherent in natural pH gradient IEF due to the need for electroneutral conditions.

Nevertheless, it is commonly accepted that IEF is a steady-state technique, but this steady state is limited and conditional. To exploit the high-resolution capability of IEF, it is necessary to understand IEF's uniqueness. IEF is a steady state or equilibrium technique in nature. Therefore, factors that affect the steady-state IEF should be avoided. For example, as mentioned in Section 19.2, interferences that disturb the formation and stability of the pH gradient, such as the existence of EOF, hydrodynamic flow within the separation channel, or impurities in the anolyte and catholyte (even adsorption of CO<sub>2</sub>), should be controlled.

### 19.3.3 RESOLUTION

The resolution in IEF is defined by the resolving power on pI ( $\Delta pI$ ) that depends on the diffusion coefficient of the ampholyte,  $D$ , the electric field,  $E$ , the mobility slope ( $-d\mu/dpH$ ), and the pH gradient ( $dpH/dx$ ) [1]

$$\Delta pI = 3 \sqrt{\frac{D (dpH/dx)}{E (-d\mu/dpH)}}.$$

The above equation shows that resolution can be improved by high  $E$ , low  $D$ , a narrow pH gradient, and a high mobility slope.

Experimentally, electric field, diffusion coefficient, and  $dpH/dx$  can be manipulated. The rate of change of mobility with a pH near the isoelectric point is intrinsic to the ampholytes and cannot be changed. Performing IEF under higher applied voltages facilitates the development of narrow focused protein zones. However, an increase in the electric field will intensify the Joule heating. As a result, a moderate voltage, which can be determined experimentally, is applied in IEF.

## 19.4 EXAMPLES OF PRACTICAL APPLICATIONS

In this section, several examples of method development procedures for protein characterization assays used for samples from biotech pharmaceutical companies are presented.

**FIGURE 19.3** (Trace 1) Monoclonal antibody 1 at 0.2 mg/mL in 4% Pharmalyte pH 3–10 and 0.35% MC. Focusing time was 6 min at 600 V/cm with a 1 min prefocusing at 300 V/cm. (Traces 2 and 3) Two consecutive runs of the same sample were performed in the same running buffer and under the same focusing conditions as that of trace 1. Sample concentration was 0.6 mg/mL. Two pI markers, pI 7.5 and pI 9.6, were spiked for pI calibration.

#### 19.4.1 MONOCLONAL ANTIBODY 1

First, following the initial conditions, 4% Pharmalyte (pH 3–10), and 0.2 mg/mL sample concentration were tested for this sample. Under the conditions, as shown in the trace 1 of Figure 19.3, the sample peak height is detected at 0.1 Abs. In the next run, the sample concentration was increased to 0.6 mg/mL. The focusing time was 6 min at 600 V/cm with a 1 min prefocusing at 300 V/cm. Two pI markers were spiked into the sample for pI calibration. The results show good reproducibility in peak pattern (traces 2 and 3 in Figure 19.3). Since the separation resolution under these conditions was satisfactory, no further method development was pursued to enhance the resolution.

#### 19.4.2 RECOMBINANT PROTEIN 1

This protein was expected to be very heterogeneous (multiple peaks). At the beginning, higher than usual sample concentration (0.4 mg/mL) was tested. However, as shown in the trace 1 of Figure 19.4, the peak height of the major peaks was only in 0.03 Abs range. In the next run, the sample concentration was boosted to 2.5 mg/mL in order to increase the peak height to above the 0.1 Abs level. Since the sample was focused into about 15 peaks, higher resolution was required. To enhance the resolution, Pharmalyte mixture (pH 3–10 and pH 5–8 at 1:3 ratio) was tested. As shown in traces 2 and 3 of Figure 19.4, the resolution was improved under these conditions.

#### 19.4.3 PROTEIN CONJUGATE 1

The purpose of developing an IEF assay for this sample was to monitor the pI values of different production lots of the product. For this sample, it was very difficult to obtain reproducible peak patterns that could match the peak pattern reproducibility of the previous two samples. As shown in Figure 19.5, the sample started to aggregate and was focused into an unstable big spike when the focusing time was longer than 4.5 min. Many additives and denatured conditions were tested, but no solution was found. However, if the focusing time was limited to 4 min (before sample started to aggregate), the peak pattern reproducibility was acceptable. The peak pattern reproducibility is shown in Figure 19.6 for this protein conjugate. This cIEF method is therefore useful in detecting pI changes in different lots.

**FIGURE 19.4** (Trace 1) Recombinant protein 1 at 0.4 mg/mL in 4% Pharmalyte pH 3–10 and 0.35% MC. Focusing time was 6 min at 600 V/cm with a 1 min prefocusing at 300 V/cm. (Traces 2 and 3) Two consecutive runs of the sample were performed at a concentration of 2.5 mg/mL in 1% Pharmalyte pH 3–10, 3% Pharmalyte pH 5–8, and 0.35% MC. Focusing time was 6 min at 600 V/cm with a 1 min prefocusing at 300 V/cm. Two pI markers, pI 5.3 and pI 7.9, were spiked into the sample for pI calibration.

**FIGURE 19.5** Effect of focusing time on sample protein conjugate 1's peak pattern.

#### 19.4.4 DEACTIVATED VIRUS 1

A second sample was also analyzed to determine pI values of different lots in production. As shown in Figure 19.7, when focusing time was limited to 6 min, the peak pattern reproducibility was satisfactory for the application. From our experiences with cIEF method development for virus samples, cIEF may not achieve the peak pattern reproducibility that can match that of monoclonal antibodies or other protein samples. However, in most cases, the reproducibility is satisfactory for the desired applications [39].

#### 19.4.5 MONOCLONAL ANTIBODY 2

The monoclonal antibody 2 protein started to aggregate before the completion of the focusing process (Figure 19.8). In the early stage of the focusing process, it went smoothly. The protein was focused into well-defined peaks. However, before the completion of the focusing process, a new peak

**FIGURE 19.6** Four consecutive runs of protein conjugate 1 at 0.25 mg/mL in 4% Pharmalyte pH 3–10 and 0.35% MC. Focusing time was 4 min at 600 V/cm. Two pI markers, pI 4.4 and pI 6.5, were spiked into the sample for pI calibration.

**FIGURE 19.7** Three consecutive runs of deactivated virus 1 at 0.15 mg/mL in 4% Pharmalyte pH 3–10 and 0.35% MC. Focusing time was 6 min at 600 V/cm. Two pI markers, pI 4.4 and pI 7.7, were spiked into the sample for pI calibration.

(indicated by an arrow in Figure 19.8) started to appear and developed quickly along the focusing time. This is a typical symptom of sample aggregation created by the focusing process. In order to eliminate the problem, 4 M urea was added to the sample, effectively eliminating the aggregation problem (Figure 19.9), resulting in a reproducible peak pattern. This example illustrates the power of the whole-column detection cIEF for facilitating fast method development.

## 19.5 METHOD DEVELOPMENT GUIDELINES

In this section, the development of protein characterization methods for samples in typical pharmaceutical laboratories will be examined. All of the method development procedures discussed in this chapter are based on the use of the whole-column detection cIEF instrument, since the IEF process can be observed and the easily associated with optimizing the focusing time. However, the basic conditions described in this chapter are also applicable to conventional cIEF method.

**FIGURE 19.8** Focusing process of sample monoclonal antibody 2. The sample concentration was 0.2 mg/mL. Focusing conditions: 4% Pharmalyte pH 5–8 and 600 V/cm.

**FIGURE 19.9** Focusing process of sample monoclonal antibody 2. The sample concentration was 0.2 mg/mL. Focusing conditions: 4% Pharmalyte pH 5–8 and 600 V/cm; 4 M urea was added to the sample.

### 19.5.1 INITIAL CONDITIONS

At the beginning of the development of a cIEF method for a new sample, the initial conditions for the first sample run must be determined. These conditions include brand name, pH range, pH gradient linearity, and concentration of CAs, electrolytes, additives, sample concentration, focusing voltage, and focusing time.

**FIGURE 19.10** Electropherograms of four commercially available CAs. Concentrations of the CAs were 8%. Focusing time was 6 min at 600 V/cm. Two internal pI markers, pI 4.22 and pI 9.46, were spiked into the samples.

**FIGURE 19.11** Three consecutive runs of Pharmalyte pH 3–10. Concentration was 8% and focusing time was 6 min at 600 V/cm. Two internal pI markers, pI 4.22 and pI 9.46, were spiked into the sample.

The most important condition in cIEF is the CA. As mentioned in Section 19.3, CAs are “special buffers” in cIEF. A CA may contain over 900 amphoteric components [2,40]. According to the literature [2] and to our knowledge, there are four different kinds of commercial CAs: Ampholine, Biolyte, Pharmalyte, and Servalyt. Experiments are needed to determine which CA results in the best resolution for a given sample. Thus, the resolution cannot be the first criterion in CA selection because it is unknown for a given protein sample. Usually, a wide pH range CA is the first choice for a sample of unknown pI value. From our experience, the first criterion in selecting the CA for cIEF should be the background UV absorption. All these CAs were designed for slab gel IEF in which the CA’s UV absorption was not a concern [41]. Figure 19.10 shows the background absorption of the four CAs at 280 nm along their entire pH gradient. In addition, as shown in Figure 19.11, the background profiles of these CAs are reproducible from run to run and relatively stable for different lots. From the point view of background absorption, Pharmalyte should be the first choice due to its low background along its entire pH gradient, as illustrated in Figures 19.10 and 19.11.

Because of the UV absorption of the CAs, from background point of view, lower the concentration of the CAs is in samples, the better the signal-to-noise ratio will be. However, the buffer capacity of the CAs is determined by their concentration [2]. The sample peaks become broad and the relationship between the peak height and the sample concentration becomes nonlinear when the buffer capacity of the CAs is saturated. There should therefore be a trade-off between the buffer capacity and the background. From the literature and our experiences, a 2–8% Pharmalyte solution (the stock solution is considered to be 100%) results in acceptable background noise, while still maintaining enough buffer capacity for most proteins at working concentrations. Thus, it is recommended that a 4% Pharmalyte solution is a good starting point for method development.

As we will discuss later in this chapter, for many samples, separation resolution can be enhanced with the use of narrow pH range CAs. In addition, if the pI value of a sample is known, a narrow pH range CA can be selected for the initial conditions. It should be noted that there has been a misunderstanding associated with the use of narrow pH range CAs. Traditionally, it is believed that narrow pH range CAs must be mixed with one or more wide pH range CAs, or one or more narrow pH range CAs of different pH ranges. From our experience, this is not necessary. A single narrow pH range CA can be used alone for cIEF. Actually, the best resolution is usually achieved using a single narrow pH range CA. For a given protein sample, as long as the pH range of a single narrow pH range CA covers the pIs of the protein, this CA should be the first choice.

Literature suggests that weak acids and bases should be used as the electrolytes when narrow pH range CAs are used [10,11]. In our experiments, we found that although weak acids and bases gave similar results, if not better, to that when using strong acids and bases; they had to be frequently refreshed in order to keep consistent results for a long batch of sample runs. This is probably due to their weak buffer capacity. In our experiments, the same anolyte (0.08 M  $\text{H}_3\text{PO}_4$ ) and catholyte (0.1 M NaOH) are used for all CAs of wide pH ranges and narrow pH ranges between 4% and 8%. The advantage of this approach is the relative simplicity of subsequent method development. Rather, different CAs can be tested without changing the electrolytes.

Focusing time is the second most important parameter for cIEF. Before the focusing time is chosen, the focusing voltage must be determined. Although theoretically, as described in the Section 19.3.3, the separation resolution is higher when a higher voltage is applied, the detection noise also increases along with the voltage [42]. The optimal voltage is around 500 V/cm [42].

Under the focusing voltage, focusing time of different samples can be easily optimized with the use of the whole-column detection cIEF because it monitors the focusing process within the separation column in an online fashion. There is a common misunderstanding related to focusing time in cIEF. The literature suggests that one must determine the end of the focusing process by the focusing current. It is believed that the focusing process is complete when the focusing current stabilizes. However, in our experiments using the whole-column detection cIEF, we found that there is no such relationship between the end of the focusing process and the current. The stabilization of the focusing current only roughly reflects the end of focusing for the CAs. Proteins are usually focused at a slower speed compared to CAs. Some proteins, such as PEGylated proteins, may require an additional 20 min of focusing time after the focusing current stabilizes. Therefore, focusing time has to be determined experimentally for each sample. In addition, the focusing time can be affected by the concentration of salts in the samples. A higher salt concentration will result in a faster focusing process, since the pH gradient created by the CAs is narrowed by the salts [43]. The focusing speed becomes slower when the concentration of CAs is higher. In addition, the focusing speed is much slower when narrow pH range CAs are used. From our experience, for most protein samples, when 4% pH 3–10 Pharmalyte is used, a 6 min focusing time is a good starting point.

For all samples, especially samples in a salt matrix, performing a prefocusing step at a voltage lower than focusing voltage reduces detection noise and increases peak pattern reproducibility. The prefocusing voltage is usually half of the focusing voltage. The step can be 1–2 min long depending on the samples.

At the end of the cIEF process, proteins are focused into narrow zones within the separation column and are concentrated hundreds of times. Confining proteins at their pI points (zero net charge) and at high concentrations for a long time increases the likelihood that they will precipitate or aggregate. Many chemicals can be used as the additives in cIEF [2] to stabilize proteins during IEF, such as sugars, nonionic or zwitterionic surfactants, and urea, thus, effectively reducing the likelihood of protein precipitation and aggregation occur during the focusing process.

For all cIEF methods, polymer solutions are added into the samples, including methyl cellulose (MC) and (hydroxypropyl)methylcellulose (HPMC). These polymers modify the capillary surface [10–12] and enhance separation resolution. The existence of the polymer in the sample solution reduces diffusion coefficients of the proteins, thus, as described in Section 19.3.3, enhancing the separation resolution. In all cIEF applications described in this chapter, 0.35–0.5% of MC are added to the samples.

Because of the UV absorption of the CAs used in cIEF, all UV absorption detections in cIEF are performed at 280 nm. At 280 nm, the absorption of the proteins is determined by the presence of two amino acids in the proteins: tyrosine and tryptophan. Thus, the sensitivity of proteins at 280 nm varies a great deal from protein to protein. It is not easy to determine the initial sample concentration. However, we found that the sensitivity of monoclonal antibodies is relatively even and predictable. For these samples and many other protein samples, 0.2 mg/mL is a good starting point for sample concentration if the samples have only one major peak (the major peak is defined as a peak having >50% of the total protein in a sample). If the samples can be separated into several major peaks (each major peak should be >20% of the total protein in a sample), the starting point can be calculated as follows:

$$\text{Number of major peaks} \times 0.1\text{mg/mL}$$

In summary, for an unknown sample, the initial cIEF analysis conditions would include 4% pH 3–10 Pharmalyte, 0.5% MC as the additive, 0.08 M H<sub>3</sub>PO<sub>4</sub> as the anolyte, 0.1 M NaOH as the catholyte, 0.2 mg/mL sample concentration, and 6 min focusing time at 500 V/cm voltage with a 1–2 min prefocusing step.

### 19.5.2 METHOD DEVELOPMENT FLOW CHART

Figure 19.12 illustrates a flow chart for the development of the cIEF method. At the beginning, it is recommended that the initial conditions described in Section 19.5.1 are tested. The second step should then involve adjusting the sample concentration. The third step is the critical step in the method development because a high-resolution method is based on good reproducibility. All methods should be attempted to ensure a reproducible peak pattern. Then, the separation resolution should be enhanced with the use of narrow pH range CAs. The final step in the method development is pI determination and sample peak identification.

### 19.5.3 pI DETERMINATION AND PEAK IDENTIFICATION

Determination of the pI of a protein using cIEF requires two basic conditions: pI markers with accurate pI values and a linear pH gradient created by the chosen CAs. Using pI markers is the only way to characterize a pH gradient within the capillary column created by CAs [44]. As for the second condition, a pI value in a nonlinear pH gradient is difficult to characterize using a limited number of pI markers since the number of pI markers in a given pH region is always limited. In most cases, these pI markers do not distribute evenly within the pH region. Curve fitting in a nonlinear pH gradient using these pI markers involves a large error that is difficult to estimate. The determination of the pI value should be performed in a single CA with good linearity in its pH gradient.

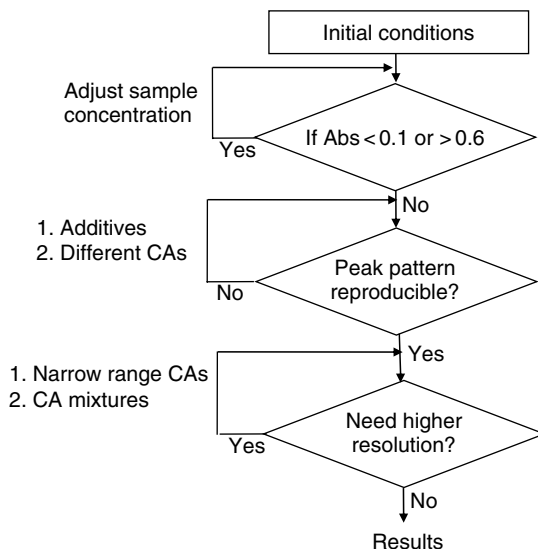

FIGURE 19.12 cIEF method development.

FIGURE 19.13 pH gradient profile of 8% Pharmalyte pH 3–10.

Profiling the pH gradient of different CAs is important for this purpose. Figure 19.13 illustrates an example with a pH gradient for Pharmalyte pH 3–10. The overall linearity of the pH gradient is good ( $r^2$  is about .99). However, the gradient bends at two places, around pH 5 and 8. If pI determination is performed around these two regions, multiple pI markers should be used to ensure good accuracy. However, in other pH regions of this CA, the linearity in the pH gradient is well above  $r^2 = .99$ . Two pI markers should therefore be adequate to calibrate the pI values.

In most practical applications, the determined pI values of a sample are only used to identify component peaks. The true pI value of a peak is not relevant in the applications, as long as the determined pI value of this peak (component) is reproducible in all samples run under identical experimental conditions. It has been proven that peaks (components) in different samples can be identified using the determined pI values within a standard deviation of 0.1 pH units (<2% RSD)

by using two internal pI markers, regardless of the linearity of the pH gradient created by the CAs [43]. This method applies to salt concentrations up to 15 mM in final sample solutions.

## 19.6 EXPANDING cIEF APPLICATIONS AND FUTURE PROSPECTS OF cIEF

In the above sections, the cIEF applications of protein characterization in biotech laboratories and pharmaceutical companies were discussed. In this section, other applications of the cIEF are presented, as well as new developments in cIEF.

### 19.6.1 ONLINE cIEF-MASS SPECTROMETER COUPLING

Coupling cIEF to mass spectrometer is a perfect match because cIEF separates proteins only based on their charges while the results of other CE methods are more or less related to the molecular weight of the samples. Early demonstrations of cIEF-MS work were published in 1996 [45,46]. For this application, a mobilization process after the focusing process is necessary to move sample zones into the MS detector. This technology has recently been applied to the field of proteomics [47–50]. One example is the analysis of *Escherichia coli* whole cell lysates using cIEF-MS for the study of intact proteins [50]. A complete discussion of the applications of cIEF in proteomics is discussed in a recent review [48].

The biggest difficulty in coupling cIEF to MS is that high concentration CAs [47] and most of the additives used in cIEF are not compatible with MS. As we have seen in the previous sections, many protein samples require these additives at high concentration in order to achieve reproducible results. This method limitation must be addressed before cIEF-MS technology can be applied as a tool for the analysis of real-world samples.

### 19.6.2 MULTIPLE DIMENSION SEPARATION

The high speed of separation and detection of the whole-column cIEF makes it attractive as a second separation dimension in a two-dimension (2-D) separation scheme. For example, using a 1-cm-long separation column, the IEF separation, and detection of the separated zones can be performed in 30 s [51]. As the second separation dimension, the whole-column detection cIEF has been successfully coupled to gel filtration chromatography [52]. The whole-column detection cIEF can also be coupled with other CE separation dimensions [53].

### 19.6.3 FLUORESCENCE WHOLE-COLUMN DETECTION FOR cIEF

Using cIEF as the second separation dimension in a 2-D separation system may require high detection sensitivity for cIEF because after the first dimension separation, the sample concentration can be very low. In this case, UV absorption detection is apparently not enough. Fluorescence is considered to be one of the most sensitive methods in optical detectors. A whole-column fluorescence detection system has been used for cIEF and other CE modes [54]. Two schemes have been proposed for the introduction of an excitation laser light beam into a narrow bore capillary column: side illumination and axial illumination. Axial illumination has the advantages of simple optical alignment and low background noise caused by scattering excitation light beam [55]. These advantages expanded the application of the whole-column cIEF [56].

The difficulty of the fluorescence detector for the cIEF is the lack of a chromophore in most proteins in the visible wavelength region. Labeling proteins with fluorescence dyes may change their pI values. In addition, multiple labeling is unavoidable for high sensitive detection.

## 19.6.4 NEW APPLICATIONS OF WHOLE-COLUMN DETECTION cIEF

### 19.6.4.1 Study of Protein Interactions

Since the entire separation column is monitored in an online fashion, the whole-column detection cIEF is an ideal tool for studies of protein–protein interactions and protein interactions with other molecules, such as phospholipids [57,58]. The basic principle of applying whole-column detection cIEF for such studies is based on the pI differences of the proteins and their complexes after interaction with the molecules.

### 19.6.4.2 Estimation of Protein Molecular Weight Based on Their Diffusion Coefficients Determined by Whole-Column Detection cIEF

At the end of focusing process, if the separation voltage is stopped, the protein zones focused within the cIEF column will start to diffuse. This diffusion is almost one dimensional along the axis of the capillary column because of its narrow inner diameter. The diffusion process can be well monitored by the whole-column detection system. From this process, the protein's diffusion coefficient can be calculated. Once the diffusion coefficient is known, the protein's molecular weight will be estimated [59]. One potential application of this method is the determination of aggregation. If the aggregation peaks of a protein can be separated from its monomer, the aggregation peaks should be identified using the diffusion method since the difference of their molecular weight from that of the monomer will be large.

## 20.1 INTRODUCTION

Many cellular processes are localized within specific subcellular compartments; therefore, recent bioanalytical research has been aimed at utilizing the natural organization found within cells to reduce the complexity of biological samples. Subcellular compartments include (i) distinct, vesicular organelles, such as nuclei, mitochondria, and acidic organelles; (ii) indistinct, continuous organelles

such as the endoplasmic reticulum, Golgi apparatus, plasma membrane, and cytoskeletal network; and (iii) the cytoplasm.

In spite of the reduction in complexity that can be achieved by cellular fractionation, an analytical separation is frequently required to separate one or more components from the cellular milieu. As evidenced throughout this book, capillary electrophoresis (CE) provides high resolution and separation efficiency, both of which are necessary for subcellular analysis. In addition, CE is advantageous because it requires very little sample volume, typically less than a nanoliter, and generally very little sample preparation. Hence, capillaries have been used to directly sample subcellular compartments within neurons,<sup>1</sup> oocytes,<sup>2</sup> and muscle tissue sections.<sup>3</sup> They have also been used to analyze individual organelles from a single cell following on-column lysis.<sup>4,5</sup>

Taking advantage of these attributes, CE has the potential to benefit diverse fields, that study the vital cellular processes that are localized within specific subcellular compartments. In fact, subcellular analysis by CE has already proven useful in different areas such as neurochemistry;<sup>1,6–14</sup> cellular physiology;<sup>2,3,15–23</sup> gene therapy;<sup>24</sup> drug accumulation, metabolism and localization;<sup>25–32</sup> disease diagnosis;<sup>33,34</sup> and proteomics.<sup>35–38</sup>

## 20.2 BACKGROUND

### 20.2.1 ORGANELLE PREPARATION

In general, the aim of subcellular analysis is to quantify an analyte within a specific subcellular compartment. Consequently, in most cases, an organelle fraction must be purified before analysis. Cellular fractionation, that is, isolation and purification of organelles, has been indispensable in the biochemical fields and, as evidenced in the literature, has been used pervasively. Since complete reviews can be found in the biochemical literature, we will only briefly describe the principles of cellular fractionation.

#### 20.2.1.1 Cellular Fractionation

To purify an organelle fraction, the first step is cell homogenization, which can be accomplished using diverse methods such as hypotonic shock or mechanical homogenization. Hard tissue samples such as muscle require harsh homogenization techniques (e.g., using a Waring blender), but soft samples such as cells from cultures can be homogenized with gentler techniques like nitrogen cavitation. The choice of a homogenization technique must take into account the sample hardness, volume, and desired organelle intactness.

Following cell homogenization, centrifugation techniques enjoy nearly universal use in the purification of subcellular organelles. Centrifugation is relatively simple and can be performed on several liters to submilliliter volumes of cell homogenate. As shown in Equation 20.1, the sedimentation velocity  $dx/dt$  per unit centrifugal field ( $\omega^2x$ ) is dependent on the size of the particle ( $r^2$ ), the density difference of the particle compared to the medium ( $\rho_p - \rho_m$ ), and the viscosity of the medium ( $\eta$ ):

$$\frac{dx/dt}{\omega^2x} = \frac{2r^2(\rho_p - \rho_m)}{9\eta} \quad (20.1)$$

With advances in separation media, organelles can now be separated based on their density, size, or both. This makes centrifugation the most versatile and practical cellular fractionation method.

Other techniques can be combined with centrifugation to achieve higher purity. These techniques include immunoisolation and electrophoretic purification. Immunoisolation holds great potential for isolating highly purified organelle fractions, since it relies on the molecular recognition of surface antigens by antibodies. Prerequisites for immunoisolation are (i) an antigen that is highly abundant on the surface of a specific organelle type; (ii) an antibody that recognizes the

antigen; and (iii) a monodisperse organelle suspension, which reduces contamination due to aggregation. Frequently, the antibody is attached to magnetic beads to allow more efficient recovery of the organelles.

### 20.2.1.2 Electrophoretic Preparation of Organelles

Although electrophoretic separations are chiefly preparatory, they provide much of the basis for the separation of intact organelles by CE. Electrophoretic separations were originally developed for proteins, but have been used since the 1970s as a purification technique for intact organelles.<sup>39–43</sup> Biological particles, including organelles, carry a net negative charge at physiological pH, and therefore, are mobilized in the presence of an electric field (see Section 20.3). Common separation modes used in electrophoretic preparations are zone electrophoresis, isotachopheresis, and isoelectric focusing modes. The separation scheme for free-flow electrophoresis (zone electrophoresis mode) is illustrated in Figure 20.1. A laminar fluid flow carries the organelles through the separation chamber, while the electric field mobilizes the organelles perpendicular to the flow. Organelle types are then separated based on their electrophoretic mobility differences. At the end of the chamber the suspension is separated into many fractions and the material can be recovered for further analysis. As such, organelles can be continually introduced into the chamber, allowing for the purification of large quantities of material.

The earliest electrophoretic techniques concentrated mainly on the preparation of mitochondria<sup>39,42,43</sup> and lysosomes,<sup>40,41</sup> but further research has made possible the purification of secretory vesicles;<sup>44</sup> clathrin-coated vesicles;<sup>45</sup> endoplasmic reticulum;<sup>46</sup> early, middle-, and late-stage endosomes;<sup>46</sup> peroxisomes;<sup>47</sup> microsomes;<sup>48</sup> and phagosomes.<sup>49</sup> These preparatory techniques have functioned as the proof-of-principle for analytical separations of intact organelles using CE, by demonstrating that isolated organelles are amenable to electrophoretic separation techniques.

**FIGURE 20.1** Free-flow electrophoresis separation. Laminar fluid flow carries the organelles perpendicularly to the applied electric field. Organelles migrate in the opposite direction of the electric field according to their electrophoretic mobility. Sample is introduced continually at the inlet and collected in many fractions following separation.

### 20.3 THEORETICAL ASPECTS

The theories describing micellar electrokinetic chromatography (MEKC), capillary zone electrophoresis (CZE), and capillary gel electrophoresis (CGE) separations of small molecules and biopolymers are described in other chapters of this book and will not be discussed here. Here, we will briefly touch upon the theoretical aspects of the electrophoretic mobility of organelles, foregoing an in depth discussion of electrokinetic theory that can be found elsewhere in original publications and comprehensive reviews.<sup>50–58</sup> The electrophoretic mobility ( $\mu_E$ ) is defined as

$$\mu_E = \frac{v}{E} \quad (20.2)$$

where  $v$  is the velocity of the particle and  $E$  is the electric field in V/cm. The electrophoretic mobility of small molecules is as given in the following equation:

$$\mu_E = \frac{q}{6\pi\eta r} \quad (20.3)$$

where  $q$  is the net charge,  $\eta$  is the viscosity of the separation medium, and  $r$  is the radius of the molecule. As shown, electrophoretic mobility depends on the electrical force and Stokes frictional drag.

On the other hand, the electrophoretic mobility of charged particles (e.g., organelles) is more complex. Figure 20.2 illustrates the forces acting upon a charged particle in an electric field ( $E$ ). While electrophoretic mobility is still governed in part by the electrical force ( $F_1$ ) and the Stokes frictional force ( $F_2$ ), it is also affected by electrophoretic retardation ( $F_3$ ) and the relaxation effect ( $F_4$ ). The electrophoretic retardation force and the relaxation effect are both caused by the ionic atmosphere (dashed circle) that surrounds the charged particle and are dependent on the zeta-potential ( $\zeta$ ), which is related to the surface charge. Electrophoretic retardation ( $F_3$ ) is caused by the force exerted upon the solvent molecules by the oppositely charged ions in the ionic atmosphere, resulting in fluid flow around the particle, which increases frictional drag. In addition, the ionic atmosphere lags slightly behind the charged particle, since its formation requires a finite amount of time, which results in a small electrical force in the opposite direction of the electric field; this is termed the relaxation effect ( $F_4$ ).

The first solution for the electrophoretic mobility of a charged particle was reported by Von Smoluchowski<sup>59</sup> for the case of a thin double layer (i.e.,  $\kappa a \gg 1$ ); where  $\kappa$  is the Debye factor and  $a$  is the particle radius. Accordingly, the electrophoretic mobility of a charged particle should follow

$$\mu_E = \frac{\varepsilon\zeta}{\eta} \quad (20.4)$$

**FIGURE 20.2** Forces acting on a charged particle. The particle is negatively charged and surrounded by a positively charged ionic atmosphere, indicated by the dashed circle.  $F_1$  is the electrical force,  $F_2$  is Stokes frictional drag,  $F_3$  is electrophoretic retardation, and  $F_4$  is the relaxation effect.

in which  $\varepsilon$  and  $\eta$  are the dielectric constant and viscosity of the liquid surrounding the particle, respectively, and  $\zeta$  is defined as follows:

$$\zeta = \frac{\sigma a}{\varepsilon(1 + \kappa a)} \quad (20.5)$$

where  $\sigma$  is the net electrokinetic charge density.

In the opposite case,  $\kappa a \ll 1$ , the electrophoretic mobility follows the Hückel equation:<sup>60</sup>

$$\mu_E = \frac{2\varepsilon\zeta}{3\eta} \quad (20.6)$$

Henry provided a solution<sup>61</sup> (Equation 20.7) for various values of  $\kappa a$  by taking into account the deformation of the electric field lines near the particle:

$$\mu_E = \frac{2\varepsilon\zeta}{3\eta} f_1(\kappa a) \quad (20.7)$$

When  $\kappa a \rightarrow 0$ ,  $f_1 = 1$  and the Henry equation reduces to Hückel's solution (Equation 20.6). Conversely, when  $\kappa a \rightarrow \infty$ ,  $f_1 = 3/2$  and the equation reduces to Smoluchowski's solution (Equation 20.4). The function  $f_1$  was recently given as a single equation,<sup>62</sup> as opposed to two power series as reported by Henry.

Equation 20.7 can be applied when any of the following conditions are met: (i)  $\kappa a \gg 1$ , (ii)  $\kappa a \ll 1$ , or (iii)  $\zeta \ll 25$  mV. In these cases, the relaxation effect is negligible. More accurate theories that take into account the relaxation effect and electrophoretic retardation have been developed by Booth,<sup>52</sup> Overbeek,<sup>53,54</sup> and O'Brien.<sup>55-58</sup>

Regrettably, the electrokinetic theories described above do not adequately describe the electrophoretic mobility of organelles. This is because the classical colloidal theories assumed the particle was rigid and nonconducting with uniform charge, whereas in reality, organelles are nonspherical, deformable, and the surface charges are mobile, which leads to polarization. This makes it difficult to interpret electrophoretic mobility with the classical theories. However, Hayes' group has aimed to describe the electrophoretic mobility of deformable particles using liposomes as a model.<sup>63,64</sup> It has been demonstrated that models that incorporate the effects of particle deformation, mobile surface charges, and polarizability predict the electrophoretic behavior of liposomes better than do traditional electrokinetic models.<sup>64</sup> Since liposomes more closely resemble biologically relevant particles, this model provides a more complete description of organelle electrophoretic mobility.

## 20.4 PRACTICAL APPLICATION

Subcellular analysis by CE can be performed in three modes: (i) an organelle fraction can be dissolved or lysed and the analytes found in the fraction analyzed; (ii) intact, isolated organelles can be separated and detected; and (iii) analytes or organelles can be directly sampled from a single cell or tissue section. Each mode of analysis will be illustrated below.

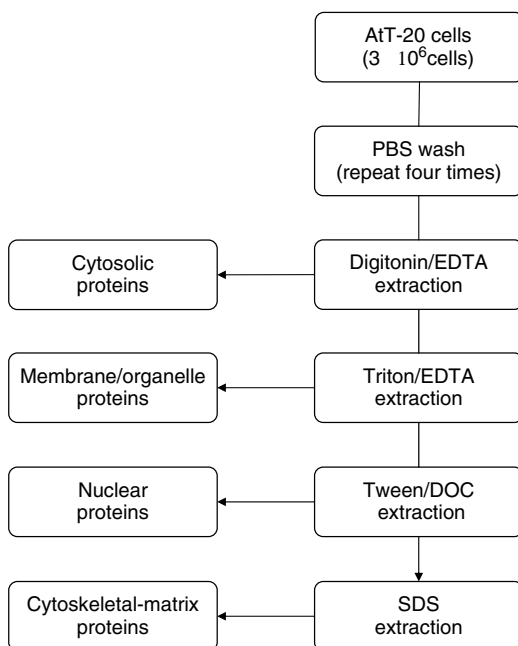

### 20.4.1 PROTEOMIC ANALYSIS OF DISSOLVED SUBCELLULAR FRACTIONS

Proteomics research has benefited greatly from subcellular fractionation, because reducing the complexity of the entire proteome to smaller organelle proteomes makes it possible to separate and detect low abundance proteins. Furthermore, since the goal of proteomics is not only to learn protein sequences but also the localization and function of proteins, subcellular analysis is advantageous because it provides the subcellular localization. Indeed, the benefits of cellular fractionation before

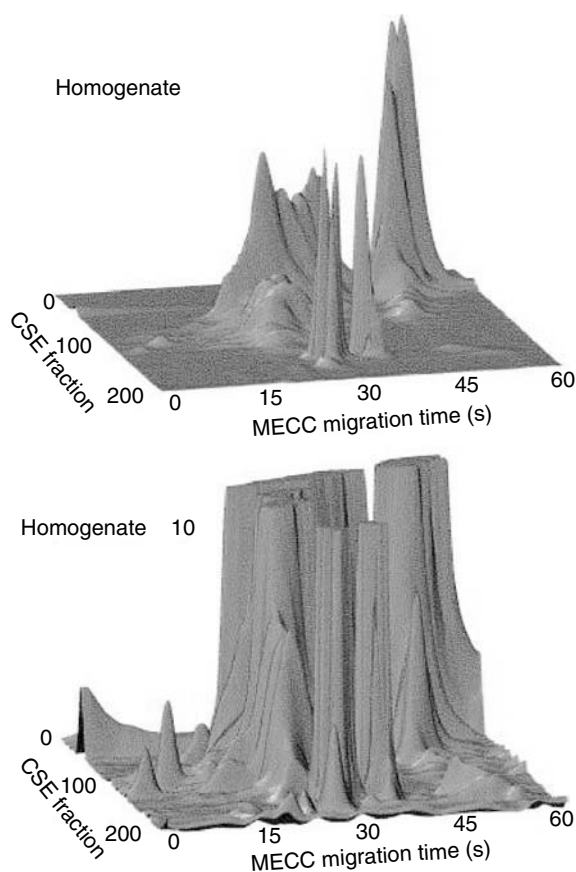

proteomic analysis have been proven with conventional two-dimensional gel electrophoresis and multidimensional liquid chromatography-tandem mass spectrometry (LC-MS/MS).<sup>65-68</sup>

Although two-dimensional gel electrophoresis provides unmatched resolution (~2000 protein spots using conventional gels), it does have some drawbacks: these include the precipitation of highly acidic or basic proteins in the first dimension (isoelectric focusing), limited sensitivity and dynamic range, low throughput, and difficulty in automating time-consuming and tedious tasks. CE, on the other hand, is easily automated, has a very low limit of detection (LOD) when combined with off-column laser-induced fluorescence (LIF) detection, and has a large dynamic range. In addition, isoelectric focusing does not need to be performed in the first dimension, thereby eliminating the precipitation of acidic and basic proteins. Separations based on CE thus show potential for increasing the throughput and sensitivity of proteomic analyses.

Working toward this goal, Dovichi and coworkers<sup>69-71</sup> have developed highly sensitive two-dimensional CE protein separations and automated the analysis. Since two-dimensional CE separations do not resolve as many proteins as traditional two-dimensional gel electrophoresis,<sup>70</sup> in order to increase the resolution and aid in the detection of low abundance proteins, a differential detergent fractionation technique was used to reduce the complexity of cell homogenates before separation.<sup>38,72</sup> Differential detergent fractionation was developed by Ramsby et al.<sup>73</sup> for isolated hepatocytes and is based on the different solubilities of proteins in various buffers. A schematic representation of the fractionation procedure is shown in Figure 20.3 where four fractions are obtained: (i) cytosolic or soluble proteins, (ii) membrane-organelle proteins, (iii) nuclear membrane proteins, and (iv) cytoskeletal-matrix proteins. The identity of each fraction was confirmed and its selectivity measured with immunoblotting using over 20 antibodies.<sup>73</sup>

**FIGURE 20.3** Schematic representation of the differential detergent fractionation procedure applied to cultured cells. Four fractions are obtained: (1) cytosolic proteins, (2) membrane/organelle proteins, (3) nuclear-membrane proteins, and (4) cytoskeletal proteins. (Modified from Fazal, M. A., et al., *J. Chromatogr. A*, 1130, 182-189, 2006. )

**FIGURE 20.4** Two-dimensional electropherogram of whole cell homogenate. AtT-20, mouse adrenal gland cells, were homogenized and the proteins were labeled with FQ. The electropherogram is shown as a landscape image, in which the fluorescence intensity is proportional to the peak height. Proteins were separated first by capillary sieving electrophoresis and then by micellar electrokinetic capillary chromatography in the second dimension. Approximately 150 fractions were transferred from the first capillary to the second capillary. (Reprinted from Fazal, M. A., et al., *J. Chromatogr. A*, 1130, 182–189, 2006. Copyright 2006. With permission from Elsevier.)

Ramsby's procedure was used by Fazal et al.<sup>38</sup> to fractionate the homogenate of AtT-20 cells (mouse adrenal gland cells) before two-dimensional CE separation. Proteins were labeled with 3-(2-furoyl) quinoline-1-carboxaldehyde (FQ) before separation and detected using LIF in a sheath flow cuvette. Capillary sieving electrophoresis was performed in the first dimension to separate the proteins based on size, using dextran in the sieving buffer; this was followed by micellar electrokinetic capillary chromatography in the second dimension to separate proteins based on hydrophobicity. The resulting two-dimensional electropherogram for the whole cell homogenate is displayed in Figure 20.4. The separation detected 51 unique protein peaks, and the origin of the large mesa, shown in the close up view, was determined using the differential detergent fractionation procedure. Figure 20.5 shows all four detergent fractions and indicates that the large mesa in Figure 20.4 was from proteins located in the nuclear protein extract. As anticipated, by performing the fractionation technique before the two-dimensional separation, the number of resolved proteins increased from 51, for the whole cell homogenate, to 231, for the detergent fractions. This increase is due to the detection of low abundance proteins that had been previously masked by highly abundant proteins in the whole

**FIGURE 20.5** Two-dimensional electropherograms of each differential detergent fraction. The digitonin fraction (A) is the cytosolic proteins, the Triton fraction (B) is the membrane/organelle proteins, the Tween fraction (C) is the nuclear-membrane proteins, and the detergent resistant fraction (D) is the cytoskeletal proteins. (Reprinted from Fazal, M. A., et al., *J. Chromatogr. A*, 1130, 182–189, 2006. Copyright 2006. With permission from Elsevier.)

cell homogenate. In addition, each detergent fraction had distinct electrophoretic features, indicating that each fraction contained unique proteins.

#### 20.4.2 QUANTIFICATION OF HYDROXYCHLOROQUINE IN THE RAT LIVER MICROSOMAL FRACTION

A more conventional subcellular fractionation approach was taken for the quantification of hydroxychloroquine (HCQ) in the microsomal fraction of mouse liver homogenates.<sup>27</sup> Microsomes are vesicles formed from the disruption of the endoplasmic reticulum and provide a convenient means of studying metabolism by the cytochrome CYP450 enzyme superfamily, which metabolizes the majority of drugs given to humans. HCQ has proven efficacious against rheumatoid arthritis, lupus erythematosus, and has been used as an antimalarial drug. It is a chiral molecule and, as shown in Figure 20.6, forms three chiral metabolites when incubated with rat liver microsomes. Since it is well known that enantiomers show different activities toward drug targets, a method for quantifying HCQ and its metabolites was developed.

Mouse livers were excised and homogenized with a Potter–Elvehjem homogenizer. The microsomal fraction was isolated by centrifuging the homogenate at  $9000 \times g$  for 15 min, to sediment nuclei, mitochondria, and membrane debris. The supernatant was centrifuged at  $100,000 \times g$  for 60 min to pellet microsomes. The microsomes were further purified by another centrifugation step to remove soluble proteins (e.g., hemoglobin). HCQ was incubated with the microsomes for 2 h. Then a liquid–liquid extraction technique was performed to recover HCQ and its metabolites. The molecules were separated by a commercial CE system with ultraviolet (UV) absorbance detection.

**FIGURE 20.6** Illustration of HCQ and its three metabolites. The chiral center in each molecule is indicated by an asterisk.

The resulting electropherogram is displayed in Figure 20.7, which shows the separation of all eight molecules. The separation was performed in Tris buffer that contained sulfated- $\beta$ -cyclodextrin and hydroxypropyl- $\beta$ -cyclodextrin, which provided the enantiomeric selectivity. Metabolites were quantified from 0.41 to 0.89  $\mu\text{M}$  with relative standard deviations of  $\sim 10\%$ . The subcellular analysis shows the preferential production of (–)-(*R*)-metabolites (Table 20.1). Compared with a previously reported high-performance liquid chromatography (HPLC) method,<sup>74</sup> the CE method allowed these researchers to quantify two more metabolites and required less time.

### 20.4.3 MEASUREMENT OF THE pH IN INDIVIDUAL ACIDIC ORGANELLES

An alternative approach to separating analytes that have been released from dissolved organelles is to quantify the analytes within intact organelles. The major aims of this type of analysis are to reveal the heterogeneity amongst organelles, determine the subcellular localization of analytes, and quantify the analytes within individual organelles. Arriaga and coworkers successfully analyzed intact nuclei,<sup>4,75,76</sup> mitochondria,<sup>3,15,17,77–80</sup> and acidic organelles<sup>16,28,81</sup> by CE-LIF. The advantages of individual organelle analysis are illustrated below using pH measurements in individual acidic organelles as an example.

Multidrug resistance is a common problem with chemotherapeutic treatments in which cancer cells become insensitive to drug treatment. It has been proposed that multidrug resistance may be related to a larger than normal pH gradient between the cytoplasm and acidic organelles in

**FIGURE 20.7** Chiral resolution of HCQ and its metabolites after incubation with mouse liver microsomes. Peaks are numbered and correspond as follows: (1) (–)-(R)-HCQ, (2) (+)-(S)-HCQ, (3) (–)-(R)-DHCQ, (4) (+)-(S)-DHCQ, (5) (+)-(S)-DCQ, (6) (–)-(R)-BDCQ, (7) (–)-(R)-DCQ, and (8) (+)-(S)-BDCQ. Electrophoresis was performed in a 50 cm, 50  $\mu\text{m}$  i.d. capillary with a separation voltage of 13 kV in 100 mM Tris/phosphate, 1% sulfated- $\beta$ -cyclodextrin, 30 mg/mL hydroxypropyl cyclodextrin, pH 9.0. The molecules were detected with UV absorbance at 220 nm. (Reprinted from Cardoso, C. D., et al., *Electrophoresis*, 27, 1248, 2006. With permission.)

drug-resistant cells as compared to drug-sensitive cells.<sup>82</sup> The larger pH gradient is hypothesized to result in drug protonation and sequestration in acidic organelles and secretion from the cell (Protonation, Sequestration, and Secretion, PSS model). When the drug is secreted from the cell, it can no longer act to halt cell proliferation, which causes drug resistance. The average pH value of acidic organelles can be determined with fluorescence microscopy and flow cytometry, but neither technique has been used to measure the pH of individual acidic organelles or reveal acidic organelle heterogeneity. To obtain this information, CE-LIF was used to measure, for the first time, the pH of individual acidic organelles in drug-resistant and drug-sensitive cell lines.<sup>81</sup>

Fluorescein tetramethylrhodamine dextran (FRD) was used as a ratiometric probe, which provides a pH-independent signal (tetramethylrhodamine), to compensate for different organelle volumes, and a pH-dependent signal (fluorescein). The ratio of the pH-independent and pH-dependent fluorescence was expected to provide a quantitative measure of the pH. Acidic organelles (lysosomes and endosomes) were specifically labeled by FRD, because the cells endocytose small amounts of the extracellular medium, which is accumulated in endosomes and eventually lysosomes. CE was performed in a poly(*N*-acryloyl aminopropanol, AAP) modified capillary to reduce both adsorption at the capillary surface and the electroosmotic flow. LIF detection was performed off-column using a

**FIGURE 20.8** Calibration of the pH measurement.  $R$ , the ratio of tetramethylrhodamine and fluorescein fluorescence, versus the pH for liposomes constructed with internal pH values ranging from 3 to 7. The average ratio and standard deviation is shown with a marker and bars at 7 pH values. The calibration curve represents a quadratic model and was determined by multiple regression analysis. **FIGURE 20.9** Electropherogram displaying CE-LIF detection of individual acidic organelles. The entire electropherogram is shown in panel a, where the top trace is the fluorescein channel and the bottom trace is the tetramethylrhodamine channel. Panel b shows an enlarged region of the electropherogram to illustrate detection of acidic organelles simultaneously in each channel. Acidic organelles were injected for 1 s at 11 kPa and separated at  $-300$  V/cm in a poly(AAP) coated capillary. (Reprinted from Chen, Y. and Arriaga, E. A., *Anal. Chem.*, 78, 821, 2006. Copyright 2006. With permission American Chemical Society.)

single excitation source (488 nm argon-ion laser) and two emission wavelengths ( $\lambda_1$ -pH independent and  $\lambda_2$ -pH dependent) that were monitored simultaneously.

To calibrate the CE-LIF detector, liposomes were constructed with internal pH values ranging from 3.1 to 8.0. The liposomes were injected onto the capillary, electrophoretically separated and detected individually following hydrodynamic focusing in a sheath flow cuvette. The calibration curve obtained is shown in Figure 20.8. To test the PSS model, acidic organelles were isolated from drug-resistant and drug-sensitive cell lines using a Dounce homogenizer and differential centrifugation. The acidic organelles were then analyzed in a fashion similar to the liposomes and the resulting electropherogram is shown in Figure 20.9; the sharp spikes correspond to the detection of individual acidic organelles. By tabulating the fluorescence in both channels and comparing the ratios with

**FIGURE 20.10** Amount of FRD per acidic organelle sorted from high to low pH. The y-axis is offset 1 unit for the CEM/c2 cells (drug-resistant). (Reprinted from Chen, Y. and Arriaga, E. A., *Anal. Chem.*, 78, 821. Copyright 2006. With permission from American Chemical Society.)

the calibration curve, the pH for each individual acidic organelle was measured. The average pH values were  $5.1 \pm 0.2$  for drug-resistant cells and  $6.1 \pm 0.9$  for drug-sensitive cells, respectively. The average pH values correlated well with fluorescence microscopy values ( $5.0 \pm 0.6$  and  $6.2 \pm 0.7$  for drug resistant and drug sensitive, respectively).

Unlike fluorescence microscopy, which measures the average pH value of all the acidic organelles in an entire cell, the individual pH measurements obtained with CE revealed a range of pH values from 3 to 7 in both cell lines, which indicated that several types of acidic organelles were being analyzed; specifically, early endosomes (pH 6–6.5), late endosomes (pH 5.5–6), and lysosomes (pH 4.5–5.5). This was confirmed by plotting the amount of FRD versus pH as shown in Figure 20.10. The more acidic organelles contained more FRD, which is consistent with the maturation of the acidic organelles as they transform from early endosomes to lysosomes, since they fuse with each other to become larger during this process.

#### 20.4.4 DIRECT SAMPLING OF DOPAMINE FROM MAMMALIAN CELL CYTOPLASM

The third approach to subcellular analysis involves using the separation capillary to sample subcellular compartments within single cells or from tissue sections. Capillaries are uniquely suited to provide not only high resolution and separation efficiency but also, due to their physical dimensions, sufficient spatial resolution to sample subcellular compartments. Most commonly, the capillary is used to sample the cytoplasm from single cells. However, the capillary can also be used to sample intact organelles from tissue sections<sup>3,15</sup> and analyze organelles released from single cells.<sup>5,76</sup>

In particular, neurochemistry has found CE especially useful for quantifying neurotransmitter concentrations in single cells. Since important cellular processes such as neurotransmitter synthesis, storage and release are affected by the cytoplasmic concentrations of neurotransmitters, methods to sample and quantify cytoplasmic concentrations of neurotransmitters from single invertebrate cells have been developed.<sup>6,7,9–11</sup> Invertebrate neurons are particularly amenable for sampling because they can be quite large, for example, the giant dopamine neuron of pond snails is  $\sim 200 \mu\text{m}$

**FIGURE 20.11** Schematic representation of the end-column amperometric detection system: (1) the outlet of the separation capillary was etched to 13  $\mu\text{m}$  i.d., (2) Ag/AgCl reference electrode, (3) flame-etched carbon fiber electrode, (4) buffer reservoir, and (5) separation capillary, 770 nm i.d. (Reprinted from Woods, L. A., et al., *Electroanalysis*, 17, 1192, 2005. With permission.)

in diameter. However, sampling from mammalian cells, which are over four times smaller, was impracticable until recently.

To overcome these difficulties, a CE system utilizing a 770 nm i.d. capillary was developed to sample and quantify dopamine from the cytoplasm of single mammalian cells.<sup>7</sup> To sample the cytoplasm, the inlet of the separation capillary was tapered to an outer diameter of 2.5  $\mu\text{m}$ , which is five times smaller than the diameter of the cells. The capillary was inserted through the plasma membrane by applying a small voltage (e.g., 2 kV) to cause the electroporation of the membrane. This voltage also electrokinetically injected the cytoplasm into the capillary, simultaneously. This system allowed as little as 380 fL of cytoplasm to be injected from a single PC12 cell, which amounts to  $\sim 40\%$  of the cell cytoplasm. The smallest percentage of cytoplasm that was sampled was 8%.

Such small injection volumes necessitate a very low LOD. This is achieved using an improved end-column amperometric detection scheme,<sup>83</sup> as shown in Figure 20.11; a 2.5  $\mu\text{m}$  flame-etched carbon fiber microelectrode is positioned inside the etched lumen of the separation capillary. The conical tip of the flame-etched microelectrode allows for better positioning of the electrode into the capillary lumen, which reduces the dead volume and hence decreases the LOD. The reported LODs for dopamine and catechol using this detection scheme were  $400 \pm 100$  and  $410 \pm 80$  zmol ( $10^{-21}$  moles), respectively. The separation and detection of dopamine sampled from a single cell is displayed in the resulting electropherogram shown in Figure 20.12. The concentration of cytoplasmic dopamine from three cells was  $240 \pm 60$   $\mu\text{M}$ , which indicated the presence of dense core vesicles in the injection plug.

#### 20.4.5 DETECTION OF INDIVIDUAL MITOCHONDRIA SAMPLED FROM MUSCLE TISSUE CROSS SECTIONS

In a similar fashion, intact organelles can also be sampled directly from a cell sample. This was first demonstrated by sampling and separating individual mitochondria from skeletal muscle tissue cross sections.<sup>3</sup> Skeletal muscle is a complex and heterogeneous tissue in which thousands of individual fibers extend approximately in parallel throughout the length of the tissue. Each fiber contains multiple nuclei and thousands of mitochondria. Using conventional histochemical stains, the heterogeneity among muscle fibers can be visualized to investigate the effects of disease and aging. However, an analytical method that could reveal heterogeneity among the organelles in a single fiber as well as fiber-to-fiber heterogeneity was desirable.

**FIGURE 20.12** Separation of dopamine (DA) and catechol (CAT) from a single mammalian cell. (a) Dopamine was separated and detected in a 380 fL injection of PC12 cell cytoplasm and (b) a standard injection of DA and CAT is used to verify the detection of dopamine. Both injections used a 3 kV injection voltage for 5 s and a bare fused-silica capillary. Dopamine was separated at 25 kV in 50 mM TES, pH 7.2 with 2% 1-propanol. (Reprinted from Woods, L. A., et al., *Electroanalysis*, 17, 1192, 2005. With permission.)

Semimembranous muscle tissues from Fisher rats were excised, frozen, and sectioned perpendicular to the fiber length, with a cryostat. The  $\sim 10 \mu\text{m}$  thick cross sections were mounted on microscope slides and frozen before use. Mitochondria were labeled with the mitochondria-specific fluorescent stain 10-*N*-nonyl acridine orange (NAO) by depositing a microdroplet on the tissue cross section and using a capillary, micromanipulator, and a microscope to visualize deposition. Mitochondria were sampled by positioning the separation capillary on top of the labeled fiber and applying suction. Since the cross-sectional area of the  $50 \mu\text{m}$  i.d. capillary was  $\sim 2000 \mu\text{m}^2$ , which is slightly smaller than the  $\sim 3000 \mu\text{m}^2$  area of a single fiber, the capillary was able to sample mitochondria from a single fiber. The labeling and sampling of mitochondria are shown in Figure 20.13, wherein the capillary lumen can be easily seen above a single muscle fiber. After the mitochondria were introduced into the capillary, the inlet was placed in separation buffer and the separation voltage applied. Mitochondria were electrophoretically separated and detected individually by off-column LIF detection as they migrated out of the capillary. Figure 20.14 displays an electropherogram showing the detection of individual mitochondria sampled from a muscle cross section.

One complicating factor in the analysis of mitochondria from tissue cross sections is that mitochondria are found in two locations in muscle tissue: (i) subsarcolemmal mitochondria are found directly beneath the sarcolemmal membrane and are easily extracted and (ii) interfibrillar mitochondria are located between the myofibrils and require exposure to a protease to be efficiently released. To release these latter mitochondria, a short treatment with trypsin was tested by depositing a microdroplet of trypsin on the fiber before sampling. Table 20.2 compares the analysis of mitochondria from muscle fiber that had undergone trypsin treatment with the analysis of mitochondria from

**FIGURE 20.13** Sampling mitochondria from a muscle cross section. A series of fluorescence images show (A) the tissue cross section labeled with a microdroplet of 5  $\mu\text{M}$  NAO using a capillary and a micromanipulator, (B) the separation capillary is positioned above the desired fiber and the mitochondria are sampled for 3 s with negative pressure, and (C) the fluorescence image indicates that the sampling was successful since some of the fluorescence in the region above the desired fiber has disappeared. (Reprinted from Ahmadzadeh, H., et al., *Anal. Chem.*, 76, 315, 2004. Copyright 2006. With permission American Chemical Society.)

**FIGURE 20.14** Detection of individual mitochondria sampled from a muscle tissue cross section. CE-LIF was performed on (1) cross sections that were labeled with 5  $\mu\text{M}$  NAO, (2) an unlabeled cross section, and (3) a solution of the free dye, NAO. The three traces show that mitochondria are detected when labeled with NAO and there is relatively little interference from other cellular components. The small spikes seen in (2) are likely caused by scattering of the excitation source or autofluorescence but only comprise 5% of the peaks detected in (1). Mitochondria were separated at  $-200\text{ V/cm}$  in a poly(AAP) coated capillary in 250 mM sucrose, 10 mM HEPES, pH 7.4. (Reprinted from Ahmadzadeh, H. et al., *Anal. Chem.*, 76, 315, 2004. Copyright 2006. With permission American Chemical Society.)

untreated muscle fiber. As can be seen, many more mitochondria, presumably interfibrillar, were released from the fiber after exposure to trypsin.

## 20.5 METHODS DEVELOPMENT GUIDELINES

### 20.5.1 ISOLATION OF MITOCHONDRIA FROM MAMMALIAN CELL CULTURE

Many complex cellular processes are best studied through the use of an appropriate cell model. Cell cultures provide a relatively stable and virtually unlimited supply of organelles for subcellular analysis. We will discuss organelle preparations that are commonly used in the author's laboratory

**TABLE 20.2**  
**Effect of Trypsin on the Number of Mitochondrial Peaks**

Cross Section Number	Number of Peaks <sup>a</sup>	
	Trypsin Treatment	No Trypsin Treatment
1	1782	350
2	2339	256
3	1285	339
Mean	1802	315
RSD (%)	29	16

<sup>a</sup> Conditions for sampling and CE-LIF analysis are the same as for Figure 20.14.

for the isolation of mitochondria from human osteosarcoma 143B cells. With minor changes, the procedure detailed below should be applicable to other mammalian cell lines.

### 20.5.1.1 Cell Lysis

Approximately  $5 \times 10^6$  143B cells should be harvested and washed three times with an ice-cold, iso-osmotic buffer, for example, 220 mM mannitol, 70 mM sucrose, 0.5 mM EGTA, 2 mM HEPES, pH 7.4 buffer (MSHE buffer). Whenever possible, the sample should be kept on ice and centrifugation performed at 4°C to prevent organelle degradation. Cells are washed by centrifuging at  $\sim 700 \times g$  for 10 min, followed by removal of the supernatant and resuspension in MSHE buffer. Approximately 3 mL of cells are then transferred into an ice-cold cell disruption chamber (Parr Instruments, Moline, IL), which is then pressurized to 500 psi. After equilibration for 15 min, the pressure is released as the cells are collected through the discharge port and kept on ice for 5 min. Disruption efficiency is generally >90% and the nitrogen pressure can be adjusted to obtain the desired efficiency. A phase-contrast microscope or trypan blue staining can be used to visually confirm cell disruption.

### 20.5.1.2 Differential Centrifugation

Following lysis, centrifugation is nearly universally implemented to separate organelle fractions based on their size or density. Centrifugation is popular because it is very versatile; it can be used to fractionate organelles from several liters of tissue homogenates or submilliliter volumes from cell cultures. The simplest centrifugation procedure is differential centrifugation, which produces crudely purified organelle fractions.

Differential centrifugation begins by pelleting nuclei at low centrifugal force (i.e.,  $600\text{--}1000 \times g$  for 10 min). The resulting nuclear fraction is always contaminated with organelles that have been trapped in the cytoskeletal network, whole cells, and large membrane debris. The postnuclear supernatant is then transferred to a new microcentrifuge tube and the light-organelle fraction can be sedimented at  $16,000 \times g$  for 10 min, and the supernatant will contain the cytosolic components. The light-organelle fraction is now enriched with mitochondria, but also contains significant amounts

of acidic organelles, microsomes, and peroxisomes. For some analyses that use organelle-specific labels, no further purification is necessary. However, if purer organelle fractions are required, the light-organelle fraction can be further fractionated as described below.

### 20.5.1.3 Density Gradient Centrifugation

The mitochondria in the light-organelle fraction can be further purified using common methods such as continuous gradient and discontinuous gradient centrifugation. While continuous gradients can be used (e.g., sucrose gradient), since the osmolarity changes quite drastically through the gradient, discontinuous gradients are preferred to reduce mitochondrial disruption. Furthermore, the mitochondrial band is harder to distinguish when continuous gradients are used, which reduces the recovery.

Discontinuous density gradient centrifugation separates organelles based on their density and has been described by Storrie and Madden.<sup>84</sup> Unfortunately, the popular medium for density gradient centrifugation, Metrizamide, is no longer produced, and therefore, the existing methods must be redesigned with appropriate new media. We have found success using Histodenz (Sigma, St Louis, MO) following the procedure of Okado-Matsumoto and Fridovich.<sup>85</sup> Briefly, a 50% (w/v) solution of Histodenz is prepared by dissolving in 5 mM Tris-HCl, 1 mM EGTA at pH 7.4. Solutions of 34%, 30%, 25%, 23%, and 20% solutions (w/v) of Histodenz are prepared by diluting the stock solution in 250 mM sucrose, 5 mM Tris-HCl, 1 mM EGTA at pH 7.4. The light-organelle fraction is suspended in ~10 mL of 25% Histodenz and the discontinuous gradient is prepared as shown in Figure 20.15. The samples are then centrifuged at  $52,000 \times g$  for 90 min at 4°C. After centrifugation is complete, the bands can be removed sequentially including the band with the purified mitochondria located at the 25/30% interface. Finally, the purity and yield of the mitochondrial preparation can be determined using enzymatic marker assays, such as cytochrome *c* oxidase (mitochondrial marker) and  $\beta$ -galactosidase (lysosomal marker).

### 20.5.2 CAPILLARY MODIFICATIONS

Mitochondria interact strongly with the surface of bare fused-silica capillaries, preventing any accurate measurement of electrophoretic mobility. Since mitochondria and the capillary surface both carry a net negative charge, the adsorption is probably not due to any electrostatic interactions, but rather to hydrophobic intermolecular interactions. To prevent the mitochondria from interacting with the capillary surface, coatings can be applied to the bare silica. Among these coatings, AAP has been reported to be more hydrophilic and hydrolytically stable in comparison with acrylamide, dimethyl acrylamide, and *N*-acryloylaminoethoxyethanol.<sup>86</sup> We have found that capillaries

**FIGURE 20.15** Density gradient centrifugation. The postnuclear supernatant, suspended in 25% Histodenz (Hz), is layered on top of the 30% and 34% Hz solutions. Then the tube is filled sequentially with the 23% and 20% solutions of Hz. Centrifugation is performed at  $52,000 \times g$  for 90 min at 4°C. The mitochondria will form a band at the 25/30% Hz interface.

coated with poly(AAP), based on Gelfi's procedure,<sup>87</sup> reduce organelle adsorption, and thereby allow reproducible separations; this coating remains stable for several months.

Covalent surface modification with poly(AAP) consist of the following steps:

1. Flush 4–5 m of fused-silica capillary sequentially with 0.1 M KOH for 3 h, 0.1 M HCl for 1 h, MeOH for 1 h with nitrogen pressure (90 psi for all flushes unless stated otherwise)
2. Heat the capillary to 110°C and flush with nitrogen at 10 psi for 8 h
3. Place the capillary in a moisture-free, inert environment (glove box) and do not remove until step (9)
4. Flush the capillary with thionyl chloride for 1 h at 65°C
5. Seal the capillary ends with a gas chromatography (GC) septum and heat for 8 h at 65°C
6. Flush the capillary with freshly distilled tetrahydrofuran (THF) for 30 min at 65°C
7. Prepare a 0.25 M vinylmagnesium bromide solution with freshly distilled THF, flush the capillary with this solution for 1 h and heat for 8 h at 70°C
8. Flush the capillary with freshly distilled THF for 1 h and water for 30 min
9. Cut the capillary into 50 cm pieces
10. Add 5  $\mu\text{L}$  of freshly prepared 10% ammonium persulfate and 2  $\mu\text{L}$  tetramethylethylenediamine (TEMED) to a monomer solution and immediately flush this solution through the capillaries for 5 min
11. Polymerize the capillaries at room temperature for 1 h
12. Flush the capillaries with water for 1 h

Freshly distilled THF must be used in each step to prevent the precipitation of vinylmagnesium bromide in the capillary. To increase the robustness of the capillary modification, steps (4) and (7) may be repeated. The AAP monomer can be synthesized in a single step reaction with >99% yield and >99% purity.<sup>86</sup> The polymerization time and concentrations of ammonium persulfate and TEMED must be optimized for each batch of AAP. The success of the procedure can be checked by measuring the electroosmotic flow, which should be  $<0.5 \times 10^{-5} \text{ cm}^2 \text{ V}^{-1} \text{ s}^{-1}$ . The success rate of the procedure described above is  $\sim 90\%$ , but decreases dramatically if freshly distilled THF or anhydrous reagents are not used.

As described above, covalently linking AAP to the capillary surface is a tedious and time-consuming task. Procedures that utilize silane chemistry are faster and easier to perform, but the resulting Si–O–Si bonds are prone to nucleophilic cleavage and degrade relatively quickly. Simpler procedures using dynamic coatings or unmodified capillaries would be beneficial and have also been investigated. Under tightly controlled conditions, it was reported that mouse liver mitochondria could be analyzed in unmodified fused-silica capillaries, but this method was not easily adapted to other samples, including rat liver mitochondria, and requires strict attention to buffer composition.<sup>88</sup> Poly(vinyl alcohol) was investigated as a dynamic capillary coating and reduced mitochondrial adsorption to values that were similar to those for poly(AAP) coated capillaries. Although such dynamic coatings show potential, poly(AAP) coated capillaries continue to be the gold standard for organelle separations.

### 20.5.3 SEPARATION CONDITIONS

To separate analytes from a dissolved organelle fraction, a useful and popular mode of separation is MEKC. As applied to subcellular analysis, the MEKC buffer is often used to dissolve the organelles and acts to separate the components based on their hydrophobicity. A common buffer utilized for this purpose is 10 mM borate, 10 mM sodium dodecyl sulfate (SDS) pH 9.5 (BS buffer), which has been used to separate doxorubicin and its metabolites from nuclear, mitochondrial, and cytosolic-enriched fractions.<sup>25,26</sup> Here, separations were performed from each fraction by injecting a small

sample plug that had been dissolved in BS buffer and separating at 400 V/cm in a fused-silica capillary while using BS buffer as the running buffer. To increase the resolution between structurally similar molecules, additive can be used to improve the selectivity. For example,  $\gamma$ -cyclodextrin has been added to BS buffer to resolve doxorubicin and a structurally similar chiral metabolite, doxorubicinol.<sup>89</sup> MEKC buffers that contain detergents (e.g., SDS) also reduce the interactions of molecules with the capillary wall; consequently, capillary surface modifications are rarely needed for an MEKC separation, greatly simplifying the analysis.

To separate intact organelles, iso-osmotic buffers must be used to reduce disruption caused by osmotic shock. For instance, 220 mM mannitol, 70 mM sucrose, 0.5 mM ethylene glycol tetraacetic acid (EGTA), 2 mM 4-(2-hydroxyethyl)-1-piperazineethanesulfonic acid (HEPES), pH 7.4, form a commonly used buffer for isolating mitochondria. The inclusion of mannitol as an osmotic support reduces glycogen binding, whereas the sucrose reduces organelle aggregation. Since organelles will spend several minutes in the running buffer during the separation, it must also be iso-osmotic. Accordingly, a buffer containing 250 mM sucrose, 10 mM HEPES, pH 7.4, has been used in the CE analysis of nuclei,<sup>76</sup> mitochondria,<sup>17</sup> and acidic organelles.<sup>81</sup> For mitochondria, the pH should be adjusted with KOH, as  $K^+$  ions are less permeant to the mitochondrial inner membrane than is  $Na^+$ , thereby reducing mitochondrial degradation. Another consideration is that large electric fields (e.g., 600 V/cm) can electrically disrupt organelle membranes.<sup>90</sup> To minimize electric field-induced organelle disruption, smaller electric fields (e.g.,  $-200$  V/cm) must then be used to separate organelles.

#### 20.5.4 ORGANELLE LABELING

Instead of performing time-consuming and tedious organelle purification techniques, it is often possible to use organelle-specific fluorescent labels to provide the necessary detection selectivity. Such labels allow crudely purified organelle fractions, prepared from differential centrifugation, to be analyzed. Many organelle-specific fluorescent labels are commercially available and Table 20.3 lists some of the most commonly used labels.

In the biological chemistry field, fusion proteins have recently shown more potential as organelle-specific labels. For subcellular analysis, fusion proteins can be expressed that contain both a fluorescent protein and a subcellular localization sequence. This combination results in organelle-specific labeling that retains the excellent photochemical properties of fluorescent proteins (e.g., intense fluorescence and photostability). We commonly use a commercially available plasmid that codes for a fusion protein of red fluorescent protein (DsRed2) and the mitochondrial targeting sequence from subunit VIII of cytochrome *c* oxidase, which contains the neomycin/kanamycin resistance gene, as described below.

---

**TABLE 20.3**  
**Organelle-Specific Fluorescent Labels**

Organelle	Fluorescent Label	Target
Nuclei	Ethidium bromide	Double-stranded DNA
Mitochondria	NAO	Cardiolipin
	Mitotracker Green FM	Reacts with thiol groups in mitochondria
	Rhodamine 123	Membrane potential dependent accumulation
Acidic organelles	Fluorescein dextran conjugate	Endocytosed into acidic compartments
	LysoTracker Green	Weak base is protonated and accumulated
Cytoskeletal network	Fluorescein Phalloidin	Actin
	Oregon Green 488 paclitaxel	Tubulin

---

Transfection of mammalian cells:

1. Suspend pDsRed2-Mito plasmid (Clontech, Mountain View, CA) in OPTI-MEM medium (Invitrogen, Carlsbad, CA) and incubate with DMRIE-C (Invitrogen) at room temperature for 30 min
2. Wash the 143B human osteosarcoma cells with OPTI-MEM
3. Layer the DMRIE-C-plasmid complex over the cells and incubate for 6 h
4. Add cell culture medium (MEM with 20% calf serum)
5. After 24 h, seed the cells onto a Petri dish at low density and culture in growth medium that contains 500  $\mu\text{g}/\text{mL}$  geneticin
6. After 5–6 days, select a single colony of cells that have been successfully transfected
7. Subculture the stably fluorescent transformants in medium [Dulbecco's modified Eagle's medium (DMEM)] containing 250  $\mu\text{g}/\text{mL}$  geneticin

In addition to mitochondria, commercial plasmids are also available that code for fusion proteins that incorporate subcellular localization signals for nuclei, endoplasmic reticulum, Golgi apparatus, peroxisomes, and actin filaments.

### 20.5.5 DETECTION METHODS

Choosing a detection scheme is an important component in designing any CE system, and as shown in the preceding examples (Section 20.4), this can be done in many ways. Owing to the small injection volumes used in CE, often the LOD must be submicromolar or lower; in these instances, achieving the required LOD becomes our chief concern when designing a detection strategy. As illustrated above, LIF, UV absorbance, and electrochemical detection may be employed for subcellular analysis by CE, but other techniques such as mass spectrometry<sup>35</sup> and biological cell sensors<sup>2</sup> have also been used.

#### 20.5.5.1 UV Absorbance

UV absorbance is the most common detection method for any CE system, primarily because nearly all compounds absorb somewhere in the UV region of the spectrum, and also because fused-silica capillaries are transparent to UV radiation. Given these advantages, UV absorbance detectors from HPLC instruments were naturally adopted into CE systems, but a problem arises when these detectors are used for subcellular analysis: subcellular analyses commonly quantify analytes that are below the LOD for UV absorbance. According to Beer's law, the sensitivity of a UV absorbance detector is related to the pathlength of the light. Therefore, UV absorbance has limited applicability to traditional CE separations due to the short path of the typical capillary diameters.

#### 20.5.5.2 Electrochemical Detection

Electrochemical detection is less widely used than UV absorbance or LIF detection, but has been used successfully by Ewing and coworkers to detect neurotransmitters within subcellular structures.<sup>6–11</sup> Electrochemical detection is attractive because it provides a lower LOD than UV absorbance, does not require sample derivatization, and in the case of amperometric detection, can be tuned to specific classes of compounds. Furthermore, unlike UV absorbance in which the sensitivity is dependent on the sample volume (i.e., the pathlength), the LOD of electrochemical detection improves when applied to miniaturized CE systems, since in this case sensitivity is related to contact between the analyte and the electrode surface. In fact, as described above, LODs in the zeptomole range for the subcellular quantification of dopamine have been reported,<sup>7</sup> with the sensitivity of these results making electrochemical detection the rival of many LIF detectors. However, the

application of electrochemical detection to subcellular analysis has been limited to the quantification of neurotransmitters.

### 20.5.5.3 Laser-Induced Fluorescence

Lastly, the most popular detection technique for subcellular analysis is LIF due to the extremely low LODs that can be attained. Mass LODs on the order of attomoles can be achieved with commercial CE-LIF instruments; and custom-built instruments, in conjunction with sheath-flow cuvettes, can reach down to the yoctomole ( $10^{-24}$  mole) scale.<sup>91</sup> LIF detection thus allows the quantification of minute amounts of analyte, and is the only detection method that has been used to detect individual organelles. We will therefore describe off-column LIF detection in further detail.

Sheath-flow cuvettes were originally developed for flow cytometry, but were adapted for use with CE by Dovichi.<sup>92–94</sup> Figure 20.16 illustrates LIF detection in conjunction with a sheath-flow cuvette. As displayed, the capillary is surrounded by sheath-flow buffer inside the cuvette. As organelles migrate out of the capillary, they are hydrodynamically focused by the sheath flow into a narrow stream. The excitation source is focused beneath the capillary outlet to excite the organelles once they have been focused. Since the diameter of the sample stream is dependent on the difference between the volumetric flow rates of the sample stream and the sheath flow, the sample stream can be narrowed to the desired width by increasing the sheath volumetric flow.

At this point, the fluorescence from each organelle can be collected by a microscope objective. As with all LIF detectors, care must be taken to choose an objective with high numerical aperture (NA) that can maximize the collection efficiency. The collected fluorescence can then be spatially filtered with a pinhole placed at the image plane to remove out-of-focus scatter from the buffer–cuvette interfaces. The size of the pinhole should be matched with the magnification of the collection objective

**FIGURE 20.16** Diagram of the sheath-flow cuvette used for LIF detection. The capillary is inserted into the sheath-flow cuvette and the laser beam is focused several micrometers away from the outlet. Sheath fluid focuses the sample as it migrates out of the capillary into a narrow stream, in which it is excited by a focused laser beam. The fluorescence is collected at a  $90^\circ$  angle from the excitation source by a high N.A. objective. (Reprinted from Johnson, R. et al., *Anal. Bioanal. Chem.*, In Press. Copyright 2006. With kind permission from Springer Science and Business Media.)

and desired detection area. For instance, if the desired spot diameter is 50  $\mu\text{m}$  and the fluorescence is collected with a 60 $\times$  objective, a 3-mm diameter pinhole is required. The collected fluorescence must also be spectrally filtered to remove Raman and Rayleigh scattering. In general, a long-pass optical filter is used to block Rayleigh scattering from the excitation source, and a bandpass filter that encompasses the fluorophore emission to exclude Raman scattering. The Raman scattering bands must be taken into consideration when choosing the emission wavelength range, since a lower LOD may be achieved at wavelengths that are not at the maximum emission of the fluorophore if it coincides with a Raman band. Finally, the fluorescence is detected using a photomultiplier tube or photodiode.

### 20.5.6 DATA ANALYSIS

Electropherograms that contain wide peaks, that is, peaks with baseline widths of several seconds or more, are routinely analyzed. However, in the case of individual organelle detection, the peak widths are much smaller, typically  $\sim 80$  ms, and the electropherograms nearly always contain wide peaks, baseline drift, and the sharp spikes that correspond to the detection of individual organelles. Special data treatment is required to discern these types of detected events. Toward this end, Jorgenson and coworkers<sup>95</sup> described an important data analysis tool, wherein a moving median filter is used to remove low-frequency background drift from a chromatogram. The median filter is shown mathematically as follows:

$$y_i = \text{median}(J_i)$$

$$J_i = \{x_{i-r}, x_{i-r+1}, x_{i-1}, x_i, x_{i+1}, x_{i+r-1}, x_{i+r}\}$$

$$i = 0, 1, 2, n - 1$$

where  $J_i$  is a subset of the input array  $X$  (data to be analyzed) centered around the  $i$ th element of  $X$ ,  $y_i$  is the  $i$ th element of the output array  $Y$ ,  $n$  is the size of the input array, and  $r$  is the median filter rank.<sup>95</sup> Consequently, peaks that do not comprise over 50% of the subset are excluded from the data set and only broad peaks remain.
